Myelodysplastic and Myeloproliferative Disorders

HEMATOLOGIC DISORDERS IN CHILDHOOD may present to an anesthesiologist in many ways. They may be the primary cause for a surgical procedure, such as hereditary spherocytosis (HS) in a child requiring splenectomy, or a factor complicating a common surgical procedure, such as sickle cell disease in a child undergoing tonsillectomy. Questions about hematologic problems, such as anemia, thrombocytopenia, decreased or increased coagulation, childhood cancer, and hematopoietic stem cell transplantation (HSCT), are often raised in the perioperative setting.

In this chapter, we address hematologic diseases and considerations that are of significance and interest to pediatric anesthesiologists. We highlight priorities of the hematologist that the anesthesiologist should incorporate in the care of a child during the perioperative period.

The Basics

LABORATORY VALUES AND DIAGNOSTIC TESTS

What is a normal hematocrit or platelet count for an infant or child who comes to the operating room? Red blood cell (RBC), white blood cell, platelet, and coagulation indexes evolve in various ways through late gestation, the neonatal period, infancy, and childhood (Table 10.1).

A term neonate has relative polycythemia, reticulocytosis, and leukocytosis compared with an older child. Neonatal platelet counts are similar to those of adults. Although in vitro function may be impaired for the first postnatal month, most in vivo assays of platelet function indicate normal or accelerated function. Both the prothrombin time (PT) and activated partial thromboplastin time (aPTT) are prolonged in preterm and term neonates because of a relative deficiency in vitamin K–dependent and contact activation factors, respectively; however, concentrations of factor VIII and von Willebrand factor (vWF) are increased.[1] The average international normalized ratio (INR), a normalized PT, is 1.0 for all age groups. Fibrinogen concentrations are comparable between term neonates and adults, although neonatal fibrinogen is qualitatively dysfunctional. The plasma concentrations of many anticoagulant factors (i.e., tissue factor pathway inhibitor, antithrombin, vitamin K–dependent glycoproteins, and proteins C and S) are decreased in preterm and term neonates. The quantity and quality of plasminogen are decreased in neonates, a condition that increases the risk for thrombosis, especially in a compromised infant.[1,2] Most of these differences between the neonate and older child or adult persist for 3 to 6 months postnatally.

After the immediate neonatal period, preterm and term infants experience physiologic anemia, presumably the result of the downregulating effect of increased oxygen supply in extrauterine life on erythropoiesis and the dilutional effect of a rapidly increasing blood volume. Preterm infants reach their nadir hemoglobin of 7 to 9 g/dL at 3 to 6 postnatal weeks, and term infants reach their nadir hemoglobin concentration of 9 to 11 g/dL at 8 to 12 postnatal weeks. Most hematologic values reach adult norms by the end of infancy (i.e., first postnatal year), although some continue to change gradually into the second decade. All of these changes underscore the importance of age-adjusted standards accompanying laboratory results for infants and children.

There is no ideal single screening test to assess the *bleeding risk* of a child in the perioperative period. *Bleeding time* appears to be greater in the infant and child (and less in the neonate) than it is in the adult, but the range of values is wide and overlapping (Table 10.1). Although bleeding time is potentially helpful in predicting posttonsillectomy and adenoidectomy hemorrhage,[3] as well as hemorrhage after percutaneous renal[4] and liver[5] biopsy, there is little evidence to support its use as a screening test to predict bleeding in the presence of a careful, inclusive clinical history.[6–8]

TABLE 10.1 Hematology Values at Different Ages

Measurement[a]	Preterm 28–32 Weeks	Preterm 32–36 Weeks	Term Neonate	1-Year-Old	Child	Adult
Hemoglobin (g/dL)	12.9	13.6	16.8	12	13	15
Hematocrit (%)	40.9	43.6	55	36	38	45
Reticulocyte count (%)	—	—	5	1	1	1.6
White blood cell count (/mm^3)	5160	7710	18,000	10,000	8000	7500
Platelet count (/mm^3)	255,000	260,000	300,000	300,000	300,000	300,000
Prothrombin time (seconds)	15.4	13	13	11	11	12
International normalized ratio (INR)	—	1	1	1	1	1
Activated partial thromboplastin time (seconds)	108	53.6	42.9	30	31	28
Fibrinogen (mg/dL)	256	243	283	276	279	278
Bleeding time (minutes)	—	3.5	3.5	6	7	5

[a]All values expressed as the mean. Age in weeks refers to gestation.
Data from Andrew M. The relevance of developmental hemostasis to hemorrhagic disorders of newborns. *Semin Perinatol.* 1997;21:70–85; Andrew M, Vegh P, Johnston M, et al. Maturation of the hemostatic system during childhood. *Blood* 1992;80:1998–2005; Goodnight SH, Hathaway WE. *Disorders of Hemostasis and Thrombosis: A Clinical Guide.* 2nd ed. New York: McGraw-Hill; 2001:31–38; Ohls RK, Christensen RD. Development of the hematopoietic system. In: Behrman RE, Kliegman RM, Jenson HB, eds, *Nelson Textbook of Pediatrics.* 17th ed. Philadelphia: WB Saunders; 2004:1599–1604.

In contrast to the standard historical laboratory tests, point-of-care testing using viscoelastic tests such as the thromboelastogram (TEG), rotational thromboelastometry (ROTEM), and Sonoclot (Sienco, Inc., Boulder, CO) allow the practitioner to receive data about the bleeding patient more quickly. The advantage of point-of-care viscoelastic testing is that it provides information of the entire clotting process from fibrin formation to clot retraction and fibrinolysis at the bedside. These tests also use whole blood, which allows the interaction of plasma derived coagulation factors with red cells and platelets, thereby providing information on platelet function. Viscoelastic point-of-care coagulation devices require trained personnel to maintain strict quality control procedures, as well as strict standardization procedures, to ensure optimal accuracy and reliability.[9] The TEG has been used to investigate the coagulation status of children undergoing spinal fusion,[10] neurosurgical procedures,[11] cardiopulmonary bypass for cardiothoracic procedures[12,13] and trauma.[14] Although the TEG may provide useful information in the surgical setting to evaluate fibrinolysis, hypercoagulability, and other coagulation perturbations, its use is usually limited to clinical scenarios with dynamic coagulation changes, such as open-heart surgery with cardiopulmonary bypass and liver transplantation.

The platelet function analyzer (PFA-100; Siemens, AG, Erlangen, Germany) is increasingly used to assess platelet abnormalities. It has the benefit of avoiding some of the difficulties of obtaining a bleeding time in children. Although several studies suggest PFA-100 analysis is equivalent or superior to the bleeding time for detecting bleeding abnormalities, there is no consensus about its role in preoperative screening.[15] Current evidence does not identify a single screening tool sensitive or specific enough to predict bleeding disorders or surgical bleeding risk in children. However, the PFA-100 analysis had the greatest probability of detecting a bleeding disorder in children.[16] With the increasing use of newer agents that modify platelet function (e.g., platelet G protein–coupled receptor P2Y12 antagonists, glycoprotein GPIIb/IIIa complex antagonists), clinicians must understand that the TEG, PFA-100, and other methods that assess platelet function may vary in their ability to monitor the effects of these agents and those of cyclooxygenase inhibitors.[17]

GUIDELINES FOR TRANSFUSION

Critical analyses of the risks and benefits of transfusions in infants and children in the perioperative period have resulted in fewer transfusions. Even for infants and children in intensive care, a restrictive transfusion threshold (i.e., 7 g/dL) reduces transfusions without increasing morbidity compared with a liberal threshold (i.e., 9.5–10 g/dL).[18,19] Data from the U.K.'s national audit of clinical transfusion, the Serious Hazards of Transfusion (SHOT), indicate that infants and children younger than 18 years of age are at greater risk for adverse transfusion-related reactions (37 and 18 in 100,000, respectively) than are adults (13 in 100,000). Most events were error related, including administrative, laboratory, clinical judgment, and handling errors.[20]

Guidelines for RBC transfusion in infants and children in the perioperative setting should be consistent with those established by the American Society of Anesthesiologists Task Force on Blood Component Therapy, which proposed that transfusion is not indicated for hemoglobin concentrations greater than 10 g/dL but is indicated for concentrations less than 6 g/dL.[21,22] When the concentration is between 6 g/dL and 10 g/dL, packed red blood cells (PRBCs) should be transfused based on the child's vital signs, adequacy of oxygenation and perfusion, acuity and degree of blood loss, and other physiologic and surgical factors.[23,24] When the concentration exceeds 10 g/dL, the decision to transfuse PRBCs should be based on the same physiologic and surgical factors. In a neonate or infant, this decision should also take into account increased baseline concentrations of hemoglobin in this population; increased oxygen consumption; increased affinity of residual fetal hemoglobin (hemoglobin F) for oxygen; and absolute blood volume (i.e., ~85 mL/kg for a term neonate and ~100 mL/kg for a preterm neonate). The threshold for transfusing a healthy neonate may be 7 g/dL in some clinical settings, but it may be 12 g/dL or greater for a neonate in other settings, such as significant lung disease requiring mechanical ventilation, chronic lung disease, cyanotic congenital heart disease, or heart failure.[23,25,26] For a preterm infant, the risks of hypovolemia, hypotension, acidosis, and postoperative apnea are magnified in the setting of operative blood loss and anemia. It is impossible to address all of the guidelines in this chapter, but many pediatric hematology and oncology consultants have clearly defined transfusion

TABLE 10.2 Commonly Used Triggers for Platelet Transfusion

Medical Condition or Procedure	Platelet Count (/mm^3)
Stable hematology-oncology or chronically thrombocytopenic patient	10,000–20,000
Lumbar puncture in stable leukemic child	10,000
Bone marrow aspiration or biopsy	20,000
Gastrointestinal endoscopy in cancer patient	20,000–40,000
Disseminated intravascular coagulation	20,000–50,000
Fiberoptic bronchoscopy in hematopoietic stem cell transplantation patient	20,000–50,000
Neonatal alloimmune thrombocytopenia	30,000
Major surgery	50,000
Dilutional thrombocytopenia with massive transfusion	50,000
Spinal anesthesia	50,000
Cardiopulmonary bypass	50,000–60,000
Liver biopsy	50,000–100,000
Nonbleeding preterm infant	60,000
Obstetric epidural anesthesia	70,000–100,000
Neurosurgery	100,000

Data from references 27, 28, 32, 35, 36.

TABLE 10.3 Indications for Leukocyte-Reduced Red Blood Cell Units

Prevention of Alloimmunization
Congenital hemolytic anemias (including sickle cell disease and thalassemia)
Hypoproliferative anemias likely to need multiple transfusions Aplastic anemia Myelodysplasia/myeloproliferative syndrome Plasma cell dyscrasias Hematopoietic stem cell transplants Hematopoietic malignancies
Therapy for Preexisting Conditions
Recurrent, severe febrile hemolytic transfusion reactions
Known HLA alloimmunization
Possible Uses
Alternative to cytomegalovirus-seronegative components (see Table 10.5)
Human immunodeficiency virus–infected patients

Modified from Simon TL, Alverson DC, AuBuchon J, et al. Practice parameter for the use of red blood cell transfusions: developed by the Red Blood Cell Administration Practice Guideline Development Task Force of the College of American Pathologists. *Arch Pathol Lab Med.* 1998;122:130–138.

thresholds for their patient populations that should be reviewed preoperatively.

Consensus committees from France, the United Kingdom, and the United States have published guidelines for platelet transfusion; these reports are based on available evidence that has been gathered and critically reviewed (Table 10.2).[21,22,27–31] Without evidence that platelet function is significantly different in the healthy infant and child, these guidelines should be applicable to these patients. The decision to transfuse platelets must take into account underlying medical conditions, platelet transfusion history, current medications, surgical bleeding, surgical interventions (e.g., cardiopulmonary bypass), and all other factors that may affect platelet function and turnover.[32–36] Sevoflurane and propofol have been reported to both suppress[37] and enhance platelet aggregation in vitro.[38] Despite these effects on platelet aggregation, no change in the bleeding time has been reported, suggesting that the possible inhibitory effects of these agents do not impair hemostasis in vivo.[39]

Transfusion guidelines for other blood products, including fresh frozen plasma (FFP) and cryoprecipitate, have been established[21,22,35,40] and are discussed later in the context of coagulation disorders. Indications[41] for transfusing FFP are usually limited to the following:

1. Replacement of documented congenital or acquired coagulation factor deficiency when a specific sterilized or combined factor concentrate is unavailable, especially in the setting of anticipated or active bleeding
2. Acquired coagulopathy resulting from massive transfusion
3. Immediate reversal of warfarin's effect when prothrombin complex concentrate (PCC) is unavailable
4. Coagulation support in disease processes such as disseminated intravascular coagulation (DIC) and thrombotic thrombocytopenic purpura
5. A source of antithrombin III for children deficient of this inhibitor who require heparin

Cryoprecipitate should be administered only for anticipated or active bleeding in children with congenital fibrinogen deficiencies or von Willebrand disease who are unresponsive to desmopressin acetate (DDAVP) or for patients with acquired hypofibrinogenemia (<80–100 mg/dL) associated with massive transfusion.

Guidelines have been established by the College of American Pathologists and other transfusion study groups for leukocyte reduction of RBC units[25] and irradiation (x-ray or γ-ray) of cellular blood components (Tables 10.3 and 10.4).[42] These guidelines are valuable when determining the specific choice of blood components that should be ordered and administered in the perioperative setting. For hematologic patients receiving chronic RBC transfusions, an extended phenotypic crossmatch and leukocyte reduction can decrease the risk of developing alloantibodies and transfusion reactions, especially in children of African descent if the local donor pool is primarily derived from Caucasian populations of Northern European descent.[43] For oncology patients, updated specific requirements for blood products including leukocyte reduction and irradiation are often indicated and should always be reviewed with oncology specialists. To reduce the risk of cytomegalovirus (CMV) transmission in susceptible patients, donated seronegative CMV blood, leukoreduced blood, or both can be used. However, the risk cannot be completely eliminated because supposed seronegative donors could be in the initial stages of viremia at the time blood is collected (Table 10.5).[44]

Hemolytic Anemias

Hemolytic syndromes are a group of disorders in which lysis of erythrocytes often leads to anemia. Although RBCs in these disorders may be characterized by abnormal morphology and shorter life span, these indices may be normal at baseline. Clinical signs of a hemolytic syndrome include anemia, splenomegaly, and jaundice, signs that may be apparent chronically or only during acute exacerbations of a disease process. Hemoglobinuria may be

a late finding if massive hemolysis has occurred. Although not well studied, in theory any hemolytic disorder may alter nitric oxide (NO) metabolism.

Many of the hemolytic anemias important to the anesthesiologist result from intracellular defects and can be classified as erythrocyte membrane defects, such as HS; enzymatic defects, such as glucose-6-phosphate dehydrogenase (G6PD) deficiency; and qualitative and quantitative defects of hemoglobin, such as sickle cell disease and thalassemia. Other hemolytic anemias that may be encountered in the operating room are largely extracellularly mediated, such as transfusion-related hemolysis and other immune-mediated anemias (alloimmune or autoimmune); this group of anemias is not reviewed here.

HEREDITARY SPHEROCYTOSIS

HS, the most common cause of inherited chronic hemolysis in North America and Northern Europe, has a prevalence of approximately 1 to 2 cases per 5000 people if mild forms of the disease are included.[45,46] First described in 1871, HS is present in many ethnic populations but is rare in African Americans. Because 75% of children inherit the disease in an autosomal dominant pattern, there is often a family history of the disorder, although autosomal recessive mutations, de novo mutations, and incomplete penetrance have been reported.[46]

Pathophysiology

Abnormalities in any of several erythrocyte membrane proteins, including the β subunit of spectrin, ankyrin, and band 3, can lead to HS. The variety of proteins affected and mutations observed in each gene account for the clinical heterogeneity of the disorder.[45] When the erythrocyte loses surface area, it changes from a biconcave disk to a sphere, which alters its stability and flow pattern through the capillaries. The deformity leads to a more rigid membrane, which predisposes it to rupture, a condition that is worsened if the membrane surface area decreases by more than 3%.[46] Damaged erythrocytes are sequestered in the splenic capillaries, which can lead to splenomegaly. The combination of intravascular and extravascular hemolysis can result in anemia, which induces extramedullary erythropoiesis. The life span of the erythrocyte is reduced from 120 days to just a few days when the RBC membrane has been deformed. If large numbers of damaged erythrocytes are lysed, unconjugated bilirubin is released, which causes jaundice and possibly gallstones in as many as 60% of children.[45] Membrane fragments from hemolytic reactions can lead to DIC. Pulmonary hypertension may occur in the HS population, presumably as a result of hemolysis-induced alterations in NO metabolism.

Clinical and Laboratory Features

Children may present at any age with the triad of anemia, splenomegaly, and jaundice that often is aggravated by concomitant viral infection. Mild, moderate, and severe forms of HS occur and are characterized by variations in laboratory results and clinical correlates. HS can manifest soon after birth and should be considered in infants who are jaundiced after the first postnatal week; resulting hyperbilirubinemia can sometimes necessitate an exchange transfusion. Mild disease occurs in 20% of children with HS; these children only occasionally present with symptomatic bilirubinate gallstones before adolescence. Approximately 5% of children have severe HS characterized by chronic anemic (hemoglobin concentration <8 g/dL) and the need for chronic transfusions. The course of this disease may be complicated by viral

infections such as parvovirus B19 infection, which can suppress reticulocyte production[46] and precipitate aplastic crises.

HS is most commonly suspected when numerous spherocytes with loss of central pallor appear on a peripheral smear. A complete blood cell count usually reveals a reduced hemoglobin and increased reticulocyte count. Osmotic fragility (OF) was regarded as the gold standard for the diagnosis of HS, but this test produces age-related results and must be performed by experienced laboratory technicians in a timely fashion. The OF test is known to give false-negative results in 10%–20% of patients, as well as false-positive results in patients with autoimmune hemolytic anemia. The updated guidelines for the diagnosis and management of HS no longer recommend the OF test as a first-line screening tool.[47] Increasingly, flow cytometry using eosin-5′-maleimide is being used to confirm the diagnosis because it requires little blood and can be performed after overnight storage.[48] In addition, as a direct result of chronic hemolysis, unconjugated bilirubin and serum lactate dehydrogenase concentrations increase, and serum haptoglobin concentrations decrease. Thrombocytopenia may develop as a result of hypersplenism.

Perioperative Considerations

Anemia, thrombocytopenia, and splenomegaly are the major considerations for a child with HS undergoing surgery. The most common disease-related operations performed in children with HS are splenectomy and cholecystectomy, individually or in combination, and these procedures may be performed by laparotomy or laparoscopy.

Splenectomy significantly increases red cell survival in most cases and reduces the severity of the anemia and jaundice. It is usually reserved for more severe cases of HS, characterized by severe anemia that require frequent RBC transfusions, poor growth, chronic fatigue, or evidence of extramedullary hematopoiesis (e.g., frontal bossing). Splenic enlargement in a child interested in participating in contact sports is another indication.[46] Splenectomy is ideally performed after the age of 6 years because of the increased risk of overwhelming infection by encapsulated organisms such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* type B in splenectomized younger children.[49] Preoperative vaccination against these organisms is essential unless surgery is required emergently.[50] Guidelines for the indications and duration of postoperative penicillin prophylaxis vary among institutions.[45]

Splenectomy in children is more frequently performed laparoscopically than by open laparotomy because the former is associated with decreased pain, quicker return of bowel function, shorter hospital stay, and improved cosmetic result. Conversion from laparoscopic to open splenectomy is necessary in fewer than 10% of cases.[51] Partial splenectomies are increasingly performed because they allow retention of some immune function against bacterial infections in younger children while reducing the sequestration of spherocytes. However, residual splenic tissue can increase in size and necessitate total splenectomy at a later time.[52,53] If anemia recurs after splenectomy, it may indicate the presence of accessory splenic tissue that was unrecognized initially. Transient postsplenectomy thrombocytosis marked by dramatic increases in platelet counts may also occur in children,[54] in addition to a general increase in the risk of thromboembolic disease.

Gallstones occur in 21% to 63% of children with HS, but cholecystectomy is usually performed only when children are symptomatic with cholelithiasis. Children who undergo splenectomy and who also have radiographically identified gallstones may undergo concurrent cholecystectomy, regardless of whether the stones are symptomatic.[55–57] Table 10.6 summarizes the clinical features and important perioperative considerations for the child with HS undergoing incidental or disease-related surgical procedures.

TABLE 10.6 Perioperative Concerns for Patients With Hereditary Spherocytosis

Preoperative Considerations
Hemoglobin, reticulocyte count, platelet count
History of transfusions and special blood requirements (e.g., extended phenotypic matching, leukocyte reduction)
History of infections, aplastic crises, and presplenectomy vaccinations
Presplenectomy antibiotic prophylaxis and immunization when indicated
Intraoperative Considerations
Appropriate antibiotic coverage
Attention to physiologic effects of laparoscopy on circulatory and respiratory function
Potential for significant blood loss (unusual in splenectomy and cholecystectomy)
Judicious use of regional anesthesia, intramuscular medications, nasogastric tubes, nasal intubation, and other methods when platelet count is low
Limited use of medications with potential bleeding risk (e.g., ketorolac)
Postoperative Considerations
Sequential hemoglobin determinations and platelet counts
Potential thrombocytosis: management as recommended by hematology consultants
Infection risk

GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

G6PD deficiency causes hemolysis in the presence of oxidative stressors. It is the most common enzyme deficiency in humans, affecting approximately 400 million people worldwide. This enzyme deficiency is inherited in an X-linked, recessive fashion. Although males are most commonly affected, females (heterozygous or homozygous for the gene) may have clinical manifestations of the disease. More than 100 variants have been described, including a relatively mild form that affects about 10% of African American males (i.e., G6PD A–) and a more severe form that affects Italians, Greeks, and other populations in the Mediterranean, African, and Asian regions (i.e., G6PD Mediterranean).[58–60] This deficiency is prevalent in geographic areas where the incidence of malaria is high, presumably because G6PD deficiency may attenuate the severity of malarial infections.

Pathophysiology

G6PD plays an important role in the hexose monophosphate/pentose phosphate shunt, which is essential for normal energy metabolism in erythrocytes. G6PD generates the reduced form of nicotinamide adenine dinucleotide phosphate (NADPH). NADPH maintains glutathione in the reduced form, which reduces peroxides and protects cells from oxidative damage in the course of normal biochemical events or in the event of excess free oxygen radical generation. Superoxide ion or hydrogen peroxide, or both, can oxidize hemoglobin, which then precipitates as insoluble membrane inclusions. These inclusions, together with the oxidative damage to cell membranes, lead to cell damage in

the G6PD-deficient child. Erythrocytes are particularly sensitive to oxidative damage because of their lack of synthetic activity. In the presence of oxidants and free radicals (e.g., produced by infection or by ingestion of certain medications and foods), this cascade of events may precipitate hemolysis in the G6PD-deficient child.[58,60]

Clinical and Laboratory Features

Clinical symptoms of G6PD deficiency may be deceptively variable, and they may occur in the neonatal period or in older age groups as episodic or chronic hemolytic anemia. Presenting signs include anemia and jaundice; in severe cases, these signs can be followed by lumbar and abdominal pain and by renal failure. Acute illness such as diabetic acidosis or ingestion of a variety of substances may precipitate a hemolytic event (Table 10.7). Fava beans, also known as broad beans, contain high concentrations of vincine and convincine, which are nonvolatile glucosides that can trigger hemolysis.[61] On a global basis, favism is likely the most common form of acute hemolytic anemia associated with G6PD deficiency.[62] Hemolysis may range from benign and transitory to severe and life-threatening; the latter situation is more likely if the triggering agent is not eliminated or controlled. Laboratory findings include normocytic anemia, increased reticulocyte count and serum bilirubin concentration, and the presence of Heinz bodies in the peripheral blood smear.

TABLE 10.7 Agents That May Precipitate Hemolysis in Patients With Glucose-6-Phosphate Dehydrogenase Deficiency

Antibiotics
Sulfonamides
Trimethoprim-sulfamethoxazole (Bactrim, Septrin)
Dapsone
Chloramphenicol
Nitrofurantoin
Nalidixic acid
Antimalarials
Chloroquine
Hydroxychloroquine
Primaquine
Quinine
Mepacrine
Other Medications
Aspirin
Phenacetin
Sulfasalazine
Methyldopa
Vitamin C (large doses)
Hydralazine
Procainamide
Quinidine
Chemicals
Moth balls (naphthalene)
Methylene blue
Food
Fava (broad) beans

Perioperative Considerations

In the perioperative setting, G6PD deficiency does not usually cause problems. The most effective management strategy centers on avoiding oxidative stressors (such as pain and anxiety) and avoiding the triggering agents (Table 10.8). Treating or eliminating precipitating causes such as infection is also paramount in safely anesthetizing G6PD-deficient patients. Monitoring for and treatment of possible complications are appropriate; transfusion is rarely required.[63]

Administration of large or excessive doses of medications such as prilocaine, benzocaine, and sodium nitroprusside may trigger hemolysis in G6PD-deficient children in the perioperative setting.[58,60,64,65] Although these children can reduce methemoglobin that is normally produced by these agents, G6PD-deficient children may not tolerate large amounts of potent oxidizing agents (i.e., superoxide ion and hydrogen peroxide) produced by methemoglobin. Infants may be particularly susceptible to symptomatic methemoglobinemia (because of their low NADPH dehydrogenase activity) and to methemoglobin-induced hemolysis if they are G6PD deficient. Treatment of methemoglobinemia with methylene blue is contraindicated in these infants because the agent itself may precipitate hemolysis[53]; there is a relative contraindication to methylene blue in all G6PD-deficient patients. G6PD-deficient patients lack the enzymes necessary to reduce methylene blue to an inactive form, leukomethylene blue. Methylene blue might also add to the oxidative hemolysis.[66] Hemolysis has occurred during cardiopulmonary bypass in G6PD-deficient children,[65,67] and methemoglobinemia has occurred in a child with partial G6PD deficiency after application of EMLA (eutectic mixture of local anesthetics) cream.[68]

HEMOGLOBINOPATHIES

Sickle Cell Disease

First identified by Herrick about 100 years ago, sickle cell disease is a group of inherited hemoglobinopathies with a diverse worldwide prevalence. The disease affects about 1 in 365 African Americans and 1 in 16,300 Hispanic births.[69] The spectrum of the disease includes sickle cell anemia (HbSS), which accounts for about 70% of the American sickle cell disease population; sickle cell/hemoglobin C disease (HbSC), accounting for about 20%; sickle cell/β-thalassemia (HbSβ-thalassemia), accounting for about 10%; and a host of other, uncommon sickle variants whose prevalence is increasing over time.[70] HbSβ-thalassemia includes HbSβ^0- and

TABLE 10.8 Perioperative Concerns for Patients With Glucose-6-Phosphate Dehydrogenase Deficiency

Preoperative Considerations
History of hemolysis and precipitating factors
Hemoglobin concentration, reticulocyte count
Intraoperative Considerations
Avoidance of triggering agents
Caution in use of high doses of agents that increase methemoglobin, especially in infants
Hemoglobin and urine output in high-risk settings (e.g., cardiopulmonary bypass)
Postoperative Considerations
Hemoglobin concentration, reticulocyte count, urine output if hemolysis occurs

HbSβ+-thalassemias. The distinction between the two is the absence of normal HbA in the former versus decreased amount of HbA in the latter; even a small amount of HbA present in the latter partially mitigates the severity of disease. While there are large phenotypic variations among the many forms of sickle cell disease, in general HbSS and HbSβ0-thalassemia are clinically similar and more severe than HbSC and HbSβ+-thalassemia. Sickle cell trait (HbAS), in which approximately 40% of hemoglobin is hemoglobin S, occurs in about 8% of African Americans and in a much smaller percentage of Hispanic and other subpopulations.[69] The sickle gene is found commonly in sub-Saharan Africa, the Mediterranean, the Arabian Peninsula and India, where sickle cell trait provides a significantly increased fitness in malaria-endemic regions. Sickle hemoglobinopathies have many implications for perioperative care because they increase perioperative morbidity and mortality.

Pathophysiology

Hemoglobin A is composed of two α- and two β-globin chains. Hemoglobin S results from a single base-pair mutation in the β-globin gene on chromosome 11, which results in the replacement of a negatively charged, hydrophilic glutamate residue with a noncharged, hydrophobic valine residue. This hydrophobic valine is exposed when HbS is deoxygenated and is stabilized by binding the same hydrophobic valine pocket on other HbS molecules, thereby leading to polymerization of HbS, precipitation and hemolysis.[71]

In contrast to prior simplistic models in which sickled cells were simply thought to block flow through the microcirculation, the pathophysiology of sickle cell disease is now understood to be considerably more complex. This understanding is, in turn, leading to more therapeutic interventions.[71–73] Any factor that promotes hemoglobin crystallization (e.g., hypoxia, acidosis, and cellular dehydration) or prolongs capillary transit time (e.g., dehydration, hypothermia, leukocytosis, thrombosis, and inflammation) increases HbS polymerization and formation of sickled cells. Inflammation, vascular endothelial adhesion abnormalities, platelets, and coagulation cascade activation all contribute to vasoocclusive episodes. The sickle red cell membrane becomes compromised by exposure to destructive oxidizing effects of precipitated HbS, thereby leading to altered permeability to sodium, potassium, and calcium, causing dehydration of the cell and irreversible sickling.[74] Membrane abnormalities of phospholipid content also contribute to its deformability, and exposure of phosphatidyl serine facilitates activation of the clotting cascade. These and other factors lead to entrapment of irreversibly sickled red cells in the microcirculation, activation of coagulation and inflammatory pathways, ischemia, and infarction of tissue. At the same time, chronic intravascular hemolysis decreases production of NO, while increased scavenging decreases the bioavailability of NO. The resulting NO deficiency causes endothelial dysfunction and disease complications, such as pulmonary hypertension, priapism, and skin ulceration.[74,75]

Clinical and Laboratory Features and Treatment

Sickle cell disease is a multisystem process involving most organs of the body and at times necessitating surgical intervention. While there is considerable variation in disease severity, all patients have a progressive clinical course. Therapeutic interventions and genetic factors account in large part for the differences in outcome. Children with persistence of hemoglobin F (which itself protects against the effects of deoxygenation on red cells) and those with HbSC or HbSβ+ have fewer complications than those with HbSS or HbSβ0.

Early diagnosis and treatment of sickle cell disease have been facilitated by the widespread use of universal neonatal screening, which was first used in the state of New York in 1975. Most screening programs for sickle cell disease use isoelectric focusing of an eluate from dried blood spot samples, a technique that is also used to screen for other disorders. A few programs use high-performance liquid chromatography. Because a small percentage of children with sickle cell disease are not African American (i.e., Native American, Hispanic, and Caucasian),[76] selective screening may not detect all affected infants. As of 2006, all 50 states and the District of Columbia screen neonates for sickle hemoglobinopathies. Families of infants diagnosed with sickle trait (HbAS) on neonatal screening may not be made aware of the diagnosis, but reports of perioperative complications suggested to be associated with sickle cell trait are exceedingly rare. Affected children born within the United States before universal neonatal screening and those born outside the United States without routine health care may not have received diagnosis and appropriate care before surgery. Notwithstanding the controversy over the utility of nonselective preoperative screening,[77] children at risk whose hemoglobin status is unknown preoperatively should have a sickle-screening test, followed by a hemoglobin electrophoretic evaluation if screening is positive. However, infants younger than 6 months of age may have a false-negative screening test result because of the presence of fetal hemoglobin, although electrophoresis is diagnostic at all ages. Children older than 10 years of age with a normal hemoglobin value, standard peripheral blood smear, and unremarkable clinical history are at low risk of having a clinically significant hemoglobinopathy.[78]

Common clinical symptoms of sickle cell disease in children include chronic hemolytic anemia, pain crises secondary to recurrent vasoocclusive episodes, acute chest syndrome (ACS), infection, renal insufficiency, osteonecrosis, and cholelithiasis. Pulmonary hypertension, priapism, and skin ulcerations may also occur and are related to the degree of red cell hemolysis.[79] Chronic pulmonary and neurologic disease (e.g., stroke) are additional causes of significant morbidity and mortality.[70] In the perioperative period, the most common complications in sickle cell children include ACS (about 10%), fever or infection (about 7%), vasoocclusive episodes (about 5%), and transfusion-related events (about 10%).[80]

Chronic hemolytic anemia is a hallmark of HbSS disease. It is characterized by a baseline hemoglobin value of 5 to 9 g/dL (often more than 9 g/dL in HbSC disease), reticulocytosis (5% to 10%), and a distinctive red cell morphology observed on a peripheral blood smear.[73] Red cell fragility and chronic hemolysis are associated with anemia, increased red cell turnover, and a propensity to form biliary stones. The anemia may be complicated by other events, such as acute splenic sequestration, typically occurring in infants and young children after a viral illness; or an acute cessation of red cell production, the equivalent of transient erythroblastopenia of childhood and typically associated with parvovirus B19 infection. For some children, chronic and acute severe anemia are managed with RBC transfusions, although these children are prone to develop alloantibodies to RBC antigens, and untreated iron overload resulting from recurrent transfusions can lead to life-threatening cirrhosis and cardiac failure. Most children are maintained on chronic folic acid therapy to prevent megaloblastic erythropoiesis that can result if increased demands for purine synthesis from red cell production are not met.

Vasoocclusive episodes in sickle cell disease occur as a result of episodic microvasculature occlusions at one or more sites. The occlusive process occurs most commonly in the phalanges (i.e.,

dactylitis or hand-foot syndrome), long bones, ribs, sternum, spine, and the pelvis; it also can occur in the mesenteric microvasculature, producing abdominal pain that may mimic a surgical acute abdomen. Pain associated with vasoocclusive episodes should be managed with a multidimensional approach including reversal of potential triggers (via warming, hydration, and ambulation), distraction, psychological and behavioral interventions, and complementary modalities in addition to analgesic medications. Initial pharmacologic management often entails scheduled antiinflammatory agents because inflammation is central to the vasoocclusive process, and these agents synergize with opioids to provide analgesia. It is essential to foster an ideal environment for pain control (e.g., calm, pleasant distractions, supportive personnel and objects). Hydroxyurea is used to prevent vasoocclusive episodes and end-organ damage, and it is now widely recommended for all patients with HbSS and HbSβ^0. Although grossly underused,[81] hydroxyurea is a safe and effective component of chronic management in decreasing the frequency of events through several mechanisms; inhibiting hemoglobin precipitation by increasing fetal hemoglobin concentrations; reducing white blood cell count; modifying the inflammatory response; and facilitating NO metabolism.[75,81–83] Inhaled NO or precursors of NO may prove to be effective therapy for vasoocclusive episodes.[84]

ACS is characterized by acute respiratory symptoms concurrent with new infiltrate(s) observed on chest radiograph.[85] ACS frequently occurs 2 to 3 days after a vasoocclusive episode, and although its clinical presentation varies, it often includes any, or all, of the following: fever, tachypnea, cough, and hypoxemia. The process may be self-limited over a period of a few days, or it may progress to respiratory failure (15%) and even death. The inconsistent presentation in part reflects the complex and variable pathogenesis of ACS. An episode may have a single or multiple causes, including infection (i.e., bacteria or atypical bacteria [often *Chlamydia* or *Mycoplasma*], viruses, or a combination of agents), pulmonary fat embolism, pulmonary infarction, and pulmonary hemorrhage.[86] Acute management includes supportive care and oxygen, antibiotics that treat encapsulated and atypical organisms, bronchodilators, pain control, ventilatory support as needed, and transfusion. Incentive spirometry or continuous positive airway pressure can be helpful, especially in the perioperative setting. Hydroxyurea therapy and chronic transfusion therapy decrease the frequency of ACS, whereas inhaled NO, NO precursors, and antioxidants (e.g., arginine and glutamine) may attenuate the process acutely.[75,81,84,87–89] Airway reactivity is also common in children with sickle cell disease, in part due to NO deficiency, and it is responsive to bronchodilator therapy.[90,91] In later life, children with sickle cell disease may develop restrictive lung disease and pulmonary hypertension as a result of repeated ACS-induced lung injury and chronic inflammation. NO deficiency, the result of decreased production, increased consumption, or altered metabolism, may also play an important role in these processes.[79,85,92]

Infections are common because of deficits in the immune system and the specific effects of splenic atrophy and dysfunction that occur over the first few years of life.[72] As a result of susceptibility to overwhelming infection by *S. pneumoniae* and *H. influenzae* type B, young children receive penicillin prophylaxis until 6 years of age and bacteria-specific immunizations in addition to those routinely administered to children. A host of infectious organisms have been implicated in ACS, and infection with gram-negative organisms (e.g., osteomyelitis caused by *Salmonella*) is common in older children and adults.[86]

Stroke is a potentially devastating complication that occurs in about 10% of children; as high as 40% have silent infarcts and 10% have overt strokes.[93] One-fourth of children have motor or cognitive deficits at the time of presentation for surgery.[94,95] A child's first stroke often appears as early as 2 to 5 years of age.[96,97] Risk factors include reduced hemoglobin concentration, increased concentration of HbS, increased leukocyte count, and a history of dactylitis. Pain episodes, ACS, and infection may precipitate strokes.[98] Children suffering an acute stroke are managed supportively with emergent exchange transfusion to reduce the concentration of HbS to less than 30%, followed by chronic transfusions and hydroxyurea administration to minimize the risk of recurrence.[99] The thrust of the current management of stroke is prevention. Yearly screening with transcranial Doppler starting at age 2 identifies most children at high risk, and subsequent management with chronic transfusion and hydroxyurea therapy may minimize the risk of a future stroke.[100–103]

Renal abnormalities can include proteinuria, hematuria, hyposthenuria, and renal tubular acidosis. Acute and chronic renal failure may develop, and angiotensin-converting enzyme (ACE) inhibitors may be of benefit of resulting hypertension.[104,105] Renal dialysis and transplantation have proven successful interventions for renal complications of the disease.[106]

HbAS is usually benign, although it may be characterized by microhematuria and hyposthenuria,[106,107] and sickling may occur under extremely altered physiologic circumstances (e.g., cardiopulmonary bypass).[108,109] There is also a small but significant risk of pulmonary embolism. An increased risk of rhabdomyolysis with exercise, as well as sudden death with extreme exertion in individuals with HbAS, has led to the controversial mandate to offer trait testing to all National Collegiate Athletic Association (NCAA) Division I athletes.[110]

Children with HbSC disease usually have a greater baseline hemoglobin concentration and fewer complications than those with HbSS disease. Because splenic function is often preserved, the risk for infection in early childhood is reduced.[78] Children with HbSC disease are more likely to have proliferative retinopathy and avascular necrosis of long bones.[72]

Children with HbSβ^0 (i.e., one sickle globin allele and one thalassemic allele expressing no β-globin) have a course identical to that of HbSS, whereas those with HbSβ^+ (i.e., one sickle globin allele and one thalassemic allele expressing β-globin at a reduced level) tend to have a more benign course that is proportional to the amount of normal β-globin expression. The coexistence of hemoglobin S with α-thalassemia produces a variable clinical picture, but it may predispose children to a significant incidence of pain episodes.[78]

Many additional approaches to sickle cell care are being investigated and are notable for targeting multiple aspects of the complex physiology. These include administration of short-chain fatty acids such as butyrate or demethylating agents such as decitabine to induce production of hemoglobin F; small molecules to interfere with polymerization; antibodies to alter cell adherence; ion channel inhibitors to decrease cellular dehydration; NO-related compounds and precursors; and manipulation of inflammatory pathways. New therapeutic targets such a BCL11A, a zinc finger protein that plays a key role in the silencing of fetal globin genes, is being targeted by multiple mechanisms.[111] HSCT is increasingly used as a curative intervention for sickle cell disease. While cure rates with HLA-matched sibling donors exceed 80%, the lack of such donors for most patients has led to the increasing use of cord blood units as well as unrelated and haplo-identical

donors. To circumvent many complications of transplantation, gene therapy protocols using a child's own modified stem cells are underway, and multiple gene editing approaches are being pursued.

Perioperative Considerations

Perioperative morbidity and mortality are greater in children with sickle cell disease than in the general population. These children often require surgical procedures. The most common include cholecystectomy[112]; ear, nose, and throat procedures[113]; and orthopedic procedures (especially hip procedures for osteonecrosis).[114] Placement of long-term vascular access for transfusions, antibiotics, analgesia, and other therapies is frequently performed. The Cooperative Study of Sickle Cell Disease reported that 7% of all deaths among children with this disease were related to surgery.[70] Early reviews reported perioperative mortality rates as great as 10% and morbidity rates as great as 50% for children with sickle cell disease.[115–118] Studies published in the 1990s indicated that the 30-day mortality rate was about 1%.[119] In a group of more than 600 patients managed according to standard guidelines of care and prospectively studied, the incidence of any complication was about 30%, and the incidences of ACS and vasoocclusive pain episodes were 10% and 5%, respectively.[80] Patient factors (e.g., age, history of pulmonary disease, number of prior hospitalizations) and surgical factors (i.e., invasive vs. superficial) appear to affect the incidence of complications. The impact of newer interventions and technologies (e.g., laparoscopic and robotically assisted cholecystectomy and splenectomy)[120–122] on perioperative morbidity and mortality rates is unclear, although more recent reports cite reduced rates of complications than in the past.[123] Although multiple anesthesia and surgical approaches are under investigation, there is a dearth of comparative studies identifying optimal perioperative care for these children.

The principles of optimal perioperative care are based on maintaining optimal physiologic parameters throughout the perioperative period, avoiding factors that may precipitate a sickle crisis, optimizing pain management, and close consultation among hematologists, surgeons, and anesthesiologists (Table 10.9).[124] The child with sickle cell disease who is undergoing surgery should be viewed and managed primarily as a hematology patient whose care is being shared with, rather than assumed by, the surgeon and anesthesiologist during the perioperative period. Avoiding unnecessary and potentially dangerous surgical procedures (e.g., exploratory laparotomy to rule out appendicitis in a child who is experiencing an abdominal pain crisis) and minimizing perioperative complications should be the focus of the multidisciplinary care team. Based on a survey of perioperative management of sickle cell disease among anesthesiologists in North America, most anesthesiologists consult with hematologists in all cases or on a case-by-case basis.[125]

Although there is no evidence to support or refute many of the long-standing guidelines for perioperative care and individual practices vary widely,[125] it seems prudent to avoid those factors that may promote intravascular sickling: hypoxia, acidosis, hyperthermia, hypothermia, and dehydration.[71] Meticulous attention to pain management is also essential because perioperative vasoocclusive pain is common and is associated with ACS. Monitoring vital signs throughout the perioperative period is mandatory, especially monitoring oxygenation with pulse oximetry. Oxygen saturation as determined by pulse oximetry may underestimate measured oxygen saturation in patients with sickle cell disease, although this is usually clinically insignificant.[126,127] Because ACS, a common (10%) and potentially life-threatening complication of surgery, occurs 1 to 3 days postoperatively, it is important to extend adherence to guidelines of care into the postoperative period, regardless of the apparent well-being of the child.[80] In light of the renal-concentrating defect found in these patients, perioperative hydration is important

TABLE 10.9 Perioperative Concerns for Patients With Sickle Cell Disease

Preoperative Considerations
Screening if unknown status in at-risk children
Primary management by hematology service (in most circumstances)
History of acute chest syndrome, vasoocclusive pain crises, hospitalizations, transfusions, transfusion reactions
Neurologic assessment (e.g., strokes, cognitive limitations)
History of analgesic and other medication use
Hematocrit
Oxygen saturation (on room air), chest radiograph
Pulmonary function tests (when appropriate)
Practice incentive spirometry at home
Work with child-life specialist if indicated
Echocardiography (when appropriate)
Neurologic imaging (for recent changes)
Renal function studies
Transfusion crossmatch (e.g., antibody-matched, leukocyte-reduced, sickle-negative)
Transfusion to correct anemia (in most circumstances)
Parenteral hydration for *nil per os* (NPO) status
Pain management
Aggressive bronchodilator therapy
Appropriate antibiotic therapy, including presplenectomy antibiotics and immunizations (as indicated)
Intraoperative Considerations
Maintenance of oxygenation, perfusion, normal acid-basis status, temperature, hydration
Availability of appropriately prepared blood (as indicated)
Replacement of blood loss
Anesthetic technique appropriate for procedure and postoperative analgesic requirements
Attention to physiologic effects of laparoscopy on circulatory and respiratory function
Appropriate antibiotic therapy
Judicious use of tourniquets, cell saver, and cardiopulmonary bypass
Postoperative Considerations
Management by hematology service
Monitoring for complications, especially acute chest syndrome and vasoocclusive pain crises
Maintenance of oxygen saturation monitoring and supplementation as needed, including prophylactic supplemental oxygen the first 24 hours regardless of oxygen saturation
Appropriate hydration (oral plus parenteral)
Appropriate antibiotic therapy
Aggressive pain management—must ensure ability to breathe deep and do incentive spirometry
Early mobilization
Incentive spirometry (possibly with continuous or bilateral positive airway pressure) and bronchodilator therapy

to maintain and may require in-hospital preoperative care, although one must be aware that overhydration may compromise vulnerable cardiovascular and respiratory physiology.

Transfusion in the perioperative period remains a controversial subject despite several studies suggesting its benefit.[80,128,129] Transfusion of non-HbS RBCs to a child with sickle cell disease has several beneficial effects: correction of anemia; dilution of HbS red cells; compensation for blood loss; and prevention of some complications (e.g., stroke). However, transfusion is not without risks, including alloimmunization,[43,130] transfusion reactions (about 7% in the perioperative period),[80] infection, iron overload, time, and expense. Although there have been many reports of surgery performed safely in children with sickle cell disease without preoperative transfusion,[131] uncontrolled studies indicate that preoperative transfusion does decrease the rate of perioperative complications.[112,119] The Preoperative Transfusion in Sickle Cell Disease Study Group demonstrated prospectively in 604 operations (70% were cholecystectomies and otolaryngologic and orthopedic operations) that simple transfusion (i.e., correction of preoperative anemia to 10 g/dL with simple transfusion) was as effective as aggressive transfusion (i.e., lowering the preoperative HbS level to <30%, often with exchange transfusion) in preventing perioperative complications and was associated with less alloimmunization and fewer transfusion-related complications in children.[80]

To directly determine if transfusion prevents perioperative complications in the current era of surgical and anesthesia practices, an international randomized trial was initiated, the Transfusion Alternatives Preoperatively in Sickle Cell Disease (TAPS) trial. However, this trial was halted early during the recruitment process as a result of an excessive number of complications in the non-transfusion group. This led to the continued recommendation of transfusion for moderate and complicated operations in sickle cell patients.[81,129] It is currently recommended that most children with HbSS undergoing most surgical procedures receive preoperative correction of anemia with a "simple" (i.e., direct) transfusion targeting a hemoglobin concentration of 10 g/dL. Children maintained on chronic transfusion programs (e.g., for stroke prevention or acute chest) should continue such management preoperatively, and common sense dictates performing surgery soon after a scheduled transfusion. Children with sickle cell disease who are undergoing magnetic resonance imaging (MRI) and other examinations under sedation/anesthesia without prior transfusion do not have increased complications.[132] Recommendations for children with HbSC disease are less clear because these children typically maintain a baseline hemoglobin concentration at about 10 g/dL. For HbSC children who have a history of ACS, frequent pain crises, underlying pulmonary disease, or other complications, it is recommended that they receive selective preoperative exchange transfusion to reduce the HbS concentration without increasing total hemoglobin.[133] Because of the high risk of alloimmunization in the sickle cell population, blood for these patients should undergo the following preparation: extended phenotype matching, including Rh, Cc, D, Ee, and Kell in addition to ABO[81,102,134]; leukocyte reduction; and screening for sickle cell hemoglobin. Directed donation of blood from family members should be avoided if the child is an HSCT because it can lead to alloimmunization and later graft rejection.

Anesthetic agents and techniques do not have a clear effect on perioperative outcomes for children with sickle cell disease.[135] Inhalational anesthetics do not affect the sickling process, although there is experimental evidence suggesting that halothane may increase the viscosity of sickled blood.[136] Pharmacokinetics of some agents commonly used with general anesthesia such as atracurium may be altered in this population.[137] Regional anesthesia has been associated with an increased risk of postoperative complications in one retrospective study,[119] but it has not been shown to affect perioperative outcome in others.[112,114] The vasodilatory and analgesic properties of regional anesthesia can be effective in the management of vasoocclusive episodes and priapism and in providing perioperative anesthetic care.[138,139]

Other aspects of anesthetic care of sickle cell disease patients merit consideration. Hyperventilation should be avoided because of its potential to reduce cerebral perfusion in children at an increased risk for stroke.[140] The use of a tourniquet in HbSS and HbAS diseases has been questioned.[141–143] However, tourniquets have been applied intraoperatively for up to 2 hours without complication, and the predominance of evidence supports their safe use as long as they are used carefully and selectively in combination with general guidelines of perioperative care.[144–147] Intraoperative blood salvage with cell saver devices has been used safely in sickle cell patients,[148] although there is some evidence that the salvage device itself may produce sickling in the processed blood, even sickle trait blood.[149] Cardiopulmonary bypass seems to present conditions that are favorable toward sickling, given the cold, hypoxic, acidotic, and stagnant environment created. Although there are reports of bypass surgery conducted in children with HbSS or HbAS with standard bypass procedures without transfusion,[150–153] these children usually are managed with aggressive exchange transfusion before or during bypass.

While comparative studies that specifically address optimal postoperative care, understanding of the pathophysiology of the disease and studies of sickle cell pain suggest that postoperative care should minimize postoperative pain to allow deep inspirations, use of incentive spirometry, and encouraging early ambulation to prevent ACS. Maintaining euvolemia, normal body temperature, and sufficient oxygenation should minimize the risk of vasoocclusive pain at this time of increased risk due to anesthesia and postoperative inflammation.

Thalassemias

Thalassemia disorders are among the most common genetic disorders worldwide. They are characterized by a perturbation of the normal 1:1 ratio of α- to β-globin polypeptide chains, usually due to reduced synthesis of one polypeptide, but also possibly due to excess genes (e.g., triplicated α-globin genes). The clinical severity of the disease is proportionate to the degree of chain imbalance, ranging from an asymptomatic carrier state to profound ineffective erythropoiesis with transfusion dependence to fetal death due to hydrops fetalis. Both α- and β-thalassemia primarily affect children of Mediterranean, African, and Southeast Asian descent. Whereas neonatal assay screening for HbS can detect many forms of α-thalassemia, these tests typically detect only profound forms of β-thalassemia. The concomitant presence of qualitatively abnormal hemoglobins (e.g., HbS, HbE) affects the clinical course of thalassemia disorders. The primary ineffective erythropoiesis and hemolytic anemia, as well as resultant disease therapy, may affect perioperative care.

Pathophysiology

Anemia in thalassemia is the result of hemolysis and ineffective erythropoiesis; the latter results, in turn, from accelerated cell apoptosis triggered in part by excess deposition of unpaired globin chains in erythroid precursors.[154] Unpaired globin subunits are oxidized and form hemichromes, whose degree of formation affects

the degree of hemolysis. Precipitation of hemichromes leads to a complex process that includes release of toxic agents and formation of reactive oxygen species; alteration of red cell membranes causes cells to become aggregates that lead to embolic complications and activation of the coagulation process. As a result of chronic anemia and ineffective erythropoiesis, bone marrow expansion and extramedullary hematopoiesis may develop in the liver and spleen. Marrow space expansion may occur at sites such as the cranium and paravertebral areas, thereby causing pathologic fractures, disfiguring bony changes, and pain. Erythroid hyperplasia and ineffective erythropoiesis lead to inappropriately low hepcidin expression (a polypeptide that inhibits iron absorption by binding to the ferroportin in the gut wall and macrophages), resulting in increased iron absorption from the gastrointestinal tract and iron overload, even in the absence of transfusion iron overload. Iron overload and deposition lead to fibrosis and cirrhosis with concomitant organ dysfunction and eventual failure. While there are many target organs for iron overload, the most relevant are liver, pancreas, heart, and pituitary; the extent of iron deposition in each can be accurately and sequentially monitored by MRI.

Clinical and Laboratory Features and Treatment

Disease severity in α-thalassemia typically reflects the complete loss of expression of between one and all four of the α-globin genes. A four-gene globin deletion typically results in hydrops fetalis with in utero or perinatal death unless diagnosed early and supported with in utero transfusions. A three-gene deletion, or hemoglobin H (HbH) disease, is relatively benign, characterized by chronic hemolytic anemia, which may be exacerbated by exposure to stress and oxidants.[155,156] The few patients with profound anemia or requiring intermittent transfusion therapy often have a two-gene deletion along with a hemoglobin Constant Spring (HbCS) mutation (HbH-Constant Spring).[155,156] A two-gene deletion alone is benign, manifest by a mild, clinically insignificant microcytic anemia. A one-gene deletion results in a silent carrier state with no anemia or microcytosis.

In contrast to α-thalassemia, β-thalassemia reflects partial or complete loss of expression of the β-globin genes. The broad spectrum of disease results from the number of genes affected and the degree to which each gene is affected. When only one β-globin gene is affected (i.e., β-thalassemia trait), mild microcytic anemia is the primary clinical manifestation. When both β-globin genes are affected, the clinical picture may be mild to moderate, potentially requiring intermittent, but not chronic transfusions (thalassemia intermedia), or severe, requiring chronic transfusions (thalassemia major or Cooley's anemia). Children with hemoglobin E (HbE)/β-thalassemia manifest a dramatic range of severity ranging from very mild to severe and transfusion-dependent.

The clinical problems in thalassemia are those associated with chronic anemia, the physiologic response to ineffective erythropoiesis, iron overload from transfusions and paradoxical increased iron absorption, as well as chelation therapy.[154] Clinical problems include transfusion-associated alloimmunization and infection, splenomegaly, bone abnormalities (due to extramedullary hematopoiesis, chelation therapy, and other factors), endocrine dysfunction (including hypogonadism, hypopituitarism, and diabetes mellitus), short stature, pulmonary hypertension, venous thrombosis and thromboembolism, and cardiomyopathy (primarily due to iron overload). Thalassemia patients also may be hypercoagulable,[157] a condition that may be exaggerated after splenectomy.[157,158]

The approach to moderate to severe disease is to balance transfusion to treat the underlying anemia and suppress erythropoiesis while minimizing and aggressively treating iron overload. Phenotypic matching and leukocyte reduction of transfused blood can reduce immune complications, and careful surveillance for end-organ damage and endocrine management is essential. When an appropriate donor is available, HSCT is recommended before severe liver damage occurs because it provides a potential cure for thalassemia. To ameliorate the course of the disease, other therapies are being investigated, including administration of erythropoietin, fetal hemoglobin modifiers (e.g., hydroxyurea, butyrate), and antioxidants. Of particular excitement is the modulation of ineffective erythropoiesis by manipulating erythropoietin gene signaling via inhibition of the JAK2-STAT5 pathway.[159] Increasing numbers of gene therapy trials are currently underway and proving successful, and gene editing approaches similar to those with sickle cell disease are being pursued.

Perioperative Considerations

Children with moderate or severe thalassemia may require cholecystectomy and vascular access placement for frequent transfusions.[160] While splenectomy can aid transfusion support, it is avoided if possible (particularly for thalassemia intermedia) because of the increased risk of embolic disease after splenectomy. If splenectomy is performed, short-term antithrombotic prophylaxis with unfractionated or low-molecular-weight heparin should be considered during and after surgery. Pneumococcal vaccination protocols, as well as prophylactic antibiotic protocols for asplenic patients, should be followed.[161] Patients with thalassemia who have undergone splenectomy should be considered at high risk for thrombosis and should be administered appropriate prophylaxis therapy when exposed to transient thrombotic risk factors such as surgery, pregnancy, and immobilization[158,162] Demineralized long bones may be prone to fracture, and older children may require osteotomies for bony deformities.

Perioperative management for thalassemia has not been extensively studied. It is important to consult with a hematologist to define transfusion parameters and the optimal preoperative hemoglobin level. In addition, one should be aware of the risk of the possible complications of iron overload in these patients: liver dysfunction; diabetes; pituitary dysfunction; and cardiac dysfunction (the latter an indication for preoperative electrocardiogram and echocardiogram).[163] Bony abnormalities of the maxillofacial area may render securing the airway challenging.[164] Similarly, extramedullary erythropoiesis can lead to paravertebral masses potentially interfering with epidural or other nerve blocks. Laparoscopic and robotic techniques for cholecystectomy[165] and splenectomy have been used successively in children with thalassemia, although perioperative hypertension may be a common problem in laparoscopic splenectomy.[166,167] Perioperative considerations and concerns for children with thalassemia, especially for those with thalassemia major, are listed in Table 10.10.

Thrombocytopenia

PLATELET DISORDERS AND BLEEDING

Platelets are an essential component of hemostatic regulation. Platelets are distributed between the bloodstream (two-thirds) and spleen (one-third). Their normal life span is 7 to 10 days. In children, the platelet number may decrease as the result of decreased production or increased consumption, or they may have abnormal function. Bleeding typical of platelet disorders often involves skin and mucous membranes. Although there are many causes of primary and secondary thrombocytopenia in infants and

TABLE 10.10 Perioperative Concerns for Patients With Thalassemia

Preoperative Considerations
Hemoglobin concentration
Transfusion crossmatch if appropriate (antibody-matched, leukocyte-reduced source for frequently transfused children)
Evaluation for endocrine dysfunction (e.g., diabetes mellitus, hypopituitarism)
Cardiac function, including echocardiogram (when appropriate)
Hepatic function, awareness of risk of cirrhosis and iron- or virus-induced damage
Airway evaluation, preparation for possible difficult airway
Presplenectomy antibiotics and immunizations (when appropriate)
Intraoperative Considerations
Careful positioning of demineralized extremities
Attention to cardiovascular function, including postsplenectomy hypertension
Attention to physiologic effects of laparoscopy on circulatory and respiratory function
Prophylaxis for thromboembolism
Postoperative Considerations
Monitoring of cardiac function
Prophylaxis for thromboembolism

TABLE 10.11 Perioperative Concerns for Patients With Idiopathic Thrombocytopenia Purpura

Preoperative Considerations
Hemoglobin concentration, platelet count
History of platelet transfusions
History of corticosteroid use
History of infections
Presplenectomy antibiotic prophylaxis and immunizations (when appropriate)
Discussion with a hematologist regarding medical therapy and platelet transfusion for a platelet count <30,000/mm^3
Discontinuation of any platelet-inhibiting medication (e.g., aspirin)
Intraoperative Considerations
Appropriate antibiotic coverage
Stress corticosteroid coverage
Medical therapy and platelet transfusion as above (platelets ideally administered after clamping of the splenic artery during splenectomy)
Judicious use of regional anesthesia, intramuscular medications, nasogastric tubes, nasal intubation, and other methods
Limited use of medications with potential bleeding risk (e.g., ketorolac)
Attention to physiologic effects of laparoscopy on circulatory and respiratory function
Postoperative Considerations
Hemoglobin concentration, platelet count
Infection
Corticosteroid coverage
Pain management

children, this discussion focuses on idiopathic thrombocytopenic purpura (ITP).

IDIOPATHIC THROMBOCYTOPENIC PURPURA

ITP is the most common cause of acute-onset thrombocytopenia in the otherwise healthy child, and it commonly manifests in the operative setting. ITP has an estimated incidence of about 4 per 100,000 children, and it is usually a benign, self-limited disorder affecting children between the ages of 2 and 10 years.[54] Primary ITP has no clear predisposing cause, but secondary ITP is triggered by a drug or medical disorder. Diagnosis is by exclusion, the differential list is extensive, and response to ITP-specific treatment usually solidifies the diagnosis.

Pathophysiology

ITP is characterized by antibody-mediated clearance by tissue macrophages, resulting in thrombocytopenia (platelet count <100,000/mm^3) and shortened platelet survival. Antibodies may also suppress megakaryocytes and platelet development. Platelet autoantibodies may exist alone or as part of immune complexes, and they usually are immunoglobulin G (IgG) in type. They often show specificity for platelet membrane glycoproteins IIb/IIIa and Ib/IX.[168] Thrombocytopenia develops when the reticuloendothelial system, typically the spleen, destroys the antibody-covered platelets.

Clinical and Laboratory Features and Treatment

Usually, ITP in children is a benign process occurring after a viral illness or immunization that manifests as petechiae of mucosal surfaces or purpura over bony prominences, thrombocytopenia, and a normal to increased mean platelet volume with increased megakaryocytes in the marrow. This process resolves within weeks or months regardless of therapy. ITP is classified as newly diagnosed (<3 months), persistent (3–12 months), and chronic (>12 months).[169]

Although platelet function in children with ITP is usually increased, treatment is often initiated only when the counts are less than 10,000 to 20,000/mm^3.[168] Observation with avoidance of activity that may lead to head trauma is an increasingly accepted treatment plan. Medical treatment most commonly consists of agents that decrease monocyte/macrophage-mediated destruction of antibody-coated platelets (e.g., steroids, intravenous immunoglobulin, anti-D immunoglobulins, vinca alkaloids). Agents that decrease antibody production (e.g., cyclophosphamide, anti-CD20 antibody) and investigational agents that stimulate the thrombopoietin receptor are reserved for those who demonstrate an inadequate response to initial therapy.[170] Platelet transfusions are recommended only for life-threatening emergencies. Splenectomy removes a major site of platelet destruction and is recommended as an option only in chronic, symptomatic ITP, or acute, life-threatening ITP unresponsive to medical treatment.[171,172] This procedure, which is commonly performed noninvasively, has a success rate of about 75%.[173–175]

Perioperative Considerations

In view of the clinical and laboratory features of ITP, the anesthesiologist providing care for the child with ITP who is undergoing splenectomy or incidental surgery should consider the concerns listed in Table 10.11. A hematologist should be consulted to assess the need for medical therapy, including platelet transfusion, before surgery.

Coagulation Disorders

Children may present for surgery with a personal or family history suggesting a bleeding disorder. The anesthesiologist must decide expeditiously whether to postpone surgery to further evaluate or treat the child. A careful medical history, physical examination, and family history, followed by laboratory evaluation in consultation with a hematologist, are important elements in screening for, diagnosing, and treating a bleeding disorder in the perioperative setting.

SCREENING

The clinical history of the child and family is the most essential screening tool. The family history should identify family members who have been labeled as "bleeders," who have required blood transfusion unexpectedly during surgery, or who returned to surgery for unexpected postoperative bleeding. A history of maternal menorrhagia may also be significant. Suggestive signs and symptoms in a child's medical history are easy bruising, mucosal bleeding, and in older girls, menorrhagia. Although diagnosing easy bruising is subjective, the clinician should suspect bleeding tendencies if skin bruising occurs in nontraumatized sites (e.g., trunk) or is unusually large without evidence of previous trauma. Mucosal bleeding includes epistaxis and gingival bleeding. Occasional nosebleeds can be common in children, but their clinical significance is enhanced by increased frequency, duration, bilaterality, and coexistence with abnormal bleeding from other sites. Gingival bleeding is common after tooth brushing or flossing, but its clinical significance is enhanced by spontaneous occurrence or chronicity, especially in the presence of good dental hygiene.[176] A history of prolonged or excessive bleeding is important when associated with umbilical cord stump dehiscence, dental work (especially extractions), and circumcision. Although mouth injuries can produce impressive blood loss acutely in any individual, recurrent or persistent bleeding from such an injury may indicate an underlying disorder.

Consultation with a hematologist and laboratory evaluation should be considered for children with a clinical history and physical examination result that suggest a bleeding diathesis, especially for children scheduled to undergo procedures associated with large blood loss or that make particular demands on hemostasis, such as tonsillectomy. Laboratory evaluation of all children, regardless of history or type of surgery, may result in false-positive results that lead to costly workups and potentially unnecessary cancellation of operations, both of which can contribute to greater health care inefficiencies and expense. Bleeding owing to medications should be distinguished from an actual bleeding disorder.

When a bleeding disorder is strongly suspected, a set of laboratory tests that include a platelet count, PT, INR, aPTT, thrombin time (TT), and fibrinogen concentration should be ordered. The PT test is most sensitive to deficiencies in factors II, V, VII, and X, and it is useful for differentiating a vitamin K deficiency from other causes. The PT is most often used to monitor the anticoagulant effects of warfarin; it is not sensitive to the effects of heparin. The aPTT test is most sensitive to deficiencies in factors VIII, IX, and XI and less sensitive to deficiencies of factor V, factor X, prothrombin, and fibrinogen. The aPTT is also prolonged in deficiencies of the contact or kallikrein/kinin system proteins, factor XII, prekallikrein, and high-molecular-weight kininogen, but these deficiencies are not associated with bleeding. Because aPTT reagents vary in sensitivity for detection of deficiencies of each factor, it is inappropriate to make a general statement about the ability of this test to detect a specific abnormality; abnormal results require discussion with a hematologist or laboratory medicine physician. Although a prolonged aPTT may be caused by a deficiency in one or more factors, it can also result from inhibition by heparin or a plasma inhibitor, such as lupus anticoagulant. Correction of a prolonged aPTT after mixing the child's plasma with normal plasma (1 : 1 mix) suggests a factor deficiency. The TT test, which determines the amount of time it takes for blood to clot, is useful for determining deficiencies or abnormalities in fibrinogen and is very sensitive to heparin contamination. Bleeding time, a TEG, and platelet function screens (e.g., PFA-100) are probably not appropriate as first-line screening tests.

Children with an upper limit of normal aPTT test result and a strongly suspicious personal or family history for a bleeding disorder may have an abnormality (e.g., von Willebrand disease). These children require further evaluation in consultation with a hematologist. Whether a procedure should be delayed for the consultation depends on several factors, including the patient's history, site and urgency of surgery, potential bleeding risks associated with the planned procedure, and results of previously discussed set of screening tests.

VON WILLEBRAND DISEASE

Von Willebrand disease (vWD) is one of the most common bleeding disorders, although studies suggest that the prevalence may be as low as 1 case per 1000 people.[177] Initially named *pseudohemophilia* because of an inheritance pattern that is different from that of hemophilia, vWD is the result of an abnormal amount, structure, or function of the vWF.[178]

Pathophysiology and Classification

The glycoprotein vWF serves two main roles in the coagulation cascade: adhering platelets to damaged subendothelium and carrying factor VIII in plasma. vWF exists as small and large multimers. Large multimers play a more active role in the binding of platelets to subendothelium than do small ones and are, therefore, necessary for platelet adhesion, whereas binding to factor VIII is independent of multimer size. The two aspects of vWF make it an essential part of primary hemostasis (through platelet binding) and secondary hemostasis (as carrier of factor VIII to sites of injury).

Classification of vWD is essential for understanding and management of this disorder. The current classification was developed by a subcommittee on vWD through the International Society on Thrombosis and Haemostasis.[179,180] The two general types are categorized as quantitative abnormalities (types 1 and 3) or qualitative abnormalities (type 2, including subtypes A, B, M, and N). All types are inherited in an autosomal dominant pattern, except types 2N and 3, which are autosomal recessive.

Because vWD is heterogeneous, clinical definitions have been proposed using categories such as mild, moderate, and severe, categories based on bleeding history (i.e., number of bleeding episodes) and laboratory measurement of factor concentration and activity.[181] As the molecular basis of vWD becomes better understood, classification of this disease likely will change to reflect the new data. For example, Rodeghiero and colleagues proposed a practical approach to diagnosing and categorizing patients with vWD to provide optimal management. Their approach includes a standardized bleeding history score, focused laboratory analysis, and a trial infusion of DDAVP in certain subtypes.[182] Better categorization of patients with vWD may predict clinical

outcomes and allow better management in the perioperative setting.[183]

Clinical and Laboratory Features and Treatment

Children with vWD may exhibit many of the clinical features associated with bleeding disorders in general, although there is a notable absence of joint bleeding. The typical symptoms of vWD reflect poor platelet adhesion and include bruising, epistaxis, and menorrhagia.

Children with vWD have traditionally been described as having prolonged bleeding times and aPTTs, but those with mild disease often have normal values. The aPTT is prolonged only if factor VIII activity is at, or below, a concentration that is determined by the sensitivity of the particular assay at an institution (often below 30%–35%). The platelet functional assay (PFA-100) has better sensitivity and specificity (both near 90%) for diagnosis of the disease.[184,185] The PFA-100 test, which measures closure time of an aperture on a membrane coated with collagen and adenosine diphosphate (ADP) or epinephrine, depends on vWF activity and platelet function. Because this test has some variability, its interpretation should be used in conjunction with results of other tests.[186] Platelet count is typically normal in all types of vWD except type 2B.

Other laboratory tests used to delineate vWD include the following: vWF antigen (vWF:A), which is a measure of the total level of vWF; vWF activity, often measured as a ristocetin cofactor activity (vWF:R), itself a measure of vWF binding to platelets through GPIb receptors; factor VIII coagulant activity; and vWF multimer analysis. Certain disease states have been associated with "acquired vWD" and include lymphoproliferative disorders or gammopathies (marked by antibodies to vWF), chronic renal failure, hypothyroidism, Wilms tumor, and certain congenital heart disease (characterized by proteolysis of vWF multimers).[187] Treatment focuses on increasing concentrations of endogenous vWF with administration of DDAVP when possible or on replacement of factors with factor concentrates.[188] DDAVP is usually effective in type 1 but less so in types 2A and 2M. DDAVP may have little or even undesired effects in some children: it may increase abnormal vWF in types 2A, 2M, and 2N; it can exacerbate thrombocytopenia in type 2B; and its repeated administration may lead to tachyphylaxis. DDAVP usually is not administered to very young children because of the risk of free water retention, hyponatremia, and central nervous system pathology, including seizures. Similarly, intravenous fluids may need to be limited after its administration to any child. Factor concentrates (including factor VIII and vWF [Humate-P (CSL Behring, King of Prussia, Pennsylvania) or Alphanate (Grifols, Barcelona, Spain)]) typically are required for types 2B, 2N, and 3. Cryoprecipitate may be used when vWF-containing concentrates are unavailable, but it is not recommended as first-line therapy because it is not virus free, and vWF in solvent or heat-treated cryoprecipitate may be abnormal.[189] Because of the complexity of response to therapies in this disease and the ever-changing availability of replacement products, determination of appropriate treatment in conjunction with a hematologist before surgery is crucial.[182,190]

Perioperative Concerns

The major preoperative concerns in children with confirmed vWD are directed toward appropriate preoperative treatment, avoidance of medications that may interfere with coagulation, and anticipation of intraoperative and postoperative bleeding (Table 10.12).[191,192]

TABLE 10.12 Perioperative Considerations for Patients With von Willebrand Disease

Preoperative Considerations
Consultation with hematologist: establish correct diagnosis and response to desmopressin (DDAVP); administer DDAVP *or* viral attenuated factor concentrates containing factor VIII and von Willebrand factor (vWF) such as Humate-P for severe vWD or for those types not responsive to DDAVP[186]
Determination of actual and desired factor concentrations and expected duration of postoperative therapy[191]
Discontinuation of any platelet-inhibiting medication (e.g., aspirin)
Intraoperative Considerations
Judicious use of regional anesthesia, intramuscular medications, nasogastric tubes, nasal intubation, and other procedures that may cause bleeding
Limited use of medications with potential bleeding risk (e.g., ketorolac)
Coagulation profiles, including platelet counts for more invasive surgeries
Treatment of bleeding with appropriate blood products
Consider use of antifibrinolytic agents (i.e., ε-aminocaproic acid, tranexamic acid)[190]
Possible use of recombinant factor VIIa for severe bleeding episodes in severe vWD type 3 or patients with inhibitors
Postoperative Considerations
Follow factor concentrations (i.e., factor VIII and vWF)
Availability of blood products and factors
Appropriate treatment of bleeding episodes
Monitor for thromboembolism in children receiving multiple concentrates or antifibrinolytic agents, or both[186]

Although regional anesthesia for these children usually is contraindicated, there are reports of its use without complications.[193]

HEMOPHILIA

Hemophilia was first reported in the *Talmud*, in which there are descriptions of 8-day-old boys exsanguinating after ritual circumcision. Widespread public attention was drawn to this disease after members of Queen Victoria's family developed sequelae from hemophilia in the late 19th and early 20th centuries. The discovery of multiple forms of hemophilia was first made in 1944 when blood from two hemophiliacs was mixed and found to clot. In 1952, hematologists explained their earlier finding by noting that a 10-year-old boy, Stephen Christmas, exhibited a type of hemophilia, factor IX deficiency, which differed from the classic form, factor VIII deficiency.

Hemophilia is a group of congenital bleeding disorders caused by deficiency in factor VIII (i.e., hemophilia A, or classic hemophilia), factor IX (i.e., hemophilia B, or Christmas disease), or factor XI (i.e., hemophilia C). During the 10-year period from 1982 through 1991, the incidence of the more common varieties, hemophilia A and B, was 1 per 5032 live male births in the United States within a six-state surveillance area; the prevalence of hemophilia A was 10.5 cases per 100,000 male births, and that of hemophilia B was 2.9 cases per 100,000 male births.[194] Because of X-linked recessive inheritance of hemophilia A and B, family history is very important in establishing the diagnosis. Although boys are usually affected, girls may rarely inherit the disorder if their fathers are affected and their mothers are carriers or in

instances of extreme lyonization (inactivation of an X chromosome). The daughter of an affected father is an obligate carrier with a 50% chance of passing it on to any of her sons. De novo mutations are relatively common (about one-third of hemophilia A and B cases) and suspected in male patients lacking a family history.[176] Hemophilia C, affecting primarily Ashkenazi Jews, is a mild form of hemophilia. It is also known as plasma thromboplastin antecedent (PTA) deficiency or Rosenthal syndrome. In the United States, its incidence is 1:100,000 adults, or 10% the incidence of hemophilia A. It is distinguished from the other two forms of hemophilia by an autosomal recessive inheritance pattern (the gene for factor XI is located on chromosome 4), lack of joint bleeding, and infrequent need for treatment. Affected female patients may notice heavy menses, and affected male patients may have frequent nosebleeds and occasionally have excessive bleeding during surgery.

Pathophysiology

Normal in vivo hemostasis initiates at sites of endothelial disruption through interaction of activated factor VII (FVIIa) and tissue factor (TF) to form a complex that activates factor IX and factor X directly. Activated factor IX in conjunction with factor VIII further activates factor X, which with factor V converts prothrombin to thrombin. Both factor VIII and factor IX are required for sufficient hemostasis, as evidenced by the severe bleeding that occurs if either is completely deficient. Factor XI activates factor IX, but its precise role in the hemostatic pathway is not completely understood.

Clinical and Laboratory Features and Treatment

The wide range of clinical features is similar for hemophilia A and B (Table 10.13). The severity of bleeding in these children directly relates to the degree of their deficiency.[184] Children with mild or moderate hemophilia may bleed excessively only after a hemostatic challenge such as trauma or surgery, whereas children with severe hemophilia may bleed spontaneously (e.g., hemarthroses).[195] Female carriers on average have 50% of normal factor concentrations and usually are asymptomatic, although they occasionally present with a clinical picture similar to that of mild cases of hemophilia.[184]

Results of a general coagulation screen are typically normal except for the aPTT, which is prolonged in proportion to the concentration of factors in the blood. The diagnosis is confirmed by measuring the specific factor concentrations.[196] If hemophilia is suspected but there is no family history, testing for vWD is prudent, especially for the types that may mimic hemophilia (i.e., types 2N and 3). Because of the variable sensitivity of the aPTT to specific factor deficiencies, the ability of this test to detect carriers varies between laboratories; diagnosis of a carrier state usually requires specific factor assays.

Hemophilias A and B are treated by replacing the deficient factor concentrations. These factor concentrations should be maintained at specified levels to prevent sequelae (Table 10.14). Exposure to plasma products should be minimized. The duration of treatment should be tailored to the severity of disease. DDAVP may be effective in selected mild cases by increasing factor VIII concentrations through the release of endogenous stores. Because tachyphylaxis limits the prolonged use of DDAVP, it is typically recommended only for minor operations.[197] For most cases, especially for those who require increased factor concentrations to be maintained for effective hemostasis, factor concentrates should be used. Although recombinant forms are preferable because they do not carry infectious risk, substitution with plasma-derived forms may be needed when supplies are limited.[184,197] For the rare patient with hemophilia C who has excessive surgical bleeding, treatment with recombinant factor XI or FFP may be required. It is essential to consult with a hematologist to determine a customized factor treatment plan for every child with hemophilia.

Children who have developed inhibitors to factor concentrates pose a challenge in the perioperative period. For years, they were denied surgery unless it was absolutely necessary, at which point they were often managed with increased concentrations of factors or a desensitization regimen. However, recently there has been improved management in these patients with the use of bypassing agents that treat bleeding by stimulating thrombin generation through pathways that do not require the missing factors (VIII or IX). Such agents include recombinant factor VIIa (rfVIIa, NovoSeven RT, Novo Nordisk Inc., Plainsboro, NJ) and activated prothrombin complex concentrates, such as FEIBA (anti-inhibitor coagulant complex; Shire, Massachusetts, USA), that have shown efficacy greater than 80%. Specific factor concentrates are preferred, however, unless patients have significantly elevated inhibitors.[198]

Perioperative Concerns

The perioperative concerns in hemophilia focus on prevention and treatment of bleeding, similar to the management of patients

TABLE 10.13 Clinical Manifestations of Hemophilia A

Clinical Manifestations	Mild (>10%)[a]	Moderate (2%–10%)[a]	Severe (<2%)[a]
Age at first hemorrhage	3–14 years or older	<2 years	<1 year
Signs in neonatal period	None	Postcircumcision bleeding	Postcircumcision bleeding, intracranial hemorrhage
Musculoskeletal bleeding	Unusual except with severe trauma	Joint and muscle bleeding with minor trauma	Spontaneous
Central nervous system bleeding	Rare except with severe trauma	Less prevalent than severe	Prevalence, 3% Mean age, 14 years
Postsurgical bleeding	Wound hematomas and oozing	Wound hematomas and oozing	Usually frank bleeding
Trauma-related bleeding	Hematomas and deep bleeding with significant trauma	Muscle and joint bleeding with minor trauma	Common with minor trauma
Dental bleeding	Often	Common	Usual
Inhibitors present	Rarely	<3%	Prevalence, 15%–20%

TABLE 10.14 Treatment Targets for Hemophilia A and B

Type of Hemorrhage	Desired Plasma Factor Levels (IU/DL) for Hemophilia A[a]	Desired Plasma Factor Levels (IU/DL) for Hemophilia B[a]	Duration (days)[b]
Muscle			
Superficical	40–60	40–60	2–3
Deep (initial)	80–100	60–80	1–2
Deep (maintenance)	30–60	30–60	3–5
Joint	40–60	40–60	1–2
Gastrointestinal Tract			
Initial	80–100	60–80	7–14
Maintenance	50	30	
Oral mucosa	30–50	30–50	2–3
Epistaxis	30–50	30–50	2–3
Renal	50	40	3–5
Surgery (major)			
Preoperative	80–100	60–80	1–3
Postoperative	30–80	30–80	4–14
Surgery (minor)			
Preoperative	50–80	50–80	1–5
Postoperative	30–80	30–80	1–5
Central Nervous System			
Initial	80–100	60–80	1–7
Maintenance	50	30	8–21

[a]Recommended targets when there are no product constraints. Targets may be adjusted lower when products are constrained.
[b]May be increased or reduced depending on clinical circumstances and severity of disease.

TABLE 10.15 Perioperative Concerns for Patients With Hemophilia

Preoperative Considerations
Consultation with hematologist, establishment of correct diagnosis
Determination and testing of treatment plan, including use of desmopressin or factors (concentrates or recombinant)
Consideration of multiple procedures performed together to reduce factor exposure
Discontinuation of any platelet-inhibiting medication (e.g., aspirin)
Intraoperative Considerations
Judicious use of regional anesthesia, intramuscular medications, nasogastric tubes, nasal intubation, and other procedures that may cause bleeding
Limited use of medications with potential bleeding risk (e.g., NSAIDs)
Follow coagulation profiles, especially factor levels (factors VIII and IX)
Anticipate and treat bleeding with appropriate blood products
Consider recombinant activated factor VII (rFVIIa) for severe bleeding
Postoperative Considerations
Maintain factor concentrations for specified time period as recommended by the hematologist
Ensure availability of blood products and factors from the blood bank
Anticipate and treat bleeding episodes

NSAIDs, nonsteroidal antiinflammatory drugs.

with vWD (Table 10.15). Many consider regional anesthesia to be contraindicated for patients with hemophilia, but there are reports of its use without complications as long as factor concentrations are maintained.[199]

HYPERCOAGULABILITY

A hypercoagulable state is a condition in which the development of thrombus is favored (i.e., thrombophilia). The condition results in an increased risk for abnormal clot formation and venous thromboembolic events (VTEs), which often are the presenting symptoms at the time of diagnosis. Thrombophilia can be acquired or congenital. The incidence of VTE among children is less than in adults, even in those with known congenital thrombophilic conditions,[200] although neonates and adolescents are at relatively high risk in the pediatric population.[201] Congenital thrombophilic conditions include factor V Leiden disorder, prothrombin gene mutation, protein C and S deficiencies, and antithrombin III deficiency.[202] Risk factors for acquired thrombophilia include the presence of a central venous catheter, infection, malignancy, surgery, or trauma.[201] Preoperative screening of nonoperative children with suspected hypercoagulability is controversial and not recommended for those who are asymptomatic, even those with a positive family history.[203]

Evidence-based guidelines for children are lacking with regard to screening and prophylactic treatment of those with suspected hypercoagulability. Current evidence suggests pharmacologic prophylaxis in the nonoperative setting is recommended only in children receiving long-term home total parenteral nutrition (TPN) and those with specific complex cardiac lesions (e.g., Fontan patients).[204] However, children who present for surgery with a strong family history of thromboses may benefit from screening and referral to a hematologist for management and consideration of pharmacologic prophylaxis, such as enoxaparin administered postoperatively. The use of nonpharmacologic prophylaxis, including early mobilization after surgery, adequate hydration, and compression stockings, is left to the discretion of individual providers and to institutional practice based on the child's medical history, family history, and risk factors for VTE.

Studies on the use of antifibrinolytic medications for preventing blood loss in high-risk surgeries (e.g., scoliosis, craniosynostosis) for patients with thrombophilia or a family history of thrombophilia are lacking. A risk/benefit discussion with the patient, family, and surgeon for each individual patient and surgery is recommended.

Hematologic Malignancies

Unlike in adults, hematologic malignancies are very common in children, accounting for over 40% of all new cancer diagnoses, the majority of which are leukemia.[205] Childhood malignancy occurs within any blood cell lineage. Each of the hematologic malignancies is a heterogeneous disease with multiple distinct biologic subtypes and thus multiple treatment options and survival rates. The hematologic malignancies are often categorized as listed in Table 10.16, which lists the groups and most common subtypes.

However, recent advances have demonstrated overlapping pathogenesis and features between some subgroups, leading to recent changes to some categorizations.[206] Fig. 10.1 illustrates the incidence of pediatric hematologic cancers by age. Acute lymphoblastic leukemia (ALL) has a spike of diagnosis between 2 and 5 years of age, acute myelogenous leukemia (AML) has a steady incidence throughout childhood, and lymphoma has a steadily rising incidence throughout childhood and adolescence. As such, children of all ages are at risk for a newly diagnosed hematologic malignancy, and each can present unique and challenging considerations during anesthetic care.

All hematologic malignancies stem from genomic alterations within a certain blood cell lineage in either the immature progenitor stage or mature stage of cellular differentiation. Leukemia is a malignant transformation of lymphoid or myeloid progenitor cells in the bone marrow, whereas lymphoma is malignant transformation of progenitor lymphoid cells (or less commonly, mature lymphocytes) in lymph nodes or other lymphatic tissues. Several subtypes of leukemia and lymphoma are very closely related and thus challenging to differentiate both clinically and histologically, especially if marrow and lymph involvement are both present at diagnosis. Histiocytoses are a group of malignant disorders characterized by abnormal function of dendrocytes, monocytes, or macrophages. Myelodysplastic syndromes and myeloproliferative neoplasms are rare malignant disorders of pluripotent hematopoietic stem cells that result in aberrant proliferation of one or more hematopoietic cell lineages and suppression of the rest.

TABLE 10.16 Incidence of Hematologic Malignancies in Childhood (Ages 0–14 Years)

Cancer	Incidence per 1,000,000	5-Year Survival (%)
Leukemias	54.1	85
Acute lymphoblastic leukemia	41.2	89
Acute myelogenous leukemia	8.4	65
Lymphomas	16.7	93
Hodgkin lymphoma	6.0	98
Non-Hodgkin lymphoma	7.5	89
Histiocytosis	–	–
Langerhans cell histiocytosis	5	85–100
Myelodysplastic syndromes	2	50

Data from references 207–210.

ACUTE LYMPHOBLASTIC LEUKEMIA

ALL is the most common childhood malignancy, accounting for 25% of all pediatric cancers and 76% of all leukemias.[207] Continued evolution of treatment protocols has led to an overall survival rate of 90% in children and adolescents in Western countries, some subgroups reaching survival rates as high as 95%.[211,212] Subgroups with lower 5-year survival rates include infant diagnosis (53% survival), adolescent diagnosis (76%), T-cell immunophenotype (82%), and a so-called high-risk categorization group (83%).[211] The incidence of ALL diagnosis peaks between the ages of 2 and 5 years and quickly declines thereafter (see Fig. 10.1).

Pathophysiology

ALL is a heterogeneous malignancy caused by mutation of lymphocyte progenitor cells at an early phase of differentiation, called lymphoblasts. The mutation arises either in B-cell or T-cell lymphoblasts in the bone marrow. Approximately 85% of ALL cases are of the pre–B-cell lineage (B-ALL), and the remaining 15% of cases originate from a progenitor T-cell lineage (T-ALL).[213] Both B-ALL and T-ALL can be further classified into several distinct genetic subtypes that influence the approach to treatment and subsequent outcomes. Leukemic potential commonly arises from a series of gene alterations that include chromosomal translocations and changes to chromosomal number. Subsequent additional genetic alterations then trigger the ultimate conversion to leukemia via inappropriate suppression or activation of regulatory proteins. These acquired genetic alterations lead to clonal proliferation and accumulation of immature blast cells in the bone marrow.[214–216]

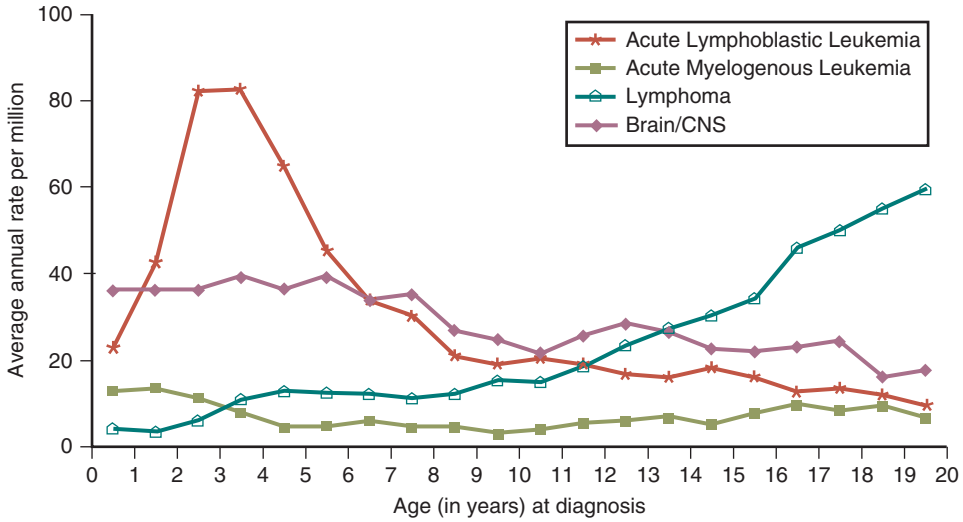

FIGURE 10.1 Age-Specific Incidence Rates for Childhood Cancer by International Classification of Childhood Cancer (ICCC) Group, All Races, Both Sexes, SEER 1986–94. (From Ries LAG, Percy CL, Bunin GR. Introduction. In: Ries LAG, Smith MA, Gurney JG, et al., eds. *Cancer Incidence and Survival among Children and Adolescents: United States SEER Program 1975-1995*. Bethesda, MD: National Cancer Institute, SEER Program, 1999. NIH Pub. No. 99-4649.)

Rapid expansion of blast cells crowds the marrow space and leads to ineffective hematopoiesis and peripheral cytopenias. Over time, leukemic cells invade other organs and tissues.

Few risk factors for developing ALL have been identified. Generally accepted risks include prior exposure to radiation (including in utero), inherited genetic polymorphisms, and genetic syndromes (e.g., Trisomy 21, Bloom syndrome, ataxia telangiectasia, and Fanconi anemia).[217,218] Children with Trisomy 21 have an 18-fold increased risk of developing leukemia during childhood, and two-thirds of the leukemic diagnoses are ALL. Survival of children with Trisomy 21 and ALL is less than in the non–Trisomy 21 population because of the frequencies of relapse and treatment-related mortality.[219,220]

Clinical and Laboratory Features and Treatment

The presenting signs and symptoms of childhood ALL are usually nonspecific in the early stages. The extent of bone marrow suppression and cytopenias influences the severity of presenting symptoms, which often include frequent upper respiratory infections, fevers, fatigue, malaise, pallor, petechiae, easy bruisability, lymphadenopathy, hepatosplenomegaly, pain in extremities, and refusal to walk.[221] When a complete blood cell count (CBC) is first obtained, it is often suggestive of leukemia. The initial CBC will typically show leukocytosis in half of children, anemia in 80% of children, neutropenia, and thrombocytopenia.[221–223] Often the child will appear pale and tired but otherwise healthy. However, children with advanced disease and a large tumor burden with extramedullary spread at diagnosis might be decidedly sicker; they can present with hyperuricemia, renal insufficiency, calcium and phosphorus abnormalities from skeletal invasion, liver dysfunction from leukemic infiltration, and mild coagulopathy.[223] At diagnosis, the presence of central nervous system (CNS) leukemia or an anterior mediastinal mass is uncommon in B-ALL; however, half of children with T-ALL have an anterior mediastinal mass, one-half have hyperleukocytosis and risk for vascular stasis, and 10% to 15% have CNS leukemia at diagnosis.[221,222,224] A bone marrow aspirate provides the definitive diagnosis, and immunophenotyping and cytogenetic studies confirm the ALL subtype and genetic characteristics that guide the child's therapy. Usually under the same anesthetic, a lumbar puncture is performed to assess the presence of lymphoblasts in the cerebrospinal fluid (CSF).

Because ALL is a heterogeneous disease, genomic data from the child's specific leukemia cells guide estimates of survival probability, response to treatments, and optimal treatment protocol.[216,225] In most pediatric oncology centers, treatment occurs in five phases: induction, consolidation and CNS preventive therapy, interim maintenance, delayed intensification, and maintenance. The intensity and time interval of each therapy is tailored to the child's risk category, which is determined by the risk of relapse of the specific tumor subtype. Of note, cranial radiation is seldom used for newly diagnosed ALL in children; outcomes are similar without it, and radiation risks chronic neurocognitive dysfunction and secondary tumors.[226,227]

Induction begins soon after diagnosis, and the goal is to administer intensive systemic and intrathecal chemotherapy to eradicate more than 99% of leukemic cells and restore normal hematopoiesis. In standard-risk ALL, three-drug treatment includes a glucocorticoid, vincristine, and asparaginase. Those at increased risk typically receive a fourth agent such as an anthracycline.[212] Remission at the end of the 4- to 6-week induction is defined as less than 5% blasts in the marrow and recovery of normal blood counts. Submicroscopic depth of remission can be further quantified by minimal residual disease (MRD) detection, typically by flow cytometry. The child's rapidity of response to induction and degree of MRD at the end of this cycle are important predictors of outcome and influence therapy in subsequent stages.[228] Although most children achieve remission at the end of induction, relapse is inevitable without continued therapy.[212] The overall health of the child during this phase is variable.[229]

Thereafter, consolidation, interim maintenance, and delayed intensification are used for 6 to 9 months depending on the treatment protocol. This phase uses high-dose intrathecal and intravenous chemotherapy to continue leukemic cytoreduction in all tissues and maintain remission. The pharmacologic regimen, duration, and intensity vary per treatment protocol. The recent addition of targeted antitumor agents (e.g., imatinib for Philadelphia chromosome–positive leukemia) has improved outcomes for children at increased risk during this phase of treatment.[225] Significant myelosuppression and toxicities of therapy are common during this period and often limit and delay chemotherapy dosages, particularly the presence of severe neutropenia. Alopecia, mucositis, anorexia, vomiting, significant infections, and fatigue are common during this period.[224] While outpatient management is usual, hospitalization is often required during intensive stages or at any time to manage sequelae of this aggressive phase. Supportive care with blood transfusions, nutritional support, infection precautions, and medications to counter toxicity are crucial.[230] The final phase is maintenance for 1.5 to 2.5 years, and this phase is managed with oral chemotherapy (methotrexate, mercaptopurine, ± additional agent) in the outpatient setting. Children at this stage often lead near-normal lives outwardly. However, some may require short-term hospitalization for neutropenic infections or deterioration of their clinical status, and many continue to suffer chronic therapy-related dysfunction, including pain, neuropathies, depression, and psychosocial dysfunction.[229]

Up to 20% of children will relapse; survival rates are significantly reduced with relapse, especially if it occurs during treatment rather than after treatment.[231] Because of increasingly poor outcomes in relapsed disease, therapies with greater toxicity or investigative therapies are often used. HSCT is a frequently used modality in relapsed children, whereas HSCT is uncommonly used during initial diagnosis, save for those at greatest risk.[232] Investigational therapies, such as adoptive T-cell therapies discussed in Chapter 11, are showing considerable promise as well.[233] The overall clinical status of children during relapse is broad, ranging from outpatient to intensive care management.

Perioperative Considerations

The newly diagnosed child with ALL will present soon after diagnosis for long-term central venous access under anesthesia to facilitate frequent intravenous chemotherapy and blood draws. Before the first anesthetic, the presence of an anterior mediastinal mass must be ruled out (see also Chapter 15), given that more than half of children with T-ALL will have a mass at the time of diagnosis, although only a minority will be symptomatic.[222] During induction and consolidation stages of therapy (in the first 6–9 months), the child will undergo multiple bone marrow aspirations and lumbar punctures. Other surgical procedures during ALL treatment are not particularly common, with the exception of revision of malfunctioned or infected central venous access. Before any anesthetic, a CBC should be reviewed. Table 10.2 lists commonly recognized minimal safe platelet counts before invasive procedures, but institutional protocols may vary for lumbar puncture and bone marrow aspiration. Strict adherence to aseptic

TABLE 10.17 Perioperative Concerns in Pediatric Cancer and Hematopoietic Stem Cell Transplantation

Preoperative Considerations
Consultation with service primarily responsible for child's care
Complete blood cell count (when appropriate)
Echocardiogram or chest radiograph, or both (when appropriate)
Transfusion crossmatch with specifications (e.g., cytomegalovirus seronegativity, leukocyte reduction, irradiation) determined in consultation with oncology service
Determination of blood typing requirements for all stem cell transplant recipients
History of acute and chronic pain medication use
Infection prophylaxis with antibiotics
Avoidance of *any* marrow-suppressive medications in stem cell transplant patients
Observation of indicated isolation precautions
Sterile technique with central line access
Intraoperative Considerations
Attention to skin, teeth, eyes, and joints; careful positioning and padding
Careful airway instrumentation in the setting of mucositis
Sterile technique with central line access
Full-stomach precautions (when appropriate, as in graft-versus-host disease)
Appropriate hydration and maintenance of urine output
Continuation of total parenteral nutrition (and other parenteral fluids with high glucose concentration)
Avoidance of high fraction of inspired oxygen (FIO_2) and restriction of hydration if prior treatment with bleomycin
Judicious use of cardiac depressants in patients with compromised cardiac function
Nausea and vomiting prophylaxis: avoid corticosteroids for antiemesis unless discussed with oncology
Administer stress dose steroids when indicated, after consultation with oncology
Regional anesthesia when safe and indicated
Postoperative Considerations
Patient-appropriate opioid and other analgesic administration
Sterile technique with central line access
Observation of indicated isolation precautions

protocols is imperative, especially for neutropenic children, as is attention to friability of oral mucosal tissue during laryngoscopy in patients with mucositis. Indiscriminant use of parenteral steroids should be avoided, especially before the diagnosis is confirmed and a treatment plan is prescribed, as it may (1) complicate the diagnosis by causing tumor cell necrosis, (2) cause tumor lysis syndrome, and/or (3) affect treatment randomization. Table 10.17 lists general perioperative considerations for all children with hematologic malignancies, and additional detailed anesthetic considerations are discussed in Chapter 11.

ACUTE MYELOGENOUS LEUKEMIA

Although far more prevalent in older adults, AML is the second most common leukemia in childhood, representing 18% of leukemias in children but 50% of all leukemic deaths in children.[207,234] The incidence of AML in children is biphasic, with a greater incidence of diagnosis before age 3 and after age 14 years (see Fig. 10.1). The increasing incidence in adolescence reflects the gradual increased prevalence throughout all of adulthood.[207] The 5-year survival of childhood AML has improved dramatically in the past several decades to 65% to 70%, but nearly half of all children diagnosed with AML eventually relapse and die from the disease. AML remains one of the major groups of childhood cancer with the worst overall survival rates, and the mortality rate increases with increasing age at diagnosis.[207,234,235]

Pathophysiology

AML is a heterogeneous malignancy of undifferentiated myeloid precursor cells. AML can arise as a de novo disease or as a secondary disease from previous cytotoxic exposures (e.g., previous cancer therapy) or myelodysplastic syndromes. Like ALL, AML is further categorized based on subtypes of tumor cytology, and as such, treatment protocols and outcomes differ among the subtypes.[236] The genesis of AML appears to be due to a series of genetic mutations that lead to rapid clonal proliferation and accumulation of maturation-arrested myeloid cells.[237] Marrow crowding and eventual infiltration of extramedullary sites lead to the development of the symptomology seen at presentation.[236]

Inherited risks are an important component in the development of childhood AML. Some of the more common risk factors include Trisomy 21, Fanconi anemia, Bloom syndrome, ataxia telangiectasia, Shwachman-Diamond syndrome, and familial monosomy 7.[238] Trisomy 21 is the most common of these syndromes and has a 10- to 20-fold increased risk of development of AML.[239] Environmental risks are not well understood in childhood AML, with the exception of the greatly increased risk of AML in children exposed to high radiation (e.g., survivors of atomic bombs in 1940s' Japan). Prior exposure to chemotherapeutics, especially topoisomerase inhibitors, and acquired marrow suppression conditions are an important cause of secondary AML.[236]

Clinical and Laboratory Features and Treatment

Clinical symptoms prior to diagnosis are usually nonspecific but often include pallor, bleeding, easy bruising, and infections, all as a result of pancytopenia. Depending on the degree of marrow suppression at the time of diagnosis, anemia and thrombocytopenia are present in the majority of patients.[236,240] The white blood cell count may range from low to high, but neutropenia is common, which predisposes to severe infections. Hyperleukocytosis (>100,000/mm^3) is present in 20% of patients with AML at diagnosis.[241] Approximately 14% of children are at risk of bleeding and thrombosis as a result of thrombocytopenia, platelet dysfunction, and anticoagulant or procoagulant factors released from tumor cells; this is particularly an issue in acute promyelocytic leukemia.[242] Extramedullary manifestations are uncommon, found in about 10% of children at diagnosis, and they most commonly occur in skin (leukemia cutis), head, neck, brain (leptomeningeal), and spinal cord.[243] When AML is suspected, a bone marrow aspiration and biopsy is diagnostic. Cytogenetic evaluation of leukemic cells in the marrow influences the treatment protocol and estimation of survival.[244]

The goal of induction is remission of leukemic cell burden, for which cytarabine, daunorubicin, and etoposide are standardly used. Compared with ALL induction, AML induction is significantly more intense with a much higher risk of life-threatening complications including infection. Although postinduction remission rates have risen over time to approximately 85% to 90%, treatment-related morbidity and mortality continue to be problematic.[245] Substantial

myelosuppression is usual, and supportive care is crucial, including hospitalization through induction therapy and aggressive management of neutropenic infections.[246] Tumor lysis syndrome is also a risk in children with high tumor burden.[247] Up to 4% of children develop early significant cardiomyopathy after daunorubicin or other anthracycline therapy.[248] CNS involvement is present in 10% to 10.30% of children; thus lumbar punctures with intrathecal chemotherapy are routine.[249,250] Like ALL, additional therapy is required after induction to avoid universal relapse of disease. Many treatment protocols use three to four cycles of intensification therapy after induction, which attempt to balance optimal tumor suppression with avoidance of severe toxicity. The role of HSCT in newly diagnosed childhood AML is typically reserved for children with high-risk AML in postremission therapy.[228] Chronic health conditions in survivors of AML are present in 55%, particularly those treated with HSCT.[251] With the high risk of relapse in pediatric AML, many children will then undergo more intensive treatment protocols, including HSCT. Thus these children are at risk for greater morbidity and mortality through this treatment.[252]

Several subtypes of AML are important to mention. Acute promyelocytic leukemia (APL) represents 5% to 10% of AML and is a form of AML in which the predominant cells are promyelocytes with specific mutation to the retinoic acid receptor gene.[253] When APL cells were found to be exquisitely sensitive to all-*trans*-retinoic acid (ATRA) and ATRA was added to treatment protocols, survival in childhood APL improved to approximately 90%, which is significantly better than AML overall.[254] The current therapy for APL omits all chemotherapy other than ATRA and arsenic trioxide; thus the toxicity profile and chronic morbidity are dramatically different than that of other AML therapy. Of note, severe coagulopathy is often present at the time of diagnosis, and the risk of bleeding and thrombosis is multifactorial, in part due to high rates of DIC and hyperleukocytosis.[242,255,256]

Children with Trisomy 21 are at significant risk of myeloid malignancies. De novo AML in Trisomy 21 has an excellent overall survival, allowing reduction of chemotherapy intensity.[257] This lower intensity chemotherapy reduces the risk of treatment-related morbidity seen in children with Trisomy 21 in the past, including a 17% incidence of early, symptomatic cardiomyopathy and 3% mortality from cardiomyopathy.[258] Transient abnormal myelopoiesis (TAM), which is currently classified as a myeloproliferative disorder rather than a myeloid leukemia, is present in at least 4% to 10% of neonates with Trisomy 21. TAM shares some similarities with AML, yet it usually undergoes spontaneous remission. Progressive cases can require chemotherapy to achieve remission and survival. Approximately 16% to 20% of these children will subsequently develop AML after remission of the myelopoietic disorder.[259,260]

Therapy-related AML (t-AML) occurs in 1% to 2% of children treated with chemotherapy or radiotherapy for a malignant or nonmalignant condition, and this subtype represents 10% to 20% of childhood AML. The onset of t-AML occurs 2 to 10 years after exposure to the causative chemotherapy drug. Prognosis is very poor overall, although the use of HSCT in early remission may improve outcomes.[261]

Perioperative Considerations

As in ALL, children with AML present soon after their diagnosis is confirmed for a surgically placed central venous access and serial bone marrow aspirates and lumbar punctures. Newly diagnosed children should be screened for hyperleukocytosis, retinoic acid syndrome, an anterior mediastinal mass, and the sequelae of pancytopenia. Because anthracycline chemotherapeutics are routine during AML therapy, the presence of cardiomyopathy must be assessed, and serial echocardiograms should be performed throughout the treatment. Aseptic technique should always be observed. In children with mucositis, care should be taken during laryngoscopy to minimize any trauma to friable oral mucosal tissue. Indiscriminant use of parenteral steroids should be avoided, especially before the diagnosis and treatment determination, as it may (1) cause tissue necrosis impairing diagnosis, (2) cause tumor lysis syndrome, and (3) affect the treatment randomization. Additional detailed anesthetic considerations are discussed in detail in Chapter 11, including recommendations for those with cardiomyopathy and post-HSCT.

HODGKIN LYMPHOMA

Hodgkin lymphoma (HL) is the eighth most common pediatric cancer and constitutes 40% to 50% of all pediatric lymphoma cases. In economically advantaged countries, the incidence of HL has a bimodal age distribution, with the first peak between 15 and 35 years and the second after the age of 55 years. As such, infantile HL is rare, but the steady rise in incidence with age leads to HL being the most common childhood cancer among 15- to 19-year-olds. Onset of disease in earlier childhood is more prevalent in developing countries.[207,262,263] Survival rates for pediatric HL are excellent; 5-year survival exceeds 97% in the United States.[207] Because of excellent survival, the current focus of treatment protocols has shifted to minimizing lifelong morbidity while maintaining these survival rates.[264,265]

Pathophysiology

HL is a B-cell lineage malignancy characterized by clonal proliferation of malignant Hodgkin/Reed-Sternberg (HRS) cells. The HRS cells accumulate within lymph nodes and other lymphatic tissues and are joined by a significant infiltrate of variable inflammatory cells, which constitute 99% of the tumor volume.[266] Established risk factors for childhood HL include immunodeficiency states, infection with Epstein-Barr virus (EBV), and family history of HL. Depending on age of diagnosis and geographic location, up to 40% to 50% of pediatric HL cases are associated with latent EBV infection, as determined by EBV^+ tumor cells.[267,268] HL is subclassified into classical HL and nodular lymphocyte predominant HL; although the prevalence of each subtype varies across age groups, classical HL constitutes approximately 80% to 90% of pediatric cases and has slightly less favorable outcomes compared with the nodular lymphocyte predominant subclass.[269]

Clinical and Laboratory Features and Treatment

Splenomegaly and painless lymphadenopathy of the cervical, supraclavicular, axillary, and occasionally inguinal lymph nodes are the presenting signs in 80% of children. Mediastinal involvement is common; 55% to 65% have a mediastinal mass with the possibility of cardiopulmonary compromise (see also Chapter 15), and 5% have pericardial involvement with the possibility of effusion at presentation. Up to 10% of children present with constitutional "B" symptoms, which include fever, drenching night sweats, and weight loss greater than 10% within 6 months before diagnosis. The presence of B symptoms has important implications for staging and prognosis.[270–272] Laboratory evaluation at diagnosis is often nonspecific, including leukocytosis, lymphopenia, eosinophilia, and monocytosis. RBC and platelet counts are usually normal except in the setting of severe metastatic disease. However,

immune suppression is often already present at the time of diagnosis.[271]

Diagnostic evaluation includes physical examination and imaging studies. A chest x-ray rapidly screens for mediastinal disease, and CT of the neck, chest, abdomen, and pelvis evaluates the extent of adenopathy. Diagnostic staging and interim assessment with positron emission tomography (PET) is increasingly used.[273] Definitive diagnosis requires an excisional lymph node biopsy because it provides the only means to obtain the scarce HRS cells for histologic confirmation.[274]

The treatment protocol depends on the child's risk stratification from the biopsy and imaging studies. Decades ago, treatment protocols with high-dose radiation therapy and chemotherapy led to excessive chronic toxicity in survivors of childhood HL. Current strategies focus on less toxic combined modality therapy that includes low doses of multiple chemotherapeutics and low-dose or even elimination of radiation therapy.[274,275] When used, the low-dose involved field radiation administered in pediatric HL is usually well tolerated, and most acute affects are transient and reversible.[275] Outcomes in relapsed HL remain favorable, and as such, children with low-risk relapse can often be cured with conventional-dose chemotherapy and radiation therapy. However, high-risk relapse often requires high-dose chemotherapy and HSCT.[276]

Perioperative Considerations

Excisional lymph node biopsy and long-term central venous access are usually performed with the patient under anesthesia soon after presentation. At least two-thirds of children will have mediastinal lymphadenopathy at diagnosis, and one-half of those will have a symptomatic anterior mediastinal mass larger than 30% of the cardiac silhouette,[270,272,277] which places them at risk of death during anesthesia.[278] Any child with significant lymphadenopathy should be suspected of having a lymphoma and be assessed for the presence of an anterior mediastinal mass before beginning anesthesia, as discussed in Chapters 11 and 15. With large, compressive mediastinal masses, the risks of general anesthesia even for minor procedures such as excisional node biopsy may warrant that the procedure be performed with the patient under local anesthesia with or without sedation.

Although chemotherapy protocols vary, most patients will be treated with a four- to seven-drug combination of a vinca alkaloid (e.g., vincristine), anthracycline (e.g., doxorubicin), bleomycin, cyclophosphamide, corticosteroid, methotrexate, procarbazine, and etoposide, as well as possible radiation therapy.[279] Thus, significant myelosuppression and toxicities of therapy may occur during treatment. Children who receive bleomycin are at risk for developing pulmonary dysfunction and acute respiratory failure, particularly after high concentrations of oxygen. Recent evidence has questioned the role of oxygen in the pathogenesis of bleomycin-induced lung injury, and the risk in children has never been confirmed (see also Chapter 11).[280–282] Among survivors of childhood cancer, those with HL have one of the greatest burdens of chronic disease, especially those treated with both chemotherapy and radiation. The rate of cardiac disease during and after treatment with anthracyclines and chest radiation is of particular concern, and survivors must be screened for cardiac disease; however, most cardiac-related mortality does not occur until years later.[283–286] As usual, attention to sterile technique, awareness of possible friability of oral mucosal tissue during laryngoscopy, and indiscriminant use of parenteral steroids should be avoided. Additional detailed anesthetic considerations are discussed in Chapter 11.

NON-HODGKIN LYMPHOMA

Non-Hodgkin lymphoma (NHL) accounts for 7% of all childhood cancers, making it the fifth most common pediatric cancer. NHL is rarely diagnosed in infancy, and the incidence increases steadily through each year of childhood. There is a clear male predominance, especially in the preadolescent age group. Among the lymphomas, NHL is more common in children younger than 10 years of age, and HL is more common in those older than 10 years. The 5-year survival of children from birth to age 19 years at diagnosis of NHL is 87%, which is considerably less than HL and nearly identical to ALL.[207]

Pathophysiology

NHL is a heterogeneous group of neoplasms that derive from lymphocyte B-cell progenitors, T-cell progenitors, mature B cells, or mature T cells and accumulate predominantly in lymph nodes and lymphoid tissues. However, up to 40% of NHL tumors arise in nonlymphatic extranodal tissues, which may create a diagnostic challenge.[287,288] Compared with HL, NHL is both a more systemic malignancy that disseminates from lymphoid tissues to extranodal tissues (and vice versa, and aggressive at the time of diagnosis.[274,289] Multiple subtypes of NHL occur in children, the most common being Burkitt lymphoma, lymphoblastic T-cell or B-cell lymphoma, diffuse large B-cell lymphoma, and anaplastic large cell lymphoma; other subtypes are rare.[274,290] A congenital or acquired immunodeficiency state is the leading risk factor for the development of NHL, which include Wiskott-Aldrich syndrome, ataxia telangiectasia, X-linked lymphoproliferative syndrome, AIDS, and posttransplant or other iatrogenic immunosuppressed states. Inherited conditions, however, predispose less than 2% of pediatric cases.[291,292]

Clinical and Laboratory Features and Treatment

Clinical presentation of NHL is similar to that of HL; most children present with painless but rapidly expanding masses, which can produce a symptomatic mass effect of surrounding tissues and structures. As such, clinical emergencies from compression of vital structures are common in NHL, including an anterior mediastinal mass, spinal cord compression, CNS involvement in 6% of children, pericardial tamponade, thromboembolism, and intestinal intussusception or obstruction.[289,293] The most common sites of primary tumor in all children with NHL are the abdomen, mediastinum, and peripheral lymph nodes, especially of the head and neck.[294] In Burkitt lymphoma, which is the most common form of pediatric NHL, the most common primary sites of disease are the head, neck, and then abdomen; however, tumor masses may also be found in bone, bone marrow, skin, testes, and CNS. Advanced disease with bone marrow and CNS involvement is present in 25% of children.[289,295]

Results of initial laboratory evaluation are variable. The CBC can be normal, but pancytopenia is present when there is extensive marrow invasion. Thrombocytopenia and anemia are signs of splenic sequestration and internal bleeding, respectively. About 20% of children experience tumor lysis syndrome at induction of treatment as a result of the high metabolic rate of rapidly proliferating NHL tumor cells. A significant percentage of these children may require dialysis.[296,297] Initial CT imaging of the neck, chest, abdomen, and pelvis evaluates the extent of disease. Because extranodal spread of noncontiguous tumor is common in childhood NHL, PET scanning has become an integral part of baseline, interim, and posttreatment staging; however, the role of PET to influence treatment protocols remains under investigation.[273,298,299]

MRI scans are usually limited to evaluation of specific tissue involvement, such as bone or brain.[290] Definitive diagnosis is made by pathologic evaluation of a lesion biopsy, and then bilateral bone marrow aspiration and biopsy and CSF cytology provide further disease staging.[289]

Treatment of pediatric NHL is focused on chemotherapy protocols that vary with the subtype of NHL and clinical staging. The advent of targeted therapies, such as rituximab, are playing an increasing role for some subtypes of NHL.[300–302] Overall, treatment cycles of many stages of pediatric NHL are very short, using high-dose pulses of chemotherapy drugs with intensive supportive care. The use of prophylactic radiation therapy has become exceedingly uncommon in pediatric NHL as it risks lifelong toxicity and has not been shown to appreciably improve outcomes in most subtypes. As such, it remains in some therapy protocols only for those with documented CNS involvement at the time of diagnosis or those with incomplete response to chemotherapy.[302–304] The usual sequelae of chemotherapy are seen during treatment, including myelosuppression, infections, mucositis, nausea and vomiting, cardiac toxicity, and neurobehavioral complications.

Perioperative Considerations

Like most pediatric hematologic malignancies, surgery during therapy is mostly limited to the initial diagnostic biopsy, placement of central venous access, and treatment of any complications of therapy. Complete resection of localized tumors is uncommonly indicated, and debulking surgery of large tumor masses is no longer indicated.[305] However, tumor invasion and destruction of the bowel or other vital organs may require urgent surgical attention. Lumbar punctures with cerebrospinal cytology and intrathecal methotrexate may be indicated as prophylaxis in some subtypes of NHL and in children with CNS disease at diagnosis.[289]

The primary anesthetic considerations specific to children with newly diagnosed NHL include anterior mediastinal mass, mass effect of tumor on the upper airway, and tumor lysis syndrome. Because of the considerable risks of anesthesia in the presence of an anterior mediastinal mass, all children with suspected NHL must receive a thorough physiologic and radiographic evaluation prior to anesthesia (see also Chapter 15). NHL lesions of the upper airway may obstruct the airway or bleed during airway management.[306,307] Although tumor lysis syndrome most frequently occurs during chemotherapy induction, it can occur spontaneously, during anesthesia and surgery, or with a dose of corticosteroids.[308] Additional discussion of anterior mediastinal mass, tumor lysis syndrome, and anesthetic considerations not specific to NHL are discussed in detail in Chapter 11.

LANGERHANS CELL HISTIOCYTOSIS

Histiocytic disorders are a group of disorders of "histiocytes," which is an archaic term for dendrocytes, macrophages, and monocytes. Histiocytosis is generally divided into Langerhans cell histiocytosis (LCH) and non-Langerhans histiocytosis. Given the rarity of the non-Langerhans subtypes, the subsequent focus of this section will be on LCH only.

The etiology and epidemiology of LCH remain poorly understood. It is an uncommon and predominantly childhood disorder with an incidence of 4 to 9 cases per million children per year, similar in incidence to Hodgkin lymphoma or AML. The usual age at diagnosis is 1 to 6 years.[208,309–311] The spectrum of childhood LCH ranges from single-system focal lesions to life-threatening multisystem disease. The overall survival rate of the more common low-risk focal disease is 99%, but high-risk disseminated disease has a survival of approximately 85%.[208,209]

Pathophysiology

LCH is an inflammatory neoplasia of myeloid dendritic cell precursors. Although the etiology is poorly understood, malignant transformation of dendritic cells leads to clonal proliferation and accumulation into lesions. The lesions are accompanied by a host of inflammatory cells that release a local cytokine storm, leading to the symptomatic destruction of surrounding tissues.[312]

Clinical and Laboratory Features and Treatment

Most childhood LCH presents with single-system focal lesions. About 30% of children present with multisystem disease, and this form is most common in the youngest of children.[309,311,313] The lesions can form in any organ system; however, nearly 80% of cases present with lytic bone lesions, followed by papular skin lesions in 40%.[314] Involvement of bone marrow, liver, lung, or spleen portends a poor prognosis. Physical symptoms depend on the site and extent of tissue lesions. Laboratory values are most notable for evidence of an inflammatory state, although anemia is common.[309,311]

LCH can be difficult to diagnose because its clinical presentation is often insidious and representative of a broad differential diagnosis. The exception is in the subset of neonates who present with a rapidly progressive disseminated disease.[208] Biopsy of a lesion, usually skin or bone, confirms the diagnosis. The histology demonstrates LCH cells surrounded by a substantial volume of inflammatory cells. Subsequent radiologic imaging with skeletal survey, CT, and PET confirm the extent of disease and influence the approach to treatment.[315] Unless the liver, spleen, or pituitary gland are directly involved, laboratory analysis is usually normal.

Treatment of childhood LCH is widely variable depending on the extent of disease and organs involved. Isolated bone lesions may be treated with surgical curettage and intralesional steroids with excellent results, but reactivation of disease can occur. Isolated cutaneous disease can be resolved with topical medications only or may regress on its own, but subsequent progression to multisystem disease may be fatal in young children. Thus most children are treated with a combination of steroids and relatively low-dose chemotherapy for 6 to 12 months. Surgical removal of lesions may be indicated in some cases, and radiation is sparingly used for invasion of critical organs or structures (e.g., CNS).[314,316–319]

Perioperative Considerations

Depending on the clinical staging, treatment administered, and presence of disease relapse, 3% to 50% of children will have diabetes insipidus before, during, or especially after treatment.[309,319] Children with polyuria and polydipsia should be fully evaluated prior to elective surgery, and children with previously diagnosed diabetes insipidus should be managed after consultation with the oncology team, as optimal treatment with desmopressin and fluid management varies among children.[320] Chemotherapy protocols are generally less toxic than in other childhood hematologic cancers, and major toxicity is less common. However, liver and lung fibrosis can occur and can be at least mildly symptomatic.[317]

MYELODYSPLASTIC AND MYELOPROLIFERATIVE DISORDERS

Myelodysplastic and myeloproliferative disorders are rare hematologic malignancies that are categorized into three distinct

groups: myelodysplastic syndromes (MDS), juvenile myelomonocytic leukemia (JMML), and Trisomy 21–specific diseases. Transient abnormal myelopoiesis of Down syndrome and myeloid leukemia of Trisomy 21 were discussed with AML and are not being discussed here.

The MDSs are a rare form of myeloid malignancy in children, accounting for just 4% of hematologic malignancies in children; the median age at diagnosis is 7 years.[206,210] Recognition of MDS is important because of its frequent evolution to pediatric AML. Five-year survival is variable (approximately 50%) and depends on the disease characteristics.[321] JMML is a rare myeloid malignancy of young children, with an average age of onset at 2 years of age.[206] Approximately 13% of patients with JMML eventually progress to AML.[322] Five-year survival is approximately 40% but specific survival is variable based on disease characteristics.[321]

Pathophysiology

MDSs are clonal hematologic disorders, characterized by abnormal proliferation and differentiation of hematopoietic stem cells. Mutation of hematopoietic stem cells early in the cell line leads to chronic cytopenia of all cell lines but with varying severity, and as such, MDS may appear similar to aplastic anemia or bone marrow failure disorders. MDS is subclassified into three groups: refractory cytopenia, refractory anemia with excess blasts (RAEB), and refractory anemia with excess blasts in transformation (RAEB-t).[206,323] Inherited bone marrow failure syndromes are associated with childhood MDS in 20% of children, including Fanconi anemia, Kostmann syndrome, Shwachman-Diamond syndrome, Diamond-Blackfan anemia, Trisomy 8 mosaicism, familial MDS, and aplastic anemia. Prior chemotherapy and radiation are important acquired factors.[206,322,324]

JMML is also a potentially lethal malignant disorder of myeloid stem cell proliferation, but in this disorder, differentiation and maturation of monocytes is not blocked, leading to isolated monocytosis.[325] Neurofibromatosis type 1 (NF1) is the primary risk factor for JMML; more than 10% of children with JMML have NF1, and another 20% have mutation of the tumor suppressor *NF1* gene.[326]

Clinical and Laboratory Features and Treatment

Children presenting with MDS are typically pancytopenic, and hepatosplenomegaly is very common.[322] Initial treatment is dependent on the severity of cytopenia. Some children, especially those with refractory cytopenia or mild RAEB, have mild disease for months or even years with only infrequent need for blood transfusions, while others present with severe disease. Regardless of presentation, progression is inevitable and the only cure for MDS is HSCT. Recent data suggest that outcomes improve in children who do not receive pre-HSCT chemotherapy and who advance to HSCT shortly after diagnosis.[327,328] Preconditioning regimen-related mortality and HSCT-related mortality are high, and survival rates in children who relapse after HSCT are dismal.[206]

In children with JMML, anemia, thrombocytopenia, and monocytosis are seen on initial laboratory studies; RBC evaluation demonstrates Hgb F in a majority of children.[322,325] Clinical presentation usually includes fever, respiratory symptoms, skin rash, adenopathy, and hepatosplenomegaly, which may be severe in advanced disease. Peripheral blood tests can confirm the diagnosis, but bone marrow studies are usually performed.[329] The clinical course can be rapidly progressive or indolent; regardless, JMML is resistant to treatment with chemotherapy, and without HSCT, survival is short with only 6% surviving 10 years.[330] Thus all patients are treated with HSCT. Despite advances in HSCT and supportive care, half of these children will not survive 5 years, and within that time period, up to 15% will progress to AML.[331]

Perioperative Considerations

Anesthetic considerations for children with MDS or JMML are similar to those discussed previously for children with AML. As most of these children will undergo HSCT, Chapter 11 details the anesthetic considerations for children before and after HSCT.

Summary

ALTHOUGH CHILDHOOD CANCER is not particularly common, it is the second most common cause of death in children younger than 15 years of age.[1,2] The most common malignancies affecting children are different from those affecting adults. Leukemia, brain tumors, lymphomas, and sarcomas of tissue and bone are the most common pediatric cancers and account for over 50% of all pediatric malignancies (Table 11.1). Embryonal tumors (e.g., neuroblastoma, Wilms tumor, retinoblastoma, medulloblastoma) are unique to early childhood, which underscores the need for these children to be cared for in pediatric centers with sufficient expertise in their management. Survival rates for most pediatric cancers have improved significantly in the past several decades; more than 80% of children diagnosed with a childhood malignancy will become 5-year survivors of their cancers,[3,4] and 5-year survival rates for acute lymphoblastic leukemia (ALL) have now increased to nearly 90%.[5] The great improvements in survival for many malignancies of childhood are directly related to advances in diagnostic modalities and the large percentage of children treated in cooperative clinical trial protocols.[5,6] Treatment options in these protocols include chemotherapy, radiation therapy, biologic modifiers, hematopoietic stem cell transplantation (HSCT), and adoptive T-cell therapies.

Children with cancer typically undergo many surgical procedures that require anesthesia. The procedures may occur before or during the cancer therapy, years into remission, or during terminal stages of the disease. Certain considerations apply to this population, including the direct effects of the tumor, effects of the chemotherapy and radiation therapy, impact of the surgical procedure, pain syndromes, and psychological vulnerabilities of the child and family. Children undergoing active treatment for cancer range from gravely ill to relatively healthy with excellent functional capacity. Survivors of childhood cancer experience various long-term and often debilitating sequelae after completion of cancer therapy. In one report, 62% of survivors of childhood cancer reported at least one chronic health condition from cancer, and 28% reported a severe or life-threatening condition.[4] These chronic health conditions may impact nearly every organ system and have considerable bearing on any anesthetic plan years into remission. The field of pediatric oncology is extensive, complicated, and ever-changing. Multidisciplinary communication in the perioperative period is crucial to ensure the safe care of these complex patients.

Principles of Cancer Therapy

Most pediatric cancers are treated with an aggressive multimodal approach that may include surgical resection, radiation therapy, and chemotherapy for control of local and metastatic disease. Equally important is supportive care to ensure minimization of toxicity from the tumor and treatment therapy, including nutritional, emotional, and psychological support. A brief review of these therapies with pertinence to the perioperative period follows,

TABLE 11.1 Incidence of Pediatric Cancer by Age

Type of Cancer	INCIDENCE (%) BY AGE GROUP				
	0–4 years	5–9 years	10–14 years	15–19 years	0–19 years
Leukemias	36.1	33.4	21.8	12.4	25.2
Central nervous system tumors	16.6	27.7	19.6	9.5	16.7
Lymphomas	3.9	12.9	20.6	25.1	15.5
Carcinomas and other malignant epithelial tumors	0.9	2.5	8.9	20.9	9.2
Soft tissue sarcomas	5.6	7.5	9.1	8.0	7.4
Germ cell, trophoblastic, and other gonadal tumors	3.3	2.0	5.3	13.9	7.0
Malignant bone tumors	0.6	4.6	11.3	7.7	5.6
Sympathetic nervous system tumors	14.3	2.7	1.2	0.5	5.4
Renal tumors	9.7	5.4	1.1	0.6	4.4
Retinoblastoma	6.3	0.5	0.1	0.0	2.1
Hepatic tumors	2.2	0.4	0.6	0.6	1.1
Other and unspecified malignant neoplasms	0.5	0.3	0.6	0.8	0.6

but additional sources are available concerning the current indications, side effects, and precautions of the available chemotherapeutic drugs.[7–9]

CONVENTIONAL CHEMOTHERAPEUTICS

Conventional chemotherapeutics, along with radiation therapy, have been the mainstay of pediatric antitumor treatment for decades. In the modern era of multidrug combination chemotherapy, molecularly targeted therapies, radiation therapy, rescue therapies, and HSCT, anticipation of precise toxicities from any given therapy in an individual patient is difficult. However, treatment protocols include a potentially vast array of antitumor agents with widely divergent mechanisms of action and toxicity profiles, and the average child with cancer will be at risk for focal or widespread toxicity to nearly every organ system.[10] Most chemotherapeutic agents are cytotoxic to rapidly dividing cells via several mechanisms. Because these agents lack specificity to tumor cells alone, the impact to healthy tissues is unavoidable and often limits effective chemotherapy dosing schedules. Concurrent administration of several chemotherapeutics with non-overlapping toxicity profiles and at lower doses lessens the additive toxicity while also increasing the simultaneous cytotoxic attack on tumor cells.[11] Regardless, bone marrow suppression, immunosuppression, myocardial toxicity, pulmonary toxicity, and dysfunction of nearly every other organ system are possible in children with cancer[12] and must be thoroughly considered when evaluating and caring for these children. These toxicities range from short-term to lifelong effects.

Several chemotherapeutic agents are of specific interest to the anesthesiologist caring for a child with cancer. Anthracycline chemotherapeutics (e.g., doxorubicin, daunorubicin, idarubicin, and epirubicin) and mitoxantrone cause cardiomyopathy in a dose-dependent fashion, an effect exacerbated by mediastinal irradiation. L-Asparaginase is associated with a 1% to 2% risk of hemorrhage or thrombosis owing to deficiencies in fibrinogen, plasminogen, antithrombin III, and von Willebrand factor, as well as hepatic dysfunction and acute hemorrhagic pancreatitis.[13–15] Bleomycin may cause acute pneumonitis with progression to pulmonary fibrosis.[16] Cisplatin and ifosfamide may cause renal tubular damage that can lead to Fanconi syndrome with electrolyte wasting.[17,18] In large doses, methotrexate (>1 g/m^2) may cause renal failure.[19,20] Corticosteroids may be directly cytotoxic to some hematopoietic tumors by inducing apoptosis, as well as causing adrenal suppression, hypertension, thromboembolism, and obesity. Specific toxicities of chemotherapeutic agents pertinent to anesthesia are discussed in detail below; Table 11.2 provides a brief list of major toxicities of the traditional chemotherapy agents. E-Table 11.1 provides a comprehensive list of traditional chemotherapeutic agents, molecularly targeted agents, and adjuvant medications used in children, with their corresponding toxicities.

Several non-chemotherapy adjunct medications and therapies are used to provide supportive care and to attenuate the toxicities of chemotherapy. With adequate treatment of toxic adverse effects, larger doses and/or additional chemotherapeutic agents can enhance the rate of remission. Such therapies include antiemetics, hematopoietic growth factors, HSCT, transfusion of blood products, and a number of medications that lessen or block organ-specific toxicity. Many of these therapies also pose acute and chronic risks to children; these risks must be balanced against their benefits.[11]

TARGETED ANTITUMOR AGENTS

Commensurate with the growing understanding of cancer biology is the recent development of "targeted" strategies that are directed specifically at cancer cells and thus limit direct toxicity to healthy cells. A commonly known example of these types of agents is the use of tyrosine kinase inhibitors (e.g., imatinib) in BCR-ABL (Philadelphia chromosome)–positive leukemia. As a result of less toxicity, oncologists can combine targeted therapies with full-dose standard chemotherapy for improved outcomes.[21–23] Targeted agents include antiangiogenic therapies, immunomodulatory therapies, gene therapies, and humanized antibodies.[23,24] Monoclonal antibodies are targeted to specific, unique tumor cell surface antigenic proteins. Small-molecule drugs, which are designed to target specific genetic signatures and biologic pathways critical to cancer growth and progression, have been developed that target tumor cell apoptotic pathways, histone deacetylation, protein farnesyltransferases, proteasome action, angiogenesis, and inhibition of the epidermal growth factor receptor tyrosine kinase.[21,23,25]

Although toxicities of these agents as a whole appear to be far less than those of traditional chemotherapeutic agents, rash, fatigue, alterations to skeletal growth plates (antiangiogenic agents), nausea, diarrhea, hypotension, and anaphylaxis have been reported.[26] The use of investigational and novel targeted antitumor agents amplifies the importance of reviewing cases with the oncologist.

RADIATION THERAPY

One quarter of all children newly diagnosed with cancer will require radiation as frontline therapy.[27] Photons (e.g., x-rays) and particle radiation (e.g., electrons, protons, neutrons) are the two major types of ionizing beam radiation. Regardless of the

TABLE 11.2 Therapy-Related Adverse Effects and Toxicity

Drug	Adverse Effects
L-Asparaginase	Hyperglycemia, hypersensitivity, hepatic dysfunction (secondary hypoalbuminemia and coagulopathies), pancreatitis, thrombosis, stroke
Bischloroethyl nitrosourea (BCNU)	Encephalopathy, hepatotoxicity, pulmonary toxicity
Bleomycin	Anaphylactoid reactions, fever, hyperpigmentation, nausea, vomiting, oxygen toxicity, pulmonary fibrosis
Busulfan	Encephalopathy, hepatotoxicity, pulmonary toxicity
Carboplatin	Myelosuppression, nausea, vomiting, nephrotoxicity, neurotoxicity, ototoxicity
Cisplatin	Nausea/vomiting, nephrotoxicity, ototoxicity, peripheral neuropathy
Corticosteroids	Adrenal suppression, avascular necrosis, cataracts, edema, gastritis, hyperglycemia, hypertension, myopathy, osteoporosis, obesity, osteopenia, tumor lysis syndrome, tumor necrosis, psychosis
Cyclophosphamide (Cytoxan)	Cardiotoxicity, hemorrhagic cystitis, myelosuppression, nausea, vomiting, syndrome of inappropriate secretion of antidiuretic hormone (SIADH)
Cyclosporine	Cortical blindness, electrolyte disturbances, encephalopathy, gingival hyperplasia, hemolytic uremia, hepatotoxicity, hyperlipidemia, hypertension, hirsutism, myositis, paresthesias, tremor
Cytarabine	Myelosuppression, mucositis, hepatitis, nausea/vomiting, neurotoxicity
Dactinomycin (Actinomycin D)	Nausea/vomiting, mucositis, myelosuppression, radiation recall?[a]
Daunorubicin (Daunomycin) Doxorubicin (Adriamycin) Idarubicin (Idamycin)	Cardiomyopathy, mucositis, myelosuppression, red-orange urine
Etoposide	Hypotension, mucositis, myelosuppression, nausea, vomiting
Ifosfamide	Hemorrhagic cystitis, myelosuppression, nephrotoxicity, neurotoxicity
Melphalan	Mucositis
Methotrexate	Hepatotoxicity, mucositis, myelosuppression, renal failure, neurotoxicity
Mercaptopurine (6-MP)	Hepatotoxicity, myelosuppression
Mycophenolate mofetil (CellCept)	Electrolyte disturbance, gastrointestinal toxicity, hypercholesterolemia, myelosuppression, rash
Procarbazine	Myelosuppression
Sirolimus	Hyperlipidemia, myelosuppression
Tacrolimus (Prograf)	Anemia, anorexia, back pain, encephalopathy, diarrhea, hyperglycemia, nephrotoxicity, pleural effusion, rash
Thiotepa	Neurotoxicity, mucositis
Thioguanine (6-TG)	Hepatotoxicity, myelosuppression
Total body irradiation	Dental/bony maldevelopment, gastrointestinal toxicity, hepatotoxicity, pulmonary toxicity
Vinblastine (Velban)	Myelosuppression, neurotoxicity, SIADH
Vincristine (Oncovin)	Neurotoxicity, SIADH

[a]Radiation recall: the "recalling" by skin of previous radiation exposure in response to the administration of certain response-inducing drugs.
Modified from Carpenter PA, Mielcarek M, Woolfrey AE. Hematopoietic cell transplantation. In: Irwin S, Rippe JM, eds. *Intensive Care Medicine*. 6th ed. Philadelphia: Lippincott Williams & Wilkins; 2008:2150–2168.

particle source, ionizing radiation leads to cell death by damaging cellular DNA. Toxicity from the effects of radiation therapy to surrounding healthy tissues is unavoidable, and the developing tissues of children are particularly susceptible to the acute and late effects of irradiation. The susceptibility of normal tissues depends on the total and fractional dose received, the inherent sensitivity of the tissue to the dose of radiation, the volume of tissue irradiated, and time course of treatment (Table 11.3).[28] Overall, normal host cells have a greater capacity to repair the damaging effects of radiation than cancer cells but require time to recover. To allow sufficient time for the healthy tissue to repair, the total dose of radiation is usually divided into a series of fractional doses over time.[29] Recent technological advances have led to three-dimensional conformal radiotherapy, which closely conforms the radiation dose to the tumor shape and minimizes radiation to the surrounding tissues.[30–32] Despite these advances to reduce the toxicity of radiation therapy to healthy tissues, children remain at risk for acute and chronic complications. Furthermore, concurrent chemotherapy may potentiate the radiation toxicity, increasing the tissue damage.

Proton radiation therapy (PRT) is a newer modality in pediatric radiation oncology and has become an established alternative to traditional photon therapy; however, PRT centers remain relatively uncommon (two dozen in the United States in 2016 [http://www.proton-therapy.org/map.htm]), which limits rapid access to frontline PRT for many children worldwide. In contrast to the destructive impact to all tissues in the path of a traditional photon beam, the specifically charged velocities of the proton beams are targeted to the calculated depth and shape of the tumor. By modulating the energy of the proton beam to become maximally energized at a specific depth of tissue, the relative dose to the healthy tissues in the plane of entry is as low as 20% to 30%, increases to 100% at the depth of tumor, and then decays to nearly no further penetration beyond the tumor (Fig. 11.1).[33] As such, the advantages of PRT include limited damage to healthy tissues surrounding the tumor and enhanced cell killing of the

TABLE 11.3 Late Effects of Radiation Therapy

Radiation Field	Late Effects	Risk Factors
Cranial	Neurocognitive deficits	>18 Gy, IV/IT methotrexate
	Leukoencephalopathy	>18 Gy with IT methotrexate
	Growth hormone deficiency	>18 Gy
	Panhypopituitarism	>40 Gy

targeted tumor tissues.[34] Despite these beneficial physical properties, the overall advantage of PRT over conventional radiation therapy is not yet uniformly supported by clinical trials, randomized pediatric trials are lacking, and long-term outcomes are yet to be realized.[27,35–38] However, there are recent reports suggesting decreased neurotoxicity, improved health-related quality of life, and reduced neuroendocrine deficits with PRT compared with historical data with conventional photon radiation therapy.[36–39]

Preoperative Considerations by Organ System

AIRWAY

Though primary tumors of the airway are rare in children,[40] various cancer treatment regimens can cause airway changes that challenge the anesthesiologist. Both chemotherapy and radiation treatment can cause mucositis and xerostomia, first appearing soon after initiating treatment.[41,42] Severe mucositis causes painful and friable oral mucosa and may threaten the airway as a result of pseudomembrane formation, supraglottic edema, bleeding, or aspiration of blood and secretions.[43,44] Graft-versus-host disease (GVHD) after HSCT may also cause significant mucositis, with up to 30% of those children developing a difficult airway.[44] Chronic radiation therapy to the head and neck may cause fibrosis, which distorts facial tissues and renders them less mobile.[45] Children who have undergone chronic radiation therapy may present a challenge during laryngoscopy, with difficult glottic visualization, poor laryngeal mask airway seal, and subglottic stenosis.[45,46]

Anesthesiologists caring for children who have undergone chemotherapy, HSCT, or radiation therapy should perform a thorough preoperative airway history and physical examination focusing on symptoms of airway compromise, prior anesthetic history, visualization of oral mucosa, and external assessment of the degree of distortion and immobility of face and neck tissues.

CARDIAC

Primary cardiac tumors are uncommon in children, but when they occur (e.g., in children with tuberous sclerosis), they are usually benign and resolve spontaneously.[47] However, cancer-related compromise of the cardiovascular system may occur and includes the effects of chemotherapy and/or radiation-induced treatment, pericarditis, and anterior mediastinal masses.

Anthracycline chemotherapeutic agents (doxorubicin, daunorubicin, idarubicin, and epirubicin) as well as the unrelated agent mitoxantrone, are well known for their cardiotoxic effects.[48,49] Cyclophosphamide, fluorouracil, vinca alkaloids, cytarabine, cladribine, L-asparaginase, paclitaxel, trastuzumab, etoposide, teniposide, and pentostatin have also been associated with cardiac toxicity.[49,50] Anthracycline toxicity primarily affects the myocardium, leading to cardiomyopathy and arrhythmias. Acute or subacute toxicity presents with symptoms ranging from only electrocardiographic (ECG) changes to fulminant heart failure shortly after the initial dose. Most children recover from acute toxicity with supportive therapy. Chronic progressive dilated or restrictive cardiomyopathy may develop within a year of treatment. The onset of symptoms can be delayed, and children may present with cardiac failure 20 or more years after treatment.[51–53] Overall, one in eight survivors of childhood cancer who received both anthracyclines and chest radiation develop a serious, chronic cardiac disease.[54] The risk of cardiotoxicity increases with increasing anthracycline doses, especially when the cumulative dose exceeds

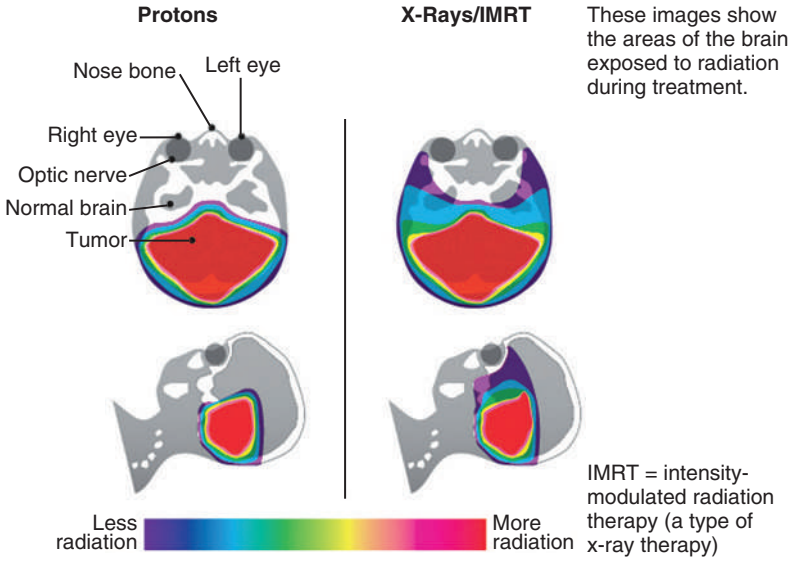

FIGURE 11.1 Rendering of the difference between photon (x-ray) and proton beam therapies for posterior fossa radiation. As radiation passes from posterior to anterior, the entry dose of radiation to healthy tissues of the posterior skull is similar. However, the exit radiation dose is markedly different: the protons lose their energy at a calculated depth, resulting in no radiation to sensitive tissues beyond the tumor (eyes, pituitary, and so on). (From SCCA Proton Therapy Center, Seattle, WA. Used with permission.)

250 to 360 mg/m^2.[53] However, there is no "safe" threshold dose for anthracyclines, as doses less than 240 mg/m^2 have resulted in cardiac damage.[55] Preventative measures include the use of newer anthracycline analogs, antioxidants, iron chelators, and alterations in the dose.[51] The cardiotoxic effects of chemotherapy are significantly compounded (perhaps tripled) by concurrent chest irradiation.[53,54,56]

Unlike anthracycline toxicity that primarily affects the myocardium, radiation therapy can damage all components of the cardiovascular system. Complications from mediastinal radiation include cardiomyopathy, pericardial effusions, pericarditis, valvular fibrosis, conduction disturbances, and accelerated arteriosclerosis.[51,56] Radiation-related myocardial fibrosis can induce a progressive restrictive cardiomyopathy, leading to pulmonary vascular disease and pulmonary hypertension. Systolic and/or diastolic dysfunction may be present. Premature arteriosclerosis affects the coronary arteries as well as the carotid arteries, pulmonary arteries, renal arteries, and aorta.[54] Fatal myocardial infarction has been reported in children 6 to 22 years of age after mediastinal radiation.[57] Valvular heart disease is predominately characterized by progressive mitral and aortic stenosis and insufficiency. Conduction disturbances range from atrial and ventricular arrhythmias, to right bundle branch block, and occasionally complete heart block requiring pacemaker placement. Radiation damage to autonomic nerves in proximity to the heart can result in tachycardia and loss of phasic respiratory variability similar to a denervated heart. Autonomic denervation can attenuate the perception of anginal pain, so providers should have a low threshold for suspicion of myocardial ischemia in those who have undergone mediastinal radiotherapy in infancy and childhood. With low doses of radiation (<25-30 Gy), short-term radiation toxicity is limited, but late toxicity occurs even at these low doses.[54,56,58,59]

Symptomatic acute heart failure after cardiotoxic cancer therapy is uncommon in childhood; however, the potential for cardiovascular compromise in the setting of major surgical stress and anesthesia should be considered. Children who have undergone cardiotoxic chemotherapy or mediastinal radiation should be examined preoperatively for clinical evidence of impaired cardiac function or arrhythmia, including history and physical examination, chest radiography, and ECG. A preoperative or recent echocardiographic evaluation is recommended for the children receiving the following[60]:

- Cumulative anthracycline dose >240 mg/m^2
- Any dose of anthracycline during infancy
- Chest irradiation >40 Gy (or >30 Gy with concomitant anthracycline treatment)
- Unknown doses of chemotherapy and radiation

ANTERIOR MEDIASTINAL MASS

Children with Hodgkin or non-Hodgkin lymphoma often have mediastinal involvement at the time of diagnosis, and half have respiratory symptoms.[61] Less common oncologic causes of anterior mediastinal mass include neuroblastoma, germ cell tumors, and ALL.[62] These children may require anesthesia for biopsy or resection of the mass, intravenous line placement, or radiologic procedures.

Children with clinical findings of superior vena cava syndrome or airway compression from anterior mediastinal mass are at the greatest risk for life-threatening perioperative complications (Table 11.4). Symptoms of orthopnea, upper body edema, stridor, nighttime cough, the need to sleep on one preferred side or position, or wheezing should alert the anesthesiologist of the need for further evaluation. Radiographic or ultrasound evidence of airway or great vessel compression, pulmonary artery outflow obstruction, ventricular dysfunction, or pericardial effusion are particularly concerning findings that necessitate a discussion about the utility of preoperative treatment to reduce the size of the mass.[63] Pretreatment is controversial because either corticosteroids or radiation may alter the tumor histology by causing tumor necrosis and render the precise diagnosis more difficult. However, diagnosis may still be possible in 95% of children after a 5-day course of

TABLE 11.4	Strongest Risk Factors for Acute Perioperative Cardiorespiratory Complications in Children With an Anterior Mediastinal Mass
Clinical signs and symptoms	
Orthopnea	
Upper body edema (signs of SVCS)	
Stridor	
Wheeze	
Night cough	
Sleeping in odd or only one position	
Diagnostic imaging findings

corticosteroids.[64] A multidisciplinary discussion of the risks and benefits with anesthesia, surgery, and oncology will clarify the optimal management for these children.

Anesthetic considerations for children with an anterior mediastinal mass are presented in detail in Chapter 15. In brief, local anesthesia and sedation are preferred. However, if general anesthesia is required, crucial perioperative considerations include maintaining spontaneous ventilation (i.e., avoiding paralysis) and being prepared to secure the airway with a tracheal tube and turn the child to the left lateral decubitus or prone position for resuscitation in the face of cardiopulmonary collapse.[65,66]

PULMONARY

Primary and metastatic lung malignancies are uncommon in children.[67] Pulmonary compromise as a direct effect of pediatric tumors is more often the result of a pleural effusion, pulmonary infiltrates, pulmonary embolus, chylous effusions, anterior mediastinal mass, or hyperleukocytosis-induced pulmonary leukostasis.[68]

Therapy-related symptomatic pulmonary dysfunction or abnormal pulmonary function tests occur in 6% of children treated with chemotherapy alone, 20% treated with both chemotherapy and radiation, and 25% after HSCT.[51] Several chemotherapeutic agents–most notably bleomycin–have the potential to cause acute or chronic lung injury, including pneumonitis, pulmonary fibrosis, or noncardiogenic pulmonary edema.[16,69] Pneumonitis presents insidiously with nonproductive cough, progressive dyspnea, and rales. Although the symptoms usually resolve with completion of the treatment, in some children pneumonitis progresses to irreversible pulmonary disease.[16,70] In adults, bleomycin-induced pneumonitis occurs in up to 46%, with a 3% mortality. The incidence of pneumonitis in children is less well established.[71,72]

Pulmonary fibrosis may present acutely during treatment or as a late sequela of chemotherapy, radiation treatment, or GVHD and may be associated with severe morbidity and mortality.[52] The administration of large concentrations of oxygen to children with bleomycin-induced pulmonary fibrosis can acutely or chronically exacerbate their restrictive lung disease.[73,74] Thus the concentration of inhaled oxygen should be adjusted to the minimum concentration required to ensure adequate tissue oxygen delivery in the perioperative period. Overall, it is important to assess the clinical and functional status of these children for symptomatic or occult pulmonary disease before administering anesthesia.[63] A thorough assessment of baseline pulmonary status is particularly important to assess the need for postoperative ventilatory support or tolerability of thoracoscopy. It is reasonable to seek preoperative pulmonary function testing in those with clinical evidence of pulmonary dysfunction, bearing in mind that formal pulmonary function testing may be a challenge in young children.

RENAL

Wilms tumor is the most common primary renal tumor in children, followed by clear cell sarcoma of the kidney, malignant rhabdoid tumor, congenital mesoblastic nephroma, and renal cell carcinoma.[75,76] Each of these tumors can directly impact renal function. Similarly, extrarenal tumors, such as neuroblastoma, can impact the renal system by infiltrating the kidneys, obstructing urinary flow, or compressing the renal vasculature.[76]

Most chemotherapeutic drugs are directly nephrotoxic in a dose-dependent manner or lead to physiologic conditions that impair renal function (e.g., sepsis, dehydration, tumor lysis syndrome [TLS]). Cisplatin, carboplatin, and ifosfamide are notorious nephrotoxic chemotherapeutic agents in children and adults, especially when combined.[77] Cisplatin causes a dose-dependent nephrotoxicity and hypomagnesemia.[18] Ifosfamide causes subclinical glomerular toxicity in up to 90% of patients, with clinically apparent toxicity occurring in 30%. Ifosfamide can also induce Fanconi syndrome in up to 7% of children, with a delayed presentation possible up to 18 months after therapy.[17,77] Methotrexate has the potential to cause severe acute renal failure in children.[19] Many other chemotherapeutic drugs cause nephrotoxicity at large doses. The syndrome of inappropriate antidiuretic hormone (SIADH) is associated with multiple chemotherapeutic agents. Many non-chemotherapeutic drugs (such as antibiotics and diuretics) commonly used in children with tumors also contribute to nephrotoxicity.[76]

Focal abdominal radiation or total body irradiation as preconditioning for HSCT can cause radiation nephritis, which presents with azotemia, proteinuria, anemia, and hypertension.[78] The cumulative dose that leads to renal damage in children has not been established.[79] After HSCT, the incidence of acute renal failure in children is as great as 40%, with chronic renal failure in 18% to 54%.[80–82]

Anesthesia providers should be aware of the size and location of renal or juxtarenal tumors to determine the risk of significant intraoperative bleeding or great vessel obstruction, particularly in tumors that involve the renal vasculature. Preoperative evaluation of children who have undergone chemotherapy or abdominal radiation treatment should focus on identifying clinical and subclinical renal dysfunction, electrolyte disturbances (hypomagnesia, hypophosphatemia), fluid overload, anemia, and hypertension. The need for preoperative dialysis should be considered in those with profound renal dysfunction. Nonsteroidal antiinflammatory drugs (NSAIDs) should be used with caution in children with renal dysfunction as NSAID-related restriction of renal perfusion may exacerbate any preexisting renal dysfunction.

HEPATIC

Primary liver tumors comprise only 1% of childhood cancers, and up to 20% of these are associated with a genetic syndrome, such

as Beckwith-Wiedemann syndrome. In young children, hepatoblastomas are the most prevalent primary hepatic tumor, followed by sarcomas, germ cell tumors, and rhabdoid tumors. Hepatocellular carcinoma is occasionally found in older adolescents.[83]

Methotrexate, actinomycin D, 6-mercaptopurine, and 6-thioguanine are associated with acute hepatic toxicity, which can present hours to weeks after a chemotherapeutic dose. Hepatic impairment is typically transient and reversible.[63] Radiation typically causes self-limited acute toxicity, but chronic hepatic fibrosis may follow large doses of radiation (>40 Gy).[52] Most concerning is the potential to develop sinusoidal obstruction syndrome (SOS) in children after HSCT. SOS is characterized by portal hypertension, liver failure, and multiorgan system failure affecting the heart, lungs, and kidneys. Up to 60% of children develop SOS after HSCT, with an associated mortality rate of 19% to 50%.[84,85]

Both acute and chronic liver disease may be found in children with cancer, associated with a coagulopathy and/or impaired drug metabolism. The dose and timing of drugs that undergo significant hepatic elimination should be adjusted accordingly. Potentially hepatotoxic medications (e.g., acetaminophen) should be used with caution in children who are particularly vulnerable to further hepatic insult. Children exhibiting chronic liver failure may have coexisting genetic syndromes, such as Beckwith-Wiedemann syndrome, which present additional anesthetic challenges.[63]

GASTROINTESTINAL

Primary gastrointestinal (GI) tumors are uncommon in children; however, various intraabdominal malignancies can affect the GI tract by intestinal obstruction, intussusception, erosive perforation, intraabdominal hemorrhage, biliary obstruction, venous or arterial obstruction, and massive hepatomegaly.[63,86] The most common GI concern in children with cancer pertains to adverse effects of the chemotherapy and radiation treatment.

As chemotherapy and radiation treatments target rapidly proliferating tissues, the gastrointestinal mucosa is particularly vulnerable. Chemotherapeutic agents are well known to cause nausea and vomiting but may also cause more serious GI pathology such as diarrhea, mucositis, stomatitis, and neutropenic enterocolitis.[87] These adverse effects may exacerbate the malnutrition and dehydration that are often found in children with cancer. Similarly, radiation doses in excess of 20 to 30 Gy can cause inflammation and edema of GI tissues.[88] Importantly, acute and chronic GVHD after HSCT (discussed in detail below) commonly impacts the GI tract, although the majority of cases are mild in the current era of prophylaxis with calcineurin inhibitors plus methotrexate or mycophenolate. The incidence of moderate to severe gut GVHD after HSCT is approximately 10%, and the mortality rate is substantial without prompt treatment.[89]

Before induction of anesthesia, children who have been treated for their cancer may have chronic nausea and vomiting or delayed gastric emptying, both of which are exacerbated by opioids. These children may be at increased risk for aspiration and should be managed accordingly. Children with GI dysfunction may also present with malnutrition, dehydration, and electrolyte imbalances that warrant correction before embarking on elective surgical procedures.

CENTRAL NERVOUS SYSTEM

Primary intracranial tumors such as astrocytomas, ependymomas, primitive neuroectodermal tumors, and gliomas represent 17% of all childhood malignancies.[2] Signs and symptoms of the tumor itself depend on the size and location of the tumor and the local mass effect on adjacent neurologic structures. Symptoms may include irritability, lethargy, macrocephaly, and vomiting. Increased intracranial pressure, herniation, stroke, seizure, or leukemic meningitis may herald acute decompensation.[62] Primary spinal tumors are uncommon but may present with acute spinal cord compression requiring immediate surgical treatment.[90] Furthermore, 3% to 5% of children with metastatic disease have some degree of spinal cord compression, often at initial diagnosis.[91,92] Detailed discussion and perioperative management of children with brain tumors is covered in Chapters 24 and 26.

Platinum chemotherapeutic agents (cisplatin, carboplatin, oxaliplatin), L-asparaginase, ifosfamide, methotrexate, cytarabine, etoposide, vincristine, and cyclosporine A may cause neurologic toxicity.[93,94] Acute toxicity is characterized by altered mental status, seizures, stroke, encephalopathy, ototoxicity, and peripheral nerve dysfunction.[11] These symptoms are often reversible with cessation of the drug. Chronic toxicity usually manifests as neurocognitive and psychiatric dysfunction, which are discussed below. Brain irradiation can also have profound neurologic effects. Radiation doses in excess of 50 Gy can cause severe focal tissue damage, myelitis, stroke, and optic toxicity. Smaller doses, less than 18 Gy, are associated with subtler neurocognitive dysfunction.[88]

As discussed in detail in Chapters 24 and 26, children who present for resection of an intracranial tumor should undergo a thorough neurologic evaluation focusing on the signs and symptoms of increased intracranial pressure (ICP) and existing neurologic deficits. The benefits of sedative premedications must be balanced against their risks in children with increased ICP. As timely postoperative neurologic examination is important in these children, the choice of anesthetic agents and timing of extubation should be tailored to facilitate as early an assessment as circumstances allow.

ENDOCRINE

Primary endocrine tumors account for less than 5% of childhood cancers.[95] Gonadal germ cell tumors (testicular, ovarian, and extragonadal tumors), thyroid adenomas and carcinomas, and pituitary tumors (craniopharyngiomas and pituitary adenomas) account for the vast majority of these childhood endocrine tumors.[96]

Most chemotherapeutic agents have minimal effect on endocrine function, and chronic endocrine dysfunction is very uncommon in survivors of childhood cancer.[97,98] However, the use of glucocorticoids leads to a dose-dependent adrenal suppression. Studies in children with cancer have demonstrated that although a majority of children with ALL recover adrenal function in 2 weeks after cessation of chronic steroid therapy, some remain suppressed to various degrees of severity for 2 to 8 months.[99] It has thus been recommended that stress-dose steroids be administered before stressful procedures in the first 1 to 2 months after cessation of therapy.[99] If the anesthesiologist considers intraoperative stress-dose steroids or steroids for antiemesis, this must first be discussed with the child's oncologist; steroids are active anticancer drugs that may cause tumor necrosis or TLS in some tumors, cause immune suppression, impact the cancer treatment protocol, and constitute grounds for a study violation.[63]

Unlike the minimal chronic endocrine suppression of chemotherapy drugs, total body irradiation (TBI) preconditioning for HSCT and focal cranial radiotherapy, especially to regions in proximity to the hypothalamus, can cause significant, chronic neuroendocrine dysfunction.[97] Cumulative radiation doses as small as 18 to 20 Gy can cause growth hormone and gonadotropin deficiency, and doses greater than 35 to 40 Gy can cause

panhypopituitarism.[100] Hypothyroidism can occur at doses of 20 Gy, typically manifesting 2 to 4½ years after therapy.[101]

HEMATOLOGY

Myelosuppression is commonplace during pediatric cancer treatment, both as a consequence of the tumor effect itself and subsequent treatment of disease. Several cancers present with anemia at first diagnosis, including neuroblastoma, rhabdomyosarcoma, Hodgkin disease, Ewing sarcoma, osteosarcoma, and leukemia.[102,103] Thrombocytopenia is common in children with hematologic cancers as well as solid tumors invading the bone marrow.[104] The presenting leukocyte count in children with leukemia is variable. Neutropenia is typical at presentation in some children with ALL, but hyperleukocytosis (>100,000/mm^3) may be present in 20% of children with acute myelogenous leukemia. Hyperleukocytosis can cause hyperviscosity and potentially fatal leukostasis as tissue perfusion is impaired by plugging of leukocytes in the vasculature.[105]

Both chemotherapy and radiation therapy can have profound effects on myeloid cell production. Chemotherapy-related myelosuppression is common and is often dose limiting. Although radiation has the potential to completely suppress myeloid cell production, this typically requires exposure of a significant percentage of marrow sites to cause clinically significant suppression. However, TBI for HSCT preconditioning, by design, results in complete destruction of the host hematopoietic cells to prepare the marrow space for new cells. TBI doses of only 3 to 5 Gy to all marrow sites are fatal if new cells are not transplanted. Recovery of hematopoiesis after HSCT follows a predictable pattern: granulocytes recover first, followed by platelets, lymphocytes, and lastly erythrocytes. During recovery, the child is susceptible to infections, bleeding, and anemia.[106] Reducing the dose of chemotherapy or stopping radiation allows cell counts to recover; however, owing to the life span of hematologic cells and the time to produce new cells, pancytopenia typically requires 4 weeks to resolve.[107,108] For prophylaxis or chronic treatment of cytopenia, both erythropoietin and recombinant human granulocyte-macrophage colony-stimulating factor may minimize anemia and neutropenia.[109]

Children with neutropenia are at increased risk for life-threatening infections. Providers should be vigilant about patient isolation and strict aseptic technique during invasive procedures or access of existing lines. Administration of medications and placement of temperature probes in the rectum can cause bacteremia and should be avoided. Similarly, catheterization of the urinary tract should also be used sparingly.[110]

COAGULATION

Abnormal bleeding in cancer patients may result from a number of factors, including thrombocytopenia, clotting factor deficiency, circulating anticoagulants, and defects in vascular integrity.[111] Even in the presence of adequate platelet numbers and function, the presence of any of these other coagulopathic defects may increase the risk of procedural bleeding. Hematologic cancers, especially any of the subsets of leukemia, often present with unexplained bleeding and a coagulopathy.[112] Disseminated intravascular coagulation may be present at the time of diagnosis of acute promyelocytic leukemia and less commonly of acute myelogenous leukemia and T-cell ALL. Patients may have lupus anticoagulant syndrome with subsequent thrombophilia or factor VIII inhibitors, leading to acquired hemophilia. Up to 8% of children with Wilms tumor have acquired von Willebrand syndrome at the time of diagnosis.[113,114]

Chemotherapy can cause a significant coagulopathic response. L-Asparaginase may be associated with up to a 2% risk of hemorrhage or thrombus via induced deficiencies in plasminogen, fibrinogen, antithrombin III, and von Willebrand factor.[13] Vitamin K deficiency in the setting of hepatic dysfunction or severe malnutrition also contributes to coagulopathy.[115] Sepsis, disseminated intravascular coagulation, hepatic failure, acute or chronic anticoagulant usage, platelet sequestration with splenomegaly, and the burden of chronic disease may also contribute to the increased risk of perioperative hemorrhage.

Venous thromboembolism (VTE) is rare in children in general but considerably more common in those with malignancy as a result of coagulation dysfunction and frequent use of long-term indwelling vascular access. Nearly 8% of children with cancer experience VTE, with the greatest incidence among those with sarcoma and hematologic malignancies.[116] The optimal timing to stop anticoagulants before surgery in children with VTE warrants discussion with both the surgical and hematology-oncology teams. These children are at risk for perioperative thrombosis,[117] and their management must strike a delicate balance between provoking additional thrombus formation and an increased risk of surgical bleeding.

PAIN

Both acute and chronic pain are common sequelae of cancer and cancer therapy. In one survey of 160 children undergoing cancer treatment, 87% of inpatients and 75% of outpatients rated their pain as moderate to severe.[118] In a survey of survivors of pediatric cancer, the single most painful experience during their treatment was a painful medical procedure or surgery.[119]

The use of general anesthesia for painful procedures, such as lumbar puncture and bone marrow biopsies, is one of the most effective techniques for reducing pain; anesthesiologists have a central role in optimizing patient comfort and parental stress during this difficult period.

Just as with other sources of chronic pain, children with cancer are often opioid tolerant and may benefit from a multimodal approach to analgesia. Regional anesthesia can be advantageous, but the benefits must be carefully weighed against the risks in those with a coagulopathy or significant chemotherapy-induced neuropathy. A multidisciplinary discussion with anesthesia, surgery, oncology, and pain service providers is essential to ensure an optimal balance between comfort and safety for these complex patients.

NEUROPSYCHOLOGY

Up to 40% of childhood cancer survivors suffer neurocognitive impairment in at least one of several areas, including academic achievement and executive function.[120,121] Intrathecal methotrexate and cranial irradiation appear to be particularly detrimental; thus children with ALL, central nervous system (CNS) tumors, and head and neck sarcomas are at the greatest risk for cognitive impairment.[122] The increasing availability of proton beam radiotherapy and its precise targeting of malignant tissue has been shown to reduce collateral tissue injury, and it may result in improved neurocognitive outcomes.[39,123–125]

The psychological response to cancer diagnosis and treatment is extremely age and individual dependent. Young children are often distressed by parental separation and anticipation of painful procedures. Many of these children benefit from an honest discussion of upcoming procedures to allow them a greater sense of control in their treatment. The placement of central access devices

and topical anesthetic creams have greatly reduced the anxiety associated with many interventions required in their treatment. Role-playing and desensitization can be particularly helpful in this age group.[126] Older children and adolescents are in many ways more profoundly affected by the psychosocial stress associated with cancer treatment. Compliance with medical treatment can be problematic in adolescents, who have difficulty coping with their diagnosis. To the extent that it is possible, adolescents should be actively involved in their own care, and assent from adolescent patients should be sought for anesthesia and invasive procedures.[60,126] Children and adolescents with cancer become isolated from peers because of school absences and the rigors of the treatment schedule, despite the natural need for peer interactions for healthy coping and adjustment. Feeling "alone" with their disease can worsen the sense of isolation from their healthy peers. As such, opportunities for peer engagement and interactions should be encouraged and provided. Peer interactions may include the child's choice of peers, as well as formal socialization or mentorship from other children with cancer or cancer survivors. Camps, group interventions, or formal coaching by childhood cancer survivors are highly effective.[127]

TUMOR LYSIS SYNDROME

Children with rapidly proliferating cancers, particularly ALL and non-Hodgkin lymphoma, are at risk for developing potentially fatal TLS. TLS has been reported in more than 40% of patients with non-Hodgkin lymphoma, although the rate of serious TLS was only 6% in one study.[128] Nonhematologic malignancies with rapid proliferation, large tumor burden, and high sensitivity to chemotherapy are also subject to TLS after initiation of therapy. TLS occurs when rapid destruction of tumor cells yields a massive release of intracellular contents, resulting in hyperuricemia, hyperkalemia, hyperphosphatemia, hypocalcemia, and acid-base derangements. The cellular outpouring most commonly precipitates acute renal failure, but arrhythmias, cardiac failure, seizures, multiorgan failure, and death may occur. TLS can present suddenly with induction of chemotherapy, radiotherapy, fever, surgery, or anesthesia but most often occurs 1 to 3 days after initiation of cytotoxic therapy.[128,129] In the current era, the incidence of severe TLS has decreased with the institution of appropriate preventative measures in high-risk children. The occurrence of perioperative TLS requires prompt and aggressive management, including hydration and diuresis, rasburicase (a uric acid–reducing agent), and allopurinol to ameliorate organ damage as well as aggressive measures to treat life-threatening arrhythmias owing to hyperkalemia (see Chapter 9; see also Fig. 9.7).[128] The cytotoxic effects of corticosteroids such as dexamethasone have been associated with TLS, and alternative perioperative antiemetics should be used in those at risk.

RETINOIC ACID SYNDROME

Retinoic acid syndrome (also referred to as differentiation syndrome) is a potentially life-threatening complication found in 2% to 27% of children treated for acute promyelocytic leukemia (APL) with all-*trans* retinoic acid (ATRA). The exact mechanism of this condition is unknown but is believed to be related to the release of inflammatory cytokines from APL cells during ATRA treatment. Retinoic acid syndrome typically occurs around 7 days after beginning treatment and is characterized by respiratory distress, fever, pulmonary infiltrates, and weight gain. Pericardial effusion, hypotension, cardiac failure, and renal failure can also occur. Thus children who were recently managed with induction therapy with ATRA for APL should be screened for pulmonary, cardiac, and renal abnormalities before undertaking general anesthesia.[130,131]

Hematopoietic Stem Cell Transplant

BACKGROUND

The first attempts to use bone marrow to treat malignancy took place over 50 years ago,[132] and the first successful pediatric transplant occurred almost 40 years ago.[133] HSCT is a potentially curative treatment for a wide range of malignant and nonmalignant pediatric disorders. HSCT is used in the treatment of many forms of leukemia, Hodgkin and non-Hodgkin lymphoma, and many types of solid tumors, including germ cell tumors, some sarcomas, neuroblastoma, Wilms tumor, and some malignant brain tumors. Additionally, it is used to treat many nonmalignant diseases, including myelodysplasia, aplastic anemia, hemoglobinopathies (including sickle cell disease and thalassemia), and congenital immune and metabolic deficiencies.[134–137] Because of the prevalence of ALL in the pediatric population, it is the primary indication for HSCT in many centers.

Hematopoietic stem cells used for transplantation can be obtained from bone marrow, "mobilized" peripheral blood, or umbilical cord blood. The source of the cells may be the child (autologous), an identical twin (syngeneic), or another individual (allogeneic). Allogeneic donor cells are commonly derived from human leukocyte antigen (HLA)-identical siblings (available in about 25% to 30% of patients), but advances in matching and supportive care have improved outcomes with HLA-matched unrelated and mismatched donors.[138,139]

CLINICAL FEATURES AND TREATMENT

The process of HSCT involves several steps:

1. The preparative or conditioning regimen, during which high-dose chemotherapy with or without irradiation or immunomodulating agents eradicates malignancy (where present), clears marrow space for incoming stem cells, and suppresses the recipient's immune system
2. Transplantation through infusion of hematopoietic stem cells
3. Transplant engraftment (>30 days after transplantation)
4. Early engraftment (30–100 days after transplantation)
5. Late engraftment (>100 days after transplantation)

Cumulative toxicity associated with HSCT is the result of the underlying illness and complications of past therapy, the transplant-conditioning regimen, complications from long-term myelosuppression, and GVHD and its treatment. The incidence of transplant-related morbidity and mortality depends on the child's age, primary disease, comorbidities, and histocompatibility between donor and recipient.[140] Overall, 100-day mortality is 5% to 20% from sibling donors and 10% to 40% from unrelated donor allogeneic HSCT.[141]

HSCT-related toxicity can involve every organ of the body through the direct and indirect effects of irradiation and chemotherapy, as discussed previously. Immunologic and physical host defenses are impaired throughout the transplantation process. Infections are among the most important causes of transplant-related morbidity and mortality.[142] Children are vulnerable to a wide range of routine and opportunistic pathogens, including bacteria, fungi, and viruses. Mucositis is common and may increase the risks of aspiration and airway compromise.[44,143] SOS, previously called venoocclusive disease, occurs in 10% to 60% of children after HSCT. Mortality rates in the setting of SOS-induced hepatorenal failure and subsequent multiple-organ failure range from

19% to almost 50%.[144] Hepatorenal syndrome and fluid retention associated with SOS mandate careful attention to fluid balance, sodium administration, and the presence of acquired coagulopathy, including thrombocytopenia that is refractory to platelet transfusions.[84,144,145] Other gastrointestinal complications include hemorrhage, infections, and opioid-induced abdominal pain and distention (i.e., opioid-associated bowel syndrome).[146] Acute pulmonary complications, which occur in 30% to 60% of children after HSCT, include infection, hemorrhage, edema, bronchiolitis obliterans, acute respiratory distress syndrome, and idiopathic pneumonia syndrome, a noninfectious inflammatory lung process.[147–149]

In the early phase after HSCT, significant cardiomyopathy and arrhythmias are uncommon (5%), but sepsis, heart failure, and cardiovascular collapse are common admitting diagnoses in 10% to 40% of children who require intensive care after HSCT.[147,150,151] Late cardiac complications depend on the dose of radiation and the cardiotoxic chemotherapeutic agents used during the conditioning regimen. Acute renal failure occurs in 30% to 50% of children and warrants judicious use of fluids[80,81,152]; hemorrhagic cystitis is also common.[153] A process of thrombotic microangiopathy similar to hemolytic uremic syndrome may occur in as many as 25% of children who were treated with cyclosporine or the calcineurin inhibitor, tacrolimus.[154] CNS complications may include infection, hemorrhage, encephalopathy, and peripheral neuropathy owing to metabolic and chemotherapeutic effects.[155]

In contrast to the myeloablative procedures described previously, pediatric centers are increasingly using reduced-intensity preconditioning regimens and even nonmyeloablative preconditioning to reduce morbidity and mortality after hematologic malignancies.[156,157] Use of these regimens is based on the observation that in some instances, minimal myelotoxicity in conjunction with profound and prolonged immunosuppression leads to successful donor engraftment.[158] This modality is mostly used in children with nonmalignant hematologic conditions, marrow failure, and immunodeficiency syndromes but is increasingly used in pediatric hematologic malignancies.

GRAFT VERSUS HOST DISEASE

GVHD is the clinical manifestation that donor T cells recognize recipient alloantigens. Acute GVHD occurs in 20% to 80% of children within the first 100 days after HSCT. The incidence depends on the histocompatibility of the donor and recipient, as well as the stem cell source.[159] It is characterized by inflammatory dermatitis, enteritis, and hepatitis. Chemoprophylaxis (cyclosporine or tacrolimus with short-course methotrexate) is crucial as the outcomes after the onset of acute GVHD are disappointing. Treatment includes continuation of immunosuppression, the addition of corticosteroids, and the introduction of salvage therapy with profound immunosuppression. These children are at very high risk of succumbing to opportunistic infections.[159]

Chronic GVHD occurs in 6% to 50% of children 100 days or more after HSCT. This broad range of incidence depends on the age of the donor and recipient, gender matching, and degree of matching between donor and recipient.[160] Chronic GVHD has many features of autoimmune diseases, impacting nearly every organ of the body (e.g., sclerodermatous changes; dry mouth and conjunctivae; esophagitis; pulmonary dysfunction, including bronchiolitis obliterans; contractures or fasciitis of extremities and soft tissue; liver dysfunction; alopecia; thrombocytopenia). The pulmonary system is involved in 30% to 60% of children. Significant cardiac and renal disease is rare in chronic GVHD. Opportunistic infections are common during chronic GVHD, in part, as a result of the immunosuppression associated with GVHD. Hemolysis is an additional manifestation of alloantigenicity, the result of major and minor blood group incompatibilities between donor and recipient.[161]

Adoptive T-Cell Therapies in Children

Along with the use of newer, small immunologic molecules and monoclonal antibodies mentioned at the start of this chapter, investigation into and use of adoptive immunotherapy using an infusion of T cells genetically engineered to express receptors targeting a specific tumor antigen (e.g., CD19 in ALL) has been growing rapidly. Pediatric indications are expanding, but most applications in children are associated with relapsed cancer or residual tumor after HSCT. Briefly, autologous T cells are removed through a central venous catheter, genetically engineered ex vivo to express receptors to the desired antigen, and then reinfused into the proband. After infusion, the cells engraft, multiply, and eradicate tumor cells for months or years.[162–164] However, sufficient engraftment and expansion depend on prior lymphodepletion, which requires significant immunosuppression with TBI and chemotherapy, with all the associated risks discussed above.[165] Trials of T cell infusion therapies in children with neuroblastoma, B cell ALL, glioma, osteosarcoma, and disialoganglioside GD2 sarcoma are underway.[162]

Three points should be understood when caring for these children before and after T-cell infusions. First, akin to children receiving HSCT, these children are immunosuppressed and at significant risk for infections. Isolation and meticulous use of sterile technique must be observed. Second, T-cell and other cellular forms of adoptive cellular therapy constitute a rapidly changing field that requires effective communication between the oncologist and the perioperative team to ensure the safe and optimal management of the child. Third, this therapy is accompanied by potentially significant morbidity and mortality. In addition to the toxicity of the preconditioning regimen, the modified T cells occasionally trigger an autoimmune response. Cytokine-release syndrome is the most serious toxicity, resulting from supraphysiologic levels of immune cell activation and the subsequent massive release of inflammatory cytokines. Mild cases manifest as fevers and myalgias, but severe cases may lead to cardiorespiratory failure, multiorgan dysfunction, and possible death if not treated early.[162–164]

Preoperative Laboratory Testing and Evaluation

As is the case for children without cancer, there is insufficient evidence to recommend any routine preanesthetic testing in children with cancer. Instead, preoperative laboratory or radiologic testing should be based on the child's history, physical exam, concurrent illnesses, and surgical procedure. Tests should be ordered only if they have the potential to influence the surgical risk or the child's perioperative management.[166] In complex patients, these tests should be ordered in advance to (1) permit corrective action to be taken and satisfactory responses recognized and (2) allow communication with the oncology team before commencing the anesthetic plan. It is helpful for the oncology service to provide up-to-date information regarding hemoglobin, platelet counts, absolute neutrophil counts, coagulation studies, the most recent echocardiogram and pulmonary test results, as well as any other

TABLE 11.5 Risk Factors for Hematologic Abnormalities in Children With Cancer

Children at Risk for Anemia
• New diagnosis of leukemia (50%–80% incidence) or lymphoma
• Recent chemotherapy, radiation therapy, or hematopoietic stem cell transplant
• Children with cancer and age less than 6 months
Children at Risk for Hyperleukocytosis Include Any New Diagnosis of Leukemia (>20% Incidence)
Children at Risk for Leukopenia and Neutropenia Include Any Child Receiving Aggressive Chemotherapy or Irradiation
Children at Risk for Thrombocytopenia Include the Following:
• New diagnosis of leukemia
• Any child receiving aggressive chemotherapy or irradiation
• Disseminated intravascular coagulation
• Splenomegaly

TABLE 11.6 Risk Factors for Coagulopathy, Electrolytes, and Renal Dysfunction in Children With Cancer

Risk Factors for Coagulopathy
Sepsis
Vitamin K deficiency or malnutrition
Anticoagulant therapy
Hyperleukocytosis
L-Asparaginase treatment
Diagnosis of T-cell acute lymphoblastic leukemia, myelomonocytic leukemia, or acute promyelocytic leukemia
Recent hematopoietic stem cell transplant
Prior splenectomy
Risk Factors for Electrolyte Abnormalities
Syndrome of inappropriate antidiuretic hormone (SIADH)
Hypercalcemia (bone tumors and neuroblastoma)
Intracranial disorder with altered level of consciousness
Dehydration or malnutrition
Aggressive hydration
Renal dysfunction
Recent tumor lysis syndrome (hyperkalemia, hyperphosphatemia, hypocalcemia)
Risk Factors for Renal Disease
Renal or ureteral compression by newly diagnosed neuroblastoma or Wilms' tumor
Sinusoidal obstructive syndrome
Tumor lysis syndrome
Nephrotoxic antitumor therapy (ifosfamide, cisplatin)
Recent hematopoietic stem cell transplant

From Latham GJ, Greenberg RS. Anesthetic considerations for the pediatric oncology patient—part 3: pain, cognitive dysfunction, and preoperative evaluation. *Pediatr Anesth.* 2010;20(6):479–489. Used with permission.

information that might affect anesthetic management. Possible factors that may require preoperative laboratory testing in the child with cancer are further discussed in the following text.

A complete blood cell count is not routinely required before anesthesia in children with cancer. However, it may be warranted based on the condition of the child, presence of comorbidities, proposed surgical procedure and potential blood loss, potential thrombocytopenia, attendant risk of prolonged bleeding, and known or suspected anemia (Table 11.5).[60]

Preoperative coagulation testing is not routinely indicated in children with cancer. A preoperative platelet count is frequently obtained for children who are scheduled for lumbar puncture, neuraxial anesthesia, surgical procedures with risk of significant blood loss, or neurosurgical procedures. If the platelet count is sufficient for the surgical procedure and the regional anesthetic plan and there is no further clinical evidence of bleeding, then additional coagulation studies are probably unwarranted. However, any history of abnormal coagulation in the setting of an appropriate platelet count does warrant further investigation.[60] Known conditions in the pediatric oncology population in which coagulopathy, renal dysfunction, or electrolyte derangements occur are listed in Table 11.6.

Perioperative Considerations

CHILDREN WITH CANCER

The perioperative complication rate after anesthesia in 177 children undergoing 3833 radiotherapy sessions was 1.3%, an incidence comparable to that for children without cancer anesthetized with propofol.[167] However, many children with cancer who present to the operating room are gravely ill with limited physiologic reserves and susceptible to relatively small changes to their physiology. Most children with standard risk leukemia in clinical remission receiving maintenance chemotherapy live a near normal lifestyle with good physical capacity; however, a significant number of children with cancer, especially those immediately before and after HSCT, can have multiorgan dysfunction and require intensive support in the hospital. It is imperative that the anesthesiologist carefully stratifies the risk of each child with cancer who presents for surgical or procedural intervention. All of the previously described considerations regarding the possible effects of pediatric cancer and its treatment on each organ system must be considered preoperatively. Prior anesthesia experiences, plus current information regarding the child's treatment protocol, cumulative chemotherapy or radiation therapy doses, major side effects, recent echocardiogram, current laboratory values, and organ dysfunction must be readily available. When all of this current information is not readily available in the electronic medical record where the child is being anesthetized, the authors recommend that an updated data summary sheet be provided by the oncology team to the anesthesiologists prior to anesthesia (Fig. 11.2).

Children with cancer undergo a host of procedures that require anesthesia during acute and chronic phases of disease. Included among these are diagnostic tumor or lymph node biopsy, tumor resection, placement and replacement of chronic indwelling venous catheters for treatment and nutrition, diagnostic and monitoring procedures (e.g., lumbar puncture, bone marrow aspirate and biopsy, lung and liver biopsy, skin biopsy, bronchoalveolar lavage, esophagogastroduodenoscopy), radiologic procedures, radiation therapy, and placement of pain management devices (e.g., indwelling epidural catheters). Splenectomy is performed as part of staging or management of some pediatric malignancies, and the procedure

may be associated with increased risk of postoperative infection, postoperative thrombocytosis, and thrombocytopenia.[168]

Lumbar puncture and bone marrow aspiration procedures are commonly performed in children with cancer, especially those with hematologic malignancies. The use of short-acting medications for a brief general anesthetic ensures complete comfort during the procedure while permitting a rapid recovery and discharge from the hospital. Propofol and a short-acting opioid or low-dose ketamine, for instance, are commonly used to achieve this goal.[169–173] The anesthesiologist must be fastidious with sterile technique when accessing central venous sites, regardless of whether the child is immunosuppressed, to avoid catheter-related infections. *It is of*

paramount importance that systems are in place to avoid the inadvertent administration of vincristine chemotherapy into the intrathecal space during lumbar punctures. Intrathecal vincristine causes severe neurologic consequences and may have contributed to nearly 100 fatalities in children with otherwise curable hematopoietic tumors.[174] *Intravenous chemotherapy should be excluded from any procedure room where lumbar punctures and intrathecal chemotherapy are performed.*

Radiation beam therapy is used in frontline treatment of many pediatric brain tumors and some extracranial solid tumors. The duration of radiation therapy varies depending on tumor type but typically occurs daily over 4 to 8 weeks, frequently concurrent with chemotherapy.[28] The goal of modern radiation therapy–both conventional photon beam and the newer proton beam therapies–is to accurately conform radiation to the tumor while minimizing radiation of healthy surrounding tissues. As such, immobility is crucial and requires general anesthesia in younger children.

Radiation treatment planning begins with a simulation, which requires anesthesia in those who will need anesthesia for the subsequent treatments. The child is ideally positioned as he or she will be for treatment, computed tomographic imaging of the tumor is obtained, and appropriate custom-made molds or masks are formed that will allow reproducible positioning during daily treatments (Fig. 11.3). For PRT, custom brass and/or acrylic molds are later fabricated that will be used to tightly shape and focus the proton beam as required to conform precisely to the tumor mass (Fig. 11.4). Provision of anesthesia in the radiation oncology suite presents key challenges. Many radiation therapy centers, especially PRT centers, are freestanding outpatient facilities separate from a hospital or children's hospital; it is therefore obligatory that all necessary equipment and medications are available to handle any potential anesthesia-related emergency, including rapid transport to a pediatric hospital. Children may suffer physical and emotional stress from daily anesthetics, procedures, diagnostics tests, chemotherapy, and previous or upcoming surgery. As much as possible, parent and child education, peer-to-peer support, distraction techniques, and reward systems may be used to ease

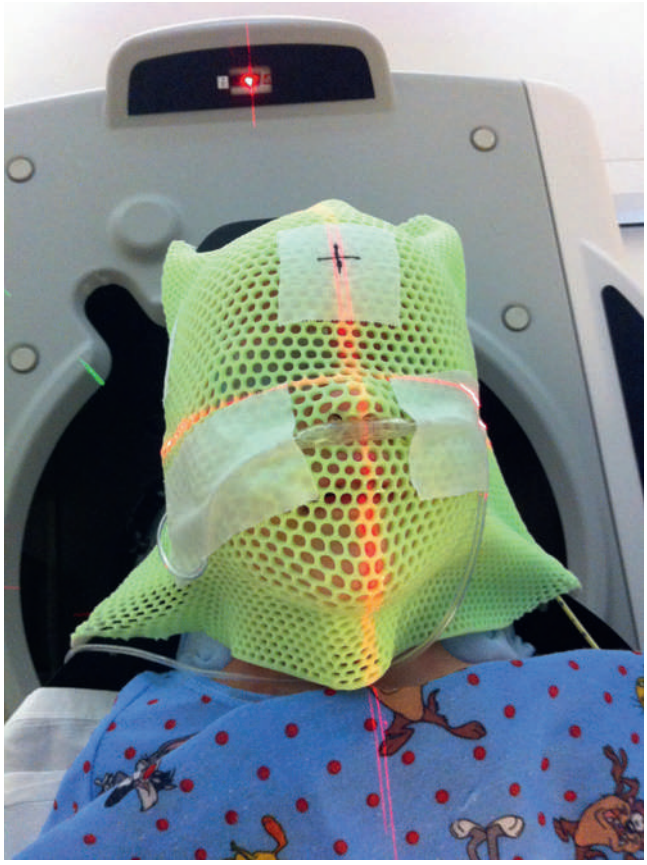

FIGURE 11.3 A custom-made mask holds this anesthetized child's head in the repeatable, exact position required for cranial radiation therapy. A nasal canula provides supplemental oxygen and end-tidal CO_2 monitoring during a total intravenous anesthetic with propofol. (Photo courtesy Andrew Pittaway, BM, BS.)

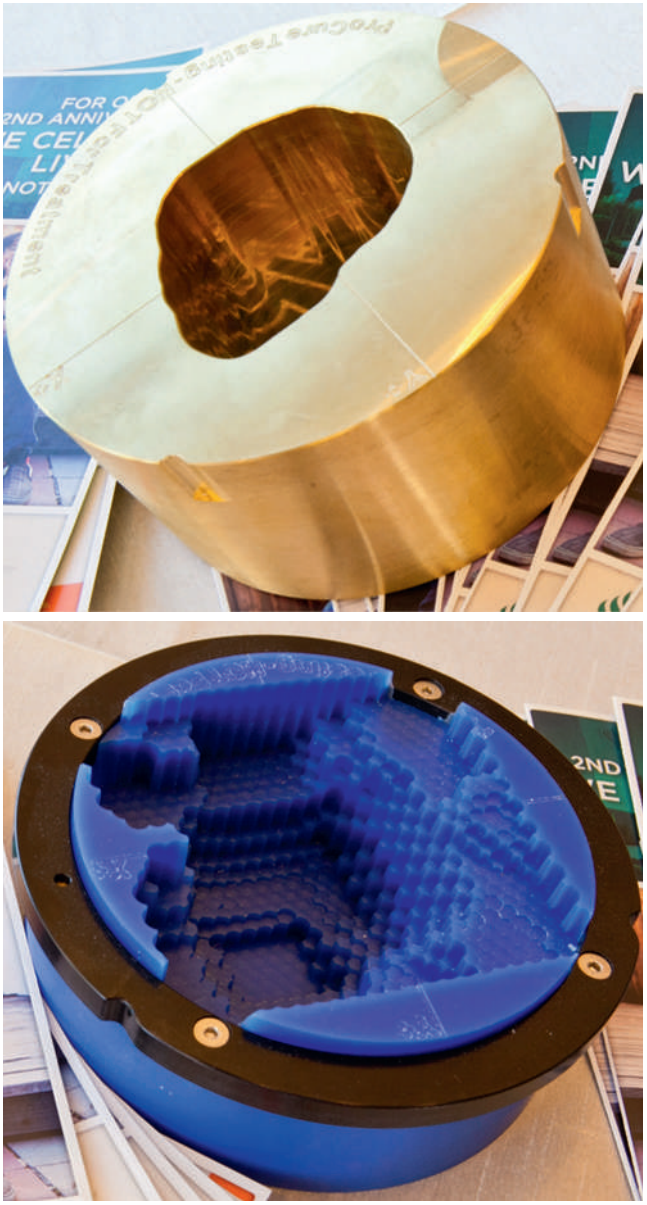

FIGURE 11.4 Upper image: an aperture made from brass composite shapes the lateral borders of the proton beam to shield healthy tissues lateral to the tumor. Lower image: a compensator made of wax or acrylic is used to control the active depth of the protons along the distal border of the tumor. Use of the aperture and compensator together shapes the lateral and distal treatment field accurately, leaving primarily entry path radiation to healthy tissues. FIGURE 11.5 An anesthetized child in a proton therapy vault. The head mold positions the child's head, and a nasal cannula provides oxygen and CO_2 monitoring. Propofol total intravenous anesthesia is used, and an anesthesia machine and rescue medications are immediately available. Video feeds in a shielded control room allow the anesthesia and radiation teams to view the patient, the propofol pump, and vital signs continuously. (Photo courtesy Karen Wong, MB, BS.)

the child's anxiety.[127,175] The parents and anesthesia team cannot remain in the treatment vault during irradiation; therefore multiple video feeds of the child and anesthesia equipment/monitor are essential for the safe care of the child under anesthesia (Fig. 11.5).

Most children will have an indwelling central venous catheter, which facilitates intravenous induction and maintenance of anesthesia. Strict aseptic technique is mandatory to avoid sepsis and the need for catheter removal, both of which risk morbidity and delays in treatment.[176] Port-a-catheters may be accessed on Monday (topical anesthetic cream may be used) and left accessed until Friday to lessen the anxiety of daily percutaneous port access. A standing anesthesia consent is used in some centers to ease the burden of daily consents, but such consent does not negate the need to evaluate the child prior to each anesthetic. The risk of anesthetizing a child with mild to moderate respiratory infection must be considered in conjunction with the risk of missing a treatment. A key consideration in choosing the anesthetic regimen includes the use of short-acting medications to allow quick recovery from anesthesia, and to this end, various anesthetic techniques have been described in the literature.[167,176–178] Total intravenous anesthesia with propofol is commonly used as it provides rapid onset of anesthesia, excellent immobility during radiation, rapid emergence from anesthesia, and theoretic antiemetic properties. Although adjunct medications such as opioids and benzodiazepines can be added, they are often unnecessary and may increase respiratory events.[167,179] A nasal cannula provides supplemental oxygen and the ability to monitor end-tidal CO_2 as a surrogate of effective ventilation via remote monitoring (see Fig. 11.3). Sevoflurane anesthesia with a laryngeal mask airway is another option with a low rate of complications.[177] If an invasive airway is needed routinely in a child receiving cranial radiation, then the head mold must be modified to allow access to the airway.

Surgical intervention may be required for acute and potentially life-threatening emergencies in children with cancer, and the effects of specific tumors may complicate the anesthesia care. Wilms tumor may be accompanied by an acquired von Willebrand condition,[113] and anterior mediastinal masses may produce superior vena cava obstruction, pulmonary artery compression, and tracheal obstruction.[180] Neuroblastoma may be accompanied by pheochromocytoma-like signs and symptoms (3% of cases),[181] venous obstruction, and in advanced stages, it may cause massive hepatic enlargement, making the potential for massive rapid blood

TABLE 11.7 Perioperative Concerns in Pediatric Cancer and Hematopoietic Stem Cell Transplantation

Preoperative Considerations
Consultation with service primarily responsible for child's care
Complete blood cell count, serum electrolytes (when appropriate)
Echocardiogram or chest radiograph, or both (when appropriate)
Transfusion cross-match with specifications (e.g., cytomegalovirus seronegativity, leukocyte reduction, irradiation) determined in consultation with oncology service
Determination of blood typing requirements for all stem cell transplant recipients
History of acute and chronic pain medication use
Anxiolytic and analgesic therapy (when appropriate)
Infection prophylaxis with antibiotics
Avoidance of *any* marrow-suppressive medications in stem cell transplant patients
Observation of indicated isolation precautions
Sterile technique with central line access
Use of support services (when appropriate)
Intraoperative Considerations
Attention to skin, teeth, eyes, and joints; careful positioning and padding
Sterile technique with central line access
Full-stomach precautions (when appropriate, as in graft-versus-host disease)
Appropriate hydration and maintenance of urine output
Continuation of total parenteral nutrition (and other parenteral fluids with high glucose concentration)
Avoidance of high fraction of inspired oxygen (FiO_2) and restriction of hydration if prior treatment with bleomycin
Judicious use of cardiac depressants in patients with compromised cardiac function
Nausea and vomiting prophylaxis
Stress corticosteroids (when appropriate)
Regional anesthesia when safe and indicated
Postoperative Considerations
Patient-appropriate opioid and other analgesic administration
Sterile technique with central line access
Observation of indicated isolation precautions

loss a significant risk. Spinal tumors may cause acute spinal cord compression, and tumor or hemorrhage in the brain may cause acute intracranial hypertension. In view of the complexity of pediatric oncologic disease, there are many considerations for the perioperative period[63] (Table 11.7).

HEMATOPOIETIC STEM CELL TRANSPLANTATION RECIPIENTS

Surgical and procedural interventions are common throughout the transplantation process and are similar to those described previously for children with cancer. Harvesting of hematopoietic stem cells from the recipient or another individual is an integral component of HSCT. Harvesting of bone marrow in children usually requires general anesthesia, although the procedure can be performed safely with the child under spinal anesthesia if required.[182] The donor is usually placed in a prone position to extract approximately 10 mL/kg (recipient weight) of marrow from the posterior iliac crests. When stem cells are obtained from peripheral blood, sedation or general anesthesia is usually required to establish vascular access. There is little evidence to support the avoidance of nitrous oxide for harvesting procedures, a concern raised in the past because nitrous oxide affects methionine synthase activity and DNA synthesis.[183]

In view of the wide range of possible complications at the time of HSCT, the many issues outlined earlier for children with cancer must be considered for children undergoing HSCT (see Table 11.7). Radiation, glucocorticoids, mucositis, and chronic GVHD may contribute to an airway that is friable and a neck that is scarred, thereby increasing the risks of airway trauma, dental injury, and difficult tracheal intubation. Chemotherapy and GVHD may affect the skin and make venous access difficult. Chronic GVHD can lead to sclerodermatous changes, which can profoundly restrict range of motion, and sicca syndrome, which may necessitate use of artificial tears. GVHD may alter gut motility and delay gastric emptying. Immune compromise increases the risk of infection from vascular access lines and therefore mandates meticulous technique at all times. Chemotherapy may compromise cardiac and pulmonary function, alter hepatic metabolism of medications, and limit renal excretion of medications and fluids. Immune compromise and modifications resulting from transplantation require special processing of blood components, as recommended by hematology and blood bank consultants, as described in the following text and in Tables 10.3, 10.4, and 10.5. It is critical to coordinate the choice of blood products with the transplant service.

Transfusion Considerations

RED BLOOD CELLS

Anemia is very common in children with cancer, with an incidence that ranges from 51% to 74% in children with solid tumors or Hodgkin disease, greater than 50% of children with Wilms tumor and osteosarcoma,[102] greater than 80% of children receiving chemotherapy, and 97% of children with leukemia.[184] There is limited evidence regarding the optimal transfusion thresholds for children with cancer, and guidelines have not been established. Accordingly, current practice patterns stem from adult oncology studies, data from other pediatric populations (e.g., intensive care), and individual institutional practice patterns.[185] The threshold for red blood cell transfusion in adults with cancer is a hemoglobin concentration of 7 to 9 g/dL in asymptomatic individuals and 8 to 10 g/dL in symptomatic individuals.[186] Whether these thresholds are appropriate for children with cancer, who range in age from infancy to adolescence and with conditions ranging from leukemia to brain tumors, is unknown. Nonetheless, these values have been adopted empirically in children.[187] In practice, pediatric oncology patients usually receive transfusions when their hemoglobin concentrations decrease to 5.5 to 8 g/dL.[184]

Several factors should be considered when determining the need for blood transfusion, including the overall clinical condition of the child, symptoms of anemia, the presence of cardiopulmonary dysfunction, the stress and anticipated blood loss of the surgical procedure, the risk of increased intraoperative hemorrhage owing to coexisting coagulopathy, and the ability of the child to tolerate a volume load. Finally, blood products should be administered cautiously in those with hyperleukocytosis as the added viscosity can trigger leukostasis.[188] Thus sound clinical judgment

and attention to the greater clinical context are warranted in each case.[189]

THROMBOCYTOPENIA

Thrombocytopenia occurs commonly in association with marrow suppression from chemotherapy, radiation, or even marrow replacement by hematologic malignancy. Additional effects on platelets include consumption during infections or disseminated intravascular coagulation, platelet sequestration with splenomegaly, and platelet dysfunction from medications.[187] The platelet count is not the sole indicator of the risk of bleeding in children with cancer, as evidenced by the occurrence of major bleeding at any platelet count[190]; treatment- or cancer-induced damage to vascular epithelium and alterations anywhere in the coagulation cascade pose additive risks for hemorrhage. Regardless, platelet transfusions play an important role in avoiding the risk of catastrophic hemorrhage in children.[191] Of note, the risk/benefit of perioperative platelet transfusion in the immediate post-HSCT period must be discussed with the oncology team, as transfusions during this time may impact the transplant engraftment.[191]

The optimal prophylactic platelet transfusion strategy in pediatric oncology remains complicated and controversial. As noted previously, the risk of bleeding is neither solely dependent on nor inversely proportional to the platelet count.[190] However, in the absence of adequate prospective trials, most practice guidelines continue to recommend a platelet count >50,000/μL for invasive procedures to >100,000/μL for CNS procedures, and 10,000-20,000/μL for lumbar punctures.[192] Despite the knowledge that these thresholds may not be appropriate for every age of child and cancer diagnosis, they remain our best guide at this time for children presenting for surgery.[191]

COAGULATION FACTOR DEFICIENCY

Perioperative administration of fresh frozen plasma or factor components is reasonable if the child with cancer has documented prolongation of prothrombin or partial thromboplastin time, verified factor deficiency, or surgical bleeding despite normal platelet levels and function. The invasiveness of the surgical procedure also should be taken into account. Cryoprecipitate and coagulation factor concentrates may also be necessary in the setting of abnormal laboratory studies and clinical coagulopathy.[189] It should be noted that fresh frozen plasma is ineffective in reversing the coagulopathy associated with L-asparaginase.[193]

BLOOD PRODUCT PREPARATION

Immunocompetent white blood cells in donor blood can elicit a profound immune response and other complications in the recipient, especially immunocompromised children. Leukoreduction by filtration eliminates greater than 99% of donor leukocytes. Most blood products in the United States and all blood products in Canada and Europe are routinely leukoreduced,[187] and leukoreduced products should be used in children with cancer. Tables 10.3 and 12.8 provides a complete list of indications for leukoreduced products. Leukoreduction reduces the rate of platelet alloimmunization, transfusion-related immunomodulation, febrile transfusion reactions, and transfusion-related infections, including cytomegalovirus (CMV) infection.[194,195] Although leukoreduction may be sufficient to prevent donor-related CMV infection, CMV-negative donor blood is recommended for CMV-negative infants and children with cancer, especially children undergoing HSCT (Table 10.5 and E-Table 12.1).[196]

Donor lymphocytes contained in the component blood products can replicate and engraft in the host, leading to a transfusion-associated graft-versus-host disease (TA-GVHD), especially in immunocompromised patients. TA-GVHD manifests days to weeks after transfusion, is resistant to treatment, and is often fatal. Leukoreduction alone is insufficient to eliminate the risk of TA-GVHD. As a result, irradiation of platelets and red blood cells is mandatory for immunosuppressed patients, including children with cancer (Table 10.4 and E-Table 12.2).[194,197,198] Irradiation of blood products can lead to cell membrane destabilization, leading to ongoing leakage of intracellular potassium and a shortened shelf life; thus irradiation optimally occurs immediately before use of the blood to avoid hyperkalemia.[197]

Children who have undergone HSCT may represent a challenge for blood typing. Major and minor ABO mismatch, as occurs in the setting of allogeneic HSCT, potentiates a shift in the ABO/Rh status of the recipient, the degree of which depends on the timing and engraftment status of the transplant. Preoperative communication with the blood bank and oncologist is warranted for all children who have recently undergone HSCT and are at risk for requiring perioperative transfusion of blood products.[199]

Effects of Anesthetic Agents on Perioperative Immunomodulation

Recent research has focused on the potential impact of multiple perioperative factors on immunomodulation and the risk of tumor recurrence. To date, research has been in vitro or in retrospective adult studies; thus some or all of the findings may not be directly applicable to children.[200,201] Theoretically, a whole host of perioperative factors could potentially suppress the host immune system or even directly augment the cancer cells, leading to the growth of minimally residual tumor cells and recurrence of cancer.[201,202] Some studies have reported potentially harmful immunosuppression or cancer cell augmentation after anesthesia with volatile anesthetics, ketamine, opioids (particularly morphine), and benzodiazepines.[200-202] Propofol has shown mixed results, and nitrous oxide, while harmful in vitro, has not been linked to cancer recurrence in adults. The use of regional anesthesia has been shown to confer protection against recurrence in some but not all studies.[201,203] Multiple other factors have shown intermittent association with poor outcomes, including surgical stress response, hypotension, hypothermia, hyperglycemia, blood transfusions, glucocorticoids, and NSAIDs.[200] In summary, data are insufficient to support altering the anesthetic plan in children on the basis of reducing the risk of tumor recurrence.

Summary

Children with cancer present a host of challenges for the anesthesiologist as virtually every organ system may be dysfunctional as a result of the underlying malignancy, the toxicity of treatment, or both. Those in cancer remission often suffer varying degrees of chronic effects of cancer treatment that impact their anesthetic care decades later. As treatment options for pediatric cancer have expanded, it has become increasingly important for providers who care for these children to maintain an open line of communication with the surgical and oncology teams. An understanding

of the physiologic and psychological aberrations in this population is essential in providing safe perioperative care for these vulnerable and complex patients.

ANNOTATED REFERENCES

Intraoperative Blood Recovery and Reinfusion: Autotransfusion
Controlled Hypotension
Normovolemic Hemodilution

DESPITE ADVANCES IN PEDIATRIC SURGERY, infants and children may sustain major operative blood loss, but little information is available about when coagulation defects will begin to appear in children.[1,2] Most studies of massive blood transfusions have involved adult patients, with little evidence from children to build a massive transfusion strategy.[3]

A rational blood transfusion strategy is imperative in children because there is limited blood available and transfusions can cause complications. In countries with sophisticated health care systems, the most common fatal hazards of transfusion are hemolytic transfusion reactions related to ABO incompatibility (usually as a result of a transfusion error), transfusion-associated circulatory overload (TACO), and transfusion-related acute lung injury (TRALI).[4] In developing countries, the risk of infectious disease transmission may be greater because of endemic infections (e.g., Dengue, Chikungunya, malaria) and the technical or logistic limitations of donor screening.[5] Recently, the neurotropic Zika virus has become of great interest because of its marked association with microcephaly in the newborn,[6] and arthrogryposis in infants, and in adults, to Guillain-Barré syndrome and cognitive dysfunction.[7] RNA testing of blood donors in areas with high prevalence rates such as Brazil and Puerto Rico was instituted in the summer of 2016, and by late 2016 in the United States.[8] In nonendemic areas, donors are currently being screened for recent travel to countries where infection is prevalent. Children suffer from noninfectious complications of transfusion more frequently than adults. A review of 133,671 transfusions found 108 adverse events in children and 277 in adults; in children there was an increase in allergic reactions (2.7 vs. 1.1/1000), febrile reactions (1.9 vs. 0.47/1000) and hypotension (0.29 vs. 0.078/1000); unlike adults, reactions were twice as likely in male children (7.9 vs. 4.3/1000).[9]

Nothing changed the use of blood products more than the threat of AIDS.[10–12] Fortunately, the risk of infection with human immunodeficiency virus (HIV), hepatitis C virus (HCV), and Hepatitis B virus (HBV) by blood transfusion today is extremely rare. Implementation of donor education programs, improved health history screening, new tests, and new test technologies (Table 12.1) have markedly altered the spectrum of transfusion-transmitted infectious agents in the developed world. The risks of some of the infectious and noninfectious hazards of transfusion are summarized in Table 12.2.

Despite marked reductions in the transmission of HIV, HCV, and HBV, transfusions can produce other deleterious effects.[13,14] Every transfusion must be medically justified and its benefits weighed against the potential infectious, immunologic, and metabolic risks.[15] It is in the child's best interest to transfuse with a clear clinical goal and in the anesthesiologist's best interest to document the reason for each transfusion. It is not acceptable medical practice to administer a transfusion when it is of questionable benefit.

Blood Volume

The circulating blood volume of the child should be estimated before induction of anesthesia. The blood volume of a preterm infant (90–100 mL/kg) constitutes a greater proportion of body weight than that of a term neonate (80–90 mL/kg), an infant between 3 months and 1 year of age (70–80 mL/kg), and an older child (70 mL/kg). Body habitus affects the blood volume calculation since the latter is normalized to body weight. For example, an obese child has a smaller blood volume per kilogram, 60–65 mL/kg, than a nonobese child of the same weight. Using the estimated

TABLE 12.1 Current Blood Screening Tests Used on Donated Blood in the United States

Hepatitis B surface antigen (HBsAg)
Hepatitis B core antibody (anti-HBc)
Nucleic acid amplification testing for HBV DNA
Hepatitis C virus antibody (anti-HCV)
Nucleic acid amplification testing for HCV RNA
Human immunodeficiency virus type 1 (HIV-1) antibody (anti-HIV-1)
HIV-2 antibody (anti-HIV-2)
Nucleic acid amplification testing for HIV-1 RNA
Human T-lymphotropic virus type 1 (HTLV-I) antibody (anti-HTLV-I)
HTLV-II antibody (anti-HTLV-II)
Serologic test for syphilis (*Treponema pallidum*)
Nucleic acid amplification for West Nile virus (WNV) RNA[a]
Trypanosoma cruzi antibody (Chagas disease)[b]
Nucleic acid testing for Zika virus RNA
Screen for bacterial contamination—Platelets only

[a]This test depends on the incidence in the geographic area.
[b]At first donation or after residence in endemic area.

TABLE 12.2 Estimated Frequency of Complications per Number of Units Transfused

Category	Complication	Frequency
Noninfectious	Allergic (urticarial)	1:100
	Febrile, nonhemolytic	1:100
	Transfusion-associated circulatory overload	1:1000
	Delayed hemolytic	1:1600
	Transfusion-related acute lung injury	1:10,000
	Acute hemolytic	1:50,000
	Fatal acute hemolytic	1:500,000
Infectious	Hepatitis B virus	1:1,000,000
	Hepatitis C virus	1:1,700,000
	Human T-lymphotropic virus type I	1:2,700,000
	Human immunodeficiency virus type 1	1:1,900,000
	Bacterial contamination of red blood cells	1:50,000
	Bacterial sepsis of red blood cells	1:500,000
	Bacterial contamination of platelets	1:2000
	Bacterial sepsis of platelets	1:75,000

Data from Galel SA. Infectious disease screening. In: Fung MK, et al. (eds.). *Technical Manual*. Bethesda, MD: AABB Press; 2014:194; Mazzei CA, Popovsky MA, Kopko PM. Non-infectious complications of transfusion. In: Fung MK, et al. (eds.). *Technical Manual*. Bethesda, MD: AABB press; 2014:684.

blood volume, the initial hemoglobin or hematocrit, and the minimum acceptable hematocrit, we can *estimate* the maximum allowable blood loss (MABL) before red blood cell (RBC) transfusion is indicated.

The minimum acceptable hematocrit varies according to an individual child's need. The balance between oxygen supply and demand depends on a number of factors, including the oxygen content of blood, cardiac output and its regional distribution, and metabolic needs. Rheologic considerations (e.g., ensuring adequate hepatic artery blood flow in liver transplant recipients) may also affect the optimal hematocrit. A child with severe pulmonary disease or cyanotic congenital heart disease often requires a greater hematocrit than a healthy child to satisfy oxygen demands. Preterm infants may require a greater hematocrit to prevent apnea, reduce cardiac and respiratory work, and possibly improve neurologic outcomes,[16] although the data are not clear.[17,18] If there is uncertainty about the need to transfuse these infants, the neonatologist should be consulted.[16,19,20] A healthy child readily tolerates a hematocrit well below 30%. It is our practice not to transfuse otherwise healthy infants up to about 3 months old until their hematocrits have decreased to 25% and hematocrits of older children have decreased to 20% if there is little potential for postoperative bleeding. *The circulating blood volume must be maintained in every case.* Observing the operative field to estimate blood loss and monitoring the vital signs, hematocrit, urine output, and the central venous pressure (CVP) help to assess the adequacy of volume replacement. If a procedure is expected to result in significant blood loss or fluid shifts, the anesthesiologist should strongly consider the use of a urine catheter, a central venous line, and invasive arterial monitoring. The child's size or age should not deter one from the use of a central venous catheter (Table 12.3). The introduction of noninvasive cardiac output monitors may further clarify the need for and response to transfusion and volume replacement (see also Chapter 52).[21]

TABLE 12.3 Estimated Predicted Blood Loss and Recommended Monitoring and Equipment

Predicted Blood Loss	Recommended Monitors or Equipment
<0.5 blood volume	Routine monitoring
0.5–1.0 blood volume	Routing monitoring + urine catheter
1.0 blood volume or more	Routine monitoring + urine catheter + CVP + arterial line
1.0 blood volume or more with potential for rapid blood loss	Routine monitoring + urine catheter + CVP + arterial line + large-bore IV line + rapid-infusion device
Severe head injury	Routine monitoring + urine catheter + CVP + arterial line + large-bore IV line
Major trauma with unknown severity	Routine monitoring + urine catheter + CVP + arterial line + large-bore IV line (preferably in upper extremity or central) + rapid-infusion device

CVP, central venous pressure; *IV*, intravenous.

There are three approaches for estimating the MABL: an approximation of circulating RBC mass, a modified logarithmic equation, and a simple proportion.[22,23] All three approaches yield clinically similar estimates of the MABL. The most straightforward method is to estimate the MABL by simple proportion.[22] For purposes of discussion, we use a hematocrit of 25% as the minimum acceptable hematocrit:

$$\text{MABL} = \frac{\text{EBV} \times (\text{Child's hematocrit} - \text{Minimum acceptable hematocrit})}{\text{Child's hematocrit}}$$

For example, a 10-kg child has an estimated blood volume of 10 (kg) × 70 (mL/kg), or 700 mL. If the child's hematocrit is 42, the MABL is calculated as follows:

$$\text{MABL} = \frac{700 \times (42 - 25)}{42}$$
$$= \frac{700 \times 17}{42}$$
$$= 285 \text{ mL}$$

These calculations only estimate the MABL. The actual hematocrit varies with the child's preexisting medical conditions, the rapidity of the blood loss, and the rate of concurrent crystalloid replacement.

It should be noted that commonly used crystalloid solutions for volume replacement actually consist of two solutions: normal saline and balanced electrolyte solutions. These are not identical solutions. Normal saline is slightly hyperosmolar (sodium concentration of 154 mEq/L [308 mOsm/L]) and may produce a non–anion gap hyperchloremic metabolic acidosis when given in large quantities (in polyvinyl bags the pH is 4.5–7.0). Balanced electrolyte solutions comprise a group of solutions that are slightly hypoosmolar (273 mOsm/L), contain one of several bases (lactate, gluconate, or acetate). and a pH of 5 to 8 (see also Chapter 9).

Initial therapy is directed at replacing fluid deficits and providing maintenance requirements (see Chapter 9). Additional fluid administration is directed at replacing blood loss and third space fluid losses. There seems to be little danger in replacing the entire MABL with crystalloid provided that the child is healthy and that postoperative oozing will not exceed the MABL. Historically, the consensus has been to replace each milliliter of shed blood with 2 to 3 mL of crystalloid.[24,25] However, more recent evidence suggests to replace each milliliter of shed blood with a smaller volume of crystalloid (i.e., 1–2 mL).[26] Colloid replacement is expensive and without clear evidence that it is superior to crystalloid, but it may be used to replace blood loss as 1 mL of 5% albumin per milliliter of shed blood.[27,28] New starch volume expanders have been introduced that may hold promise in the future for use in children, but the long-term safety implications for their use are as yet unclear.[29,30]

In our example of the 10-kg child with a 700-mL blood volume and a 285-mL MABL, the child's blood volume can be restored by administering either 570 mL of isotonic crystalloid or 285 mL of 5% albumin. However, if the blood loss exceeds the MABL or if the hematocrit decreases to 20% to 25% (particularly if additional blood loss is expected during or after surgery), then transfusion with packed red blood cells (PRBCs) or whole blood (if available) is indicated. If postoperative bleeding is likely to occur (e.g., posterior spinal fusion, open heart operations, burn wound excision and grafting), it is reasonable to transfuse to a level greater than the minimum acceptable hematocrit. This is especially true if a greater hematocrit can be achieved without exposing the child to additional units of blood. If a unit of blood has been started, it is reasonable to give the child an additional 5% to 10% volume rather than a fraction of a new unit postoperatively. It is our practice to administer as much of the unit as can be safely tolerated rather than expose the child to another unit of blood postoperatively. Blood banks often prepare several aliquots from one unit of blood, especially for neonates and infants. In this manner, a single donor unit can be assigned to a particular child with each aliquot infused as needed at different times.

If PRBCs are used to replace the shed RBCs, then the volume of PRBCs needed to restore a specific hematocrit may be calculated quite simply. For example, if the hematocrit of a 10-kg child has decreased to 23% and the intraoperative blood loss is expected to continue postoperatively, then the anesthesiologist can use the following formula to estimate the volume of PRBCs needed to achieve a final hematocrit of 35% as follows:

$$\text{Volume of PRBCs} = \frac{(\text{Desired Hct} - \text{Present Hct}) \times \text{Estimated Blood Volume (70 mL/kg} \times \text{10 kg)}}{\text{Hematocrit of PRCBs}}$$
$$= \frac{(35 - 23) \times (70 \times 10)}{60}$$
$$= 140 \text{ mL PRBCs}$$

Because this volume is less than 1 unit, it may be reasonable to transfuse more volume than calculated–that is, up to a hematocrit of 40% (~200 mL PRBCs) to allow an additional margin of safety for postoperative blood loss. A prospective study by the American College of Surgeons National Quality Improvement Program–Pediatrics involving 50 institutions found that there were significant differences in transfusion practices among institutions and that transfusions were more likely in infants and children 2 years of age or younger (odds ratio [OR]) 5.9–3.4), ASA class IV (OR 3.2), preoperative septic shock (OR 14.5), and preoperative cardiopulmonary resuscitation (OR 8.1).[31]

Blood Components and Alternatives

In countries with well-developed health care systems, most whole blood collected from donors is fractionated into components. A unit of whole blood can provide 1 unit of PRBCs, 1 unit of whole blood–derived platelets, and 1 unit of fresh frozen plasma (FFP). Apheresis technology can be used to collect any one of these three components selectively. Separation of the individual components from blood allows each to be stored under conditions that optimally preserve its function–for example, at refrigerator temperature (4°–10°C) for PRBC, at less than –18°C for FFP, and at room temperature (20°–24°C) for platelets. Most children with specific disease states (e.g., anemia, clotting factor deficiencies, thrombocytopenia) require only one of these fractions, which is why use of component therapy is widespread.

RED BLOOD CELL–CONTAINING COMPONENTS

Blood components containing RBCs are indicated for the treatment of symptomatic deficits of oxygen-carrying capacity.[32,33] PRBCs are the most widely available RBC-containing blood component, although in settings where the collection facilities do not have the capability to make components, whole blood may be the only component available. Donor whole blood is collected in a preservative-anticoagulant solution that contains citrate, phosphate, dextrose (glucose), and adenine (CPDA) or just citrate, phosphate, and dextrose (CPD). In the latter case, the platelet-rich plasma is removed after centrifugation of the whole blood unit, and a solution containing adenine, dextrose, and occasionally mannitol is added to the PRBCs. The additive-solution systems permit storage for 42 days (compared with 35 days for CPDA) and better preservation of 2,3-diphosphoglycerate (DPG) levels. The characteristics of the CPDA and additive-solution PRBCs and of whole blood at the time of outdate are shown in Table 12.4; the hematocrit is reduced in the additive-solution PRBCs and the total volume is increased, but the red cell mass remains the same.

RBCs carry glycoconjugate antigens of the ABH histo-blood group system on the cell surface that are determined by three common alleles at the ABO locus on chromosome 9.[34] During

TABLE 12.4 Composition of Components Containing Red Blood Cells at Outdate

Parameter	CPDA-1 Whole Blood[a]	CPDA-1 RBC[a]	Additive Solution RBC[b]
Storage time (days)	35	35	42
Volume RBC (mL)[c]	203	203	203
Residual plasma (mL)[c,d]	248	50	30
Hematocrit (%)	40	72	53
pH	6.98	6.71	6.6
Adenosine triphosphate (% of day 1)	56	45	60
2,3-DPG (% of day 1)	<10	<10	<10
Total supernatant K^+ (mEq/unit)	5–7	5–7	5–7

CPDA, citrate, phosphate, dextrose, and adenine solution; *DPG,* 2,3-diphosphoglycerate; *RBC,* red blood cell.
[a]Outdated at 35 days.
[b]Outdated at 42 days.
[c]Based on collection of 450 mL of whole blood with a hematocrit of 45%.
[d]The concentration of factors V and VIII is reduced to 20% to 50% of normal levels (0.2 to 0.5 units/mL). The other clotting factors are quite stable.

TABLE 12.5 ABO Compatibility of Blood Components

Recipient ABO Group	Acceptable Component ABO Groups (Second Choice): Whole Blood	PRBC	FFP/Cryo	Platelets
O	O	O	O (A, B, AB, plasma)	O (A, B, AB)
A	A	A (O)	A (AB)	A (AB)[a]
B	B	B (O)	B (AB)	B (AB)[a]
AB	AB	AB (A, B, O)	AB	AB[a]

Cryo, cryoprecipitate; *FFP,* fresh frozen plasma; *PRBC,* packed red blood cells.
[a]Can come from group apheresis platelets (or whole blood–derived platelets for small child) if plasma is removed or replaced.

TABLE 12.6 Rh(D) Compatibility of Blood Components

Recipient Rh(D) Type	Acceptable Component Rh(D) Types (Second Choice): Whole Blood or PRBCs	FFP/Cryo	Apheresis Platelets	Whole Blood–Derived Platelets
Positive	Rh-positive (Rh-negative)	Any	Any	Rh-positive (Rh-negative)
Negative	Rh-negative (Rh-positive)[a]	Any	Any	Rh-negative (Rh-positive)[a,b]

Cryo, cryoprecipitate; *FFP,* fresh frozen plasma; *PRBCs,* packed red blood cells.
[a]Depending on inventory, the blood bank may switch to Rh(D)-positive, particularly for male patients or postmenopausal females.
[b]Consider Rh immune globulin for females with childbearing potential receiving whole blood–derived platelets from Rh(D)-positive donors.

TABLE 12.7 Common Initial Doses of Blood Components and Expected Effects in Children

Component	Dose	Effect
Packed red blood cells	10–15 mL/kg	Increase hemoglobin by 2–3 g/dL[a]
Platelets[b]	5–10 mL/kg	Increase platelet count by 50,000–100,000/mm^3
Fresh frozen plasma	10–15 mL/kg	Factor levels increase by 15%–20%
Cryoprecipitate	1–2 units/kg	Increase fibrinogen by 60–100 mg/dL
Fibrinogen concentrate	70 mg/kg	Increase in fibrinogen level of 120 mg/dL

[a]Note that the hematocrit of PRBCs varies from ~60% to 70% for packed red blood cells in citrate, phosphate, dextrose (glucose), and adenine (CPDA) versus ~55% for packed red blood cells in additive-solution systems; the total volume of packed red blood cells is, however, the same.
[b]This recommendation may be reduced pending the impact of the prophylactic platelet dose (PLADO) trial, as published for all age groups[35] and for the pediatric age range.[36]

the first year of life, infants begin to elaborate alloantibodies to whichever A or B antigens they lack. These isoagglutinins are invariably present after a few months and constitute a formidable immunologic obstacle to transfusion or transplantation across this ABO barrier. The RBCs for transfusion must be compatible with the ABO isoagglutinins of the intended transfusion recipient. Similarly, components with a large volume of plasma (e.g., whole blood, FFP, apheresis platelets) must be compatible with the A or B surface antigens expressed on the recipient's RBCs. PRBCs must be ABO *compatible* with the recipient, whereas whole blood must be ABO *identical* because of the larger volume of donor plasma and, hence, AB isoagglutinins. Table 12.5 summarizes the permissible combinations.

Only RBCs express the Rh(D) antigen. Rh(D)-positive patients may receive Rh(D)-positive or Rh(D)-negative RBCs. Rh(D)-negative patients are routinely given Rh(D)-negative RBCs for any elective transfusions, but in the setting of massive transfusion it may be necessary to switch to Rh(D)-positive RBCs to preserve the supply of Rh(D)-negative RBCs. The blood bank usually determines when to make this substitution based on the inventory and does so more quickly for a patient who is a male or a postmenopausal female (Table 12.6). The objective is to avoid exposing a female with childbearing potential to Rh(D)-positive RBCs and possibly triggering the production of the anti-D alloantibody, which is responsible for the most severe forms of hemolytic disease of the newborn. Table 12.7 shows the common initial volume of PRBCs needed to increase the hemoglobin level by 2 to 3 g/dL.

The changes that occur to RBCs during storage under conventional blood bank conditions have been well described.[37] These observations have generated physiologically plausible hypotheses about how such changes may impair the function of the banked RBCs in vivo. The reduced hemoglobin level of 2,3-DPG and its corresponding decrease in the P_{50} value may reduce the ability of stored RBCs to relinquish bound O_2 compared with 2,3-DPG–replete RBCs. The depletion of nitric oxide (NO) may reduce the vasodilatory properties of the RBCs, hence impairing their ability to maintain the patency of the small vessels in the microcirculation and blood flow to the tissues.[38] Numerous changes in the composition and behavior of the RBC plasma membrane, including the loss and oxidation of membrane lipids and proteins and the rearrangement of some membrane constituents,[39] correlate

with changes in the shape and elasticity of the RBC membrane.[40–42] The loss of elasticity in particular can impede the rapid movement of the RBCs through the microcirculation.

These hypotheses and some supportive data from animal models[43] have led to a number of observational clinical studies (mostly in trauma, critical care, colorectal surgery, and cardiac surgery) of outcomes after using stored PRBCs, but the results have been inconclusive.[44–46] One prospective, observational study from 30 North American Centers in 296 children younger than 18 years of age who received blood stored 14 days or longer reported increased multiple organ dysfunction (OR 1.87) and increased pediatric intensive care unit (PICU) stay (~3.7 days) but no difference in mortality.[47] A small study of pediatric cardiac surgical patients found that children who received blood older than 3 days required additional RBC and FFP transfusions but this study was underpowered.[48] About half of such observational studies found a statistical association between an unfavorable clinical outcome measure and the transfusion of RBCs that had been stored for a greater time. However, no such association was reported in the other half of the studies, including two that were extensions of previous studies with positive findings. A small number of randomized, controlled trials (RCTs) addressed this issue without statistically significant differences in outcomes between patients receiving RBCs stored for different amounts of time,[49] although two of them were underpowered.[50,51] Knowing that RBCs change during storage raises the question of whether these changes affect children in a clinically meaningful way, a question that remains unanswered by the observational studies.[52]

In the past few years, several RCTs have addressed these issues in four different patient populations, two of which were in pediatric cohorts. A multicenter RCT conducted in Canada randomized low–birth-weight neonates in ICUs to receive PRBCs stored 8 days or less or the standard of care, which was to provide aliquots from one unit of PRBCs to each infant until transfusion was no longer required or the donor unit was depleted.[48] There were no differences in the incidence of infections, bronchopulmonary dysplasia, necrotizing enterocolitis, death, or the composite between the two groups. Children in Uganda between the ages of 6 months and 6 years who presented with severe anemia (hemoglobin <5 g/dL) and lactic acidosis (lactate >5 mmol/L) were randomly assigned to receive PRBCs stored 10 days or less or 35 days longer.[49] There were no differences in lactate clearance, left ventricular strain, as assessed by β-naturietic peptide or, in a subset of patients, correction of cerebral tissue oxygen saturation as measured by near-infrared spectroscopy. Two studies in adults compared clinical outcomes after transfusion with PRBCs stored for different periods of time. Patients 12 years of age or older undergoing complex cardiac surgery and very likely to require PRBC transfusion were randomly assigned to receive PRBCs stored 10 days or longer or 28 days or less.[50] No differences were observed in the change in the Multiple Organ Dysfunction Score (MODS) or mortality at 7 or 28 days, in length of ICU or hospital length of stay, or in the frequency of serious adverse events. Adult patients in ICUs in Canada were randomly assigned to receive PRBCs stored 8 days or less versus the standard of care, which was to issue the oldest units first.[51] No differences were found for 30- or 90-day mortality, ICU or hospital length of stay, changes in MODS, or several other clinical endpoints. There is no apparent clinical benefit derived by transfusing units of PRBCs, which have been stored for a period of time that is substantially shorter than that of the PRBCs routinely supplied by our current inventory practices for these vulnerable populations.

PLATELETS

Platelets may be obtained from a unit of whole blood or collected by apheresis. Platelets from whole blood are separated by centrifugation and suspended in 40 to 60 mL of plasma at a concentration that is two to four times greater than in the circulation. Each unit contains a minimum of 5.5×10^{10} platelets and is stored at 20°C to 24°C with gentle continuous agitation for a maximum of 5 days. One unit of whole blood–derived platelets can be expected to increase the platelet count in an 18-kg child by 15,000/mm^3 and in a 70-kg adult by 5000 to 10,000/mm^3.[41,53] A unit of platelets obtained by apheresis contains at least 3×10^{11} platelets in 200 to 400 mL of plasma, or the equivalent of approximately 6 units of whole blood–derived platelets. A common dose for children is 0.1 to 0.3 unit/kg of body weight, or 10 to 15 mL/kg (see Table 12.7); this dose usually produces an increment of 30,000 to 90,000/mm^3. However, in several prophylactic platelet dose trials for medical causes of bleeding, doses equivalent to the standard dose of 1 pheresis unit (or 6 units of whole blood–derived platelet concentrates) per meter squared, half of this dose and double this dose were compared in 1272 adult and children who received at least 1 platelet transfusion.[54,55] Blood losses were determined with the World Health Organization (WHO) bleeding scale: grade 0 = no bleeding, grade 1 = petechiae, grade 2 = mild blood loss, grade 3 = gross blood loss, and grade 4 = debilitating blood loss. No differences were observed in bleeding outcomes (WHO grade ≥2) among the three doses. The subset of 200 children were found to have a greater risk for bleeding than adults for unknown reasons, but bleeding in this age group also did not differ by platelet dose received and was seemingly unrelated to platelet counts.[42] The recommended platelet dose may be reduced in the near future, but this change awaits further discussion by the blood transfusion and hemostasis community.[56–58] This trial assessed the use of platelets to prevent bleeding events and did not address patients undergoing surgical procedures with ongoing bleeding.

In the setting of dilutional thrombocytopenia with ongoing blood loss or a consumptive coagulopathy (e.g., disseminated intravascular coagulation), larger doses (≥0.3 unit/kg) may be required to boost the platelet count above 50,000/mm^3. Because platelets are suspended in plasma that contains the anti-A and anti-B isoagglutinins, they should be ABO compatible with the recipient's RBCs. Some blood donors have high-titer isoagglutinins that can produce hemolysis in transfusion recipients if a large enough volume of plasma is given.[59] The transfusion of plasma-incompatible, whole blood–derived platelets to adult recipients does not produce clinically significant hemolysis because the volume of plasma given is so small relative to the plasma volume of an adult. However, apheresis platelets (and whole blood–derived platelets for small children) should be ABO compatible with the recipient's RBCs. Matching for Rh(D) antigen is not necessary for apheresis platelets because platelets do not express Rh antigens and they contain virtually no RBCs. However, whole blood–derived platelets may contain enough RBCs to provoke Rh alloimmunization, so platelets from Rh(D)-negative donors are given preferentially to Rh(D)-negative recipients with childbearing potential. If a premenopausal female receives whole blood–derived platelets from an Rh(D)-positive donor, Rh immune globulin (Rhogam) can be administered within 72 hours to prevent alloimmunization. Platelets should never be withheld in an emergency situation because of Rh(D) incompatibility.

Platelets are essential to hemostasis associated with the vascular injury of surgery and are necessary for the control of surgical bleeding. Platelets are also required for the maintenance of an

intact endothelial barrier to spontaneous blood loss. The number of platelets required to provide adequate hemostasis in the surgical setting is much greater than the number needed to provide prophylaxis against spontaneous hemorrhage. A platelet count of 40,000 to 50,000 /mm^3 is considered adequate to prevent spontaneous bleeding or bleeding from minor invasive procedures (e.g., lumbar puncture, line placement) in an otherwise stable child. If overt signs of bleeding are present or a more significant hemostatic challenge in the form of a surgical procedure is imminent, sustaining a level of 30,000 to 50,000/mm^3 for several days may be required.[60–64] A target level of 50,000/mm^3 is appropriate in the setting of massive transfusion.[61,65–67] Platelets may also be required for children with adequate counts but in whom platelet function is impaired in some forms of congenital heart disease and following cardiopulmonary bypass.[68,69] Many medications (e.g., aspirin; other nonsteroidal antiinflammatory agents, including ibuprofen and naproxen; dipyridamole; platelet P2Y12 receptor blockers such as clopidogrel or prasugrel; or glycoprotein IIa/IIIb receptor inhibitors such as abciximab, eptifibatide, or tirofiban; serotonin uptake antagonists such as Zoloft) and some medical conditions (e.g., renal failure with blood urea nitrogen levels above 60 mg/dL) cause abnormal platelet function, which may interfere with surgical hemostasis, in which case it may be necessary to maintain the platelet count at a somewhat greater concentration, at least until the effect of the medication dissipates or the child's platelets have largely been replaced by banked platelets.[70,71] In a few settings, such as intracranial, ophthalmic, and otologic surgery, even greater concentrations (100,000/mm^3) may be sought, although the appropriate threshold in these settings has not been examined in detail.

There is no clear-cut threshold value below which the platelet count predicts clinical bleeding in the perioperative period. Each child must be individually assessed by constantly observing the surgical field for evidence of abnormal bleeding.[72] Unfortunately, we lack a well-validated bedside tool to assess platelet function. The utility of the thromboelastogram and other devices to measure platelet function under controlled flow conditions, such as microfluidic flow devices[73,74] and the platelet function analyzer (PFA-100), are currently under investigation but are not at this time able to predict risk for hemorrhage.[75–78] The standard technique for diagnosis and evaluation of thrombocytopathies remains Born-O'Brien platelet aggregometry, but it is not useful in the intraoperative or intensive care setting.[79] Most commonly, dilutional thrombocytopenia rather than a newly acquired platelet function defect is the cause in the operative setting and in massive transfusion.

A child occasionally presents for surgery with a previously characterized platelet dysfunction that may be associated with bleeding. If the child has a normal platelet count, it is reasonable practice to ensure that the blood bank has an adequate platelet supply available for the operating room and to withhold transfusion of platelets until pathologic bleeding occurs.

Several additional points should be considered[80]:

1. Not all hospitals have platelets in the inventory. Unless the need is anticipated before surgery, platelets may not be available when they are required. Therefore, a preemptive request for platelets may have to be arranged.
2. For children who are thrombocytopenic before surgery, platelets should be infused just before the surgical procedure to ensure the greatest concentrations during the time of peak demand. The start of the procedure should *not* be delayed to obtain the results of a posttransfusion platelet count.
3. Platelets should be filtered only by large-pore filters (≥150 μm) or leukocyte-reduction filters (if indicated). Micropore filters may adsorb large numbers of platelets, thereby diminishing the effectiveness of the platelet transfusion.
4. Platelets are suspended in plasma, which may help to replenish coagulation factors other than factors V and VIII, which are labile, and factor VII, which has an especially brief half-life.
5. Platelets should not be refrigerated or placed in a cooler with ice before administration, because cold-exposed platelets are rapidly cleared from the circulation.

SPECIAL PROCESSING OF CELLULAR BLOOD COMPONENTS

Leukocytes collected with whole blood donations partition into both the platelet and the PRBC components; few intact leukocytes are present in FFP. Passenger leukocytes are responsible for most febrile, nonhemolytic transfusion reactions, human leukocyte antigen (HLA) alloimmunization, and transmission of cytomegalovirus (CMV). To prevent the complications from these leukocytes, blood components should be passed through leukocyte-reduction filters that effectively remove leukocytes (by a 2–3 log reduction) immediately after collection (prestorage leukoreduction) or at the bedside (pretransfusion). This technique is superior to washing or freezing-deglycerolizing, which was used in the past. Table 12.8 lists those patients who may benefit from leukocyte-reduced cellular components (i.e., PRBCs or platelets). It should be noted that anaphylaxis may very rarely occur when using white-cell reduction filters.[81]

CMV transmission can also be reduced by screening donors for CMV exposure (testing for antibody to CMV), although leukocyte reduction is the more widely used approach. Even though primary CMV infection is benign in children with intact immune systems, some pediatric populations are at risk for developing systemic disease and should be protected from blood-borne CMV transmission. Only patients who have not previously been infected with CMV (i.e., CMV-seronegative) are at risk. Children who are particularly vulnerable to systemic CMV infections are listed in E-Table 12.1.

Transfused lymphocytes may mediate a graft-versus-host process in some recipients with impaired cellular immunity. Because this process involves the bone marrow as well as the usual targets (i.e., skin and gastrointestinal tract), the fatality rate is substantial. Transfusion-associated graft-versus-host disease (TA-GVHD) can be prevented by exposing cellular blood components to gamma irradiation that disables the donor lymphocytes.[82] Children who are considered to be at risk for TA-GVHD and who should receive irradiated cellular components are listed in E-Table 12.2. This complication can also occur in children with intact immune

TABLE 12.8 Indications for Leukocyte-Reduced Cellular Blood Components

• To prevent further febrile, nonhemolytic transfusion reactions in a child with a history of such reactions
• To prevent human leukocyte antigen alloimmunization in a child who may require long-term platelet transfusion support (e.g., leukemia, lymphoma)
• To prevent human leukocyte antigen alloimmunization in a transplant recipient
• To prevent cytomegalovirus infection and disease in a susceptible child

E-TABLE 12.1	Children at Risk for Cytomegalovirus Disease[a]
CMV-seronegative pregnant women	
Transfusion of mother	
Intrauterine transfusion	
Exchange transfusion	
Neonatal transfusion (low birth weight)	
Children with HIV infection or AIDS

Autologous	
Allogeneic, if donor is also CMV seronegative	
Children undergoing solid organ transplantation, if donor is also CMV seronegative	

AIDS, acquired immunodeficiency syndrome; *CMV*, cytomegalovirus; *HIV*, human immunodeficiency virus.
[a]Applies to CMV-seronegative patients only.

E-TABLE 12.2	Children at Risk for Transfusion-Associated Graft-Versus-Host Disease
•	Children with T-cell immune defects (e.g., severe combined immunodeficiency syndrome, Wiskott-Aldrich syndrome, DiGeorge syndrome)
•	Children undergoing chemotherapy for leukemia, lymphoma, or neuroblastoma
•	Children undergoing hematopoietic stem cell transplantation
•	Children receiving fludarabine
•	Fetus: intrauterine transfusion
•	Neonate: exchange transfusion
•	Neonate: low birth weight
•	Children receiving platelets from HLA-matched donors
•	Children receiving red blood cells or platelets from blood relatives

HLA, human leukocyte antigen system.

systems in the unusual circumstance when the transfusion donor is homozygous for an HLA haplotype that is shared with the recipient. In this case, the recipient's immune system, although fully functional, cannot recognize the donor lymphocytes as foreign. The donor lymphocytes mount a GVHD attack on the recipient's tissues, recognizing the mismatched haplotype. This situation is more likely to occur when the donor is a blood relative of the recipient. It is for this reason that blood and HLA-matched platelets donated by family members are routinely irradiated.

Because irradiation damages the cell membrane, irradiated RBCs lose K^+ at a greater rate than usual. As a result, the shelf life of irradiated RBC is only 28 days (from a maximum permitted of 42 days). The problem of increased amounts of circulating K^+ can be obviated by irradiating units close to the time of issue or washing the unit if it was irradiated early in the storage period.

FRESH FROZEN PLASMA

FFP represents the fluid portion of whole blood that is separated and frozen within 8 hours of collection. After thawing at 37°C, which usually requires 30 minutes, it may be administered within 24 hours if stored at 1°C to 6°C. The volume of 1 unit varies from 180 to 300 mL and represents 7% to 10% of the coagulation factor activity in a 70-kg patient. It contains all of the clotting factors and regulatory proteins at approximately the native concentration, but after 6 hours at 1°C to 6°C, the concentrations of the labile factors V and VIII begin to diminish, as does that of the short-lived factor VII.[83] FFP does not provide functional platelets, nor does it contain leukocytes or RBCs. Thawed FFP may be used for transfusion up to 7 days after thawing; however, it must be labeled as thawed plasma to indicate that it has reduced levels of factors V, VII, VIII, and protein S.

FFP should be ABO compatible with recipient red cells because it contains the anti-A and anti-B isoagglutinins appropriate to the donor's ABO blood group. If the recipient's blood type is not known, plasma from a donor with blood type AB, which contains neither anti-A nor anti-B, may be administered. Because the citrate anticoagulant is present in the plasma, rapid administration of FFP is more likely to be associated with citrate toxicity than the transfusion of components with smaller volumes of plasma (e.g., PRBCs).

FFP is all too often administered without justification by evidence-based medicine.[84] One major surgical indication for FFP is to correct the coagulopathy associated with massive blood transfusion (see Table 12.7). Other indications include correction of a prolongation in the prothrombin time (PT) before surgery or in the setting of bleeding, the emergency reversal of warfarin, or the presence of a specific congenital or acquired coagulation protein deficiency for which a factor concentrate or a recombinant factor is not available (e.g., for factor X deficiency).[85] Administration of vitamin K should not be overlooked in children with hepatic insufficiency, who have been exclusively breastfed,[86–88] who have been treated with warfarin, broad-spectrum antibiotics (which often eliminate normal vitamin K–producing gastrointestinal flora), or total parenteral nutrition for inadequate oral caloric intake, or who have had a prolonged hospitalization. Correction of a mild increase in the PT (e.g., international normalized ratio [INR] <1.5) is rarely necessary. Fig. 12.1 shows the relationship between the level of coagulation factors and the in vitro clotting time–in this case, the PT. Relatively modest levels of coagulation factors can support normal hemostasis, even though the PT is prolonged. When the PT is markedly increased (see Fig. 12.1, point A), the transfusion of 1 unit of FFP, which increases the coagulation factor levels by 7% to 10% in an adult, dramatically decreases the PT. When the PT is only mildly prolonged, as at point C, where factor levels are already adequate for hemostasis, infusion of 1 unit of FFP (in an adult) decreases the PT to a much smaller

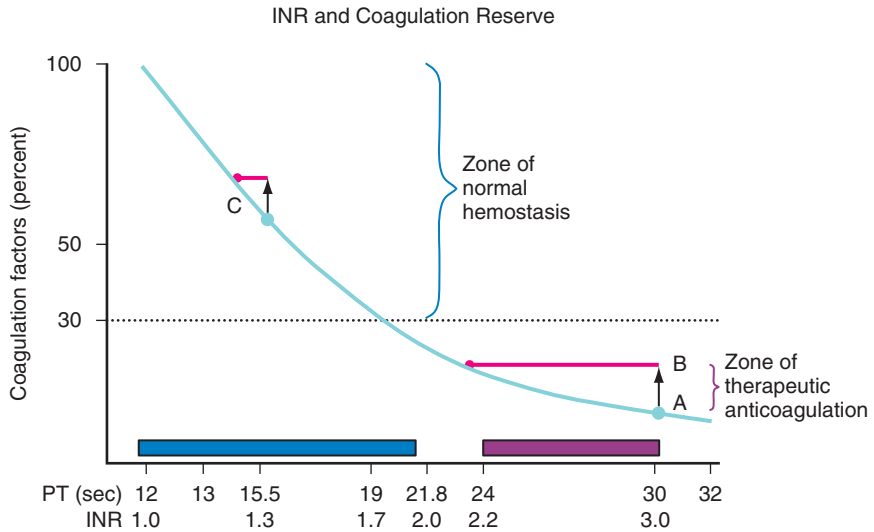

FIGURE 12.1 Nonlinear relationship between levels of coagulation factor and clotting test results. Decreases in clotting factor levels to about 30% of normal prolong the clotting test times but still support normal hemostasis. Treating an adult or child at point **A** with fresh frozen plasma to raise the level of coagulation factors to point **B** has a marked effect on the prothrombin time and the international normalized ratio (INR). The same amount of fresh frozen plasma administered to an adult or child at point **C**, however, has only a minor effect on the prothrombin time (PT). (Modified from Dzik WH, Stowell CP. Transfusion and coagulation issues in trauma. In: Sheridan RL, ed. *The Trauma Handbook of Massachusetts General Hospital*. Philadelphia: Lippincott Williams & Wilkins; 2004:139.)

extent. This small decrease in the PT does not clinically improve hemostasis.

CRYOPRECIPITATE

Cryoprecipitate is prepared by thawing FFP at 4°C to 10°C and removing most of the plasma, leaving behind precipitated protein that is then resuspended in a small volume of residual plasma (15–25 mL) and refrozen. This component contains 20% to 50% of the factor VIII from the original unit of plasma. It also contains von Willebrand factor (vWF), fibrinogen (approximately 250 mg), and factor XIII. Cryoprecipitate is indicated for the treatment of factor XIII deficiency, dysfibrinogenemia, and hypofibrinogenemia (see Table 12.7).[89–98] It has not been used for the treatment of von Willebrand disease or hemophilia A since the advent of clotting factor concentrates and recombinant factor VIII. Plasma concentrates of factor XIII and fibrinogen have been licensed in the United States for use in patients with these congenital deficiencies.

PATHOGEN INACTIVATION/REDUCTION

Techniques to inactivate or reduce the level of infectious agents have been in place for plasma derivatives such as intravenous (IV) immunoglobulin and plasma-derived clotting factors for over 20 years. More recently, pathogen inactivation technologies have been applied to RBCs, FFP, and platelets with the goal of eliminating a wide range of infectious organisms.[99] There are several potential advantages of these technologies over screening by donor history and testing for specific organisms, particularly for those pathogens that frequently cause asymptomatic infection, have a long serologic "window" period before screening tests become positive, are newly emerging, or are completely new and unrecognized.[100]

There are two general approaches to pathogen inactivation: methods that disrupt lipid membranes (solvent detergent treatment[101] and methylene blue plus visible light exposure[102]) and methods that target RNA and DNA (or nucleic acid techniques) [amotosalen[103] or riboflavin[104] plus ultraviolet (UV) light exposure, or UV light exposure alone].[105] The nucleic acid–targeted techniques also inactivate leukocytes and eliminate the risk of transfusion-transmitted graft versus host disease, which may make gamma irradiation of cellular components for susceptible patients unnecessary.[106]

However, these techniques do have limitations. Even though inactivation techniques can achieve a 5 or 6 log reduction in infectious particles, they may not be completely effective in components with high pathogen loads.[107] In addition, the lipid-targeted techniques do not inactivate nonlipid enveloped viruses such as hepatitis A virus, hepatitis E virus, and parvovirus B19, and none of the techniques inactivates prions. These procedures also damage or deplete plasma proteins[108,109] and platelets, which may reduce their effectiveness.[110] Although there is no evidence to date of major adverse effects,[111] there is the potential for toxicity such as the formation of plasma or membrane protein neoantigens,[101] or from long-term effects of exposure to amotosalen. Finally, these treatments are relatively complex and expensive.

In the United States, several pathogen-inactivated component systems have been licensed by the Food and Drug Administration (FDA): plasma[112] and platelets[113] treated with amatosalen and UV-A light; plasma treated with riboflavin and UV light[104]; and solvent/detergent-treated plasma.[101] There are currently no licensed systems for pathogen inactivation of RBCs, although several are under investigation.

PLASMA-DERIVED FACTOR CONCENTRATES AND RECOMBINANT FACTORS

The most commonly administered factor concentrate is factor VIII, used in the treatment of hemophilia A. Children with hemophilia can have many problems related to their disease, including splenomegaly, abnormal liver function, and joint disease related to hemarthrosis. In the past, the use of pooled plasma products was associated with very high rates of transmission of viral hepatitis (especially HCV) and HIV.[114–116] The use of more rigorous viral removal and inactivation processes and the introduction of recombinant factor VIII and IX products[117–121] have greatly reduced these problems.[89–96,122] Initial concerns that there may be an increased incidence of inhibitors in children who receive recombinant therapy compared with plasma-derived factor therapy have been confirmed by the SIPPET trial (Survey of Inhibitors in Plasma-Product Exposed Toddlers),[123] which showed that toddlers treated with plasma-derived factor VIII containing VWF had a nearly twofold lower incidence of inhibitors than those treated with recombinant factor VIII. However, the study failed to show a significant difference with regard to high-titer inhibitors and did not include any of the newer concentrates that have appeared since the trial started in 2010. Therefore, final conclusions regarding the use of recombinant factors remain unclear. Mild hemophilia A usually responds well to desmopressin (1-deamino-8-D-arginine vasopressin [DDAVP]) therapy.[124,125]

New extended half-life factor concentrates are now available for both hemophilia A and B. For factor VIII and factor IX concentrates, these include fusion to either albumin or the monomeric Fc fragment of immunoglobin G1 (IgG1). Conjugation with polyethylene glycol (glycosylation) is another modification technique.[126] The optimal use of these concentrates is under current investigation.

Von Willebrand disease is routinely treated with DDAVP or plasma-derived factor VIII concentrates that are also rich in vWF, such as Humate-P, Alphanate, Koate DVI, and Wilate,[127] with dosing in ristocetin cofactor units per kilogram, not factor VIII units. A newly available alternative is a recombinant VWF,[128] although this product is so far only approved for those 18 years or older. In children who have von Willebrand disease and are resistant to DDAVP or for whom DDAVP is contraindicated (e.g., central nervous system [CNS] bleeding, allergic reaction, brain tumor, recent CNS surgery), it is reasonable to withhold treatment with blood-derived products until surgery has begun unless surgery is performed in an area where even minor bleeding can produce serious complications. These children often do not demonstrate pathologic bleeding. Adjunctive therapies that can further limit hemorrhage include use of the antifibrinolytic agent ε-aminocaproic acid (Amicar) and tranexamic acid (Cyklokapron), a competitive inhibitor of plasminogen, both being administered orally or intravenously, and topical hemostatic agents, including topical collagen and fibrin glues.

Children with hemophilia B (i.e., Christmas disease or factor IX deficiency) are managed with recombinant human factor IX and highly purified factor IX (preparations with various amounts of factors VII, X, and prothrombin) that are treated to inactivate or remove viruses.[91,92,94,129–142] Careful planning of any surgical procedure for these children includes close communication with the child's hematologist to ensure optimal therapy while reducing unnecessary transfusions (see Chapter 10).

PROTHROMBIN COMPLEX CONCENTRATES

Prothrombin complex concentrates (PCC) have been used to rapidly reverse vitamin K–based anticoagulants in the setting of

significant hemorrhage, especially in the CNS. They consist of either three-factor (II, *low VII*, IX, and X, proteins C and S) or four-factor (II, *high VII*, IX, and X, proteins C and S) human plasma-derived products. These have been primarily used in adults; pediatric experience is limited.[143] The advantages appear to be a more rapid reversal than the administration of FFP or vitamin K (without, however, any difference in clinical outcomes) and for some patients, reduced volume of administration.[144–147] One systematic review concluded that four-factor PCC more reliably corrected the INR than three-factor PCC, whereas another suggested that protocols based on body weight offer an advantage over individual physician decisions.[148,149] However, in the setting of intracranial bleeding in patients taking warfarin, four-factor PCC has not proven superior to FFP. The efficacy of PCCs in the operating room setting to treat perioperative coagulopathy is unclear.[150]

DESMOPRESSIN

DDAVP, a synthetic analog of vasopressin, can increase the levels of factor VIII:C (i.e., coagulant activity) and factor VIII:vWF in children with mild hemophilia A or von Willebrand disease.[125,151–156] An IV dose of 0.3 µg/kg (maximum 20 µg; a subcutaneous preparation is available in Europe) increases the levels of both factors twofold to threefold within 30 to 60 minutes, with a half-life of 3 to 6 hours.[152] Intranasal DDAVP is also effective, but onset is less rapid and, in younger children for whom a sustained inhalation may be more difficult, part of the dose may find its way into the gastrointestinal tract, bypassing nasal blood vessels. Between 80% and 90% of children with von Willebrand disease are responders,[157,158] and affected children should be tested for their responsiveness to IV DDAVP. This treatment is best suited to treat bleeding from surgical procedures, which ceases within 2 to 3 days. When bleeding continues beyond this period, as is the case with some orthopedic procedures, daily IV Humate P (or Alphanate or Koate DVI) can obviate possible tachyphylaxis with DDAVP. Products rich in the vWF allow better control over peak concentrations of factor VIII. When in excess of 200%, factor VIII predisposes to postoperative deep venous thrombosis and pulmonary embolism.

DDAVP has been used to treat the coagulopathy associated with platelet dysfunction, uremia, and cirrhosis.[159,160] It may reduce elective surgical bleeding when the potential for blood loss is substantial, such as in cardiac surgery and spinal fusion.[125,161–166] Although initial reports apparently demonstrated a benefit in patients who did not have a preexisting coagulopathy, other controlled studies failed to show an effect despite increases in factor VIII:C and vWF, and its use for these indications has largely been abandoned.[167–169] Because of the potential for hyponatremia from water retention, use of DDAVP is avoided in children younger than 2 years, in children with CNS lesions, including a brain tumor, history of CNS irradiation, or recent neurosurgery or CNS trauma.[170]

ALBUMIN, DEXTRANS, STARCHES, AND GELATINS

Solutions of several high–molecular-weight molecules (i.e., colloids) have been used for volume replacement, although systematic reviews have determined they offer no advantage over crystalloid solutions. These colloids include albumin, dextrans, starches, and gelatins.

Albumin has the longest track record and the fewest adverse effects.[171,172] In the past, dextrans (i.e., high– and low–molecular-weight glucose polymers) were administered for volume expansion and hemodilution in children,[173,174] but currently their primary use is for antithrombosis, although their value for even this indication is questionable.[175]

Starches are branched polysaccharide polymers available in high–, medium–, and low–molecular-weight ranges (480,000-70,000 Da). Although they expand blood volume, they also alter hemostasis by diluting clotting factors and impairing platelet function and the coagulation cascade.[176,177] In addition, starches accumulate in the reticuloendothelial system and carry the potential for unknown long-term adverse effects.[178] Minor coagulation changes have been reported when the dose exceeded 20 mL/kg.[179–181] A 6% hydroxyethyl starch (HES 130/0.4) yielded clinical and physiologic profiles similar to those for 5% albumin in volumes up to 16 mL/kg in noncardiac surgery and in volumes up to 50 mL/kg in cardiac surgery, although at smaller cost.[182,183] A meta-analysis of randomized controlled trials of hydroxyethyl starch concluded that mortality, creatinine, and blood loss did not increase, although platelet counts and the duration of ICU stay significantly decreased. The authors recommend against their use in pediatric patients.[184] Several major reviews regarding the use of starches and gels in adult patients who are critically ill have raised substantive concerns regarding adverse effects on coagulation[185,186] and renal function,[187,188] and they found inadequate overall safety data, even for the third-generation products.[26,189] If these concerns have been raised in adult populations, we should hold even greater concern about their use in children.

Gelatins are polypeptides derived from bovine collagen that seem to have a minimal effect on coagulation and provide reasonable plasma volume expansion. However, life-threatening anaphylactic or anaphylactoid reactions have been reported, and their use in children remains somewhat limited.[171,190–194] A systematic review identified a lack of safety and efficacy data in neonates and children.[195]

RED BLOOD CELL SUBSTITUTES

Blood substitutes offer the promise of agents with universal compatibility, minimal infectious risks, and prolonged shelf life (years rather than days) to carry oxygen to vital organs.[196] Early efforts to develop these products involved human, bovine, and genetically engineered hemoglobin polymer solutions, perfluorocarbons, and lipid-encapsulated hemoglobin. Most failed in clinical trials because of severe complications such as renal failure, stroke, and vasoconstriction.[197,198] The last of the hemoglobin-based oxygen carriers under investigation, Hemospan (Sangart, Inc., San Diego, CA), failed in clinical trials and is no longer being investigated.[199–201] Liposome-encapsulated hemoglobin[202] is currently under investigation as a means to carry oxygen to compromised tissues such as cerebral infarction.[203] At this juncture, none of these attempts at investigation of blood substitutes have reached the pediatric population.

Massive Blood Transfusion

Massive blood transfusion may be defined as replacement of a patient's entire blood volume one or more times or as more than 30 mL/kg PRBC transfused in less than 4 hours with ongoing uncontrolled bleeding (see http://www.surgery.med.umich.edu/pediatric/trauma/protocols/MassiveTransfusionProtocol4113.pdf [Last downloaded 8/26/2016]). In a retrospective study of 1113 combat trauma injuries in children younger than 18 years, those children who received 40 mL/kg or more in the first 24 hours had a greater risk for mortality compared with those who received

TABLE 12.9 Approximate Time for Expedited Release of Red Blood Cells

ABO Group	Crossmatch	Preparation in Blood Bank (minutes)	Risk of Incompatibility
O	None	5	RBC alloantibody
ABO specific	None	15	RBC alloantibody

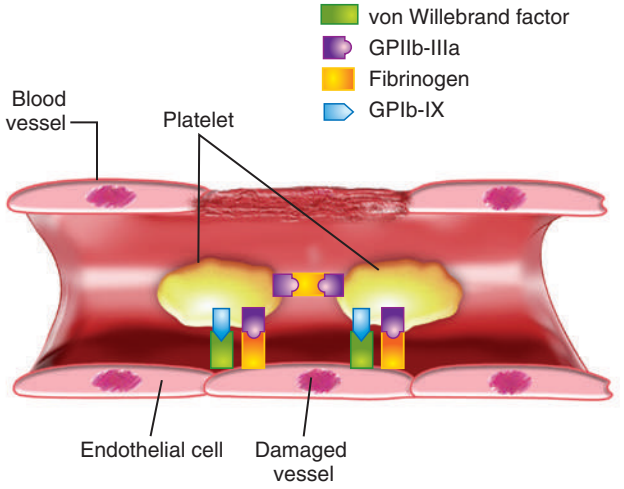

FIGURE 12.2 A blood clot forms when platelets adhere to one another through the GPIIb-IIIa complex (*purple*), which serves as a receptor for the adhesive protein fibrinogen (*orange*). Platelet interaction with an injured vessel wall requires synergy between the GPIb-IX (*blue*) and GPIIb-IIIa complexes and the adhesive proteins of von Willebrand factor (*green*) and fibrinogen, respectively. In high-velocity gradients, the efficacy of GPIb-IX interaction with the von Willebrand factor is significantly impaired.

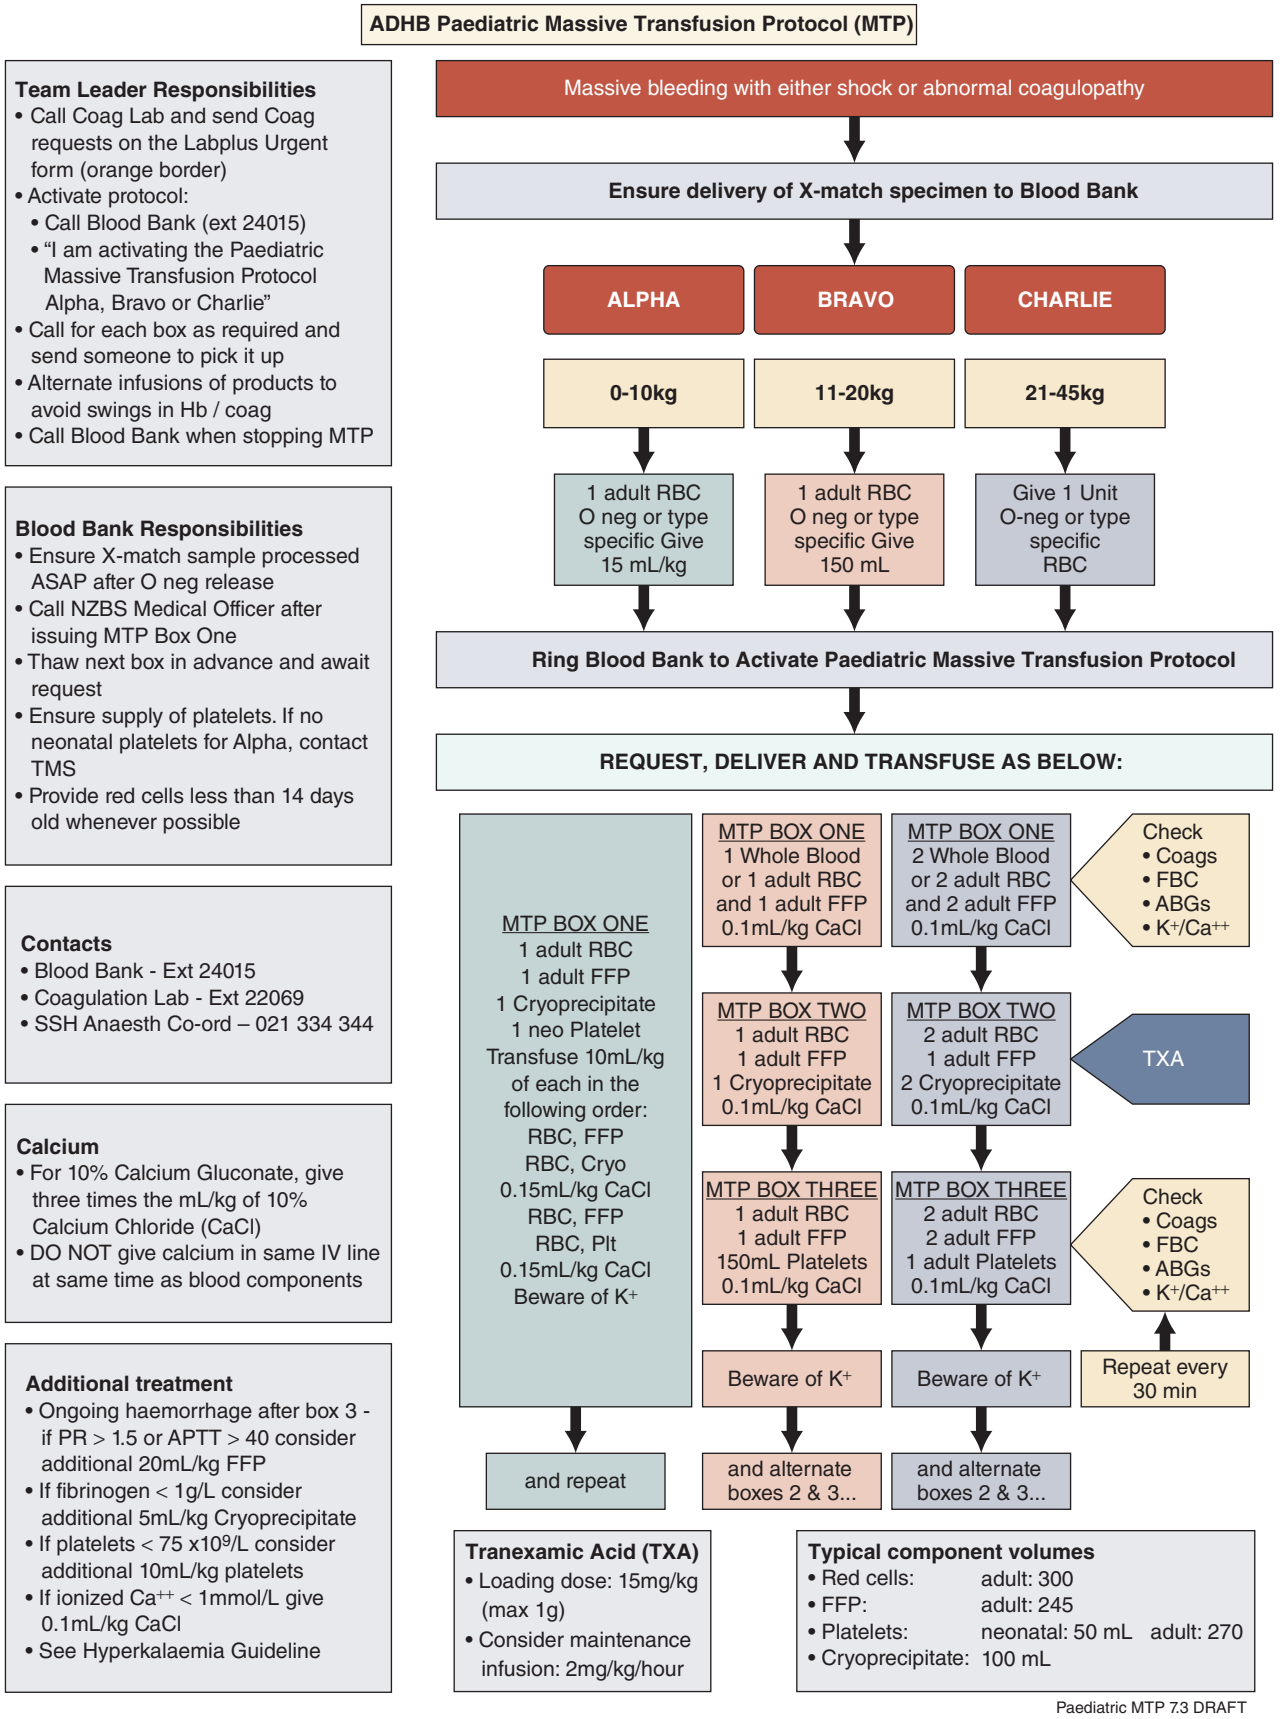
less than 40 mL/kg.[204] There are few other published pediatric data.[205] In children, the anesthesiologist must think in terms of percent of blood or blood volumes lost rather than units of blood transfused. The composition of each blood component must be considered to anticipate problems and determine at what stage of a massive transfusion these problems may occur (see Table 12.3). Transfusion of large quantities of blood components may seriously affect coagulation, potassium and calcium concentrations, acid-base balance, body temperature, oxygen-hemoglobin dissociation, and hematocrit (i.e., oxygen-carrying capacity).

Most blood banks have a system for the expedited or "emergency" release of blood products, when there is inadequate time to perform complete serologic testing, including the crossmatch. Group O Rh-negative blood can be transfused into any child without the need for a crossmatch; group O Rh-positive blood may be transfused into male patients. After the blood bank has a sample of the child's blood, then switch to group-specific blood and then to blood that has completed standard compatibility testing. Table 12.9 illustrates the process and risks associated with expedited release of RBCs.[206] This switch usually occurs "behind the scenes" in the blood bank but underscores the critical importance of getting a properly labeled patient specimen as quickly as possible and before the patient's blood is substantially diluted by banked group O RBCs and accurate testing is compromised. Many institutions also have developed massive transfusion protocols that incorporate the mechanism in place for abbreviated serologic testing as well as the expedited provision of specific blood components (E-Fig. 12.1).



With massive blood loss, infusing crystalloid solutions alone or in large quantities may worsen the underlying coagulopathy, such as from trauma-induced bleeding, and may result in increased ICU stay.[207] Protocols using fixed ratios of PRBCs, FFP, and platelets (1 : 1 : 1) have been used in combat situations but have not been systematically examined or proven to offer advantage compared with standard component approaches in noncombat associated adults or children.[208–210] Additionally there are likely differences between controlled massive bleeding compared with massive rapid bleeding which add to the difficulty of systematic study. The approach to trauma patients has been termed "damage control," which means correcting hypothermia, maintaining adequate perfusion, and early administration of clotting factors and platelets to correct coagulopathy; systematic pediatric trauma studies are lacking.[211]

COAGULOPATHY

The coagulation system involves platelets, coagulation proteins, and localized tissue factor, which initiate all steps of hemostasis. Fig. 12.2 shows that an initial step is platelet adhesion to a wound or site of vessel wall injury, with adhesion being mediated by the vWF through its receptor on the platelet, the glycoprotein Ib–glycoprotein IX complex (GPIb-IX), and fibrinogen through the fibrinogen receptor on the platelet, the glycoprotein IIb–glycoprotein IIIa complex (GPIIb-IIIA). In flowing blood, initial platelet attachment is facilitated by vWF, whereas platelet spreading and more secure (shear stress-resistant) platelet-platelet aggregation is driven by fibrinogen and by the GPIIa-GPIIIa complex. However, there is also evidence that platelets attach even to intact endothelium, which has an activated phenotype, as after inflammatory cytokine exposure or sepsis. Platelets attach to the endothelium through high-molecular-weight von Willebrand multimers. Fibrinogen is attached to endothelium through upregulated integrins and selectins.

Initial platelet hemostasis (i.e., platelet plug formation) is accompanied by the local generation of fibrin, which is the end product of at least three surface-active enzyme complexes. Clotting is initiated by the tissue factor/factor VIIa surface-active enzyme complex and amplified by the factor VIIIa/IXa/X and factor II/Va/Xa complexes. A mural platelet thrombus, which includes platelets and fibrin, then forms a scaffold on which healing of the vessel wall can take place. The fibrin component of a platelet thrombus forms beneath, not above aggregating platelets,[212] as was previously thought. The scaffold is removed when it is no longer needed by thrombolysis and the effects of macrophages.

The surface-active enzyme complexes (Fig. 12.3) are active on the phospholipid surfaces provided by platelets, leukocytes, and endothelial cells but not in the bulk of the blood. Initially it was believed that formation of the tissue factor/factor VIIa complex, as shown, was critical for the action of recombinant FVIIa (rFVIIa) and for activation of factors X and IX. However, the high doses of rFVIIa necessary to achieve clinical hemostasis are far in excess

E-FIGURE. 12.1 An example of a pediatric massive paediatric transfusion protocol: Starship Children's Hospital, Aukland, New Zealand, with permission.

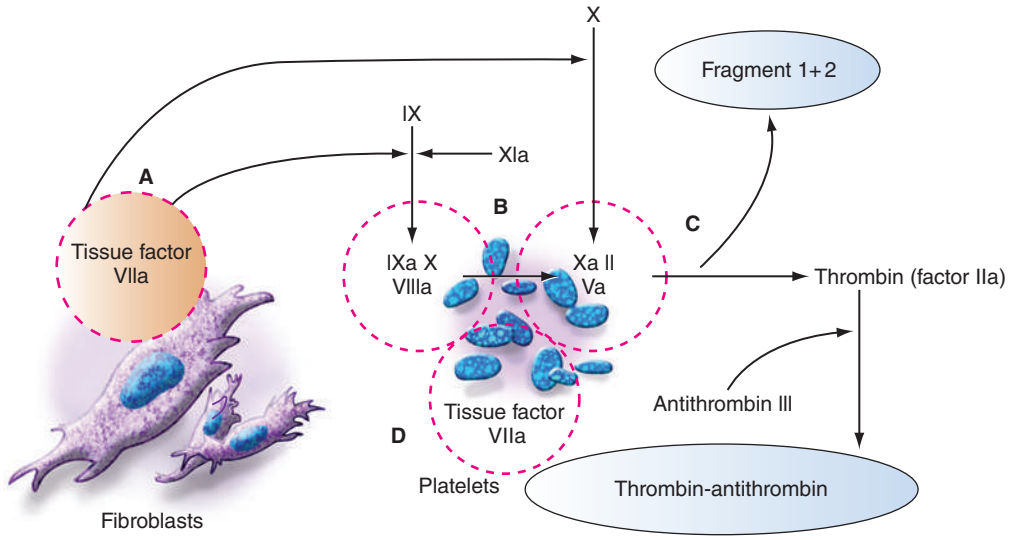


FIGURE 12.3 The key clotting factor enzyme complexes in coagulation. Tissue factor **(A)** (shown on the surface of a fibroblast) initiates coagulation, leading to the activation of clotting factors IX and X (shown on the surface of a platelet) and the processing of prothrombin (factor II) to form thrombin (factor IIa). Factor XIa has a contributory role in factor IX activation. Key to this cascade are three surface-active enzyme complexes: **(A)** the complex of tissue factor and factor VIIa; **(B)** the complex of factor IXa, factor VIIIa, and factor X; and **(C)** the complex of factor Xa, factor Va, and factor II (where the letter "a" denotes the activated form of a factor). Prothrombin fragment 1 + 2 and thrombin-antithrombin complexes are markers of the generation of thrombin. Fragment 1 + 2 is an inactive fragment formed during the processing of prothrombin; thrombin-antithrombin complex is formed when antithrombin III binds to thrombin, resulting in the inactivation of thrombin. In addition, **(D)** high doses of rFVIIa are able to generate thrombin in the presence of platelet-associated recombinant FVIIa and recombinant FVIIa can contribute to the assembly of the IXa-X-VIIIa complex via the activation of factor IX. Not shown in this diagram is the important influence of blood flow; for example, arteriolar and arterial velocity gradients, along with the presence of red cells, promote collisions between platelets and, consequently, platelet aggregation. (Modified with permission from Grabowski EF. The hemolytic-uremic syndrome toxin, thrombin, and thrombosis. *N Engl J Med.* 2002;346:58–64.)

of those required to saturate available tissue factor, suggesting that rFVIIa must also operate in large part independent of tissue factor,[213] especially in view of the observation that rFVIIa can bind to platelets directly via platelet anionic phospholipid[214] or via platelet GPIb.[213] In this regard, the conventional coagulation cascade shown in Fig. 12.4 is oversimplified, although it is a convenient approach to understanding the PT and partial thromboplastin time (PTT). All of the steps must be considered in the milieu of flowing blood, such that the high-velocity gradients of arterioles (i.e., mucous membranes of the uterus, gastrointestinal tract, upper respiratory tract, oral cavity, and gums) and arteries favor thrombi with a greater proportion of platelets (i.e., white thrombi), and low-velocity gradient states, such as those found in stasis or blood accumulation within a body cavity, favor a greater proportion of red cells (i.e., red thrombi). This explains why a patient with von Willebrand disease, characterized by a defect in the protein that allows blood platelets to adhere to a wound, tends to bleed from mucous membranes, sites of high-velocity (arteriolar) gradients, whereas hemophiliacs tend to bleed into joint spaces and muscle planes, sites of low- or near-zero–velocity gradients.

The coagulopathy associated with massive blood transfusions is usually attributable to the dilution of clotting factors or platelets, or both. The point at which the deficiency in clotting factors is sufficient to produce a coagulopathy depends on the volume of blood lost and the type of blood component transfused (i.e., PRBCs or whole blood). Dilutional thrombocytopenia sufficient to cause clinical bleeding depends on the starting platelet count and the volume of blood replaced (Fig. 12.5). In some cases, the cause of bleeding is a consumptive coagulopathy such as fibrinolysis or disseminated intravascular coagulation (DIC).[65,215–235] In other scenarios, bleeding is caused by hypothermia, severe metabolic acidosis, poor tissue perfusion, and the release of tissue factors. Body temperature should be maintained by using efficient blood-warming devices, acidosis should be treated, and normovolemia and cardiac output should be restored to prevent a coagulopathy from developing.[222,236–239]

DILUTIONAL THROMBOCYTOPENIA

In an effort to formulate a plan to manage children who require massive blood transfusions, we must rely on our clinical experience and data extrapolated from adults and limited pediatric studies. A study of adult trauma patients during the Vietnam War reported that the onset of clinical bleeding occurred after about 15 units of whole blood or 1.5 blood volumes had been transfused. The incidence of coagulopathy was unrelated to an abnormal PT or PTT but correlated closely with a platelet count of less than 65,000/mm^3.[65,240] Studies of massive blood loss with *whole blood* replacement also support the conclusion that the coagulopathy at these levels of blood loss results from thrombocytopenia rather than a clotting factor deficiency.[65,222–231] Fig. 12.6 compares the calculated reduction in platelet count with the observed decline in platelet count in adults and children; when normalized for blood volumes shed, the observed changes were nearly identical.

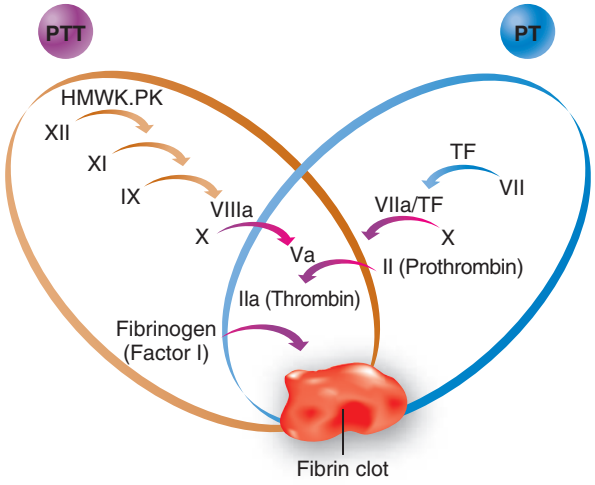

FIGURE 12.4 The conventional activated partial thromboplastin time (aPTT) is considered to be a measure of the intactness of the intrinsic coagulation system, which includes clotting factors XII, XI, IX, VIII, V, X, II, and I (fibrinogen). The prothrombin time (PT) is a measure of the intactness of the extrinsic coagulation system and encompasses tissue factor–bearing membrane surfaces and microparticles and factors VII, V, X, II, and I. In the PTT test, the blood clots without the need for an exogenous agent and comprises an *intrinsic* or complete clotting system. In practice, an agent such as diatomaceous earth is added to speed the reaction in the laboratory, and the term *activated* is added to the designation (aPTT). In the PT test, the blood clots by virtue of an *extrinsic* activator (i.e., tissue factor). This view in the diagram obscures the central role of tissue factor in clot initiation. Tissue factor circulates in an inactive form in the blood and is no longer considered only an extrinsic factor to the blood itself.

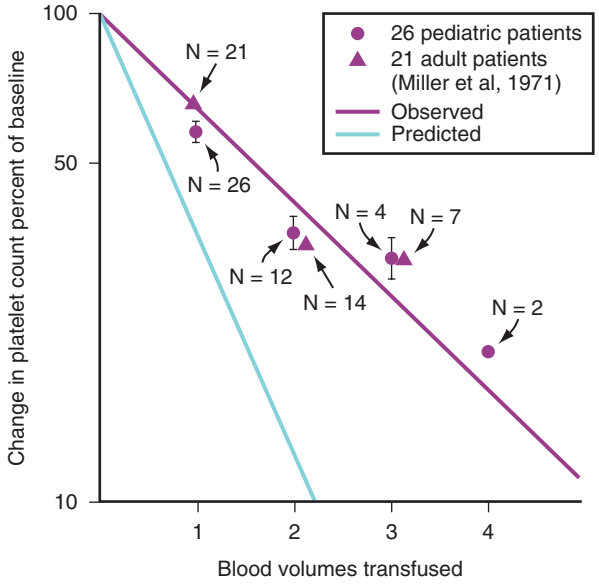

FIGURE 12.6 Percent of change in platelet count versus blood volumes transfused in young healthy adults and children.[65,66] The adult estimates assumed that these were ideal 70-kg men with a blood volume of 70 mL/kg such that 10 units of whole blood was estimated to be equivalent to 1 blood volume. The *magenta line* represents observed values, whereas the *blue line* represents calculated values. This difference suggests increased bone marrow production and/or splenic recruitment of platelets during massive transfusion. (From Miller RD, Robbins TO, Tong MJ, Barton SL. Coagulation defects associated with massive blood transfusions. *Ann Surg.* 1971;174:794–801; Coté CJ, Liu LM, Szyfelbein SK, et al. Changes in serial platelet counts following massive blood transfusions in pediatric patients. *Anesthesiology* 1985;62:197–201.)

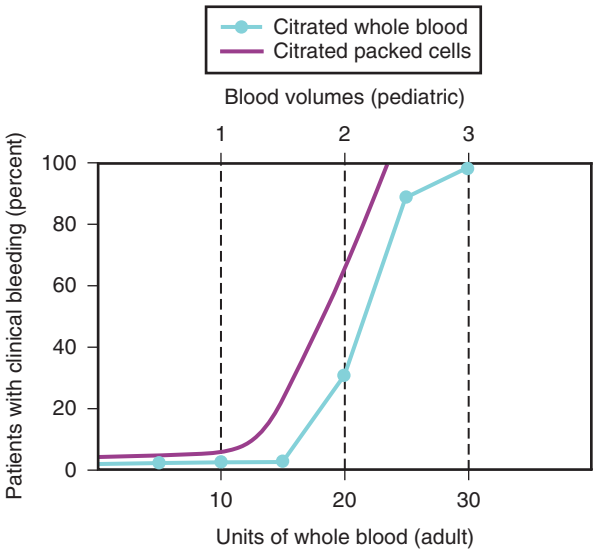

FIGURE 12.5 A study that considered the use of citrated whole blood (*blue line*) in adults found that bleeding in most cases resulted from dilutional thrombocytopenia. The *magenta line* represents estimated points of dilutional clotting factor deficiency if solely citrated packed cells are transfused. (Modified from Miller RD. Transfusion therapy and associated problems. *ASA Refresher Courses in Anesthesiology* 1973;1:107.)

The observed and calculated decrements differ because platelets are mobilized from the bone marrow, spleen, lungs, and lymphatic tissues. The platelet count usually does not decrease to concentrations that may cause bleeding in children until 2.0 to 2.5 blood volumes have been shed[66] or until 20 to 25 units of whole blood are transfused in adults.[66,229,241] Clinical bleeding does not usually occur in children whose platelet counts exceed 50,000/mm^3, despite blood losses as great as 5.0 blood volumes (Fig. 12.7A).[66] Consequently, children should be monitored for thrombocytopenia and possible transfusion of platelets or clotting factor deficiency (see further) after the loss of the first 1.0 to 1.5 blood volumes. After the platelet count has decreased to 50,000/mm^3, it is likely that approximately one platelet dose (i.e., 6 units for an adult or 10-15 mL/kg for a child) will be required for each blood volume replaced. If a coagulopathy develops earlier than expected (i.e., before a 1.0-blood volume loss), a search should be initiated for other causes of bleeding, such as increased arterial or venous pressure in the surgical field or DIC.

The starting platelet count is important for estimating how much blood loss can be tolerated before critical thrombocytopenia occurs. For example, with a starting platelet count of 600,000/mm^3, dilutional thrombocytopenia is unlikely to occur until 4.0 or more blood volumes have been shed, whereas with a starting count of 100,000/mm^3, dilutional thrombocytopenia should be anticipated after 1.0 blood volume has been lost (see Fig. 12.7B). Prophylactic transfusion of platelets typically is not indicated without documented evidence of dilutional thrombocytopenia, visible microvascular bleeding, and ongoing blood loss, although

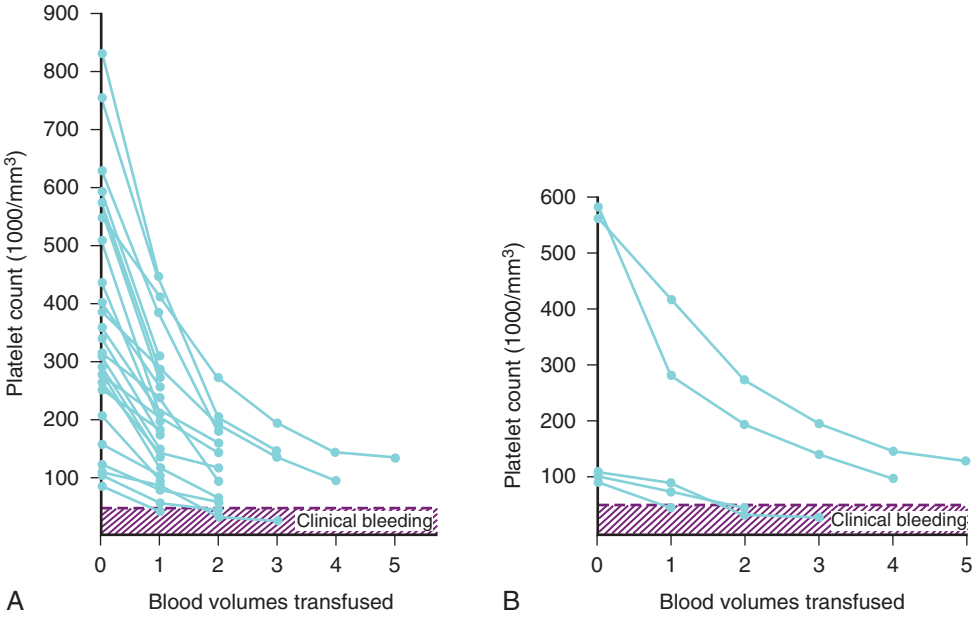

FIGURE 12.7 **A**, Serial changes in platelet counts are plotted for 26 pediatric patients whose blood loss was 1 to 5 blood volumes. Most of the children suffered from severe thermal injuries, and many had relatively large platelet counts at baseline. Clinically evident signs of coagulopathy appeared when the platelet count decreased to less than 50,000/mm^3. **B**, Platelet counts of five children abstracted from **A**. The baseline platelet count is invaluable in estimating potential platelet needs in relation to blood volumes transfused. A low initial count suggests the need for early exogenous platelet transfusion, whereas a high initial platelet count indicates that exogenous platelets may not be required until several blood volumes or more have been lost. The three children who developed a coagulopathy began surgery with a relatively low platelet count, whereas the two children with a very high platelet count did not require platelet transfusion despite the loss of 4 and 5 blood volumes. (It should be noted that these children received sufficient FFP so as to maintain the PT and PTT within a normal range.) (Reproduced with permission from Coté CJ, Liu LMP, Szyfelbein SK, et al. Changes in serial platelet counts following massive blood transfusions in pediatric patients. *Anesthesiology* 1985;62:197–201.)

it should be anticipated based on the starting platelet count and the volume of blood lost.[66,72,218,222,242]

Although the primary platelet defect in massive transfusion is thrombocytopenia, some data suggest that platelets may not function normally (i.e., thrombocytopathy) after massive trauma or in the presence of hypothermia.[238,243,244] This has not been our experience in the children we studied whose temperature remained within the normal range.[66,223] The only simple test to assess platelet function is the bleeding time. However, this test is also sensitive to thrombocytopenia and its predictive value is of equivocal utility.[218,243,245] The PFA-100 test shows less potential as a rapid screening tool than it once did, because the device uses citrated blood warmed to 37°C and is relatively insensitive to milder defects in platelet-vessel wall interaction, such as that in mild von Willebrand disease. There remains a critical need for a point-of-care device or simple test to assess platelet function, as noted previously. Currently, the platelet count is our best indication for the need for platelet transfusions in situations involving rapid blood loss.[246] Other devices such as thromboelastography to measure whole blood clotting have been used to guide transfusion therapy, but their efficacy in improving outcomes has not been established.[247]

In several in vitro and animal model systems, recombinant factor VII (rFVIIa) activates factors IX and X on the surface of activated platelets, probably through the binding of rFVIIa to the platelet membrane (from which rFVIIa can also be taken up into storage sites within the platelet) and subsequent recruitment of circulating tissue factor. Although this has significantly improved hemostasis in hemophiliacs with inhibitors to factor VIII, there is limited evidence that rFVIIa reduces mortality for off-label use, as in cardiovascular surgery, trauma, and intracerebral hemorrhage. Dosing in children appears to be greater than in adults, but this has not been systematically examined and is anecdotal.[248] This factor increases the risk of thromboembolism, hence its use should also consider the possibility of this sequela.[249]

Basic clotting studies (e.g., PT, PTT, fibrinogen, platelet count) should be performed before elective surgery when major blood loss can be anticipated to determine the cause of underlying coagulopathies and provide adequate quantities of blood components.

FACTOR DEFICIENCY

Laboratory results for developing deficiencies in clotting factors are integral when managing component therapy in massive transfusions. The PT (for the extrinsic system) measures the adequacy of factors VII, X, and V; prothrombin; and fibrinogen,[65] whereas the PTT (for the intrinsic system) measures the adequacy of factors XII, XI, IX, VIII, X, and V; prothrombin; and fibrinogen (see Fig. 12.4). Banked whole blood contains normal plasma concentrations of all of the clotting factors and regulatory proteins, with the exception of factors V and VIII (20%–50% of normal at the time of outdate), as well as factor VII. For a coagulopathy to develop because of a clotting factor deficiency, factor VIII must be less than 30% of the normal concentration and factor V less than 20% of normal.[223] For these to occur, at least 3.0 blood volumes must be exchanged with *whole blood*. In this scenario,

the first coagulation test that is abnormal is the PTT because factor VIII is diluted to less than 30%.[219]

If blood loss is replaced with PRBCs, as is the current practice with modern blood banking techniques, the amount of plasma that is transfused is minimal because ~70% was sequestered in the FFP fraction when it was separated. Massive replacement of blood loss with PRBCs and no other blood products quickly dilutes all of the clotting factors, including fibrinogen (see Fig. 12.4).[3,218–222,228,230,231,250–252] Data have confirmed that the PT and PTT are prolonged in children with multiple clotting factor deficiencies (e.g., during massive transfusion) at concentrations of clotting factors that are greater than in children with single clotting factor deficiencies (e.g., congenital coagulopathies).[230,231] This was also documented in adult patients who were transfused exclusively with PRBCs and crystalloid; the dilution of multiple clotting factors correlated with the volume of blood and crystalloid transfused.[197] Replacing 1.0 to 1.5 blood volumes with PRBCs and crystalloid exclusively dilutes clotting factors to approximately 30% of normal. Because moderately prolonged PT and PTT values exist without overt signs of clinical bleeding,[230] administration of FFP should be initiated with the onset of a clinical coagulopathy. However, the anesthesiologist should anticipate that PRBCs and crystalloid solutions or albumin will dilute the concentration of clotting factors so that FFP is begun after ~1.0 blood volume of blood loss has been replaced to avoid falling behind in the clotting indexes. Documented deficiency of fibrinogen (<80 mg/dL) may also be corrected by transfusing FFP, but marked deficiency, particularly in the presence of a consumptive coagulopathy (e.g., DIC, fibrinolysis), may require the addition of cryoprecipitate (0.2 to 0.4 unit/kg).[3,252–255]

Our experience with 26 children (12 ± 4 years old, weight of 41.9 ± 15.8 kg) who underwent 22 Harrington rod procedures, three tumor excisions, and one Whipple procedure received no FFP or whole blood despite losing between 0.5 and 1.0 blood volume. They exhibited no clinical signs of coagulopathy. Slight prolongations of the PT or PTT occurred when the blood loss was equal to 1.0 blood volume or less (Table 12.10). Two children who lost 1.5 to 2.0 blood volumes exhibited prolonged PT and PTT values. The only child who developed signs of a clinical coagulopathy lost 2.0 blood volumes.[256,257]

TABLE 12.10 Changes in Prothrombin and Partial Thromboplastin Times During Massive Blood Transfusions in Children

PT and PTT Times (sec)	Baseline[a] (*n* = 26)	0.5[b] (*n* = 16)	0.75[b] (*n* = 12)	1.0[b] (*n* = 10)
Prothrombin Time				
Mean ± SD	10.9 ± 0.96	12.5 ± 0.77	13.2 ± 0.76	13.6 ± 0.98
Range	9.3–12	11.4–14.0	11.4–14.2	11.9–15.8
Partial Thromboplastin Time				
Mean ± SD	31.8 ± 4.4	38.0 ± 4.9	40 ± 5.4	45.1 ± 13.1
Range	25–45.9	28.1–59.6	33–51.5	25.6–60.0

PRBCs, packed red blood cells; *PT*, prothrombin; *PTT*, partial thromboplastin.
[a]Baseline normal values for blood volume may be greater in infants younger than 3 months.
[b]Blood volume loss. *NOTE:* Not all children in this subset lost a half blood volume or more.

The magnitude of the increase in PT or PTT that is predictive of a clinical coagulopathy is not well defined. However, the consensus panel of the National Institutes of Health and others suggest that when either clotting index exceeds 1.5 times normal (or INR >2.0), it should be considered pathologic.[72,225,229,258–261] Our studies suggest that the PT and PTT are prolonged to more than 1.5 times normal when the blood loss is 1.5 blood volumes or more and the blood loss has been replaced with only PRBCs and crystalloid or 5% albumin.[256,257] Our clinical practice is to initiate FFP after 1.0 blood volume blood loss (Table 12.11). At that point, FFP is administered in a ratio of 1 unit for every 2 units of PRBCs transfused. The indications for and timing of FFP depend on which blood product has been transfused, the volume of that transfusion as it relates to the child's blood volume, and whether the blood loss will continue perioperatively. The PT, PTT, fibrinogen concentration, and platelet count should be measured after each blood volume has been replaced and used to guide the need for additional FFP and platelets.

Recombinant factor VIIa (rFVIIa; NOVOSeven) is approved for use in the United States for hemophiliac patients with high-titer inhibitors and congenital factor VII deficiency. Anecdotal reports describe its effectiveness in controlling hemorrhage in a variety of other settings including congenital heart disease.[1,2,262–266] However, in several randomized clinical trials during partial hepatectomy, liver transplantation, prostate surgery, pelvic (orthopedic) surgery, trauma, and upper gastrointestinal tract bleeding rFVIIa failed to confer any benefit.[267–272] In a large randomized clinical trial of rFVIIa in children with intracranial hemorrhage, the largest-dose group showed only a small improvement in hematoma expansion, and 10% also experienced thromboembolic complications. In adults who received rFVIIa, the frequency of major thromboembolic complications was 1.4% to 10%, including acute myocardial infarction and stroke.[273] Until controlled trials demonstrate a clear benefit for its use, rFVIIa should be used with great caution for off-label indications,[263,267–272,274,275] and even then only for life-threatening bleeding.

Several studies[272,276] have compared transfusion strategies in adults for treating trauma incurred during combat in the Middle East. A consensus conference and other reviews on massive transfusion concluded that the evidence did not support the up-front use of a 1 : 1 : 1 ratio of units of PRBC, FFP, and platelets, but it did support the early use of an antifibrinolytic medication (i.e., tranexamic acid).[208–211,276] The consensus conference also recommended an integrated approach to managing massive transfusion that included rapid provision of PRBCs, the use of antifibrinolytics, and a foundation ratio of blood components

TABLE 12.11 Minimal Fresh Frozen Plasma Recommendations According to the Type of Blood Product Transfused and the Volume of Blood Lost

Type of Blood Replaced	FFP Indicated	Volume FFP to Be Transfused
Whole blood	After 2.0–3.0 blood volumes lost and each blood volume thereafter	25%–33% of each blood volume lost
PRBCs	After 1.0 blood volume lost and each blood volume thereafter	1 unit FFP/2 units PRBCs

FFP, fresh frozen plasma; *PRBCs*, packed red blood cells.

directed by the results of standard coagulation testing (e.g., PT, PTT, platelet count, fibrinogen) or clot viscoelasticity, or both.[276]

The dilutional coagulopathy associated with massive blood transfusion is reasonably predictable. When using whole blood, dilutional thrombocytopenia usually develops first and may occur as early as after the first blood volume has been replaced (if the initial platelet count is <50,000/mm^3). In most cases, clotting factors (particularly factors V and VIII) are not diluted until the blood loss exceeds three blood volumes. On the other hand, when PRBCs are used to replace blood loss, all the clotting factors and platelets may be diluted after as little as 1.0 blood volume is lost. However, the predictable coagulopathy of dilution is only an approximate guide. The PT, PTT, fibrinogen, and platelet count should be assessed during massive transfusions to guide replacement therapy.

DISSEMINATED INTRAVASCULAR COAGULATION AND FIBRINOLYSIS

DIC and fibrinolysis are frequently associated with shock, trauma, and other forms of tissue damage, with release of procoagulants (e.g., tissue factor) and fibrinolytics (e.g., tissue plasminogen activator). In the presence of massive blood loss, these processes must be differentiated from dilutional coagulopathy. Differentiation may be difficult, because both are associated with pathologic oozing of blood in the surgical field and each may result in prolongation of the PT and PTT, as well as thrombocytopenia.[277–280] With massive replacement using whole blood or PRBCs and *adequate* FFP, the fibrinogen concentration should remain normal; with uncompensated (acute) DIC, it may be decreased. However, replacing the blood loss with PRBCs, albumin, and crystalloid also leads to a reduction in fibrinogen.

The most helpful test for DIC and fibrinolysis is documentation of a significant increase in the level of D-dimer, a small peptide fragment generated during the digestion of fibrin by ongoing thrombolysis (i.e., through plasmin), along with evidence on the peripheral blood smear of schistocytes and helmet cells (i.e., microangiopathic hemolytic anemia).[281–283] Abnormal RBCs and RBC fragments are believed to arise from the slicing action of immobilized fibrin strands in the microcirculation, although the precise mechanism remains unknown. A scoring system to screen for potential DIC has been developed but not evaluated in the operating room setting.[284] If pathologic oozing in the surgical field is observed and 1.0 blood volume or less has been lost in a child who had a normal platelet count and PT and PTT values preoperatively, the child may have developed a consumptive coagulopathy.

The most effective treatment for DIC is to eliminate the cause, such as correcting shock, acidosis, or sepsis.[279,280] Heparin therapy remains controversial even in children with thrombotic manifestations of DIC. It is not advisable in children with active bleeding, especially in the operative setting.[278,282,283,285]

HYPERKALEMIA

RBCs leak potassium into the extracellular fluid during storage, particularly as the units of PRBCs age. The concentration of adenosine triphosphate (ATP) decreases, and the ATPase-driven Na^+/K^+ pump activity decreases. At the point when the unit of packed RBCs reaches its maximum shelf life, approximately 5–7 mEq of K^+ are present in the extracellular fluid of each unit. Since the volume of extracellular fluid is different for whole blood and packed RBCs collected in CPDA-1 or Additive-Solution systems, the concentration of K^+ is the highest in CPDA-1 packed RBCs and the lowest in CPDA-1 whole blood units (E-Table 12.3). The K^+ leak is doubled and more rapid from RBCs that have been irradiated.[82,286] To avoid the accumulation of large amounts of extracellular K^+, irradiated RBCs may be stored for a maximum of 28 days (vs. 35 or 42 days for whole blood or PRBCs).

Although extracellular K^+ is present in banked RBCs, clinically important hyperkalemia has not been reported after the slow transfusion of blood through peripheral IV lines but has occurred in children undergoing rapid transfusion particularly through a central venous line.[287–293] A study of serum potassium in neonates after exchange transfusion with PRBCs documented a decrease in serum potassium concentrations.[294] A retrospective study of children undergoing massive intraoperative but slow transfusion with PRBCs documented transient, but not life-threatening, hyperkalemia.[295] It appears that clinically important hyperkalemia does not usually occur when PRBCs are administered *at normal, slow infusion rates through peripheral IV access*.[296,297] This may be explained by the combination of the small absolute amount of K^+ (~6 mEq); its rapid reabsorption into the potassium-depleted, transfused RBCs; the large volume of distribution; and dilution with crystalloid or albumin during administration. Hyperkalemia in the setting of massive transfusion is usually the consequence of extensive tissue injury, extremely rapid transfusion, acidemia resulting from inadequate tissue perfusion, hypothermia, and hypocalcemia.[298]

The need to relate the size of the patient to the rate of blood replacement is infrequently a problem in adults, but it is vitally important to consider in an infant or small child. An alert from the Society for Pediatric Anesthesia[299] described 4 deaths among 11 children who developed hyperkalemia during transfusion; 8 were younger than 1 year, and 6 were younger than 6 months old. The Perioperative Cardiac Arrest Registry reported eight hyperkalemic cardiac arrests related to blood transfusion.[299,300] Hyperkalemia may become a problem when large volumes of whole blood or PRBCs are administered very rapidly in adults (rates ≥120 mL/minute) and in infants and children undergoing rapid blood transfusion, particularly through a central venous catheter.[301] A rapid transfusion rate of 120 mL/minute in a 70-kg adult is equivalent to 1.5 to 2 mL/kg per minute of blood, which is relatively easy to infuse in an infant or small child using a pressure bag or a rapid-transfusion device. An adult sustained a cardiac arrest and died after receiving Adsol-preserved PRBCs with a supernatant potassium concentration of 24 to 34 mEq/L at a transfusion rate of 6.4 mL/kg per minute through a rapid infusion device (see Chapter 52).[302] Similar and greater transfusion rates are possible in infants and children without such devices.[292,295,303,304]

The principle is to avoid falling behind in replacing the blood loss and to avoid a situation in which a rapid and massive infusion of blood is required. Warming the blood and administering it through a peripheral IV line (rather than a central venous catheter) reduce the risks of hyperkalemia on the cardiac conduction system.[305] When the rate of infusion of whole blood or PRBCs exceeds 1.5 to 2.0 mL/kg per minute, the electrocardiogram (ECG) must be closely monitored. If ventricular arrhythmias occur with peaked T waves in the setting of hyperkalemia (see Fig. 9.7), appropriate treatment should be instituted (e.g., calcium chloride or calcium gluconate, hyperventilation, sodium bicarbonate, albuterol, glucose and insulin; see Tables 9.8 and 28.6); Kayexalate is the slowest and least effective intervention in this situation and is not recommended as an acute intervention. Intraoperative washing of PRBCs with autotransfusion devices has been recommended to avoid hyperkalemia in pediatric patients who require rapid, massive blood transfusion.[306]

E-TABLE 12.3 Estimate of Amount (mEq) of Cell-Free K^+ per Unit of RBC at Outdate

Parameter	CPDA-1 packed RBC	AS-1 RBC packed RBC	AS-1 RBC packed RBC
Vol whole blood collected	450 mL	450 mL	500 mL
Vol RBC (45% hct)	203 mL	203 mL	225 mL
Vol plasma (55% plasma)	247 mL	247 mL	275 mL
Vol anticoagulant/ preservative (a/p)	63 mL	63 mL	63 mL
Vol unit total	513 mL	513 mL	563 mL
Vol plasma + a/p	310 mL	310 mL	338 mL
Vol plasma + a/p removed for platelets and plasma	(–250 mL)	(–270 mL)	(–290 mL)
Vol residual plasma + a/p	60 mL	40 mL	48 mL
Vol additive solution (a/s)	0 mL	100 mL	100 mL
Vol plasma + a/p + a/s	60 mL	140 mL	148 mL
Vol unit total	266 mL	343 mL	373 mL
Hematocrit	76%	59%	60%
Concentration K^+[a]	78.5 mEq/L	50 mEq/L	50 mEq/L
Total K^+ per unit[b]	4.7 mEq	7 mEq	7.4 mEq

[a]Measured at outdate for nonleukoreduced, nonirradiated units: 35 days for CPDA-1 and 42 days for AS-1.
[b]Concentration K^+ x volume residual plasma + a/p + a/s = mEq K^+ per unit.

Rapid, massive transfusion of whole blood or PRBCs to a neonate, particularly blood that has been stored for several weeks, can cause hyperkalemic cardiac arrest. It is common practice to administer RBC-containing components that are relatively young to avoid hyperkalemia in neonates requiring massive blood transfusion. If relatively young units are not available and time permits, it may be possible to wash the PRBCs to reduce the potassium concentration. However, RBC transfusion to an actively bleeding infant should not be delayed to obtain less than 7-day-old PRBCs or to wash the units. Similarly, blood for intrauterine transfusion, exchange transfusion, or for neonates should be relatively young (usually <7 days).

These practices are consistent with the recommendations from the Society for Pediatric Anesthesia Wake Up Safe quality improvement initiative, which suggests that anesthesiologists anticipate the blood loss, transfuse early, and cautions that transfusing the hypovolemic child slowly and through a peripheral IV catheter rather than rapidly through a central venous catheter.[299] If the infant requires irradiated RBC blood components, it is preferable to transfuse them soon after irradiating the blood to minimize the potassium concentration.

HYPOCALCEMIA AND CITRATE TOXICITY

Citrate works as an anticoagulant for stored blood components by chelating ionized calcium (iCa^{2+}). As citrate in the blood component is transfused, it is rapidly taken up and metabolized by nucleated cells in the body, although the primary site for clearance is the liver. During massive transfusion, particularly of whole blood or FFP, the influx of citrate may temporarily overwhelm the capacity of the recipient to clear it, resulting in its accumulation, which causes the plasma concentration of iCa^{2+} to decrease.[205,307–311] The residual plasma fraction in a unit of PRBCs, which contains the citrate, is a much smaller volume than in a unit of whole blood or FFP. Clinically, it is rare for the iCa^{2+} level to decrease unless the transfusion rate is very rapid; in adults, this rate must be 1.0 or more units of whole blood or FFP in 3 to 4 minutes.[307] This effect on the iCa^{2+} concentration has been reported in neonates undergoing exchange transfusion and is more likely to occur in more-premature and lower-weight infants. Pulseless electrical activity has been reported in two preterm infants who developed hypocalcemia during dilutional transfusion with FFP.[311,312] In adult cardiac surgical patients who received whole blood at 1.5 mL/kg per minute, the ventricular function curve did not improve (i.e., cardiac output did not increase although the iCa^{2+} decreased). When a similar volume of heparinized blood was administered at the same rate, the Frank-Starling response to volume loading was normal (i.e., cardiac output increased, but iCa^{2+} level did not change).[313] These case reports and the adult cardiac surgical study confirm that a decrease in iCa^{2+} concentration of clinical importance (i.e., decreased cardiac contractility) may be expected when the rate of infusion of citrated whole blood exceeds 1.5 to 2.0 mL/kg per minute.[307,313]

The change in the iCa^{2+} concentration after transfusion of large volumes of PRBCs is less than that observed with whole blood or FFP. Although measurable decreases in the iCa^{2+} concentration have been observed during rapid transfusion, they have only rarely been associated with cardiac toxicity in adults. The rates of infusion of citrated whole blood that produce hypocalcemia and hyperkalemia are almost identical, whereas the cardiac electrophysiologic effects produced by hypocalcemia and hyperkalemia are opposite. It is important to observe the ECG for abnormalities, especially widening of the QRS complex, prolonged QT interval, and peaking of the T wave.[223,314]

Both hypocalcemia and hyperkalemia are treated by the administration of exogenous calcium. Evidence from healthy animals and children with extensive thermal injuries demonstrated that calcium chloride and calcium gluconate dissociate at similar rates; hepatic metabolism of the gluconate moiety is not necessary (Fig. 12.8).[315] Studies during the anhepatic phase of liver transplantation reported a similar degree of ionization of calcium chloride and calcium gluconate, confirming that hepatic metabolism is not required to ionize calcium from calcium gluconate.[316] Calcium chloride and calcium gluconate are both indicated to treat acute ionized hypocalcemia, with the caveat that calcium gluconate, which contains one-third of the ionizable calcium of calcium chloride (by weight), be administered at a threefold greater dose (milligrams per kilogram) than the latter. Frequent, small boluses are as effective as single large boluses and result in smaller fluctuations in plasma iCa^{2+} values.[315] Ideally, both forms of calcium should be slowly administered through a large peripheral or central vein, because both are sclerosing medications.

The volume of plasma and therefore the absolute amount of citrate in a unit of FFP are slightly less than the amounts in a unit of whole blood. However, the citrate load can be more rapidly delivered in FFP because it can be infused more rapidly owing to its low viscosity. It is easy to give a large citrate load in a brief period. Caution is urged when FFP or whole blood is rapidly infused, especially if the child already has a low iCa^{2+} concentration or impaired hepatic function (e.g., neonates and children undergoing liver transplantation).[312] Fig. 12.9A shows the changes in iCa^{2+} concentrations that occurred in children who had extensive thermal injuries and who received rapid FFP infusions at 1.0 to 2.5 mL/kg per minute for 5 minutes. The maximum decrease in iCa^{2+} levels occurred between the fourth and fifth minutes with a similar nadir in the iCa^{2+} concentration in the three fastest rates of FFP infusion.[317]

If exogenous calcium is administered *during* rapid FFP transfusion, large decreases in the iCa^{2+} level can be avoided (see Fig. 12.9B). We transfused FFP at 2 mL/kg per minute for 10 minutes (equivalent to an average adult receiving 1400 mL FFP over 10 minutes) in six children with extensive burn injuries and despite very significant decreases in iCa^{2+} levels, found no consistent adverse circulatory changes. However, because these children had extensive burn injuries, we presumed they were hypermetabolic and therefore able to more rapidly metabolize the excess citrate, which limited our ability to extrapolate these data to children without burn injuries (see Chapter 36).[317]

In dogs anesthetized with halothane, we determined that citrate-induced ionized hypocalcemia caused significantly greater cardiovascular depression as the expired concentration of halothane increased.[318] These findings are consistent with the combined myocardial depression caused by ionized hypocalcemia and calcium channel blockade caused by the halothane.[319,320] Although halothane exerts the greatest calcium channel blocking activity of the inhalational anesthetics, all inhalational anesthetics depress the myocardium through this mechanism to some extent as well as through other mechanisms involving calcium flux, which augments the myocardial dysfunction associated with citrate-induced ionized hypocalcemia.[321–324]

The adverse cardiac effects of citrate-induced hypocalcemia may be increased if FFP is rapidly administered through a central venous catheter because there is less time to dilute the FFP and metabolize the citrate before it enters the heart and coronary vessels. FFP may be more safely administered through a peripheral IV line. Calcium should be administered *during* rapid transfusion of FFP (>1 mL/kg per minute) to attenuate this transient but

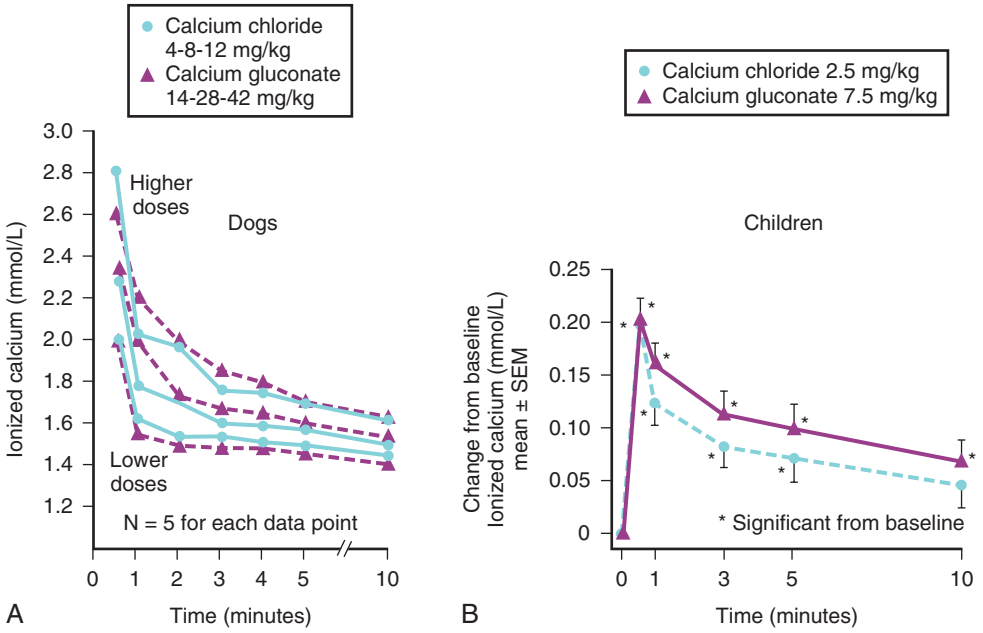

FIGURE 12.8 **A**, Changes in arterial iCa^{2+} levels in dogs after three equal elemental calcium doses of calcium chloride (4, 8, and 12 mg/kg) or calcium gluconate (14, 28, and 42 mg/kg). The rate of change in the iCa^{2+} concentration was identical for each form of calcium at each dose. There was no significant difference between the largest and smallest doses after 2 minutes, suggesting that frequent small doses are equally effective and perhaps safer than large boluses of exogenous calcium. **B**, Changes in arterial iCa^{2+} levels in children who received equal elemental doses of calcium chloride and calcium gluconate. At 30 seconds, both forms of calcium dissociated equally; these data indicate that hepatic metabolism of the gluconate moiety is not required to liberate ionized calcium from calcium gluconate. (From Coté CJ, Drop LJ, Daniels AL, Hoaglin DC. Calcium chloride versus calcium gluconate: comparison of ionization and cardiovascular effects in children and dogs. *Anesthesiology* 1987;66:465–470.)

potentially dangerous citrate toxicity, especially in the presence of potent inhalational anesthetics.[318–322] Neonates and small infants are particularly vulnerable to developing citrate toxicity because it is easier to administer a relatively large volume of FFP or platelets over a brief period and because citrate may not be eliminated as rapidly (i.e., first-pass effect through the liver) in infants.[312] In addition to thermally injured patients, children undergoing liver transplantation and cardiac surgery are likely to require FFP and develop hypocalcemia.[325,326] Liver transplantation recipients are particularly susceptible to decreased iCa^{2+} levels during the anhepatic phase and the pre-anhepatic phase of surgery because of impaired hepatic blood flow and the reduced ability to metabolize citrate.[327–331] An IV preparation of calcium should always be available when a major transfusion with FFP is anticipated.

ACID-BASE BALANCE

Massive transfusions usually occur in one of two situations: severe trauma with shock or major surgery with massive blood loss. In the first situation, severe metabolic acidosis may occur because of low cardiac output and diminished oxygen delivery. Correction of the acidosis may be a necessary part of the resuscitation, along with blood volume replacement. In this situation, impaired coagulation may occur because of the acidosis.[220,236,332–334] In the operating room, intravascular volume is usually maintained, and because most instances of massive blood loss are anticipated, replacement of acute blood loss is more controlled. Even with repeated massive blood loss, metabolic acidosis is not usually a problem provided severe hypovolemia is avoided.[335–337] Sodium bicarbonate therapy must be governed by the child's acid-base status because metabolic acidosis does not usually occur with massive transfusion unless accompanied by severe hypovolemia, low cardiac output, or hypoxemia.

After a massive blood transfusion, a moderate to severe metabolic alkalosis caused by the large volume of transfused citrate and its conversion to bicarbonate is common.[308,326,338–340] Thus it is important to determine the acid-base status *before* administering sodium bicarbonate to avoid overcorrecting the pH and shifting the oxyhemoglobin dissociation curve further to the left.

HYPOTHERMIA

Hypothermia may contribute to problems associated with major blood loss and its replacement. Although hypothermia decreases oxygen consumption and reduces oxygen demand, it may also increase oxygen consumption if the child shivers and decrease tissue delivery of oxygen by a leftward shift of the oxygen-hemoglobin dissociation curve as well as induce a refractory ventricular tachycardia in the presence of severe hypothermia (about 32°C).[223,341] Hypothermia may also profoundly compromise platelet function and impair the coagulation cascade.[220,236–238,332,333,342–344]

Prevention of hypothermia by all available means is considered an essential part of damage-control resuscitation of trauma patients.[345–348] Hypothermia (<34°C in adults) by itself is an independent risk factor for mortality.[349] Banked blood products are stored between room temperature and 4°C, depending on the blood component. In the setting of large transfusion volumes, all blood products should be infused through a blood warmer. No other method should be considered (e.g., storing blood in a warming cupboard, immersing in hot water, microwave) because

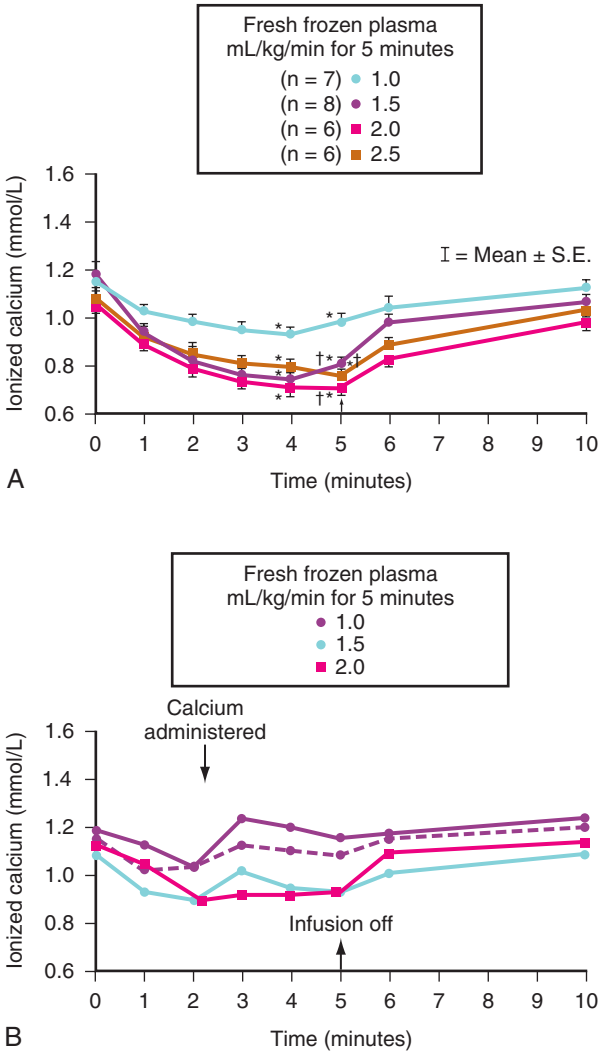

FIGURE 12.9 **A**, Changes in arterial iCa^{2+} levels in children with severe thermal injuries during infusions of fresh frozen plasma at a rate of 1.0 to 2.5 mL/kg per minute for 5 minutes through an infusion pump. Notice the dangerous although transient decrease in the iCa^{2+} concentration, with the nadir occurring between the fourth and fifth minutes. Ionized hypocalcemia occurs when the infusion rate equals or exceeds 1 mL/kg per minute. **B,** Changes in iCa^{2+} levels occurred in four thermally injured children who received calcium chloride (*arrow*) after 2 minutes of fresh frozen plasma infusion. There were no sharp increases or decreases in iCa^{2+} levels. (From Coté CJ, Drop LJ, Hoaglin DC,et al. Ionized hypocalcemia after fresh frozen plasma administration to thermally injured children: effects of infusion rate, duration, and treatment with calcium chloride. *Anesth Analg*. 1988;67:152–160.)

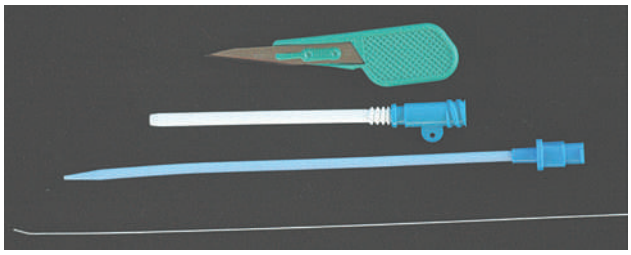
RBCs hemolyze readily with prolonged warming or overheating (>42°C). Warming blood and all other IV infusions with a high-capacity blood warmer, using hot air warming blankets and radiant warmers, placing plastic wrap around extremities, inserting a heated humidifier in the anesthesia circuit, covering the child's head, and maintaining a warm to hot operating room contribute to maintaining thermal neutrality. Rapid-transfusion devices markedly improve the rapidity of transfusion and the thermokinetics involved.[350–356] In one case, one author (CJC) and two nurses transfused more than 50 L of blood products and crystalloid in less than 1 hour, while maintaining the child's temperature at 34.5°C or greater.[350]



MONITORING DURING MASSIVE BLOOD TRANSFUSION

If massive blood loss can be anticipated, adequate monitoring should be instituted *before* surgery begins so that baseline information can be recorded. Large-bore peripheral IV access is preferable (E-Fig. 12.2) because these catheters have reduced resistance and they deposit blood products into the peripheral circulation for dilution (avoiding hypothermia and hyperkalemia in the heart), unlike a CVP line. If a child arrives in the operating room in shock (e.g., trauma patient), the physician must be careful to differentiate hypovolemia from other causes of shock (e.g., tension pneumothorax, cardiac tamponade) (see Chapters 39 and 40); invasive monitoring may assist in diagnosing the cause of the child's volume status. Our philosophy is one of aggressive invasive monitoring to provide maximum data for evaluation and management of a critically hypovolemic child.

1. Routine monitoring includes an ECG, blood pressure cuff, stethoscope, temperature, pulse oximetry, and expired carbon dioxide; a pulse oximeter placed on the tongue may be particularly valuable in special circumstances when a child is vasoconstricted, hypothermic, or without peripheral pulses.[357,358] Hypovolemia may occasionally manifest as pulsus paradoxus, identified with a pulse oximeter.[359]
2. A urinary catheter allows quantitation of urine output and assessment of organ perfusion and intravascular volume status.
3. An arterial catheter enables continuous blood pressure monitoring, arterial blood gas measurements, and determinations of hematocrit, glucose, calcium, potassium, and clotting parameters. The adequacy of the circulating blood volume may be inferred from the shape of the arterial waveform, presence of the dicrotic notch, and absence of exaggerated respiratory variation (Fig. 12.10).
4. A CVP line provides critical information, and its ease and safety of insertion have been demonstrated for children of all sizes[360]; ultrasound may improve the success and safety of insertion.[361,362] CVP readings vary depending on the location of the catheter tip and whether there is rapidly running fluid in the same catheter.[363,364] In the latter case, the infusions should be interrupted intermittently to obtain accurate readings. It is our clinical impression that in healthy, anesthetized, supine children, a very small change in CVP (2–3 mm Hg) may represent a change of as much as 10% to 15% of a child's blood volume. In most children, right-sided pressures correlate well with left-sided pressures; the right atrial CVP usually is an accurate indicator of cardiac filling pressures of both ventricles. A CVP line provides access for blood sampling and a reliable site for IV administration of medications, fluid, and blood. However, a CVP line cannot always be relied on as a volume administration line because resistance is large through the long, narrow lumen. A centrally placed introducer is a reliable volume line; however, it is preferred to give rapid transfusions through a peripheral catheter as to reduce the potential for hyperkalemic, hypocalcemic, or hypothermia-induced cardiac arrest.[299,305]
5. Continuous noninvasive cardiac output devices may provide further clinical guidance (see Figure 52.10).[21]

Monitors and the data they generate are helpful, but anesthesiologists must rely on more than numbers. It serves no purpose to have sophisticated monitoring if the data provided cannot be interpreted and related to clinical events. The final monitor is ultimately the anesthesiologist's attention and judgment.

Thromboelastography provides a standardized means of quantitating the rapidity and quality of clot formation and a means for identifying fibrinolysis.[365,366] This device was first used primarily

E-FIGURE. 12.2 Rapid infusion catheters (RICs) are available. A 20-gauge catheter is inserted into a peripheral vein and a guidewire is advanced. A moderate skin nick is made with a scalpel blade, and the dilator (*blue catheter*) is advanced into the vein. The RIC (*white catheter*; Rapid Infusion Catheter Exchange Set, Arrow International, Erding, Germany) is then advanced into the vein, and the dilator and guidewire are removed. The RIC is sutured in place (*side hole on white catheter*). In this case, an 8.5-F catheter that is only 6.4 cm long is in place, providing a large-bore, low-resistance catheter that is able to adequately function with rapid transfusion devices (see Fig. 52.1 and E-Figs. 52.1 and 52.2). These catheters are available in smaller sizes and from various manufacturers, and the devices are best combined with large-bore extension catheters.

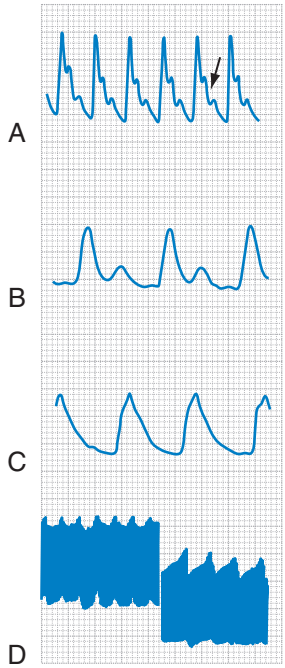


FIGURE 12.10 Changes in the contour of an arterial tracing with hypovolemia. **A**, The normal tracing shows a sharp upswing of the arterial pulse wave and position of the dicrotic notch. **B**, There is movement of the dicrotic notch and widening of the pulse wave. **C**, The pulse wave widens further. **D**, There is further widening of the pulse wave and loss of the dicrotic notch. An exaggerated ("picket fence") respiratory variation of pulse wave is shown in the *right* tracing compared with the *left*. Factors other than hypovolemia, such as hypothermia, deep anesthesia, vasodilator therapy, or damped tracing (e.g., clot, air bubble), may produce artifactual changes in the shape of the arterial waveform.

during massive blood transfusion situations related to liver transplantation, trauma, and cardiac surgery.[345,347,365–376] Some studies have found that thromboelastographic screening was not useful in predicting bleeding after cardiac surgery and was associated with a large percentage of false-positive results.[377,378] The use of heparinase improves the accuracy of the results by eliminating the effects of heparin, although this requires two machines to simultaneously sample blood (with and without heparinase) to have results within a useful period.[379] This monitor may also be used to guide the effectiveness of antifibrinolytic therapy.[372,373,380] The exact role of thromboelastography in the routine care of pediatric cardiac surgical patients, liver transplant recipients, and children who have had massive blood loss with ongoing coagulopathy has not been established.[247] Tables 12.10 and 12.11 summarize the expected changes in various blood components when administered on a per kilogram basis and the estimated FFP requirement.

INFECTIOUS DISEASE CONSIDERATIONS

It is important to use basic precautions when administering blood products and contacting body fluids to minimize the risk to anesthesiologists. Blood and body fluids, even in infants, may transmit hepatitis B, hepatitis C, and HIV through parenteral exposure (e.g., cuts, needlestick), mucous membrane contact, or exposure to nonintact skin.[10,381–390] Accidental needlesticks are the most common means of exposure to anesthesiologists in the operating room. The introduction of safe IV needles, a needleless IV system, the use of stopcocks, and never recapping used needles has reduced the incidence of this problem.[391–394] The incidence of HIV seroconversion after needle puncture is estimated to be 0.2% to 0.5% (~1 in 300), although the conversion rate is much greater after a needlestick injury from individuals with hepatitis.[10,381,387–389,395,396] All institutions should have needlestick, mucous membrane, or nonintact skin exposure to blood protocols to immediately evaluate and institute treatment (see also Chapter 50).[397–400]

Anesthesiologists must practice universal blood and body fluid precautions (e.g., gloves, goggles) and should minimize the use of needles, especially the practice of recapping needles. The management of infants may be less than optimal with the use of three-way stopcocks because of the fluid required to flush the system and the ease of introducing air into the IV line. In these infants, single-use needles without recapping or needleless systems are recommended. If an anesthesiologist is exposed to an HIV-positive patient or is punctured by a needle of unknown origin, the need for immediate institution of prophylactic medical therapy should be determined.[394,396] Early institution of drug therapy is recommended to reduce the potential for seroconversion (see Tables 50.6 and 50.7).

Methods to Reduce Patient Exposure to Allogeneic Blood Components

Public awareness of the infectious hazards of transfusion, particularly from HIV and the hepatitis viruses, generated considerable interest in the 1980s and 1990s in developing techniques to avoid allogeneic transfusion. These techniques can minimize transfusions and the associated risks, assuaging the fears of parents and sparing the blood supply for patients for whom these options were not suitable. Within the medical community, awareness of the hazards of transfusion prompted a more thoughtful approach to transfusion, greater tolerance of asymptomatic anemia, more attention to medical treatment of anemia, and greater focus on surgical hemostasis. The amount of blood transfused for many surgical procedures has decreased steadily during the past 20 years. During the same period, the risks associated with transfusions have also dramatically decreased. After the HIV and hepatitis C viruses were identified, sensitive tests, some based on amplification technology for viral RNA, were developed to screen the donor population. Transfusions are associated with other deleterious effects, but two of the most significant risks, bacterial infection and mistransfusion, do not differ materially between banked allogeneic and autologous blood. As the risk differential between allogeneic transfusion and its alternatives narrows, a balanced appraisal of the benefits and untoward effects of each is appropriate.

ERYTHROPOIETIN

Use of recombinant erythropoietin to promote endogenous RBC production can reduce the need for allogeneic RBC transfusions and has proved useful in many populations, including preterm infants, children receiving chemotherapy, children with renal failure, children of Jehovah's Witnesses, and children undergoing elective major reconstructive surgery, spinal surgery, liver transplantation, or cardiac surgery.[401–406] Coordination with the hematology department, blood banking, and the primary patient care team is required to take full advantage of this form of therapy.[402,407–425] Although usually well tolerated, erythropoietin should be used with careful

monitoring in patients with hypertension. Erythropoietin is available in a lyophilized (freeze-dried form for reconstitution) or in a dilute albumin solution; some members of the Jehovah's Witness faith prefer the lyophilized formulation.

PREOPERATIVE AUTOLOGOUS BLOOD DONATION

Donation and storage of blood before elective surgery have reduced the use of allogeneic RBCs.[408,421,426–440] Banked units of PRBCs may be stored for 35 to 42 days in the liquid state,[441,442] permitting the donation of several units and the time required for the patient (usually teenagers) to regenerate the RBC mass before surgery. Children unable to mount an erythropoietic response to phlebotomy may only succeed in making themselves anemic, so administration of iron, vitamin C, and folate is important, as is monitoring for reticulocytosis to ensure that the bone marrow is replenishing the donated RBCs. Autologous donation should not be attempted in children with significant cardiac ischemic disease (e.g., hypertrophic cardiomyopathy) or those with an active infection because bacteria can seed the collected unit and overgrow during storage. Autologous donation should be discouraged before procedures for which RBC transfusion is unlikely. Donated blood that is not used by the donor is usually discarded rather than entered into the general blood bank inventory as it is not screened for infectious agents.

Patients or family of pediatric patients may wish to obtain blood from family members or friends (i.e., directed donation). Despite the perception that this donor pool may be safer than the pool of volunteer, allogeneic donors, there is no evidence that this is true. Directed donors are considered to be allogeneic donors and are screened and tested in the same manner as any volunteer donor. Because there is a greater risk of transfusion-associated GVHD with cellular components from a donor who is a blood relative, these units are irradiated to eliminate the possibility of this fatal complication of transfusion.[443–445]

INTRAOPERATIVE BLOOD RECOVERY AND REINFUSION: AUTOTRANSFUSION

Recovery of blood from an operative site and reinfusion after some form of processing has been applied to major vascular, cardiac, and multiple trauma situations for many years.[432,437,438,446–458] The common techniques used wash the recovered blood in a centrifuge so the product consists of the child's RBCs suspended in saline at a hematocrit of 50% to 60%.[448,455] Cellular debris, excess citrate or heparin, free hemoglobin, activated clotting factors, and clotted blood are almost completely removed. Autotransfusion avoids the infectious and immunologic risks of allogeneic transfusion and, if reinfusion is carried out in the operating room, minimizes the opportunity for mistransfusion.[447,455,456,459]

Intraoperative blood recovery is not widely used in infants and children.[407,408,458,460–462] The equipment is designed for adults, although some manufacturers have adapted standard devices for pediatric use.[463,464] We have found blood recovery to be a useful adjunct to minimize allogeneic blood transfusion during scoliosis surgery. This technique may also be used in conjunction with preoperative autologous blood donation, further reducing the need for allogeneic RBC transfusions.[446,451,452,461] The capital investment for the devices and the costs for the disposables and a trained operator, however, are significant. Nonetheless, these expenses can be offset if 2 to 3 fewer units of allogeneic RBCs are transfused. Development of pediatric-sized equipment has made this technique more widely used and more cost-effective even in smaller children.[465]

Indications

Indications include any major surgical procedure in which the use of more than 2 units of banked PBCs is likely or in which massive blood loss is occurring; children with rare blood types; and multiple trauma with massive hemorrhage.

Contraindications

Major contraindications to blood-recovery devices include contamination of the operative field by bacteria (e.g., bowel trauma, abscess), cancer, and sickle cell disease (e.g., sickling in the device). Recovered blood should not be processed for reinfusion if the surgical field contains topical clotting agents, some topical antibiotics (e.g., polymyxin, neomycin), or other foreign materials (e.g., methylmethacrylate). Surgery for a malignancy is considered to be a relative contraindication because of the theoretical concern that malignant cells may be recovered and reinfused; this can be avoided by discarding blood recovered from the operative field while the tumor is being manipulated.[466–468]

CONTROLLED HYPOTENSION

Controlled hypotension has long been used to reduce intraoperative blood loss or to provide a relatively bloodless operating field.[407,462,469–481] Hypotensive anesthesia may be accomplished with many techniques, including continuous infusion of vasodilators, β-adrenergic blockade, deep inhalational anesthesia, and large-dose opioid infusions (e.g., remifentanil).[470,481–485]

Controlled hypotension is reserved for older children and teenagers undergoing major reconstructive (e.g., craniofacial surgery) or orthopedic surgery. The choice of technique and the degree of induced hypotension depend on the surgical procedure. For procedures in which a dry surgical field is the endpoint with little potential for rapid blood loss, a technique that may take some time for recovery is acceptable (e.g., deep inhalational agent with or without β-blockade). If surgery carries the possibility of rapid or massive blood loss, a technique that is rapidly reversed (e.g., nitroprusside, nitroglycerin, remifentanil) is probably safer. Controlled hypotension with mean arterial pressure (MAP) of 55 to 60 mm Hg is used much less in recent years than in the past, especially for patients cared for in the prone position. Moderate hypotensive techniques with a MAP of 65 to 70 mm Hg are a more common practice and are likely associated with less risk, although no studies have been published in this regard.[425] The main concern regarding the use of this technique is reported cases of blindness after surgery performed with the patient in the prone position[486–490]; risk factors for blindness include duration of anesthesia, extensive blood loss, anemia, large crystalloid fluid administration, and others (see also Chapters 32 and 34).

General Concepts

All potent inhalational anesthetics decrease the cerebral metabolic rate for oxygen consumption ($CMRO_2$) and increase cerebral blood flow. Isoflurane appears to offer the greatest advantage because it induces the greatest depression of $CMRO_2$, and it has been used as the sole hypotensive agent.[491–497] One of the most important considerations of any hypotensive technique is its effect on cerebral blood flow. Brain ischemia has been documented in adults when a MAP of 55 mm Hg is combined with hypocarbia; we would not recommend this degree of hypotension in prone procedures. Maintenance of normal arterial carbon dioxide tension ($PaCO_2$) is vitally important to ensure adequate cerebral blood flow; the relationship of cerebral blood flow to $PaCO_2$ is described in greater detail in Chapter 26. To optimize cerebral blood flow, we typically

maintain the MAP at 65 to 70 mm Hg or greater and the $PaCO_2$ at 35 to 45 mm Hg.

Because hypotensive anesthesia with inhalational anesthetics depresses myocardial function and requires time to wash out, a rapid offset is difficult to achieve; we advocate alternative strategies (e.g., vasodilating agents, remifentanil) that provide more precise control of blood pressure without depressing the heart.

If β-blockade is to be used safely, the clinician must understand the differences in half-lives. Esmolol is very short acting, with a half-life in children of approximately 3 minutes[498]; nonanesthetized children have a greater requirement (in micrograms per kilogram) than adults.[499] In nonanesthetized children, a loading dose of 500 μg/kg per minute is followed by a maintenance infusion at a rate of 25 to 200 μg/kg per minute. Because there is limited published experience using esmolol in children under anesthesia, a smaller starting dose (25–50 μg/kg per minute) and titration of dose every 3 to 5 minutes (increase by 12.5–25 μg/kg per minute) are suggested. Labetalol[500–503] and propranolol[504,505] have longer half-lives, greater time to peak effect, and the effects are less controllable and not recommended. Acute β-blocker toxicity can be reversed with high-dose IV glucagon (50 μg/kg followed by an infusion of 0.3–3.0 μg/kg per minute [extrapolated from adult data])[506–508] and possibly with vasopressin.[509] Intralipid rescue has also been proposed for propranolol toxicity but may not be effective for less fat-soluble β-blockers.[510–512]

Pharmacology

Sodium Nitroprusside

Sodium nitroprusside has a very rapid onset of action (seconds), brief duration of action (minutes), and minimal side effects when used in the recommended dose range.[513] This agent must be administered by an infusion pump through a separate IV site and with a second pump to provide a continuous, uninterrupted, and stable infusion rate.

DOSAGE. The initial infusion rate for sodium nitroprusside is 0.5 to 1.0 μg/kg per minute.[514,515] The rate can be increased as needed to achieve the desired MAP.[516,517] A satisfactory reduction in systemic perfusion pressure can usually be obtained well below the recommended maximum rate of 10 μg/kg per minute.

TOXICITY. Cyanide toxicity is characterized by an unexplained metabolic acidosis, increased blood lactate, and an increased mixed venous oxygen content.[517,518] The nitroprusside radical interacts with the sulfhydryl groups of erythrocytes, releasing cyanide. If the amount of cyanide released overwhelms the capacity of the rhodanese system, cyanide toxicity (i.e., binding to the cytochrome electron transport system) results. This produces a change to anaerobic metabolism, metabolic acidosis, an increase in mixed venous oxygen content, and eventually death[517,519–523]; several pediatric anesthetic-related deaths have resulted from cyanide toxicity and its treatment.[520–522]

Three responses to sodium nitroprusside infusion may herald impending cyanide toxicity: more than 10 μg/kg per minute required for a response, tachyphylaxis developing within 30 to 60 minutes, and immediate resistance to the drug.[518] If any of these occur, sodium nitroprusside should be discontinued and the child investigated for possible cyanide toxicity. Treatment of cyanide poisoning is directed at reversal of the binding of cyanide to the cytochrome enzymes. This can be accomplished by producing methemoglobinemia with amyl nitrite. Methemoglobin has a greater affinity for cyanide than it does for the cytochrome system, forcing the reaction in the direction of forming cyanmethemoglobin. The breakdown of cyanmethemoglobin is promoted by administering thiosulfate, which reacts with the cyanide to form nontoxic thiocyanate, which is then excreted by the kidneys. Hydroxocobalamin may prevent toxicity by formation of cyanocobalamin (see also Chapter 18).[524]

Sodium nitroprusside is a safe medication if doses remain within guidelines established by various investigators.[525–527] For children, this is a maximum of 50 μg/kg per minute for 30 minutes and 8 to 10 μg/kg per minute for 3 hours, with frequent blood gas analyses.[517,527] The potential for toxicity and the availability of less toxic vasodilators have decreased its use for controlled hypotension; it is most commonly used for short-term control of blood pressure in special situations.

Nitroglycerin

The main advantages of nitroglycerin are its relatively rapid onset of action (minutes), lack of tachyphylaxis and toxicity, and brief duration of action (minutes); the major disadvantage is the limited achievable reduction in blood pressure.

DOSAGE. Nitroglycerin is administered by an infusion beginning at a rate of 1 μg/kg per minute; the dose is increased until the desired response is obtained. Resistance to the hypotensive effects of nitroglycerin may occur in children. However, in view of the reduced potential for toxicity compared with nitroprusside, nitroglycerin appears to be a reasonable alternative.

TOXICITY. Nitroglycerin is relatively free of toxic side effects in the usual doses applied during hypotensive anesthesia.[477,528,529] However, several reports have described nitroglycerin-induced methemoglobinemia.[530,531] Pulse oximetry may be of value in making the initial diagnosis (i.e., decreased saturation). However, if this occurs, accurate saturation determinations are not possible because of the interference in light absorbance caused by methemoglobin at both ends of the absorbance spectrum used by pulse oximeters.[532,533] The use of other adjuncts (e.g., potent inhalation agents, other vasodilators, β-adrenergic blockade, or opioids) reduces the total dose of nitroglycerin administered.

Remifentanil

Remifentanil-induced hypotension is increasing in popularity because of its relative safety, ease of administration, and titratability, particularly if a patient must be awakened during spinal fusion. Administration should be the same as for any other vasoactive anesthetic agent. It requires dedicated IV access, with the infusion as close to the IV catheter as possible and with a separate pump to avoid fluctuations in the rate of administration. The half-life of this drug is so brief that interruptions while changing IVs or boluses when giving other medications need to be avoided. We have found that the combination of a low-dose inhalational agent, low-dose propofol, and a remifentanil infusion provides excellent operating conditions. Systemic arterial pressure can be controlled by the rate of opioid infusion without fear of residual opioid effect at the end of the procedure, and this combination does not significantly interfere with sensory and motor potential monitoring. If an intraoperative wake-up is needed, a longer-acting opioid such as fentanyl should be administered before awakening.

DOSAGE. For most children, the starting dose is 0.1 μg/kg per minute, which is then increased or decreased depending on the child's response and the degree of surgical stimulus.[514] A steady-state blood concentration of remifentanil of 14 μg/L would typically achieve a 30% decrease in MAP.[534,535]

The anesthesiologist should expect variable opioid requirements during spinal fusions (doses as great as 2 μg/kg per minute and as small as 0.05 μg/kg per minute). Analgesic doses of a

long-acting opioid such as morphine or hydromorphone should be administered approximately 10 minutes before discontinuation to provide adequate analgesia on awakening. This technique often allows a smooth but rapid extubation despite a very long surgical procedure.

General Concepts of Hypotensive Anesthesia

Before using controlled hypotension, it is important to understand the rationale for using this technique.[536] If it is used to reduce surgical blood loss, the preparation and monitoring of a child are different from the approach in a procedure in which the main objective for reducing the perfusion pressure is to improve operating conditions (e.g., microsurgical techniques). In the former case, direct assessment of circulating blood pressure and volume with an arterial line and central venous catheter is important, whereas in the latter case, only a direct means of measuring blood pressure (arterial line) is needed.

Anesthetic Management

All inhalational anesthetic agents have been used as a single drug to produce controlled hypotension, but profound cardiovascular depression may be difficult to control.[493–495,537,538] We do not advocate hypotensive anesthesia using potent inhalational agents as the sole hypotensive agent because the cardiovascular depression is not rapidly reversed if a problem arises. However, small to moderate concentrations of inhalational anesthetic reduce the amount of vasodilator, β-blocker, or opioid necessary to reduce blood pressure.[539]

Short-acting β-adrenergic blockers offer an alternative method to decrease MAP by directly depressing cardiac output. However, β-adrenergic blockade removes a valuable guide to the depth of anesthesia and volume status. Because the cardiac output in children approximately 2 years old or younger depends on heart rate (see Chapter 18), β-adrenergic blockade is not recommended in this age group. Low-dose, short-acting β-adrenergic blockade may be a reasonable adjunct to hypotensive anesthesia with inhalational anesthetics as a means of reducing the concentration of the anesthetic or as a supplement to reduce the vasodilator requirements.[540] A rapid-acting β-blocker such as esmolol may be the best compromise because its half-life is brief (3 minutes) and it is administered as an infusion.

Monitoring and Management Principles

The following baseline parameters are monitored: oxygen saturation and expired carbon dioxide, ECG, temperature, hematocrit, blood glucose, arterial blood gases, acid-base status, MAP, and CVP. Arterial pressure is measured using an arterial line.

When the desired MAP has been attained, a new baseline CVP should be measured and maintained at this level or a slightly greater level than the new reduced CVP value throughout the procedure. To use any hypotensive technique safely, normovolemia is maintained at all times. This means that even small (1- or 2-mm Hg) decreases in the CVP prompt an appropriate fluid response. A small change in cardiac filling pressures in a healthy, supine, anesthetized pediatric patient may represent a significant reduction in circulating blood volume. Even during hypotensive anesthesia, the kidneys should produce 0.5 to 1.0 mL/kg of urine per hour. The failure to detect urine output frequently is caused by obstruction or kinking of the urinary catheter. If the catheter is patent, an IV fluid challenge should be considered.

After hypotension has been induced and the surgical field is bloodless, the MAP should be slowly increased in 5- to 10-mm Hg increments until increased bleeding is observed in the surgical field. At that time, the MAP can be again reduced by approximately 5 mm Hg to achieve optimal conditions. With this method, it is sometimes necessary to reduce the MAP only 10% to 20% from baseline to achieve satisfactory hemostasis with hypotensive anesthesia.

POSITION. Make the operative field the highest point of the child's body to take advantage of gravitational forces to help reduce blood pressure and minimize any possible impedance to venous drainage that may contribute to blood loss. If the head is the surgical site, the arterial transducer must be calibrated at head level rather than heart level to ensure adequate cerebral perfusion pressure.[529,541]

LABORATORY VARIABLES. An adequate hemoglobin must be maintained to have sufficient oxygen-carrying capacity; we maintain the hemoglobin at 9 to 10 g/dL during controlled hypotensive anesthesia. This is important for children undergoing spinal instrumentation, in which traction on the spinal cord may alter spinal cord blood flow and to prevent possible blindness.

Arterial blood gases must be carefully evaluated on a 30- to 60-minute basis to diagnose changes in oxygenation, ventilation, or perfusion or the development of drug toxicity (e.g., metabolic acidosis with nitroprusside) or adverse anesthesia events.[542–544] A large difference between arterial and expired carbon dioxide values may indicate a pulmonary shunt or air embolization. An increase in mixed venous oxygen content may signal cyanide toxicity. Adequate PaO_2 must be maintained at all times. Normocarbia should be maintained to ensure cerebral perfusion.[513,545,546] Although we do not advocate the routine use of β-adrenergic blockade, blood glucose values should be measured serially because β-adrenergic blockade inhibits glycogenolysis and has resulted in unsuspected hypoglycemia in children.[475,547,548]

Contraindications

The risks of hypotensive anesthesia are significant.[549] The risk/benefit ratio must always be considered on an individual basis, particularly with neurosurgical patients and those undergoing spinal instrumentation; any systemic disease compromising the function of a major organ is a relative contraindication. Most reported complications are related to inexperience of the practitioner, inappropriate patient selection, unfamiliarity with the drugs involved, or inattention to details such as blood volume status, pH, $PaCO_2$, blood glucose, or not using infusion pumps to carefully titrate medications. If a child is healthy and meticulous attention is paid to all the physiologic variables, the benefits of improved surgical technique, reduced surgical time, and decreased need for blood transfusion may outweigh the potential risks.

NORMOVOLEMIC HEMODILUTION

Intentional isovolemic hemodilution is a useful strategy for reducing allogeneic blood transfusions.[407,408,432,462,550–560] Two basic methods can be applied:

1. Allow the surgical blood loss to continue until the child's hematocrit value is in the high teens and maintain that hematocrit value until near the end of the procedure. At that time, the hematocrit can be increased to the desired value by transfusing PRBCs. This technique allows surgical bleeding to occur at a reduced hematocrit value, resulting in reduced loss of RBC mass.
2. Blood can be removed from a child at the beginning of the operation while replacing the volume with crystalloid solution

and then returning the blood at the end of the procedure or when significant bleeding occurs.

The latter technique is preferable because it reserves a quantity of the child's own blood, which can be returned at the end of the surgical procedure. For a Jehovah's Witness, this technique often conforms to religious guidelines if direct continuity is maintained with the child's circulation.[550,561–568]

During acute normovolemic hemodilution under anesthesia, the distribution of blood flow improves with the reduced hematocrit. Improved blood rheology is the major compensatory mechanism for maintaining oxygen delivery despite a reduced hematocrit. Oxygen extraction increases in the presence of an inadequate circulating blood volume or when the hematocrit decreases to less than 20%. If the hematocrit decreases to less than 15%, subendocardial myocardial ischemia may develop.[569–572] At this extreme level of anemia, dissolved oxygen begins to assume a more important role in oxygen delivery.[573] In several reports, extreme acute normovolemic hemodilution (hemoglobin as low as 2 g/dL) was well tolerated;[569,574–577] we cannot endorse the use of this technique in children because it is impossible to assess the effects of such an extreme hemoglobin concentration on the long-term cognitive ability. Nonetheless, these reports[569,577] indicate that healthy children can tolerate these extreme hematocrit concentrations provided they are anesthetized, normovolemic, slightly hypothermic, and ventilated with 100% oxygen. We limit the absolute minimum hematocrit to 15%, but we prefer to maintain the hematocrit closer to 20% at all times; if the surgery involves the prone position, then a greater hematocrit might be safer.[486–490]

Technique and Key Concepts

Arterial blood is collected from the arterial line into sterile blood bags that contain the appropriate anticoagulant. Each bag is weighed before any blood is transferred and then continuously during filling by placing it on a scale. The bag is frequently but gently agitated to ensure an even distribution of the anticoagulant. The total volume of blood to be withdrawn should be calculated preoperatively to reduce the hematocrit to the 20% to 25%. Care must be taken to replace the blood removed with 5% albumin milliliter for milliliter or 1.5 to 2 mL of lactated Ringer solution for each milliliter of blood removed. Sometimes, an even greater volume of replacement fluid is needed.[557] A reasonable estimate of the adequacy of replacement is to obtain a baseline CVP and then maintain the same CVP as blood is withdrawn and replaced. It is preferable to hemodilute before the surgical incision to monitor changes in hemodynamic indices, although it can be performed during the initial phases of surgery. The major concern is to maintain a normal circulating blood volume and provide adequate oxygen-carrying capacity. It is important to make an educated guess about how much blood loss is anticipated during the surgery so that autologous blood can be reinfused in place of homologous blood. Because a small-pore filter (20-μm) traps many more platelets than a large-pore filter (≥150 μm), the former is best avoided at this juncture.

Indications

Hemodilution may be indicated in any procedure in which blood loss is expected to exceed one-half of the child's blood volume.

Contraindications

Hemodilution is contraindicated in children with sickle cell disease, septicemia, cyanotic cardiac disease, or compromised function of any major organ that may be significantly affected by changes in perfusion and oxygenation. We do not recommend combining extreme hemodilution (hematocrit <25%) with controlled hypotension. Children with moderate anemia are not good candidates because not enough units can be removed to make the technique effective.

Complications

The major complications of hemodilution are related to blood volume status, hemoglobin content (i.e., removing too much blood), and coagulopathy (i.e., dilution of clotting factors). Anesthesiologists must pay meticulous attention to blood volume replacement. As long as normovolemia is maintained and the hematocrit exceeds 20%, problems with organ perfusion or oxygenation should not occur. Sepsis becomes a concern if strict sterile techniques are not followed during the collection process.

Advantages

The benefits of normovolemic hemodilution are that the units of blood collected at the beginning of the procedure pose no risk of infection (unless contaminated by bacteria during the collection process) or mistransfusion (if they are not removed from the operating room) when they are returned to the child at a later time. It yields a net saving in loss of RBC mass because the surgical losses occur at a hematocrit of 20% rather than 40% to 45%. The net use of banked PRBCs may be reduced if 2 or 3 units can be removed at the beginning of the procedure. This technique is generally reserved for teenagers undergoing spinal instrumentation; however, with the association of blindness and anemia, fewer anesthesiologists feel comfortable with this technique.

The Jehovah's Witness Patient

The children of Jehovah's Witnesses present a particular medical and legal dilemma.[578–581] Transfusion management of anyone with a religious objection to transfusion depends in part on the urgency of the surgical procedure and underlying medical condition of the child. If not emergent, a meeting with the patient (or the parents or guardian if a minor), the patient's spiritual advisor (if the child so chooses), and representatives of the team that will be caring for the child should be held to allow the child to clearly articulate his or her wishes with respect to the refusal of transfusion and its consequences and to discuss possible alternatives, including the use of erythropoietin, iron therapy, acute normovolemic hemodilution, intraoperative cell recovery and reinfusion, and the use of antifibrinolytic medications.[575,576,582–585] Specific inquiries should be made about each child's beliefs regarding the use of albumin, plasma, cryoprecipitate, platelets, and intraoperative cell recovery and reinfusion if the circuit is not continuously connected to the child and, in particular, what the child's response would be if a life-threatening event occurred while he or she was under anesthesia.[561,586] These discussions should be carefully documented in the child's record and informed consent signed beforehand. Not all hospitals or physicians are willing to participate in these cases, in which case arrangements should be made to transfer the child to the care of institutions or physicians who are willing to work within these constraints.

The courts have consistently ruled that the adult patient or emancipated minor has a right to refuse transfusion.[562,587] Physicians have the moral and legal obligations to respect those beliefs if an adult or teenager has made an informed decision and understands that he or she may die or suffer permanent injury without a transfusion if a life-threatening situation occurs. However, in

the case of a minor child, the Supreme Courts in the United States and Canada have ruled that the fate of the minor child cannot be determined by the parents' religious convictions. The most important issue is full and open discussion of the effort that will be made to respect the person's religious beliefs and avoid blood transfusions. Optimizing the child's hemoglobin concentration is paramount for elective surgery where blood loss is anticipated. In the case of minor children about whom a mutual understanding cannot be reached on avoiding blood transfusions, a court order can be obtained to save the child's life. The parents should be informed about this possibility beforehand.[588] The ethics of this issue are discussed in Chapter 5.

ACKNOWLEDGMENT

The authors wish to thank Richard M. Dsida for his prior contributions to this chapter.

This study of children with severe anemia demonstrated that longer-stored RBCs were just as efficacious in delivering option and correcting lactic acidosis as RBCs stored for a short time and thus complements the ARIPI study that showed equivalent clinical outcomes (see Fergusson paper later in list).

Dzik WH, Stowell CP. Transfusion and coagulation issues in trauma. In: Sheridan RL, ed. *The Trauma Handbook of the Massachusetts General Hospital*. Philadelphia: Lippincott Williams & Wilkins; 2004:128-147.

This chapter discusses the issues and complications of massive transfusion and provides a practical guide for management of this difficult clinical situation.

Fergusson DA, Hébert P, Hogan DL, et al. Effect of fresh red blood cell transfusions on clinical outcomes in premature, very low-birth-weight infants: the ARIPI randomized trial. *JAMA*. 2012;308:1443-1451.

This RCT is one of four demonstrating that the duration of RBC storage does not affect patient outcomes.

Lacroix J, Hébert PC, Hutchinson JS, et al. Transfusion strategies for patients in pediatric intensive care units. *N Engl J Med*. 2007;356:1609-1619.

This landmark multicenter clinical trial compared outcomes in pediatric patients randomly assigned to red blood cell transfusion thresholds of 9.5 g/dL or 7 g/dL. There were no differences with respect to new or progressive multiple-organ failure, mortality, or other clinical outcomes between the two groups, which highlights the capacity of even acutely ill pediatric patients to tolerate anemia.

Ness PM, Cushing MM. Oxygen therapeutics: pursuit of an alternative to the donor red blood cell. *Arch Pathol Lab Med*. 2007;131:734-741.

This review provides a comprehensive and balanced summary of the development of synthetic oxygen carriers and the current challenges they face in making the transition from the laboratory to the clinic.

Slichter SJ, Kaufman RM, Assmann SF, et al. Dose of prophylactic platelet transfusions and prevention of hemorrhage. *N Engl J Med*. 2010;362:600-613.

This paper presents new data regarding platelet transfusion for nonoperative, thrombocytopenic patients including 200 children.

Cystic Fibrosis
Sickle Cell Disease
Summary

RESPIRATORY PROBLEMS ARE COMMON in children. The anesthesiologist often encounters pulmonary complications ranging from mild acute respiratory tract infections to chronic lung disease with end-stage respiratory failure during perioperative consultations, intraoperatively, or in the intensive care unit. This chapter discusses the basics of respiratory physiology, how to assess pulmonary function, and the practical anesthetic management of specific pulmonary problems. Airway and thoracic aspects pertinent to ventilation are discussed in Chapters 14 and 15; pulmonary issues specific to neonates, intensive care, and various disease states are addressed in the relevant chapters.

Respiratory Physiology

The morphologic development of the lung begins at several weeks after conception and continues into the first decade of postnatal life.[1] Intrauterine gas exchange occurs via the placenta, but the respiratory system develops in preparation for extrauterine life, when gas exchange transfers abruptly to the lungs at birth.

Development of the lung, which begins as an outgrowth of the foregut ventral wall, can be divided into several stages (Fig. 13.1). During the embryonic period, in the first few weeks after conception, lung buds form as a projection of the endodermal tissue into the mesenchyme. The pseudoglandular period extends to the 17th week of life, during which rapid lung growth is accompanied by formation of the bronchi and branching of the airways down to the terminal bronchioli. Further development of bronchioli and vascularization of the airways occurs during the canalicular stage of the second trimester. The saccular stage begins at approximately 24 weeks, when terminal air sacs begin to form. The capillary networks surrounding these air spaces proliferate, allowing sufficient pulmonary gas exchange for extrauterine survival of the premature neonate by 26 to 28 weeks. Formation of alveoli occurs by lengthening of the saccules and thinning of the saccular walls and has begun by the 36th week after conception in most human fetuses. The vast majority of alveolar formation occurs after birth, typically continuing until 8 to 10 years postnatally. At birth, the neonatal lung usually contains 10 to 20 million terminal air sacs (many of which are saccules rather than alveoli), one-tenth the number in the mature adult lung. After birth, growth of the lungs occurs primarily as an increase in the number of respiratory bronchioles and alveoli rather than an increase in the size of the alveoli.

The abrupt transition to extrauterine gas exchange at birth involves the rapid expansion of the lungs, increased pulmonary blood flow, and initiation of a regular respiratory rhythm. The development of a respiratory rhythm, detectable initially by intermittent rhythmic fetal thoracic movements, begins well before birth and may be necessary for normal anatomic and physiologic lung development. Interruption of umbilical blood flow at birth initiates continuous rhythmic breathing. Amniotic fluid is expelled from the lungs via the upper airways with the first few breaths, with residual fluid draining through the lymphatic and pulmonary channels in the first days of life. Changes in the partial pressures of oxygen (P_{O_2}) and carbon dioxide (P_{CO_2}) and in hydrogen ion concentration (pH) cause an acute decrease in pulmonary vascular resistance and a consequent increase in pulmonary blood flow. Increased left atrial and decreased right atrial pressures reverse the pressure gradient across the foramen ovale, causing functional closure of this left-to-right one-way flap valve. Ventilatory rhythm is augmented and maintained in part by the increased arterial oxygen relative to the prior intrauterine levels.

Breathing is controlled by a complex interaction involving input from sensors, integration by a central control system, and output to effector muscles.[2] Afferent signaling is provided by peripheral arterial and central brainstem chemoreceptors, upper

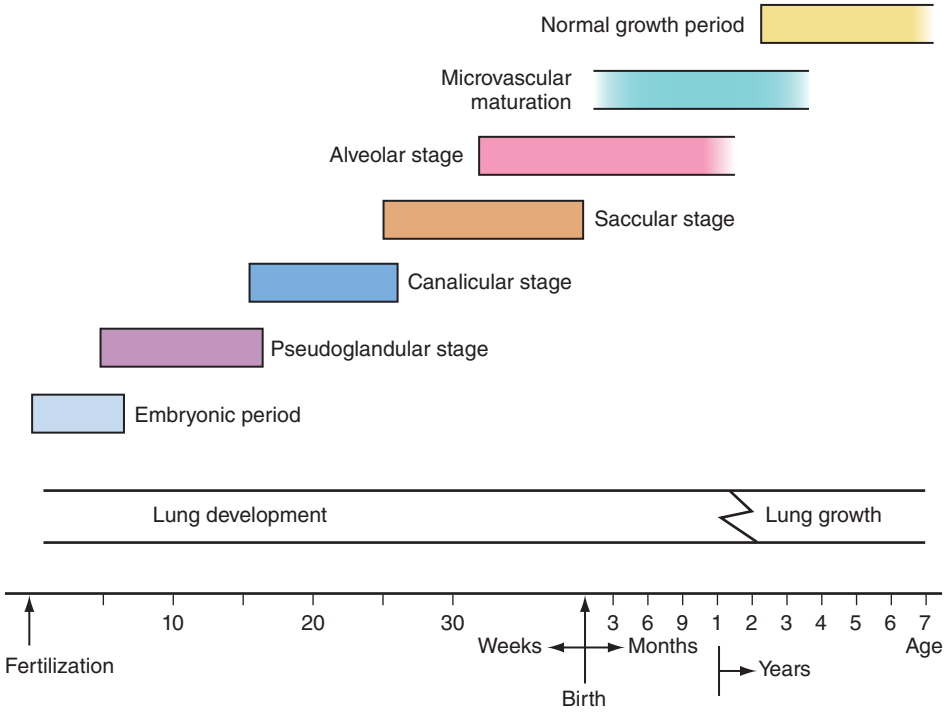

FIGURE 13.1 Timetable for lung development. (Modified with permission from Guttentag S, Ballard PL. Lung development: embryology, growth, maturation, and developmental biology. In: Tausch HW, Ballard RA, Gleason CA, eds. *Avery's Diseases of the Newborn.* 8th ed. Philadelphia: WB Saunders; 2004:602.)

airway and intrapulmonary receptors, and chest wall and muscle mechanoreceptors.

The peripheral arterial chemoreceptors consist of the carotid and aortic bodies, with the carotid bodies playing the greater role in arterial chemical sensing of both arterial O_2 tension (Pao_2) and pH. The central chemoreceptors, responsive to arterial CO_2 tension ($PaCO_2$) and pH, are thought to be located at or near the ventral surface of the medulla.

The nose, pharynx, and larynx have a wide variety of pressure, chemical, temperature, and flow receptors that can cause apnea, coughing, or changes in ventilatory pattern. Pulmonary receptors lie in the airways and lung parenchyma. The airway receptors are subdivided into the slowly adapting receptors, also called pulmonary stretch receptors, and the rapidly adapting receptors. The stretch receptors, found in the airway smooth muscle, are thought to be involved in the balance of inspiration and expiration. These receptors may be the sensors in the Hering-Breuer reflexes, which prevent overdistention or collapse of the lung. The rapidly adapting receptors lie between the airway epithelial cells and are triggered by noxious stimuli such as smoke, dust, and histamine. Parenchymal receptors, also known as juxtacapillary receptors, are located adjacent to the alveolar blood vessels; they respond to hyperinflation of the lungs, to various chemical stimuli in the pulmonary circulation, and possibly to interstitial congestion. Chest wall receptors include mechanoreceptors and joint proprioreceptors. Mechanoreceptors in the muscle spindle endings and tendons of respiratory muscles sense changes in length, tension, and movement.

Central integration of respiration is maintained by the brainstem (involuntary) and by cortical (voluntary) centers. Although the precise mechanism of the neural ventilatory rhythmogenesis is unknown, the pre-Bötzinger complex and the retrotrapezoid nucleus/parafacial respiratory group, neural circuits in the ventrolateral medulla, are thought to be the respiratory rhythm generators.[3] These neuron groups fire in an oscillating pattern, an inherent rhythm that is moderated by inputs from other respiratory centers. Involuntary integration of sensory input occurs in various respiratory nuclei and neural complexes in the pons and medulla that modify the baseline pacemaker firing of the respiratory rhythm generators. The cerebral cortex also affects breathing rhythm and influences or overrides involuntary rhythm generation in response to conscious or subconscious activity, such as emotion, arousal, pain, speech, breath-holding, and other activities.[2]

The effectors of ventilation include the neural efferent pathways, the muscles of respiration, the bones and cartilage of the chest wall and airway, and elastic connective tissue. Upper airway patency is maintained by connective tissue and by sustained and cyclic contractions of the pharyngeal dilator muscles. The diaphragm produces the majority of tidal volume during quiet inspiration, with the intercostal, abdominal, and accessory muscles (sternocleidomastoid and neck muscles) providing additional negative pressure. The elastic recoil of the lungs and thorax produces expiration. Inspiration is an active and expiration a passive action in normal lungs during quiet breathing. During vigorous breathing or with airway obstruction, both inspiration and expiration become active processes.

Another effect of age is a change in chest wall compliance. In adults the end-expiratory volume is equivalent to the functional residual capacity (FRC). In infants the chest wall is more compliant, so the tendency of the lung to collapse is not adequately counterbalanced by chest wall rigidity. Infants stop expiration at a lung volume greater than FRC, with the inspiratory muscles braking expiration. When this braking mechanism is impaired, as occurs with general anesthesia, the infant has a tendency to develop atelectasis.

Preoperative Assessment

The preoperative assessment of the respiratory system in a child is based on the history, physical examination, and evaluation of vital signs. Because ventilation is a complex process involving many systems besides the lung, the pulmonary appraisal must also include an assessment of airway, musculoskeletal, and neurologic pathology that might affect gas exchange under anesthesia or in the postoperative period. The potential impacts of esophageal reflux and cardiac, hepatic, renal, or hematologic disease on gas exchange and pulmonary function should be considered. Further investigations, such as laboratory, radiographic, and pulmonary function studies, may be indicated if there is doubt as to the diagnosis or severity of the pulmonary disease.

Because children may be unwilling or unable to give a reliable history, parents or caregivers are often the sole source or an important supplemental source of information during initial evaluation. Risk factors in the history that are associated with an increased risk of perioperative events include a respiratory tract infection within the preceding 2 weeks, wheezing during exercise, more than three wheezing episodes in the past 12 months, nocturnal dry cough, eczema, and a family history of asthma, rhinitis, eczema, or exposure to tobacco smoke.[1,4] Viral upper respiratory tract infections (URIs) are common in children, and the time, frequency, and severity of infection should be established. If wheezing is present, the precipitating causes, frequency, severity, and relieving factors should be determined. Chronic pulmonary diseases often have a variable clinical course, and the details of acute exacerbations of chronic problems should be elicited.

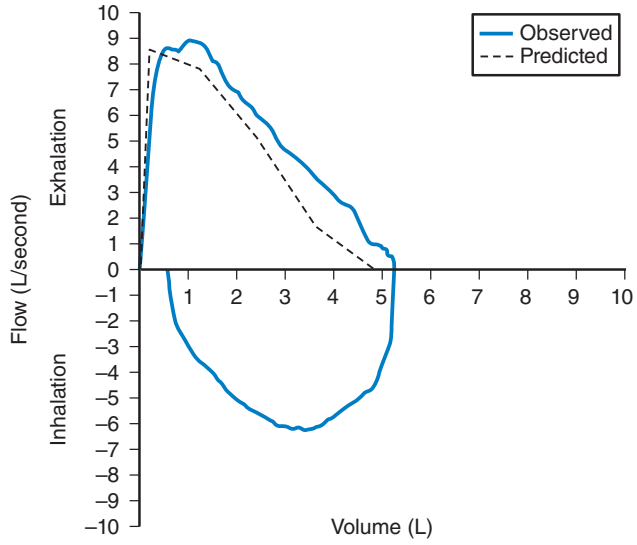
In younger children the gestational age at birth, the current postmenstrual age, neonatal respiratory difficulties, and prolonged intubation in the neonatal period are particularly important to ascertain. Apneic episodes, subglottic stenosis, and tracheomalacia are possible complications of prematurity and prolonged intubation that may be exacerbated in the perioperative period. Whereas congenital lesions often manifest at birth, symptoms of airway collapse or stenosis may become evident only later in life.

Physical examination begins when you enter the room. Particularly with young children, your best opportunity to observe them before they react to your presence is from across the room, and inspection from a distance can provide useful information. The respiratory rate is a sensitive marker of pulmonary problems, and scrutiny of the rate before a young child becomes agitated and hyperventilates is an important metric. Pulse oximetry is a useful baseline indicator of oxygenation. Nasal flaring, intercostal retractions, and the marked use of accessory respiratory muscles are all signs of respiratory distress. General appearance is also important. Apathy, anxiety, agitation, or persistent adoption of a fixed posture may indicate profound respiratory or airway difficulties, and intense cyanosis can also be detected from a distance. Weight may relate to pulmonary function; children with chronic severe pulmonary disease are often underweight owing to retarded growth or malnourishment, whereas severe obesity can produce airway obstruction and sleep apnea. Inspection of the chest contour may reveal hyperinflation or thoracic wall deformities.

Closer physical examination adds further information. Atopy and eczema may be associated with hyperreactive airways. Auscultation may reveal wheezes, rales, fine or coarse crepitus, transmitted breath sounds from the upper airway, altered breath sounds, or cardiac murmurs. Chest percussion can provide an estimate of the position of the diaphragm and serve as a useful marker of hyperinflation. Patience, a gentle approach, and warm hands improve diagnostic yield and patient satisfaction.

Pulmonary Function Tests

Further pulmonary investigations include chest imaging, measurement of hematocrit, arterial blood gas analysis, pulmonary function tests, and sleep studies. Special investigations are not routinely indicated preoperatively and should be reserved for cases in which the diagnosis is unclear, the progression or treatment of a disease needs to be established, or the severity of impairment is not evident. In most cases a comprehensive history and careful physical examination are adequate to establish an appropriate anesthetic plan. Before requesting a new investigation, the clinician should have a clear idea of the question the test is expected to answer and how the answer will modify anesthetic management and outcome. Many tests are difficult to perform in children who have short attention spans and who cannot sit still for any length of time. Judgment must be exercised when ordering these tests for young children, and due consideration must be given to the child's age and level of maturity and the influence of the parents.



Pulmonary function tests include dynamic studies, measurement of static lung volumes, and diffusing capacity. Pulmonary function tests enable clinicians to (1) establish mechanical dysfunction in children with respiratory symptoms, (2) quantify the degree of dysfunction, and (3) define the nature of the dysfunction as obstructive, restrictive, or mixed obstructive and restrictive.[5] Table 13.1 presents common indications for pulmonary function testing in children.

The dynamic studies, which are the most commonly used tests, include spirometry, flow–volume loops, and measurement of peak expiratory flow. Spirometry measures the volume of air inspired and expired as a function of time and is by far the most

TABLE 13.1 Uses of Pulmonary Function Studies in Children

• To establish pulmonary mechanical abnormality in children with respiratory symptoms
• To quantify the degree of dysfunction
• To define the nature of pulmonary dysfunction (obstructive, restrictive, or mixed obstructive and restrictive)
• To aid in defining the site of airway obstruction as central or peripheral
• To differentiate fixed from variable and intrathoracic from extrathoracic central airway obstruction
• To follow the course of pulmonary disease processes
• To assess the effect of therapeutic interventions and guide changes in therapy
• To detect increased airway reactivity
• To evaluate the risk of diagnostic and therapeutic procedures
• To monitor for pulmonary side effects of chemotherapy or radiation therapy
• To aid in predicting the prognosis and quantitating pulmonary disability
• To investigate the effect of acute and chronic disease processes on lung growth

Spirometry Parameter	Units	Predicted Value	Observed Pre	Observed Percent Pred
FVC	Liter	4.86	5.28	109
FEV_1	Liter	4.19	4.68	112
FEV_1/FVC	Percent	86	89	103

FIGURE 13.2 Normal pulmonary function test. The normal flow–volume curve obtained during forced expiration rapidly ascends to the peak expiratory flow (highest point on curve), then descends with decreasing volume, following a reproducible shape that is independent of effort. In this normal flow–volume curve, the forced vital capacity (FVC), forced expiratory volume in 1 second (FEV_1), and FEV_1/FVC ratio are all within the normal range for this child's age, height, gender, and race. The shapes of both the inspiratory and expiratory limbs are normal as well. *Pre,* prebronchodilator; *Pred,* predicted value.

frequently performed test of pulmonary function in children. With a forced exhalation after a maximal inhalation, the total volume exhaled is known as the forced vital capacity (FVC), and the fractional volume exhaled in the first second is known as the forced expiratory volume in 1 second (FEV_1). Fig. 13.2 illustrates a normal pulmonary function test (normal flow–volume loop and spirometry parameters).

An obstructive process is characterized by decreased velocity of airflow through the airways (Fig. 13.3), whereas a restrictive defect produces decreased lung volumes (Fig. 13.4). Examination of the ratio of airflow to lung volume assists in differentiating these components of lung disease. Normally, a child should be able to exhale more than 80% of the FVC in the first second. Children with obstructive lung disease have decreased airflow in relation to exhaled volume. If the volume exhaled in the first second divided by the volume of full exhalation (FEV_1/FVC) is less than 80%, then airway obstruction is present (Table 13.2; Fig. 13.3).

The FEV_1 needs to be interpreted in the context of the FVC. A small FEV_1 alone is insufficient evidence on which to make a diagnosis of airflow obstruction. Those with restrictive lung disease have both decreased FEV_1 and FVC–decreased flow rate and reduced total exhaled volume. Restrictive lung disease is associated with a loss of lung tissue or a decrease in the lung's ability to expand. A restrictive defect is diagnosed when the FVC is less than 80% of normal with either a normal or an increased FEV_1/FVC (see Table 13.2 and Fig. 13.4).

Most children with respiratory problems have an obstructive pattern; isolated restrictive diseases are far less common. Asthma

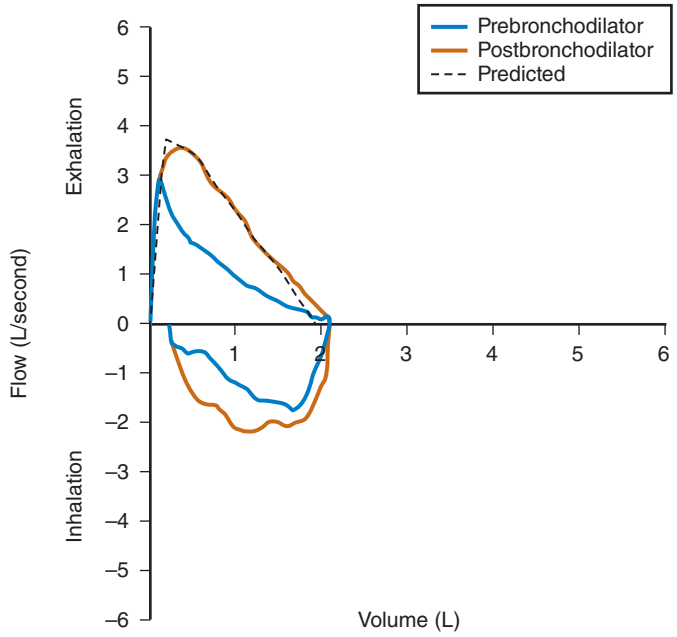
TABLE 13.2 Characteristics of Obstructive and Restrictive Patterns of Lung Disease

	DISEASE CATEGORY	
Measurement	**Obstructive**	**Restrictive**
FVC	Normal/decreased	Decreased
FEV_1	Decreased	Decreased
FEV/FVC	Decreased	Normal

FEV_1, forced expiratory volume in 1 second; *FVC,* forced vital capacity.

is the most common obstructive pulmonary disease in children. Rare causes of obstruction include airway lesions, congenital subglottic webs, and vocal cord dysfunction. Restrictive lung disease can arise from limitations to chest wall movement, such as chest wall deformities, scoliosis, or pleural effusions, or from space-occupying intrathoracic pathology such as large bullae or congenital cysts. Alveolar filling defects (e.g., lobar pneumonia) also reduce lung volume and can be considered as restrictive processes. Although the diseases arise from specific isolated genetic disorders, children with cystic fibrosis (CF) and sickle cell disease (SCD) can have highly variable pulmonary pathologic processes with both obstructive and restrictive components of lung disease. Bronchopulmonary dysplasia may also result in both obstructive and restrictive pathology.

Pulmonary function tests can also be used to differentiate fixed from variable airway obstruction and to localize the obstruction as above or below the thoracic inlet (Figs. 13.5 through 13.7, E-Fig. 13.1). This information can be gleaned from distinctive changes in the configuration of the flow–volume loop, a graphic representation of inspiratory and expiratory flow volumes plotted against time. A fixed central airway obstruction, such as a tumor or stenosis, may obstruct both inspiration and expiration, flattening the flow–volume curve on both inspiration and expiration (see Video 14.1). The child with tracheal stenosis, for example, has flattening of both inhalation and exhalation curves (see Fig. 13.6). A variable obstruction tends to affect only one part of the ventilatory cycle. On inhalation, the chest expands and draws the airways open. On exhalation, as the chest collapses, the intrathoracic airways collapse. Variable extrathoracic lesions tend to obstruct on inhalation more than exhalation, whereas variable intrathoracic lesions tend to obstruct more on exhalation. This produces the characteristic flow–volume patterns.



In addition to diagnostic uses, spirometry is used to assess the indication for, and efficacy of, treatment. For example, the obstruction in patients with asthma is usually reversible, either gradually over time without intervention or much more rapidly after treatment with a short-acting bronchodilator. An improvement in FEV_1 of 12% and 200 mL in adults or approximately 3 mL/kg is considered a positive response. In addition to confirming the diagnosis of asthma, the degree of airflow obstruction, as indicated by the FEV_1, is one measure of asthma control. A low FEV_1 or an acute decrease from baseline may indicate a child whose asthma is not under good control and therefore who potentially is at greater risk for a perioperative exacerbation (see Fig. 13.3).

Because it measures the amount of air entering or leaving the lung rather than the amount of air in the lung, spirometry cannot provide data about absolute lung volumes. Information about FRC and lung volumes calculated from FRC, such as total lung capacity and residual volume, must be obtained by different means, such as gas dilution or body plethysmography. Gas dilution is based

13

E-FIGURE 13.1 A magnetic resonance angiogram accompanies the flow loop in Fig. 13.7, demonstrating anomalous aortic anatomy compressing the trachea. (Courtesy Brian O'Sullivan, MD.)

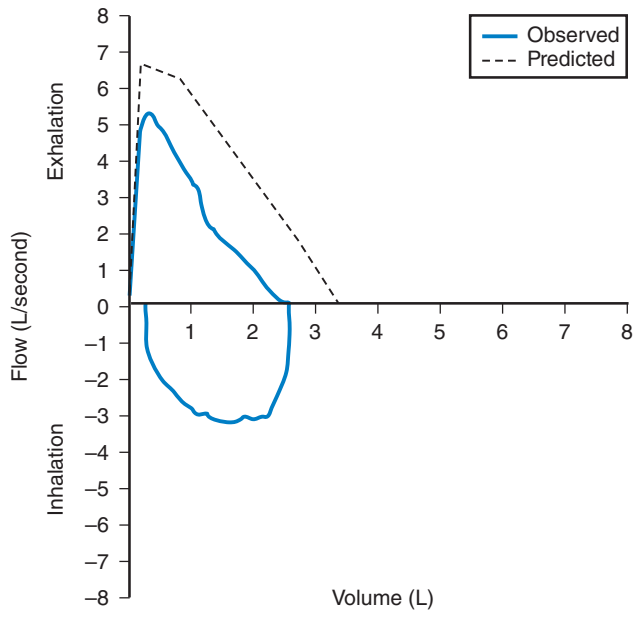
Spirometry Parameter	Units	Predicted Value	Observed Pre	Observed Percent Pred	Observed Post	Observed Percent Pred	Percent Change
FVC	Liter	1.94	2.15	111	2.14	110	0
FEV_1	Liter	1.71	1.30	76	1.82	106	40
FEV_1/FVC	Percent	90	60	67	85	94	42

FIGURE 13.3 This flow–volume curve demonstrates a reversible obstructive defect. The forced expiratory volume in 1 second (FEV_1) as a percentage of forced vital capacity (FVC), or total volume exhaled, is decreased in patients with airway obstruction. The observed curve shape before bronchodilator use *(blue curve)* is scooped. After administration of a short-acting bronchodilator, the observed curve shape *(brown)* appears normal, and there is an increase in both FEV_1/FVC and FEV_1. This child has asthma and demonstrates a marked (40%) increase in FEV_1 after treatment with a short-acting bronchodilator. Reversible airflow obstruction is one of the hallmarks of asthma. *Post,* postbronchodilator; *Pre,* prebronchodilator; *Pred,* predicted value.

on measuring the dilution of nitrogen or helium in a circuit in closed connection to the lungs, whereas body plethysmography calculates lung gas volumes based on changes in thoracic pressures.

Perioperative Etiology and Epidemiology

Respiratory problems account for most of the perioperative morbidity in children[6,7] and cause almost one-third of perioperative pediatric cardiac arrests.[8] Adverse events include laryngospasm, airway obstruction, bronchospasm, hemoglobin oxygen desaturation, prolonged coughing, atelectasis, pneumonia, and respiratory failure.[4,9-11] The incidence of perioperative adverse respiratory events in one study of 755 children was 34%,[9] whereas in another observational study of 9297 children it was 15%.[4] The triggers of these problems included airway manipulation, alteration of airway reflexes by anesthetic drugs, surgical insult, and depression of breathing caused by anesthetic and analgesic medications. Various pulmonary diseases common among children can further affect the frequency of perioperative respiratory complications; one retrospective study identified obesity as an additional risk factor.[11]



Studies have consistently reported greater respiratory morbidity among younger compared with older children.[4,6,7,11-14] In particular, neonates are sensitive to respiratory problems for many reasons. Although the FRC approaches adult capacity (in liters per kilogram) within days after birth, a persistently large closing capacity increases the likelihood of alveolar collapse and intrapulmonary shunt. Residual patency of the ductus arteriosus can also contribute to shunting. The greater metabolic rate of the infant increases oxygen requirements and decreases the time to arterial desaturation after an interruption to ventilation and gas exchange. The work of breathing is also greater in young infants as a result of high-resistance, small-caliber airways, increased chest wall compliance, and reduced lung parenchymal compliance.

UPPER RESPIRATORY TRACT INFECTION

Upper respiratory tract infections (URIs) are a common problem among young children. Children are typically infected several times a year, possibly even more frequently if they are in day care. Viruses cause the majority of URIs, with rhinoviruses constituting approximately one-third to one-half of etiologic species[15,16]; other common childhood respiratory viruses include adenoviruses and coronaviruses.

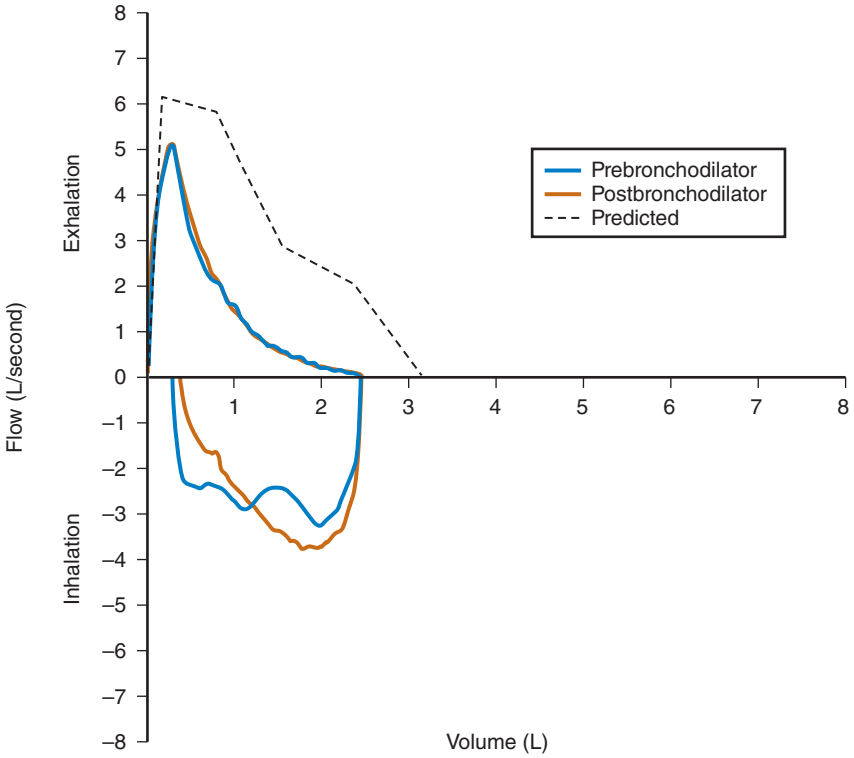
Although most URIs are short-lived, self-limited infections and are by definition limited to the upper airway, they may increase airway sensitivity to noxious stimuli or secretions for several weeks after the infection has cleared. The mechanisms probably involve a combination of mucosal invasion, chemical mediators, and altered neurogenic reflexes.[15] URIs may also impair pulmonary function by decreasing FVC, FEV_1, peak expiratory flow, and diffusion capacity.[17,18]

Children with a recent or current URI have an increased incidence of perioperative laryngospasm, bronchospasm, arterial hemoglobin desaturation, severe coughing, and breath holding compared with uninfected children (Table 13.3).[4,13,14,19-22] However, most complications can usually be predicted and successfully managed without long-term sequelae by suitably experienced and prepared clinicians.[15,20,22-25] An approach to the child with a URI is to detect the pathologic process and associated comorbidity, establish the acuteness and severity of the URI, and then decide whether to modify the anesthetic technique or postpone surgery (Table 13.4, Fig. 13.8).

Spirometry Parameter	Units	Actual	Predicted	Percent Pred
FVC	Liter	2.59	3.34	77
FEV_1	Liter	2.14	3.00	71
FEV_1/FVC	Percent	83	92	90

FIGURE 13.4 Flow–volume curve demonstrating a restrictive defect. The flow–volume curves in children with restrictive defects are near-normal in configuration but smaller in all dimensions. The ratio of forced expiratory volume in 1 second (FEV_1) to forced vital capacity (FVC) is normal, but both FEV_1 and FVC are reduced. The curve shape appears normal. This child has interstitial lung disease. *Pred,* predicted value.

The basis for diagnosing a URI is a careful history and physical examination, with further investigations in limited situations. Because they are usually familiar with their child's state of health, the parents or caregivers can provide helpful insight into the presence and severity of a URI. The child should be evaluated for fever (defined as a temperature >100.4°F [38°C]), change in demeanor or behavior, dyspnea, productive cough, purulent sputum production, nasal congestion, rales, rhonchi, and wheezing. A chest radiograph may be considered if the pulmonary examination is questionable, but because the radiographic changes lag behind clinical symptoms, it is typically of limited value. Although laboratory tests may confirm the diagnosis of a viral or bacterial URI, they are not cost-effective or practical in a busy surgical setting.



For children with symptoms of an uncomplicated URI who are afebrile with clear secretions and who are otherwise healthy, anesthesia may proceed as planned, because the problems encountered are typically transient and easily managed.[4,15,20,22-25] Elective surgery is usually postponed for children with more severe symptoms that include at least one of the following: ***mucopurulent secretions***; ***lower respiratory tract signs*** (e.g., wheezing) that do not clear with a deep cough; ***pyrexia*** >100.4°F (38°C); or a ***change in sensorium*** (e.g., not behaving or playing normally, has not been eating properly).[15,25]

The decision to proceed with surgery becomes much more difficult when the signs of the URI are between the extremes of mild and severe. For these intermediate URIs, other considerations play a greater role in assessing the risk/benefit ratio. These include the presence of comorbidities such as asthma, cardiac disease, or obstructive sleep apnea; a history of prematurity; the frequency of URIs; prior cancellations; the type, complexity, duration, and urgency of the surgery; the age of the child; and the socioeconomic implications for the family. The comfort level and experience of the anesthesiologist may also be an underestimated but important factor in the decision to proceed with or postpone surgery, because less experienced anesthesiologists have a greater incidence of complications.[4] The need to admit a child postoperatively because of anesthetic complications or an exacerbation of the URI may expose other children to a contagious illness.

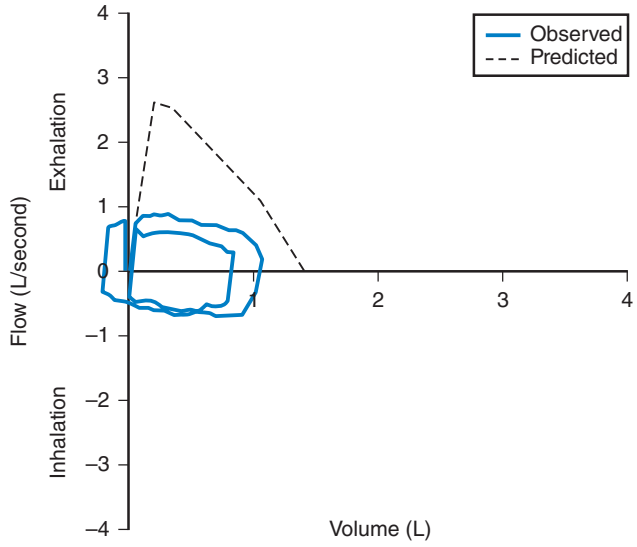

FIGURE 13.5 Pulmonary function test demonstrating a nonreversible obstructive defect. The ratio of forced expiratory volume in 1 second *(FEV_1)* to forced vital capacity *(FVC)* is decreased, as is the FEV_1. After administration of a short-acting bronchodilator, there is no significant improvement in the FEV_1, in contrast to the pattern in Fig. 13.3. This child has cystic fibrosis with a nonreversible obstructive defect. *Post,* postbronchodilator; *Pre,* prebronchodilator; *Pred,* predicted value.

If the decision is to proceed with general anesthesia, management is directed toward avoiding stimulation of the potentially sensitized airway. Use of an endotracheal tube (ETT) should be avoided, when possible, because it increases the risk of complications, especially in younger children.[4,20] Although managing the airway with a face mask holds the smallest frequency of airway complications,[4] it may be inappropriate for certain cases. The laryngeal mask airway (LMA) is associated with fewer episodes of respiratory events than the ETT, but its use may similarly be contraindicated by the type of surgical procedure and the need to protect the airway from pulmonary aspiration of gastric contents.

Whichever airway technique is chosen, it is essential that the depth of anesthesia be adequate to obtund airway reflexes during placement of an airway device. The optimal depth of anesthesia at which to remove an airway device is less clearly defined. The frequency of emergence complications after awake and deep extubation appears to be similar in children with and without an URI.[4,14,20,26] In contrast the incidence of arterial oxygen desaturation and coughing after removal of the ETT or LMA in awake children was greater.[27,28]

The optimal time when an anesthetic can be given to a child after a URI without increasing the risk of adverse respiratory events remains contentious, but most clinicians wait 2 to 4 weeks after resolution of the URI before proceeding.[4,14,29] This reflects a balance of three critical factors: the time interval to diminish both upper and lower airway hyperreactivity; the perioperative respiratory risk, which includes a recurrence of the URI; and the need to perform the procedure.

The incidence of laryngospasm after maintenance of anesthesia with propofol was significantly less than with sevoflurane in an observation study of more than 9000 children.[4] One might attribute this finding to a differential effect of propofol versus sevoflurane on airway reflexes.[30] The effects of spraying the vocal cords with lidocaine on the incidence of laryngospasm and bronchospasm are unclear.[4] However, after applying topical lidocaine gel lubricant to the LMA in children with URIs, the frequency of adverse airway events was significantly less than without lidocaine lubricant.[31] Prophylactic treatment with glycopyrrolate, ipratropium, or albuterol does not affect the incidence of URI-related adverse events,[32,33] although one observational study reported that prophylactic salbutamol reduced perioperative airway sequelae in children with URIs.[34] Nasal vasoconstrictors (such as phenylephrine or oxymetazoline nose drops) have been recommended for reducing oropharyngeal secretions in children with URIs, but their efficacy remains anecdotal.[25]

Spirometry Parameter	Units	Predicted Value	Observed Pre	Observed Percent Pred

LOWER AIRWAY DISEASE

Acute lower respiratory tract infections in infants and children may result in rapid deterioration necessitating aggressive intervention, including tracheal intubation and ICU admission. Many children are treated with antibiotics on the presumption that the infection is bacterial. However, many may be affected by viruses. In infants and children up to 18 months of age, respiratory syncytial virus is a very serious and common viral infection that infects the lower respiratory tract.[35] Other viruses that also infect the lower respiratory tract include parainfluenza virus, adenovirus, and human metapneumovirus.[36] Acute inflammation of the small airways may result in bronchiolitis with edema of the small airways leading to desaturation, hypercapnia, and acute respiratory failure. Bronchiolitis management can involve several days of continuous positive airway pressure (CPAP), high-flow nasal prongs, or tracheal intubation until the acute infection has resolved.

Croup or laryngotracheobronchitis, defined as acute inflammation of the airway (below the vocal cords), has been attributed primarily to parainfluenza virus as well as to adenovirus.

Asthma is one of the most common chronic diseases of childhood, affecting an estimated more than 6 million children in the United States.[37,38] A history of wheezing is associated with an increased risk of perioperative bronchospasm.[4] Rare perioperative complications associated with asthma include anaphylaxis, adrenal crisis, and ventilatory barotrauma such as pneumothorax or pneumomediastinum.[39] An anesthetic approach to children with asthma should include a basic understanding of the disease, an assessment of the child's current state of health, modification of anesthetic technique as appropriate, and recognition and treatment of complications if they occur.

(Modified from Tait AR, Malviya S. Anesthesia for the child with an upper respiratory tract infection: still a dilemma? *Anesth Analg.* 2005;100:59–65.)

It is difficult to define asthma with precision because the exact pathophysiology remains unclear. The word *asthma* derives from the Greek *aazein,* which means "to breathe with open mouth or to pant."[40] A working definition of asthma is a common chronic disorder of the airways that is complex and characterized by variable and recurring symptoms, airway obstruction, inflammation, and hyperresponsiveness of the airways.[37]

Clinical expressions of asthma include wheezing, chest tightness or discomfort, persistent dry cough, and dyspnea on exertion. Severe respiratory distress can occur during acute exacerbations and may be characterized by chest wall retraction, use of accessory muscles, prolonged expiration, pneumothorax, and progression to respiratory failure and death. In some children the development of chronic inflammation may be associated with permanent airway changes, referred to as *airway remodeling*, that are not prevented by or fully responsive to current available treatments. There is a strong association between asthma and atopy, or immunoglobulin E (IgE)-mediated hypersensitivity.[37]

The diagnosis of asthma can be challenging because cough, wheezing, and bronchospasm may arise from many disease processes. Asthma itself is unlikely to be a single disease entity, and the disease process is markedly modified by various genetic and environmental factors.[37,40] Many young children wheeze, and there is no definitive confirmatory blood, histologic, or radiographic

diagnostic test. Given the difficulty with diagnosis, the label "preschool wheezers" may be a more appropriate description for young children with reversible airway obstruction than a diagnosis of "asthma."[40]

The Tucson birth cohort study was the largest longitudinal study in the United States to attempt to differentiate wheezing or asthma phenotypes in children who did not subsequently develop asthma.[41-43] This study examined 826 children at ages 3 years and 6 years from a cohort of 1246 neonates. By the age of 6 years, 48.5% of the children had experienced at least one documented episode of wheezing and were categorized into three groups. "Transient wheezers" were children who wheezed only in response to viral infections, typically during the first 3 years of life. "Non-atopic wheezers" were children who wheezed beyond the first few years of life, often in response to viral infections, but who were less likely to persistently wheeze in later childhood. "Atopy-associated wheezers" were children who had a reversible wheeze together with a tendency toward IgE-mediated hypersensitivity; they had the greatest risk of persistent symptoms into late childhood and adulthood.[41]

The development of asthma is a complex process that probably involves the interaction of two crucial elements: host factors (specifically genetic modifiers of inflammation) and environmental exposures (e.g., viral infections, environmental allergens, pollution) that occur during a crucial time in the development of the immune system.[37] Therefore, the population of young children who wheeze includes a spectrum of disorders rather than one specific pathologic process.

Asthma must be differentiated from other distinct causes that produce similar symptoms (Table 13.5). Tracheomalacia or bronchomalacia may produce wheezing, but this tends to be present from birth (which is unusual for asthma), and the wheezing is commonly of a single pitch heard loudest in the central airways, whereas asthma typically produces polyphonic sounds from the lung periphery. Breathing difficulties owing to chronic aspiration are often related to feeding times. Unremitting wheeze or stridor is often caused by a fixed obstruction or foreign body.

Chronic cough is the most common manifestation of asthma in children. Many children who cough may never be heard to wheeze but still have asthma. A cough with or without wheeze may be caused by a viral infection, whereas a persistent, productive cough may suggest suppurative lung disease such as CF.[39] A positive response of the cough to asthma medications suggests the diagnosis of asthma.

TABLE 13.5 Causes of Wheezing in Children

Acute	
Bronchiolitis	Pneumothorax
Asthma	Endobronchial intubation
Foreign body	Herniated ETT cuff
Inhalation injury	Aspiration Anaphylaxis
Recurrent or Persistent	
Bronchiolitis	Mediastinal mass
Asthma	Tracheomalacia/bronchomalacia
Foreign body	Vascular ring
Bronchopulmonary dysplasia	
Cardiac failure	Tracheal web/stenosis
Cystic fibrosis	Bronchial stenosis
Recurrent aspiration	Roundworm infestation
Sickle cell disease	

ETT, endotracheal tube.

The exact incidence of perioperative complications in the pediatric asthma population is difficult to ascertain because of variations in the definition of asthma, the definition and detection of complications, the presence of coexisting diseases, overlap with adult populations, and changing anesthetic management techniques.

A retrospective review of 706 adult and pediatric patients with a rigorous definition of asthma reported an incidence of documented bronchospasm in the perioperative period of 1.7% and no instances of pneumonia, pneumothorax, or death.[44] Of 211 children younger than 12 years of age, none developed bronchospasm at the time of surgery. A retrospective review of more than 136,000 computer-based anesthesia records found a 0.8% incidence of bronchospasm in patients with asthma.[45] By contrast, older studies from the 1960s reported that 7% to 8% of asthmatic patients wheezed.[46,47] A blinded, prospective study of 59 asthmatic patients detected transient wheezing after tracheal intubation in 25% of cases; however, most events were brief and self-limited.[48] An observational study of 9297 children reported an overall incidence of 2% for bronchospasm; in the subgroup of 2256 children with a history of respiratory problems, the incidence was 6%.[4,39] An editorial review of the subject of asthma and anesthesia concluded that, although the true incidence of major complications is small, severe adverse outcomes do result from bronchospasm, and children with asthma are at heightened risk for severe morbidity.[49]

Both the severity and the control of asthma must be established preoperatively. These two aspects of the current disease state should be clearly differentiated.[50] For example, asthma may be severe yet well controlled, whereas even mild asthma may be poorly controlled. Both situations may present a heightened potential for perioperative complications, because even the child with intermittent but poorly controlled asthma can have a severe exacerbation.

Severity and control of asthma may be assessed by the frequency of symptoms, limitation of effort tolerance, night awakenings, medication use, emergency department attendance, hospitalizations, and need for ventilatory support. An approach to assessment of severity and control in children aged 5 to 11 years is outlined in E-Tables 13.1 through 13.3. A history of a nocturnal dry cough, more than three wheezing episodes in the past 12 months, or a history of past or present eczema is associated with an increased risk of bronchospasm.[4]

Maintenance treatment of asthma is based on a stepwise approach, so that the type of therapy is often an indication of severity. Short-acting inhaled β-agonists are first-line therapy, with inhaled corticosteroids for those patients with persistent symptoms poorly managed by bronchodilators as the preferred second step. Alternative treatments at this step include a leukotriene receptor antagonist, a mast cell stabilizer such as cromolyn sodium or nedocromil, and a methylxanthine bronchodilator such as theophylline. The third step in therapy involves increasing the dose of inhaled corticosteroid or adding an alternative treatment to a smaller dose of corticosteroid; a long-acting β-agonist, a leukotriene receptor antagonist, or theophylline may be considered. Step 4 involves a medium dose of corticosteroid together with a long-acting β-agonist. The final steps of therapy involve a high dose of inhaled corticosteroid or commencing an oral corticosteroid (E-Fig. 13.2). Recently biologics directed at the basic pathophysiology of asthma offer the hope of personalized medicine.[51] Such medicines include

E-TABLE 13.1 Classification of Asthma Severity in Children 5 to 11 Years of Age Who Are Not Currently Taking Long-Term Control Medication

Components of Severity[a]	Intermittent Asthma	PERSISTENT ASTHMA		
		Mild	*Moderate*	*Severe*
Impairment				
Symptoms	≤2 days/week	>2 days/week but not daily	Daily	Throughout the day
Nighttime awakenings	≤2 times/month	3–4 times/month	>1 time/week but not nightly	Often 7 times/week
Short-acting β_2-agonist use for symptom control (not prevention of EIB)	≤2 days/week	>2 days/week but not daily	Daily	Several times per day
Interference with normal activity	None	Minor limitation	Some limitation	Extremely limited
Lung function	Normal FEV_1 between exacerbations			
	FEV_1 ≥80% predicted	FEV_1/FVC >80%	FEV_1 = 60%–80% predicted	FEV_1 <60% predicted
	FEV_1/FVC >85%	FEV_1 ≥80% predicted	FEV_1/FVC = 70%–80%	FEV_1/FVC <75%
Risk				
Exacerbations[b] requiring oral systemic corticosteroids	0–2/year	≥2 in 1 year		
	Consider severity and interval since last exacerbation. Frequency and severity may fluctuate over time for patients in any severity category.			
	Relative annual risk of exacerbations may be related to FEV_1.			

[a]Level of severity is determined by both impairment and risk. Assess impairment domain by patient or caregiver recall of the previous 2 to 4 weeks and results of spirometry. Assign severity to the most severe category in which any feature occurs.
[b]Exacerbation is defined as an acute episode of signs and symptoms requiring oral systemic corticosteroids. More than two exacerbations per year indicates persistent asthma. There are no data indicating correspondence of frequency of exacerbations with severity category within the classification of persistent asthma. In general, more frequent exacerbations and more intense exacerbations (e.g., requiring urgent, unscheduled care hospitalization or admission to an intensive care unit) indicate greater underlying disease severity.
EIB, exercise-induced bronchospasm; *FEV_1,* forced expiratory volume in 1 second; *FVC,* forced vital capacity.

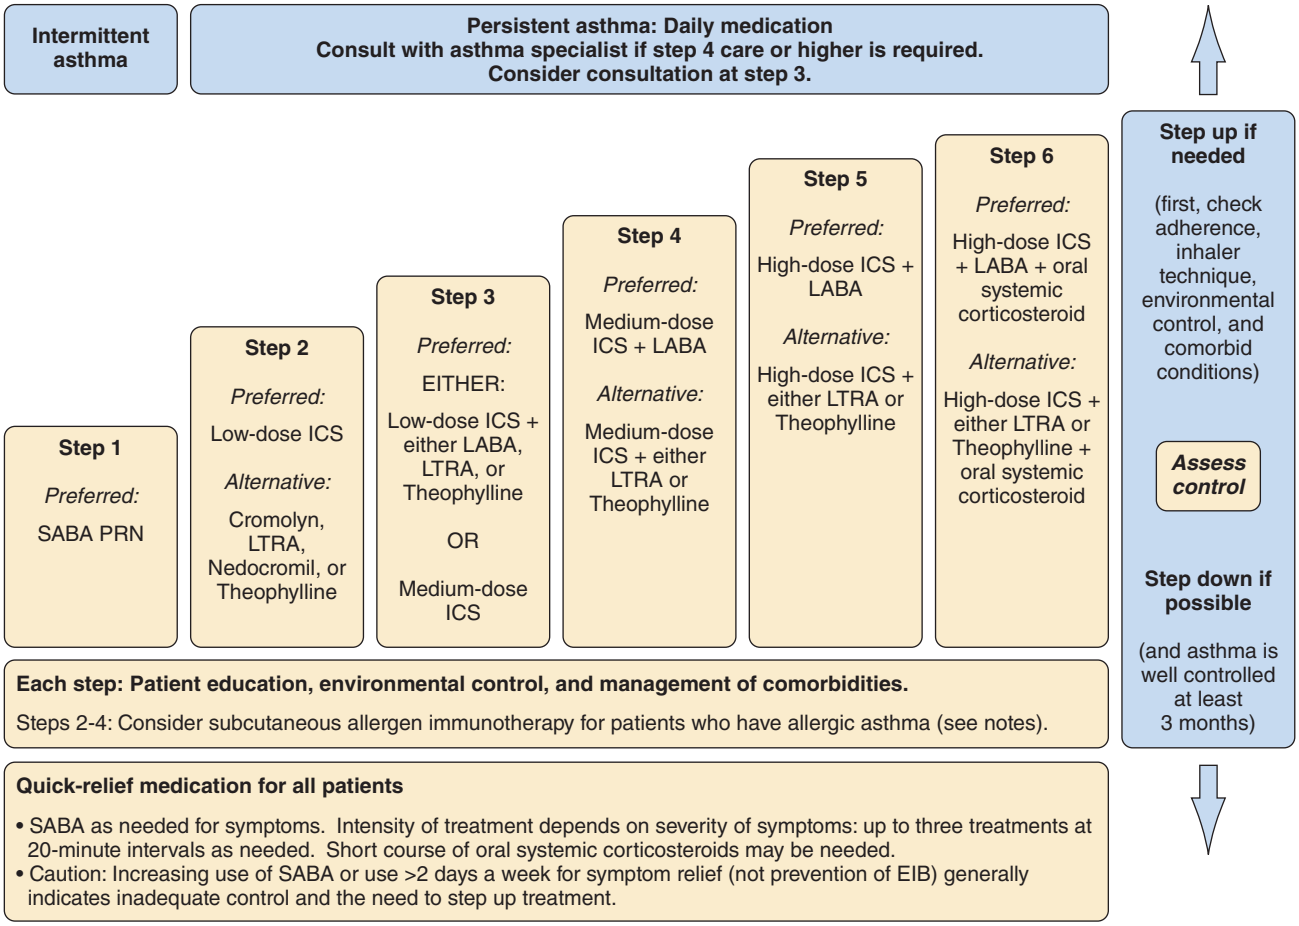
E-TABLE 13.2 Classification of Severity After Asthma Becomes Well Controlled, by Lowest Level of Treatment Required to Maintain Control

	Intermittent Asthma	PERSISTENT ASTHMA		
		Mild	*Moderate*	*Severe*
Lowest level of treatment required to maintain control[a]	Step 1	Step 2	Step 3 or 4	Step 5 or 6

[a]See E-Fig. 13.2 for treatment steps. Reproduced from National Asthma Education and Prevention Program. Full report of the expert panel: guidelines for the diagnosis and management of asthma (EPR-3). Bethesda, MD: National Heart, Lung, and Blood Institute, National Institutes of Health; 2007.

E-TABLE 13.3 Assessment of Asthma Control in Children 5 to 11 Years of Age



Components of Control[a]	Well Controlled	Not Well Controlled	Very Poorly Controlled
Impairment			
Symptoms	≤2 days/ week but not more than once on each day	>2 days/ week or multiple times on <2 days/week	Throughout the day
Nighttime awakenings	≤1 time/ month	>2 times/ month	>2 times/ week
Interference with normal activity	None	Some limitation	Extremely limited
Short-acting β_2-agonist use for symptom control (not prevention of EIB)	≤2 days/ week	≥2 days/ week	Several times per day
Lung function			
FEV_1 or peak flow	>80% predicted/ personal best	60%–80% predicted/ personal best	<60% predicted/ personal best
FEV_1/FVC	>80% predicted	75%–80% predicted	<75% predicted
Risk			
Exacerbations[b]	0–1/year	2–3/year	>3/year
Reduction in lung growth	Evaluation requires long-term follow-up.		
Treatment-related adverse effects	Medication side effects can vary in intensity from none to very troublesome and worrisome. The level of intensity does not correlate to specific levels of control but should be considered in the overall assessment of risk.		

[a]The level of control is based on the most severe impairment or risk category. Assess impairment domain by patient or caregiver recall of previous 2 to 4 weeks and by spirometry or peak flow measures. Symptom assessment for longer periods should reflect a global assessment, such as inquiring whether the patient's asthma is better or worse since the last visit.

[b]Exacerbation is defined as an acute episode of signs and symptoms requiring oral systemic corticosteroids.

EIB, exercise-induced bronchospasm; *FEV_1*, forced expiratory volume in 1 second; *FVC*, forced vital capacity

Reproduced from National Asthma Education and Prevention Program. Full report of the expert panel: guidelines for the diagnosis and management of asthma (EPR-3). Bethesda, MD: National Heart, Lung, and Blood Institute, National Institutes of Health; 2007.

Key: **Alphabetical order is used when more than one treatment option is listed within either preferred or alternative therapy.** *ICS,* Inhaled corticosteroid; *LABA,* inhaled long-acting beta$_2$-agonist; *LTRA,* leukotriene receptor antagonist; *SABA,* inhaled short-acting beta$_2$-agonist

Notes:

- The stepwise approach is meant to assist, not replace, the clinical decision making required to meet individual patient needs.
- If alternative treatment is used and response is inadequate, discontinue it and use the preferred treatment before stepping up.
- Theophylline is a less desirable alternative due to the need to monitor serum concentration levels.
- Step 1 and 2 medications are based on Evidence A. Step 3 ICS + adjunctive therapy and ICS are based on Evidence B for efficacy of each treatment and extrapolation from comparator trials in older children and adults—comparator trials are not available for this age group; steps 4-6 are based on expert opinion and extrapolation from studies in older children and adults.
- Immunotherapy for steps 2-4 is based on Evidence B for house-dust mites, animal danders, and pollens; evidence is weak or lacking for molds and cockroaches. Evidence is strongest for immunotherapy with single allergens. The role of allergy in asthma is greater in children than in adults. Clinicians who administer immunotherapy should be prepared and equipped to identify and treat anaphylaxis that may occur.

E-FIGURE 13.2 Stepwise approach for managing asthma in children 5 to 11 years of age. (Reproduced from National Asthma Education and Prevention Program. Full report of the expert panel: guidelines for the diagnosis and management of asthma [EPR-3]. Bethesda, MD.: National Heart, Lung, and Blood Institute, National Institutes of Health; 2007.)

omalizumab which is directed against IgE and mepolizumab and reslizumab directed against interleukin 5.

Most children with asthma have disease that is intermittent or persistent but mild and will be treated with inhaled short-acting β-agonists on an as-needed basis, alone or in combination with low-dose inhaled corticosteroids or an adjunctive therapy. Poor control may relate to poor compliance with medication, inadequate inhaler technique, or incorrect diagnosis. Severe asthma is diagnosed when symptom control is poor despite high doses of corticosteroids (see steps 5 or 6 in E-Fig. 13.2). A small group of children have "brittle asthma" that is difficult to control despite optimal therapy and may lead to life-threatening respiratory compromise. A history of severe attacks or admission to intensive care is particularly ominous.

Special investigations are not routinely indicated but may be useful in specific circumstances. A chest radiograph is not usually helpful to assess the severity of asthma but can help diagnose a superimposed infection, pneumothorax, or pneumomediastinum during an acute exacerbation. Pulmonary function tests are important in monitoring long-term responses to therapy but are of little use in the immediate, routine preoperative workup of cases at a stable clinical baseline. Measurements of nitric oxide and various inflammatory markers are primarily of use as research tools at present, but their role in asthma management is evolving.[52]

Although an assessment of disease severity is essential, an important caveat is that many asthma deaths in the community setting occur not in those with severe disease but in those with what was thought to be mild or moderate disease. Asthma is often undertreated,[50] so the sensitivity of medication prescription as a marker of disease activity must be viewed with some caution. Some studies have found a poor correlation between assessment of disease severity and the occurrence of perioperative bronchospasm. However, disease *activity*, as noted by recent asthma symptoms, use of medications for symptom treatment, and recent therapy in a medical facility for asthma, is significantly associated with perioperative bronchospasm.[44]

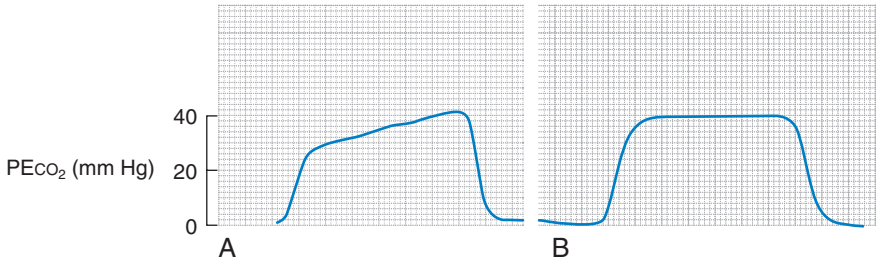
Children should continue their regular medications before anesthesia. Midazolam has been reported to be a safe premedication for asthmatics.[53] Corticosteroids may help prevent postintubation bronchospasm in adults,[54] although controlled clinical data to substantiate this practice in children are lacking.[39] Inhaled β-agonists before or shortly after induction of anesthesia attenuate the increases in airway resistance associated with tracheal intubation.[55,56] Ketamine is the traditional choice of intravenous (IV) induction agent in children with severe asthma, although its superiority over other agents has not been substantiated in clinical trials.[57,58] Propofol is typically preferred over thiopentone because it causes less bronchoconstriction.[48,59] Desflurane is associated with an increased risk of bronchospasm compared with sevoflurane or isoflurane, and because it can increase airway resistance in children, should be avoided in asthmatics.[4]

Tracheal stimulation is a potent stimulus for bronchospasm.[4] In children with a URI, in whom the airways may be acutely hyperactive, the avoidance of tracheal intubation is associated with a reduced incidence of pulmonary complications.[4,19] There are inadequate clinical outcome data on the perioperative management of asthma to make definitive recommendations about airway management. Nevertheless, avoidance of tracheal and vocal cord stimulation by use of a face mask or an LMA instead of an ETT whenever possible seems a sensible approach. If tracheal intubation is mandatory, a deep plane of anesthesia is preferred to blunt airway hyperreactivity. Similarly, unless contraindicated by other factors, deep extubation is preferred for the same reason. Surgical stimulation is another trigger of bronchospasm, and anesthetic depth and analgesia should be adequate to prevent this response.

Intraoperative bronchospasm is characterized variously by polyphonic expiratory wheeze, prolonged expiration, active expiration with increased respiratory effort, increased airway pressures, a slow upslope on the end-tidal CO_2 monitor waveform (Fig. 13.9), increased end-tidal CO_2, and hypoxemia. Other causes of wheezing must be excluded, such as partial obstruction of the ETT (secretions or herniation of the cuff causing obstruction), main-stem intubation (deep endobronchial intubation), aspiration, pneumothorax, or pulmonary edema. Mechanical obstruction of the circuit or ETT must also be excluded.

First-line treatment for bronchospasm involves removing the triggering stimulus if possible, deepening anesthesia, increasing the fraction of inspired oxygen (FIO_2) if appropriate, decreasing the positive end-expiratory pressure (PEEP), and increasing the expiratory time to minimize alveolar air trapping. In severe status asthmaticus, ventilation strategy focuses primarily on achieving adequate oxygenation, rather than attempting to normalize $PaCO_2$ at the potential cost of inducing pulmonary barotrauma. All children who experience anything more than minor bronchospasm should also receive corticosteroids, if they have not already done so.

Inhaled β-agonists can be delivered by nebulizer or by a metered-dose inhaler down the airway device with specially designed adaptors (Fig. 13.10). Alternatively, a 60-mL syringe can be used to deliver doses of the nebulizer into the breathing circuit (E-Fig. 13.3). However, the efficiency of delivery through an inhaler that is actuated at the elbow of the breathing circuit is poor, especially in small-diameter ETTs.[60] To improve the delivery efficiency of



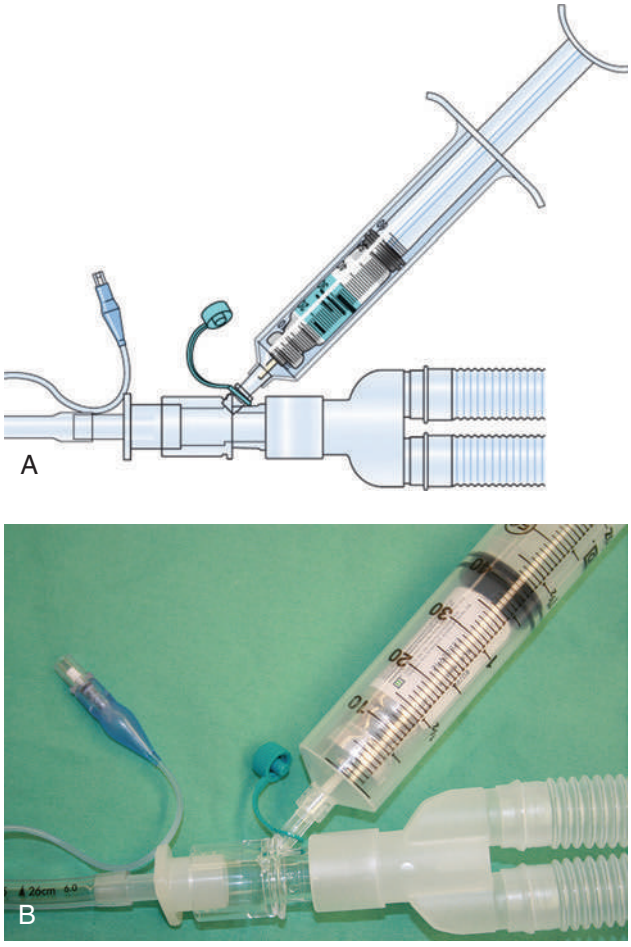


FIGURE 13.9 A, Tracing of expired carbon dioxide ($PECO_2$) in a child with acute bronchospasm. Notice the slowly rising $PECO_2$ value. **B,** Tracing from the same patient after administration of inhaled albuterol. Note that the $PECO_2$ waveform now has a flat plateau, indicating relief of the bronchospasm and efficient elimination of CO_2 from all areas of the lungs.

E-FIGURE 13.3 **A** and **B,** A 60-mL syringe may be attached to a port in the circuit to administer aerosolized drugs such as albuterol.

FIGURE 13.10 Adaptor that allows administration of albuterol through an endotracheal tube (ETT) and timing of that dose with inspirations to provide maximum delivery; notice that the nebulized albuterol is directed down the ETT *(arrow)*. Use of a long intravenous catheter that extends to the tip of the ETT is an alternative method to further improve drug delivery.

the aerosol in pediatric-size ETTs, the inhaler may be actuated 10 to 20 times at the elbow or once or twice into a narrow-gauge catheter that is passed to the end of the ETT.[60,61]

If IV salbutamol (albuterol) is available, the IV route is preferred over tracheal administration. Onset of bronchodilation in a child with acute symptoms should be rapid with good effect at a plasma salbutamol concentration of 1 µg/L.[62] Salbutamol (10 µg/kg IV) may be repeated, followed by an infusion of 5 to 10 µg/kg per minute for the first hour until there is an improvement in the bronchospasm. Thereafter, salbutamol should be infused at 1 to 2 µg/kg per minute until the bronchospasm resolves. Epinephrine (0.05-0.5 µg/kg per minute) is also an effective bronchodilator.

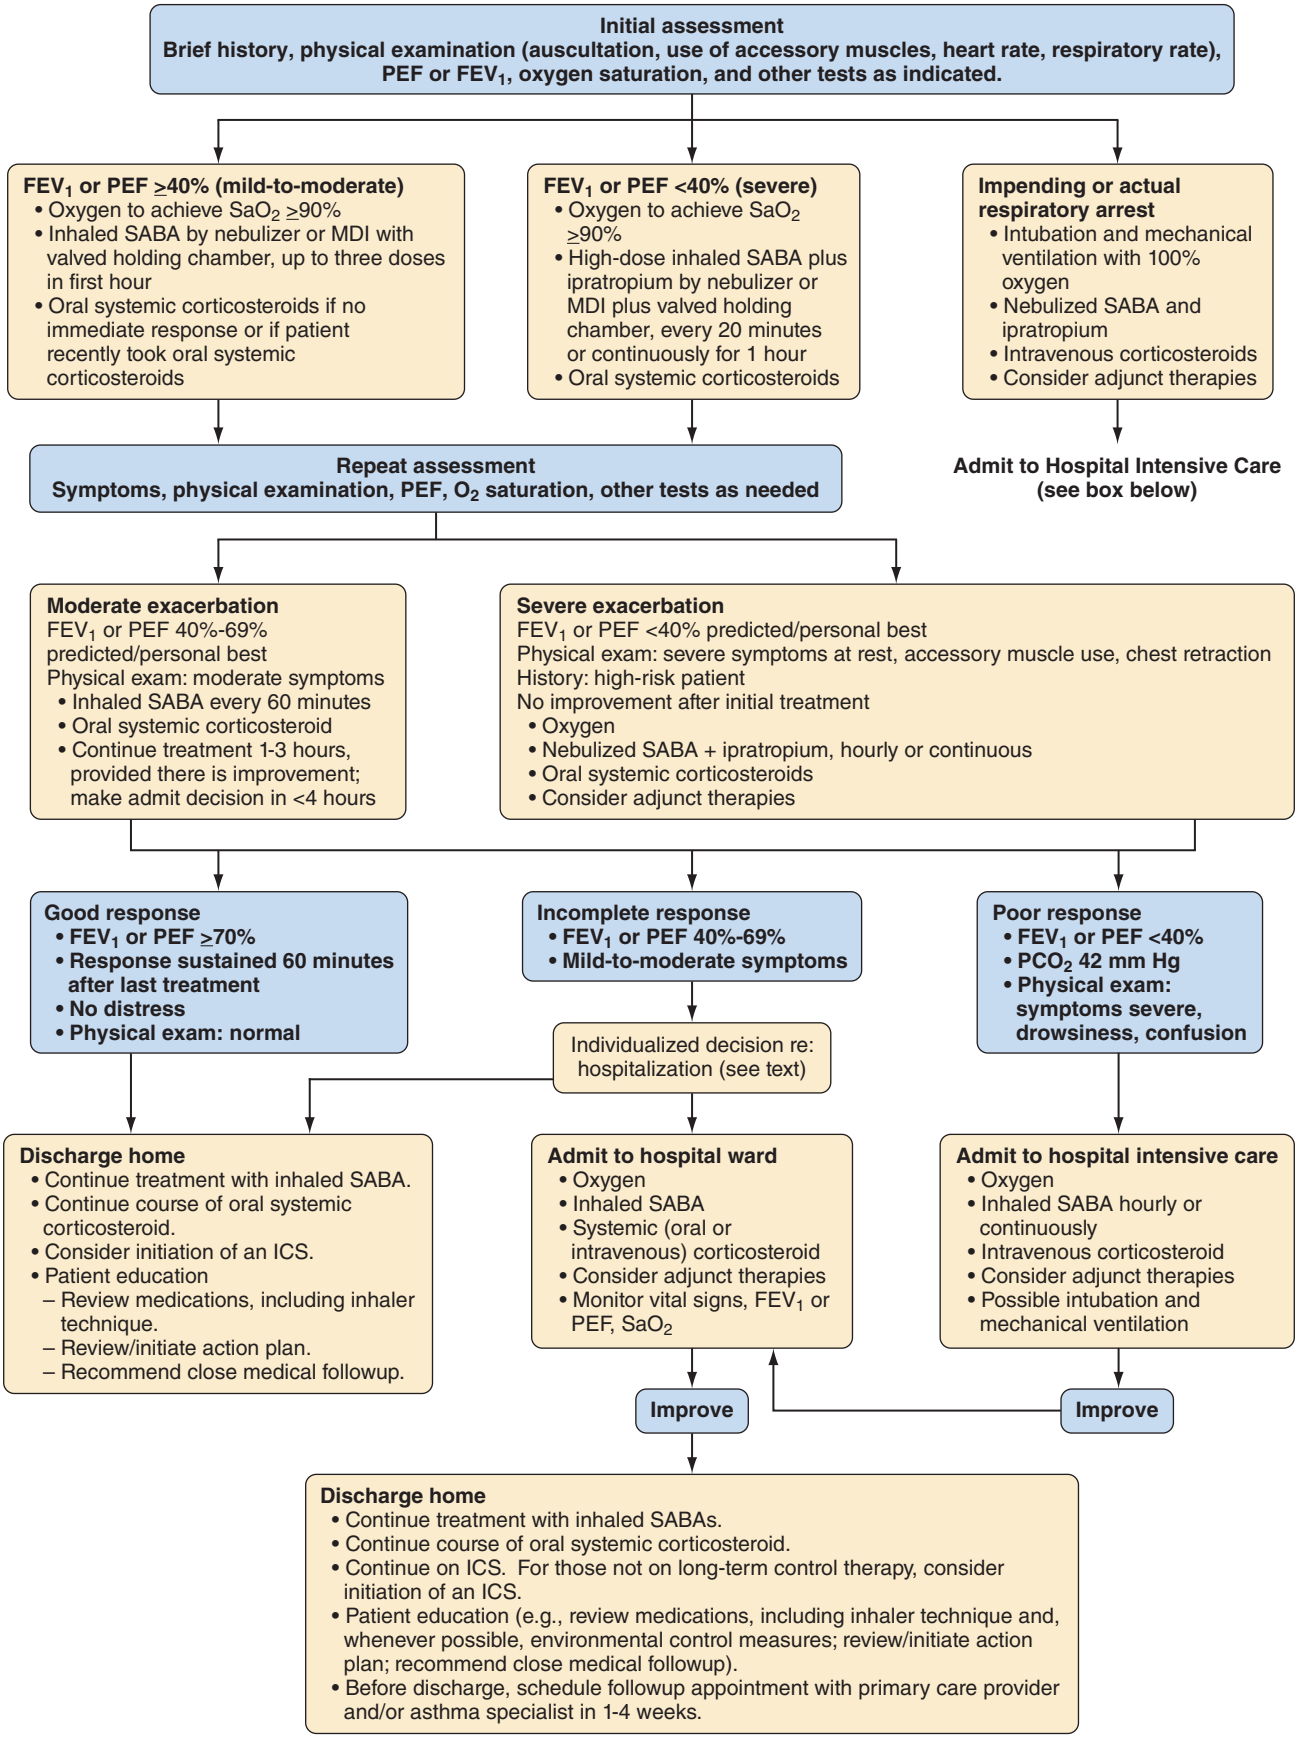
The anesthesiologist may be involved in the management of status asthmaticus when consulted to assist a child in the emergency department or on the wards. A drowsy, silent child with a quiet chest on auscultation despite therapy is in imminent danger of respiratory arrest and requires emergent tracheal intubation by an experienced practitioner. Signs and symptoms to assess the severity of an asthma exacerbation are outlined in Table 13.6, and an algorithm for management issued by the American National Heart, Lung and Blood Institute is presented in E-Fig. 13.4.

Oxygen is recommended for most children to maintain the oxygen saturation at greater than 90%. Repetitive or continuous administration of short-acting β-agonists is first-line therapy for all children and is the most effective way of reversing airflow obstruction. The addition of ipratropium to a β-agonist may produce additional bronchodilation and may have a modest effect to improve outcome. Systemic corticosteroids should be given to those who do not respond completely and promptly to β-agonists. For severe exacerbations unresponsive to the treatment listed earlier, IV magnesium may decrease the likelihood of intubation, although the evidence is limited. Current recommended drug doses are listed in E-Table 13.4.

There is much debate about the role of methylxanthines such as aminophylline in the management of acute exacerbations of asthma. In some countries, aminophylline is considered a first-line treatment for asthma, whereas in others it is considered second-line or used less frequently. The difference in practice may be attributed to its equivocal clinical efficacy in the treatment of acute exacerbations of asthma and to complications from toxicity (including vomiting).[63-66]

Antibiotics are not recommended except for comorbid conditions. Aggressive hydration is not recommended in adults or older children, although it may be indicated in younger children who become dehydrated as a result of decreased oral intake and increased respiratory rate. In general, chest physical therapy and mucolytics are also not recommended.

Children with severe atopy-associated asthma are possibly at greater risk for developing anaphylaxis in response to neuromuscular blocking drugs, antibiotics, and latex.[39] Bronchospasm caused by anaphylaxis is differentiated from that due to asthma; it produces additional systemic signs such as angioedema, flushing, urticaria, and cardiovascular collapse.



Adrenal crisis during major surgical stress is a potential complication associated with severe asthma caused by iatrogenic suppression of the hypothalamic-pituitary-adrenal axis.[39] Adrenal suppression should be considered in any child who is taking significant doses of corticosteroids for a prolonged period. Short courses of prednisolone used to treat acute flares of asthma may affect function for up to 10 days, but prolonged dysfunction is unlikely. Large doses, prolonged therapy for more than a few weeks, and evening dosing may suppress adrenal function for up to 1 year. Prophylactic corticosteroid administration may be indicated for those receiving prolonged systemic corticosteroids, when their corticosteroid regimen is interrupted by the surgical schedule, or for those who have received high-dose inhaled corticosteroids in the recent past (see Chapter 27).

CYSTIC FIBROSIS

CF is an autosomal recessive disorder that is caused by one of more than 1500 mutations in the gene coding for the CF transmembrane conductance regulator (located on chromosome 7), a protein that regulates chloride and other ion fluxes at various epithelial surfaces.[67,68] The different gene defects may variously impact the protein's translation, cellular processing, or function as a chloride channel gating. The incidence of CF is approximately 1 of every 2000 births in Caucasians, making it the most common fatal inherited disease in this population.

The disruption of electrolyte transport in the epithelial cells of the sweat ducts, airways, pancreatic ducts, intestine, biliary tree, and vas deferens causes increased sweat chloride concentrations, viscous mucus production, lung disease, intestinal obstruction, pancreatic insufficiency, biliary cirrhosis, and congenital absence of the vas deferens. The clinical outcome is widely variable, even among children with identical mutations at the CF locus. Absence of the gene influences expression of several other gene products, including proteins important to the inflammatory response, ion maturational processing, transport, and cell signaling. These other proteins are potential modifiers of the phenotype and may help explain the substantial differences in clinical severity.

Lung disease is the main cause of morbidity and mortality in CF, and consequently it is the focus of anesthetic concern. The pathophysiology involves mucus plugging, chronic infection, inflammation, and epithelial injury.[69-71] Mucus clearance defends the lung against inhaled bacteria. The mucociliary transport system requires two fully functioning layers to be effective. The base layer of ciliary epithelia bathed in a watery liquid (sol) is overlaid by a more viscous gel (mucus) that is responsible for transporting

E-FIGURE 13.4 Management of asthma exacerbations in emergency department and hospital-based care. *FEV*$_1$, forced expiratory volume in 1 second; *ICS*, inhaled corticosteroid; *MDI*, metered dose inhaler; *Pco*$_2$, partial pressure carbon dioxide; *PEF*, peak expiratory flow; *SABA*, short-acting β_2-agonist; *SaO*$_2$, oxygen saturation. Bethesda, MD: National Heart, Lung, and Blood Institute, National Institutes of Health; 2007.)

E-TABLE 13.4 Doses of Drugs for Asthma Exacerbations in Emergency Settings or Hospital

Medication	Adult Dose	Child Dose[a]	Comments
Inhaled Short-Acting β_2-Agonists			
Albuterol/Salbutamol			
Nebulizer solution (0.63 mg/3 mL, 1.25 mg/3 mL, 2.5 mg/3 mL, 5.0 mg/mL)	2.5–5 mg every 20 minutes for 3 doses, then 2.5–10 mg every 1–4 hours as needed, or 10–15 mg/hour continuously	0.15 mg/kg (minimum dose 2.5 mg) every 20 minutes for 3 doses, then 0.15–0.3 mg/kg up to 10 mg every 1–4 hours as needed, or 0.5 mg/kg per hour by continuous nebulization	Only selective β_2-agonists are recommended. For optimal delivery, dilute aerosols to a minimum of 3 mL at a gas flow of 6–8 L/minute. Use large-volume nebulizers for continuous administration. May mix with ipratropium nebulizer solution.
MDI (90 µg/puff)	4–8 puffs every 20 minutes up to 4 hours, then every 1–4 hours as needed	4–8 puffs every 20 minutes for 3 doses, then every 1–4 hours inhalation maneuver as needed. Use valved holding chamber. Add mask in children <4 years.	In mild-to-moderate exacerbations, MDI plus valved holding chamber is as effective as nebulized therapy with appropriate administration technique and coaching by trained personnel.
Bitolterol			
Nebulizer solution (2 mg/mL)	See albuterol dose.	See albuterol dose; thought to be half as potent per milligram as albuterol	Has not been studied in severe asthma exacerbations. Do not mix with other drugs.
MDI (370 µg/puff)	See albuterol MDI dose.	See albuterol MDI dose.	Has not been studied in severe asthma exacerbations.
Levalbuterol (R-albuterol)			
Nebulizer solution (0.63 mg/3 mL, 1.25 mg/3 mL)	1.25–2.5 mg every 20 minutes for 3 doses, then 1.25–5 mg every 1–4 hours as needed	0.075 mg/kg (minimum dose 1.25 mg) every 20 minutes for 3 doses, then 0.075–0.15 mg/kg up to 5 mg every 1–4 hours as needed	Levalbuterol administered in one-half the dose of albuterol provides comparable efficacy and safety. Has not been evaluated by continuous nebulization.
MDI (45 µg/puff)	See albuterol MDI dose.	See albuterol MDI dose.	—
Pirbuterol			
MDI (200 µg/puff)	See albuterol MDI dose.	See albuterol MDI dose; thought to be half as potent per milligram as albuterol	Has not been studied in severe asthma exacerbations.
Systemic (Injected) β_2-Agonists			
Epinephrine 1:1000 (1 mg/mL)	0.3–0.5 mg every 20 minutes for 3 doses SC	0.01 mg/kg up to 0.3–0.5 mg every 20 minutes for 3 doses SC	No proven advantage of systemic therapy over aerosol.
Terbutaline (1 mg/mL)	0.25 mg every 20 minutes for 3 doses SC	0.01 mg/kg every 20 minutes for 3 doses, then every 2–6 hours as needed SC	No proven advantage of systemic therapy over aerosol.
Anticholinergics			
Ipratropium bromide			
Nebulizer solution (0.25 mg/mL)	0.5 mg every 20 minutes for 3 doses, then as needed	0.25–5 mg every 20 minutes for 3 doses, then as needed	May mix in same nebulizer with albuterol. Should not be used as first-line therapy; should be added to SABA therapy for severe exacerbations. The addition of ipratropium has not been shown to provide further benefit once the patient is hospitalized.
MDI (18 µg/puff)	8 puffs every 20 minutes as needed up to 3 hours	4–8 puffs every 20 minutes as needed up to 3 hours	Should use with valved holding chamber and face mask for children <4 years. Studies have examined ipratropium bromide MDI for up to 3 hours.
Ipratropium with albuterol			
Nebulizer solution (each 3-mL vial contains 0.5 mg ipratropium bromide and 2.5 mg albuterol)	3 mL every 20 minutes for 3 doses, then as needed	1.5 mL every 20 minutes for 3 doses, then as needed	May be used for up to 3 hours in the initial management of severe exacerbations. The addition of ipratropium to albuterol has not been shown to provide further benefit once the patient is hospitalized.
MDI (each puff contains 18 µg ipratropium bromide and 90 µg albuterol)	8 puffs every 20 minutes as needed up to 3 hours	4–8 puffs every 20 minutes as needed up to 3 hours	Should use with valved holding chamber and face mask for children <4 years.

E-TABLE 13.4 Doses of Drugs for Asthma Exacerbations in Emergency Settings or Hospital—cont'd

Medication	Adult Dose	Child Dose[a]	Comments
Systemic Corticosteroids			
Prednisone	40–80 mg/day in 1 or 2 divided doses until PEF reaches 70% of predicted or personal best	1 mg/kg in 2 divided doses (maximum = 60 mg/day) until PEF is 70% of predicted or personal best	For outpatient "burst," use 40–60 mg in single or 2 divided doses for 5–10 days in adults (children: 1–2 mg/kg per day, maximum 60 mg/day, for 3–10 days).
Methylprednisolone	As for prednisone.	As for prednisone.	As for prednisone.
Prednisolone	As for prednisone.	As for prednisone.	As for prednisone.

Notes:
There is no known advantage for higher doses of corticosteroids in severe asthma exacerbations, nor is there any advantage for intravenous administration over oral therapy, provided gastrointestinal transit time or absorption is not impaired.
The course of systemic corticosteroids for an asthma exacerbation requiring an emergency department visit or hospitalization may last from 3 to 10 days. For corticosteroid courses of less than 1 week, there is no need to taper the dose. For slightly longer courses (e.g., up to 10 days), there probably is no need to taper, especially if patients are concurrently taking inhaled corticosteroids.
Inhaled corticosteroids can be started at any point in the treatment of an asthma exacerbation.
[a]Children <12 years of age.
ED, emergency department; *MDI,* metered-dose inhaler; *PEF,* peak expiratory flow; *SABA,* short-acting β-agonists; *SC,* subcutaneous.

TABLE 13.6 Formal Evaluation of Asthma Exacerbation Severity

	Mild	Moderate	Severe	Subset: Respiratory Arrest Imminent
Symptoms				
Breathlessness	While walking Can lie down	While at rest (infant—softer, shorter cry, difficulty feeding) Prefers sitting	While at rest (infant—stops feeding) Sits upright	
Talks in	Sentences	Phrases	Words	
Alertness	May be agitated	Usually agitated	Usually agitated	Drowsy or confused
Signs				
Respiratory rate[a]	Increased	Increased	Increased	
Use of accessory muscles; suprasternal retractions	Usually not	Commonly	Usually	Paradoxical thoracoabdominal movement
Wheeze	Moderate, often only end expiratory	Loud; throughout exhalation	Usually loud; throughout inhalation and exhalation	Absence of wheeze
Pulse/minute[b]	Slightly increased	Increased	Tachycardia	Bradycardia
Pulsus paradoxus	Absent <10 mm Hg	May be present 10–25 mm Hg	Often present >25 mm Hg (adult) 20–40 mm Hg (child)	Absence suggests respiratory muscle fatigue
Functional Assessment[c]				
PEF (% of predicted or of personal best)	≥70%	Approx. 40%–69% or response lasts <2 hours	<40%	<25% (PEF testing may not be needed in very severe attacks)
Pao_2 (while breathing room air)	Normal (test not usually necessary)	≥60 mm Hg (test not usually necessary)	<60 mm Hg: possible cyanosis	
Pco_2	<42 mm Hg (test not usually necessary)	<42 mm Hg (test not usually necessary)	>42 mm Hg: possible respiratory failure (see text)	
Sao_2% (while breathing room air) at sea level	>95% (test not usually necessary)	90%–95% (test not usually necessary)	<90%	

[a]Guide to rates of breathing in awake children: at age <2 months, normal rate is <60 breaths/minute; at 2–12 months, <50/minute; at 1–5 years, <40/minute; at 6–8 years, <30/minute.
[b]Guide to normal pulse rates in children: at age 2–12 months, normal rate is <160 beats/minute; at 1–2 years, <120/minute; at 2–8 years, <110/minute.
[c]Pao_2 or Pco_2 or both may be tested. Hypercapnia (hypoventilation) develops more readily in young children than in adults and adolescents.
Pao_2, arterial oxygen tension; *Pco_2*, partial pressure of carbon dioxide; *PEF*, peak expiratory flow; *Sao_2*, oxygen saturation.
Modified from National Asthma Education and Prevention Program. Full report of the expert panel: guidelines for the diagnosis and management of asthma (EPR-3). Bethesda, MD: National Heart, Lung, and Blood Institute, National Institutes of Health, 2007.

particles along the tips of the cilia. Normally, mucus is transported at about 10 mm/minute, expelling foreign particles and pathogens from the lungs. The efficacy of clearance depends on adequate hydration of the mucus.[72] Lack of regulation of sodium absorption and chloride secretion decreases liquid on the airway luminal surfaces, slows mucus clearance, and promotes the formation of adherent plugs in the airway.[73] Increased secretions, viscous mucus, and impaired ciliary clearance contribute to airway impaction, providing a nidus for infection.

At birth, the lung structure is almost normal.[67] However, chronic and recurrent bacterial infections occur early in life, assisted by the pooling of secretions and impaired neutrophil bacterial killing on airway surfaces.[69,74] Repeated and persistent infections stimulate a chronic neutrophilic inflammatory response, ultimately destroying the airway walls. Early pathogens include *Staphylococcus aureus* and *Haemophilus influenzae*. *Pseudomonas aeruginosa* typically invade later in life, acquire a mucoid phenotype, and form a biofilm in the lung, an event that is associated with accelerated decline in pulmonary function. The invasion of the lung by antibiotic-resistant pathogens such as certain strains of *Burkholderia cepacia* is often devastating, markedly increasing the death rate from lung disease.

Various insults such as bacteria, viruses, and airborne irritants can cause acute exacerbations of respiratory symptoms of cough and sputum production. This is often accompanied by systemic manifestations such as weight loss, anorexia, and fatigue. These changes from baseline are termed *pulmonary exacerbations*.[75]

Recurrent exacerbations are associated with progressive airway obstruction, bronchiectasis, emphysema, ventilation/perfusion mismatching, and hypoxemia. Growth of blood vessels with advancing bronchiectasis predisposes to hemoptysis. Bronchial hyperreactivity and increased airway resistance are common, whereas bullae formation can lead to pneumothorax.

Pulmonary function abnormalities typically have an obstructive pattern[76] and include increased FRC, decreased FEV_1, decreased peak expiratory flow rate, and decreased vital capacity (see Fig. 13.5). Compensatory hyperventilation typically produces a reduced $PaCO_2$, although hypercapnia may supersede in end-stage pulmonary pathology. End-stage cor pulmonale may lead to cardiomegaly, fluid retention, and hepatomegaly.

Malnutrition is a common problem in CF that follows from pancreatic insufficiency, failure of enzyme secretion, impaired gastrointestinal motility, abnormal enterohepatic circulation of

bile, increased caloric demand owing to severe lung disease, and anorexia of chronic disease.[67] Low weight and body mass index are closely associated with, and can predict, poor lung function.

CF-related diabetes arises from progressive pancreatic disease and scarring that compromises the pancreatic islets. More than 12% of teenagers older than 13 years with CF have insulin-dependent diabetes, and the incidence increases with age. Evidence is accumulating that diabetes contributes to the lung disease and worse outcome.[69-71] In addition, classic diabetic complications occur in older CF patients. Hepatic dysfunction decreases plasma cholinesterase and clotting factors II, VII, IX, and X, whereas malabsorption of vitamin K may also contribute to coagulation issues.[77]

When CF was first distinguished from celiac syndrome in 1938, life expectancy was approximately 6 months. Since then, substantial advances in sustained multidisciplinary supportive care have increased the median survival time to 35 years (E-Fig. 13.5).[67,78] Currently almost half of the CF population are adults.[77]

The pillars of treatment include nutritional repletion, relief of airway obstruction, and antibiotic therapy for lung infection. Organ transplantation, and in particular lung transplantation, has been used in an attempt to improve quality of life and prolong survival, but a clear benefit remains to be demonstrated.[78]

Corrector and potentiator therapies are recently developed treatments that are directed at the molecular defects in the CF transmembrane conductance regulator.[79,80] Correctors are principally targeted at cellular misprocessing, while potentiators aim to correct channel's function. Ivacaftor was the first developed drug in this area, and it is a potentiator that targets a number of mutations in cystic fibrosis transmembrane conductance regulator (CFTR) gene, including the G551D mutation.

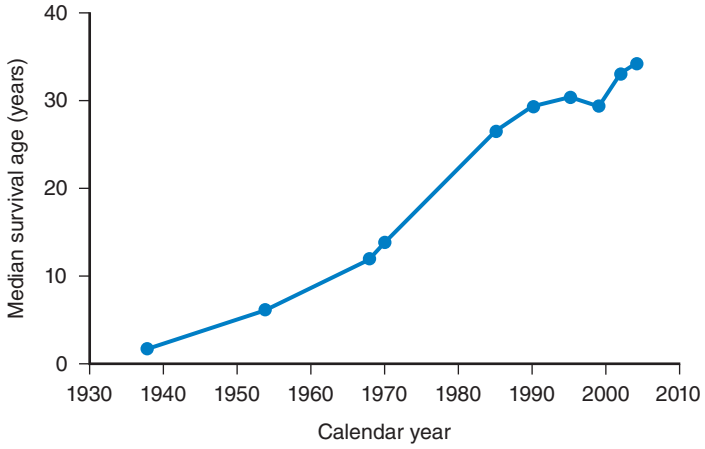
The multisystem nature of the disease and changing demographics mean that children present for a wide variety of surgical procedures. The most common indications for anesthesia in children are nasal polypectomy and ear, nose, and throat surgery, as a result of the frequency of upper airway pathologic processes such as chronic sinusitis and nasal polyps (Table 13.7).[81,82] The investigation or correction of gastrointestinal disorders is the next most common procedural category that requires anesthesia in the CF population. Other indications for anesthesia include bronchoscopy and pulmonary lavage, gastrointestinal endoscopy, sclerosing injection of varices resulting from portal hypertension, insertion of venous access devices, and incidental surgical problems.[82-84]

Because of the increasing longevity of this population, the pediatric anesthesiologist may also be involved in the care of adults.[77] Surgical procedures in adults typically include treatment of recurrent pneumothorax, cholecystectomy, and lung or cardiac transplantation. Consultation may also be requested for obstetric cases as increasing numbers of patients survive to adulthood.

TABLE 13.7 Most Frequent Indications for Anesthesia in Cystic Fibrosis

Neonates	Children/Teenagers	Adults
Meconium ileus	Nasal polypectomy	Esophageal varices
Meconium peritonitis	Intravenous access	Recurrent pneumothorax
Intestinal atresia	Ear/nose/throat surgery	Cholecystectomy
		Lung (liver) transplantation

Modified from Della Rocca G. Anaesthesia in patients with cystic fibrosis. *Curr Opin Anaesthesiol.* 2002;15:95–101.



Pulmonary disease is the predominant concern when planning anesthesia for these patients. Historically, morbidity and mortality from pulmonary complications were significant–for example, in 1964, a retrospective study reported a perioperative mortality rate of 27%,[85] but by 1972, this incidence had decreased to 4%.[81] More recent studies have confirmed low mortality but an appreciable rate of morbidity after general anesthesia for lung lavage; bronchoscopies; and ear, nose, and throat surgery in children with CF. With a combined cohort of 700 children, the frequency of perioperative complications was between 5% and 13%.[82,86-89] In a study of 18 patients with CF undergoing anesthesia for pleural surgery, the risks for this surgery were considered substantial, although the anesthetic hazards of CF could be minimized with careful management.[90] The effects of anesthesia on pulmonary function in children with CF are unclear. In a small study of children undergoing injection of esophageal varices, pulmonary function test results deteriorated 48 hours after general anesthesia.[91] In contrast, in almost 100 children in two studies, no difference in pulmonary function tests measured before compared with after a variety of surgical procedures was observed.[82,92] Although acute pulmonary morbidity may pose challenges, the effects of the anesthetic management techniques on pulmonary function tests are difficult to predict.

An assessment of the severity, current state, and progression of pulmonary disease should guide anesthetic planning. Fitness is a positive predictor of survival,[67] and exercise tolerance is a useful marker of pulmonary function. The quality and quantity of secretions, recent and chronic infections, use and effectiveness of bronchodilators, and number of hospitalizations are also important points to elucidate in the history. Examination of the cardiopulmonary systems should aim to detect compromise of cardiac, pulmonary, and hepatic function. Special investigations are not routinely indicated but may quantify organ dysfunction in end stages of the disease. Arterial blood gas analysis, chest radiography, pulmonary function tests, electrocardiography, echocardiography, and liver function tests may assist the planning of anesthetic technique in selected children.[84]

Children are often emotionally vulnerable, not simply because of the usual preoperative anxieties but because of the psychological consequences of progression of an ultimately fatal disease. A preoperative visit should aim to allay distress; oral benzodiazepines have been successfully used as anxiolytics.[82,89] Prophylactic use of osmotic laxatives may be indicated if opioid-induced ileus is anticipated.[84]

Because desiccation of mucous secretions is a central pulmonary issue in CF, general anesthesia poses specific problems. During spontaneous ventilation under normal conditions, inspired gases are warmed to body temperature and saturated with water vapor, reaching this state at the isothermic saturation point just distal to the carina.[93,94] This ensures that the lower airways are kept moist and warm. The alveolar environment in optimal circumstances has a saturated water vapor pressure of 47.1 mm Hg and an absolute humidity of 43.4 g/m^3 at 98.6°F (37°C).

The inspiration of cold, desiccated anesthetic gases and vapors can impair the warming and humidification of the airways. The use of any airway device (oropharyngeal airway, laryngeal mask, or ETT) bypasses the nasal and oropharyngeal passages and delivers cold, dry gas farther down the airway.[95] This shifts the isothermic saturation point distally, forcing bronchi that normally function in optimal conditions to take part in heat and gas exchange.[94]

E-FIGURE 13.5 Median survival age for patients with cystic fibrosis at various times since the first description of the disease. Data before 1970 are gleaned from the then-current literature. Data since 1985 are from the Cystic Fibrosis Foundation Data Registry and represent projections of median survival age for a child born in that year with cystic fibrosis. (Reproduced from Davis PB. Cystic fibrosis since 1938. *Am J Respir Crit Care Med*. 2006;173:475–482.)

These parts of the airway are less adapted to moisture exchange and tend to dehydrate more rapidly, thereby impairing the mucociliary escalator and predisposing to impaction of secretions.[96,97] By directly impairing mucociliary motion as well as blunting the cough response and ventilatory drive, inhalational anesthetics can exacerbate this problem.

It is therefore particularly important to minimize mucus desiccation in the perioperative period. Inhalation of hypertonic saline (7% sodium chloride) accelerates mucus clearance, increases lung function, and improves quality of life[98-100]; this is now typically part of the routine maintenance management of CF. Nebulized saline treatments should continue up to the start of anesthesia and recommence after the procedure. Inhaled gases should be humidified, or an artificial "nose" should be inserted into the circuit to conserve airway moisture and minimize the risk of inspissating secretions. Although removal of pulmonary secretions is considered important in principle, a small prospective trial of intraoperative bronchial wash-out and physical therapy reported an acute increase in airway resistance with no significant long-term benefit in measures of lung function.[101]

At the conclusion of surgery, complete reversal of neuromuscular blockade should be confirmed. Whenever possible, the trachea should be extubated and the child encouraged to breathe spontaneously. A 30- to 40-degree head-up position assists movement of the diaphragm and ventilation. Postoperatively, physiotherapy, airway humidification, carefully titrated analgesics, and early mobilization should enhance clearance of secretions and minimize atelectasis. The use of neuraxial, regional or local anesthesia, as well as nonopioid analgesics, are useful strategies to avoid respiratory depression.[102,103] Ambulatory surgery is optimal, if feasible, because it minimizes disruption to the patient's schedule and decreases exposure to nosocomial infection.

SICKLE CELL DISEASE

SCD is an inherited hemoglobinopathy that results from a point mutation on chromosome 11 (see also Chapter 10). The mutant gene codes for the production of hemoglobin S, a mutant variant of the normal hemoglobin A. This leads to widespread and progressive vascular damage.[104,105] Clinical features of the disease include acute episodes of pain, acute and chronic pulmonary disease, hemorrhagic and occlusive stroke, renal insufficiency, and splenic infarction, with mean life expectancy shortened to just over 3 decades.[106] Perioperative problems and management are covered in more detail in Chapter 10; the discussion here is limited to a brief review of the pulmonary pathology of SCD.

Acute chest syndrome (ACS) is an acute lung injury caused by SCD. Diagnostic criteria include a new pulmonary infiltrate involving at least one lung segment on the radiograph (excluding atelectasis) combined with one or more symptoms or signs of chest pain, pyrexia greater than 101.3°F (38.5°C), tachypnea, wheezing, or cough.[107-109] Precipitants include infection, fat embolism after bone marrow infarction, pulmonary infarction, and surgical procedures.[109-111] Potential risk factors for the development and severity of perioperative ACS may include a history of lung disease, recent clustering of acute pulmonary complications, pregnancy, increased age, and the invasiveness of the surgical procedure.[104] ACS was associated with younger-age patients, reduced body temperature, and greater blood loss in a study of 60 children with SCD undergoing laparoscopic surgery.[112]

The risk of ACS is small (<5%) after minor surgeries such as inguinal hernia repair and distal extremity surgery, whereas it is severalfold greater (10% to 15%) after intraabdominal and major joint surgery.[111,113,114] Although the overall perioperative mortality from SCD is quite small, <1%,[111,115] ACS can prolong postoperative hospitalization, and cause respiratory failure and death. ACS typically develops about 3 days postoperatively and persists for approximately 8 days, with a 3.3% mortality.[110]

SCD also causes chronic lung damage, known as sickle cell lung disease (SCLD).[116] Because lung function has not yet been assessed longitudinally in a cohort from early childhood to adulthood, the precise pathology of and relationship between the obstructive and restrictive patterns of lung disease is unclear.[117] Children appear to develop a predominantly obstructive pattern,[118] whereas adults develop a more restrictive pulmonary defect.[116,119,120] In the later stages of lung damage, both vital and total lung capacities decrease, gas diffusion is impaired, and pulmonary fibrosis, pulmonary artery hypertension, right-sided cardiomyopathy, and progressive hypoxemia may occur.[116,120] The development of pulmonary artery hypertension, which can precede clinically apparent lung damage, is a particularly ominous sign of disease progression and is associated with a heightened risk of sudden death.[119] Recurrent ACS is an independent risk factor for the development of end-stage SCLD, but subtle evidence of parenchymal and vascular damage commonly precedes clustered episodes of ACS.[116]

Assessment of lung function should include a history of the occurrence, frequency, severity, and known precipitants of ACS and a search for progression of chronic lung damage. A recent chest radiograph can serve as a baseline for comparison if postoperative radiographs are needed and can also delineate lung pathology. Early features of lung damage include decreased distal pulmonary vascularity and diffuse interstitial fibrosis, whereas later stages are characterized by pulmonary fibrosis, pulmonary hypertension, and right ventricular hypertrophy.[116,121] Pulmonary function testing can reveal the need for bronchodilators and the presence of obstructive or restrictive lung disease.

Although the risk of developing ACS in the perioperative period is increased, distinct genotypes, wide variation in disease severity, differing chronic treatment protocols, varied surgical procedures, and logistical complexities have made research into the optimal perioperative management difficult. Well-delivered anesthetic and postoperative care may be the best guarantor of a good outcome.[104,105]

Perioperative management frequently includes red blood cell transfusion in an effort to decrease the risk of perioperative ACS. The Transfusion Alternative Perioperatively in Sickle Cell Disease study prospectively enrolled 67 patients undergoing low- and medium-risk surgery with or without preoperative transfusion.[122] Although limited by early closure of the study, the small sample size, and too few patients enrolled in the low-risk surgery group to allow for subgroup analysis, the prevalence of clinically important events, including ACS, in the nontransfused group exceeded that in the transfused group. The authors concluded that preoperative transfusion may reduce the risk of ACS in patients with a homozygous HbSS genotype.

If preoperative transfusion is performed to attenuate SCD exacerbations, an exchange transfusion aimed at decreasing the concentration of hemoglobin S to 30% is no more effective than simply correcting the anemia to a hematocrit of 30%. However, exchange transfusion is more likely to lead to transfusion-related complications including the development of uncommon antibodies such as Kell and Duffy antibodies.[110] Consequently, if a decision is made to transfuse in the hope of preventing ACS, the target should be a hematocrit of 30% rather than a specific dilution of hemoglobin S.

The risk of ACS after low-risk surgeries or procedures without transfusion appears to be small.[123] A study of patients undergoing magnetic resonance imaging (MRI) with deep sedation reported an incidence of ACS of 1.2% within 1 month of the MRI,[124] whereas nontransfused patients undergoing minor surgery in the Cooperative Study of Sickle Cell Disease had a similar incidence of ACS of 1.4%.[110] A survey of North American pediatric anesthesiologists found that most clinicians do not transfuse children who are at low risk for perioperative complications after minor procedures, whereas a greater number transfuse sicker children undergoing more invasive procedures.[125]

The one group of children with SCD who are at high risk for complications are those who have experienced or are at risk for a stroke. Risk factors for strokes include low hemoglobin, hypertension, and male gender as well as three single-nucleotide polymorphisms.[126,127] Serial transcranial Doppler ultrasound and MRI of the brain have been used to detect pathologic changes in blood flow or subclinical strokes, respectively, and in these children blood transfusion has been effective in reducing subsequent strokes.[128,129] Silent cerebral strokes have been detected in up to 30% of asymptomatic children with SCD.[126] To reduce the risk of stroke, these children have transfusions at regular intervals, based on the results of the serial investigations. However, this approach raises concern about iron overload and other complications associated with repeated blood transfusions. A recent study to limit the number of transfusions in those at risk for a stroke had to be stopped prematurely because two strokes occurred despite serial transcranial Doppler monitoring.[130] Chronic hydroxyurea therapy has also been shown to be effective in reducing the risk of stroke.[131] The perioperative management of children with a history of stroke continues to evolve.

Children with SCD frequently develop postoperative atelectasis. It is unclear whether this relates to an underlying sickle cell lung disease, difficulty with analgesia, other causes, or a combination of factors. Pain management can be difficult in these children. Large doses of opioids can depress ventilation and cause atelectasis.[132] ACS tends to involve the lower segments of the lung,[109] suggesting an association between atelectasis and ACS; incentive spirometry can prevent the development of atelectasis and pulmonary infiltrates.[133] Regional analgesia, supplemental nonopioid analgesics, prophylactic incentive spirometry, early mobilization, and good pulmonary toilet may decrease the incidence of atelectasis and ACS.

Treatment of ACS is focused on supporting gas exchange. Supplemental oxygen, noninvasive ventilatory support such as CPAP, or intubation and mechanical ventilation are indicated by the degree of dysfunction. Bronchodilators, incentive spirometry, and chest physiotherapy may be useful in preventing disease progression. In the presence of a significant ventilation/perfusion mismatch, correction of anemia can improve arterial oxygenation. Erythrocyte transfusion increases oxygen-carrying capacity, decreases fractional peripheral tissue extraction, and increases returning venous oxygen levels. Because the mean arterial oxygen content in the presence of a shunt is significantly affected by the oxygenation of blood returning from nonventilated parts of the lung, increasing venous oxygen levels can improve arterial oxygen content. Although transfusion has not been directly linked to improved outcomes, both exchange and simple transfusions can improve oxygenation.[109]

Summary

Pulmonary complications are a major cause of perioperative morbidity in the pediatric population. Although preexisting pulmonary pathologic processes in children can present significant challenges to anesthetic delivery, a thorough assessment of the problem combined with meticulous anesthetic management allows most children to undergo surgical interventions without long-term adverse sequelae. Consultation with a pediatric pulmonologist is indicated when appropriate for specific problems as outlined in this chapter; a team approach may markedly improve operative and postoperative outcomes.

THE DIFFERENCES BETWEEN THE pediatric and adult airways are important determinants of the anesthetic technique. Knowledge of normal developmental anatomy and physiologic function is required to understand and manage both the normal and the pathologic airways of infants and children (Video 14.1). Techniques and principles to assist in this management are reviewed in this chapter.

Developmental Anatomy of the Airway

The classic works by Negus, Eckenhoff, and Fink and Demarest shaped the foundation of our knowledge about the structure and function of the pediatric and adult airways.[1–3] They suggested that there are five major anatomic differences between the neonatal and adult airways, which are outlined in this section, although recent studies suggest that not all of these long-held beliefs are valid.[2–4] In addition, the relatively large head of an infant offsets the need to place anything under the head to achieve a proper "sniffing position." Older children have airway features that represent a transition between the neonatal and adult anatomy.

TONGUE

It is generally held that the tongue of the neonate and infant is relatively large in proportion to the rest of the oral cavity and therefore more easily obstructs the airway, especially in the neonate. However, magnetic resonance imaging (MRI) studies demonstrated that in children 1 to 11 years of age,[5] there is proportional growth of the tongue and other soft tissues in relation to the bony structures of the oral cavity although that study did not examine neonates and infants (who are 1-12 months of age). The contribution of the tongue to upper airway obstruction with sedation or induction of anesthesia is relatively minor; much of the obstruction in older children is more likely attributable to the collapse of the nasopharynx and epiglottis, although the tongue may still contribute to obstruction in all age groups.[6,7]

POSITION OF THE LARYNX

The larynx in the infant is more cephalad than in the adult, classically described at the level of C3-4 in the former compared with C4-5 in the latter (Fig. 14.1). MRI and computed tomography (CT) have confirmed the more cephalad position of the larynx in children and demonstrated that the hyoid bone is at the level of C2-3 in infants and children up to 2 years of age.[8] Consequently, the distances between the tongue, hyoid bone, epiglottis, and roof of the mouth in infants are less than those in older children or adults.

The proximity of the tongue base to the more superior larynx also makes visualization of laryngeal structures more difficult because it produces a more acute angle between the plane of the tongue and the plane of the glottic opening. It is for this reason that a straight laryngoscope blade, which lifts the tongue from the field of view during laryngoscopy, facilitates visualization of an infant's larynx. This anatomic relationship is further complicated in certain conditions such as the Treacher Collins anomaly and other syndromes associated with mandibular and midfacial hypoplasia that make direct visualization of the glottis difficult and sometimes impossible with direct laryngoscopy (Fig. 14.2). The reason for this difficulty is that with mandibular and midfacial hypoplasia, the base of the tongue is positioned more caudally (known as glossoptosis), in closer proximity to the laryngeal inlet than normal. The result is a more acute angle between the plane

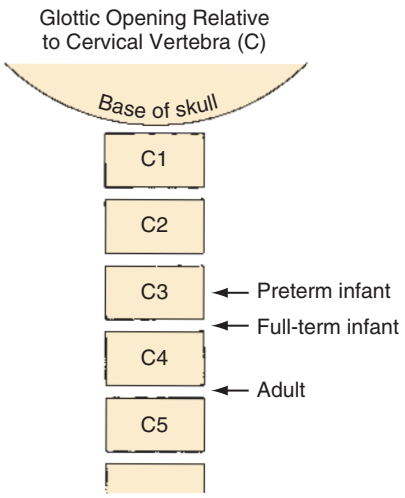

FIGURE 14.1 In a preterm Infant, the larynx is located at the middle of the third cervical vertebra (C3); in a full-term infant, it is at the C3-4 interspace; and in an adult, it is at the C4-5 interspace. (Adapted from Negus VE. *The Comparative Anatomy and Physiology of the Larynx*. Oxford: Butterworth-Heinemann; 1949.)

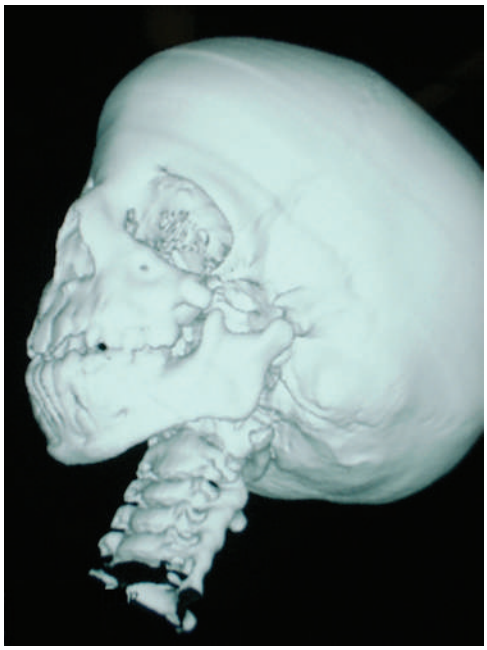

FIGURE 14.2 Three-dimensional reconstruction of a child with the Treacher Collins anomaly demonstrates the retrognathic and more posterior position of the mandible, the midfacial hypoplasia, and the closer proximity and exaggerated angle between the base of the tongue and the laryngeal inlet (almost 90 degrees), which makes direct visualization of the larynx difficult.

of the tongue and the plane of the laryngeal inlet (often 90 degrees) (Fig. 14.3). In this situation, conventional rigid laryngoscopy provides excellent visualization of the esophageal inlet rather than the laryngeal inlet, necessitating the use of special equipment or special techniques to intubate the trachea.

EPIGLOTTIS

The epiglottis in the infant is narrow, omega shaped, and angled away from the axis of the trachea, which contrasts with that in the adult, which is flat and broad, and its axis is parallel to the trachea (Figs. 14.4 and 14.5). This shape allows the epiglottis to approach the uvula during infant breastfeeding; separating breath from fluid and allowing respiration at the same time as swallowing. The shape of epiglottis makes it more difficult to directly lift in the neonate and infant with the tip of a laryngoscope blade.

VOCAL FOLDS

The vocal folds (cords) in an infant are angled such that the anterior insertion is more caudad than the posterior insertion, whereas the axis of the folds in the adult is perpendicular to that of the trachea (compare Fig. 14.4A with Fig. 14.5A). This anatomic feature alters the angle at which the tracheal tube approaches the laryngeal inlet and occasionally leads to difficulty with tracheal intubation, especially with the nasal approach. In the latter case, the tip of the endotracheal tube (ETT) may be held up at the anterior commissure of the vocal folds.

SUBGLOTTIS

Classic teaching holds that the narrowest part of an infant's larynx is the cricoid cartilage; in an adult, it is the rima glottidis. This teaching was supported by an MRI and CT studies in young children (<2 years of age) who were sedated with oral medications and breathing spontaneously.[8,9] In contrast, another study in children 2 months to 13 years of age undergoing MRI with propofol sedation and spontaneous respirations reported that the narrowest portions of the pediatric larynx were the glottic opening and the immediate sub–vocal cord level and that this finding did not change relative to the dimensions of the cricoid ring throughout childhood.[10] These observations contradict the classic observations of autopsy specimens dating back to 1897[11] and other subsequent anatomic autopsy studies.[12–17] The most likely reason for these apparent contradictory observations is that the more recent studies were conducted in spontaneously breathing children with variable portions of the respiratory cycle and that soft tissue collapse gives the appearance of a narrower airway above the cricoid cartilage. Nonetheless, when a relatively large-diameter tube is inserted into the glottic aperture, the tube readily passes through the distensible vocal cords but may meet resistance below the cords (e.g., the nondistensible cricoid ring region). Although these studies demonstrate in vivo dynamic, physiologic relationships, the cricoid cartilage is *functionally* the narrowest portion of the upper airway.

Growth of the subglottic airway occurs rapidly during the first 2 years of life; thereafter, growth of the airway is linear.[17] The cricoid and thyroid cartilages reach adult proportions by 10 to 12 years of age, thus eliminating both the angulation of the vocal cords and the narrow subglottic area.

In adults, the rima glottidis is the narrowest part of the airway,[18] and an ETT that traverses the glottis passes into the trachea without resistance. However, in about 70% of adult cadavers, the narrowest portion of the airway was identified in the subglottic region.[19] The range in diameter for adult females is 10 to 16 mm, and for adult males it is 13 to 19 mm. The likely reason that ETTs pass easily through the rima glottidis into the trachea of an adult is that overall, the narrowest portion of the airway is still larger than the most commonly used ETT sizes. The apparent subglottic narrowing in adults is generally not evident unless there is the need to pass a larger-diameter ETT such as a double-lumen tube. In contrast, in a child, it is common for an ETT to pass easily through the vocal folds (glottic opening) but not through the subglottic region (Fig. 14.6; see Video 14.1). The larynx in both

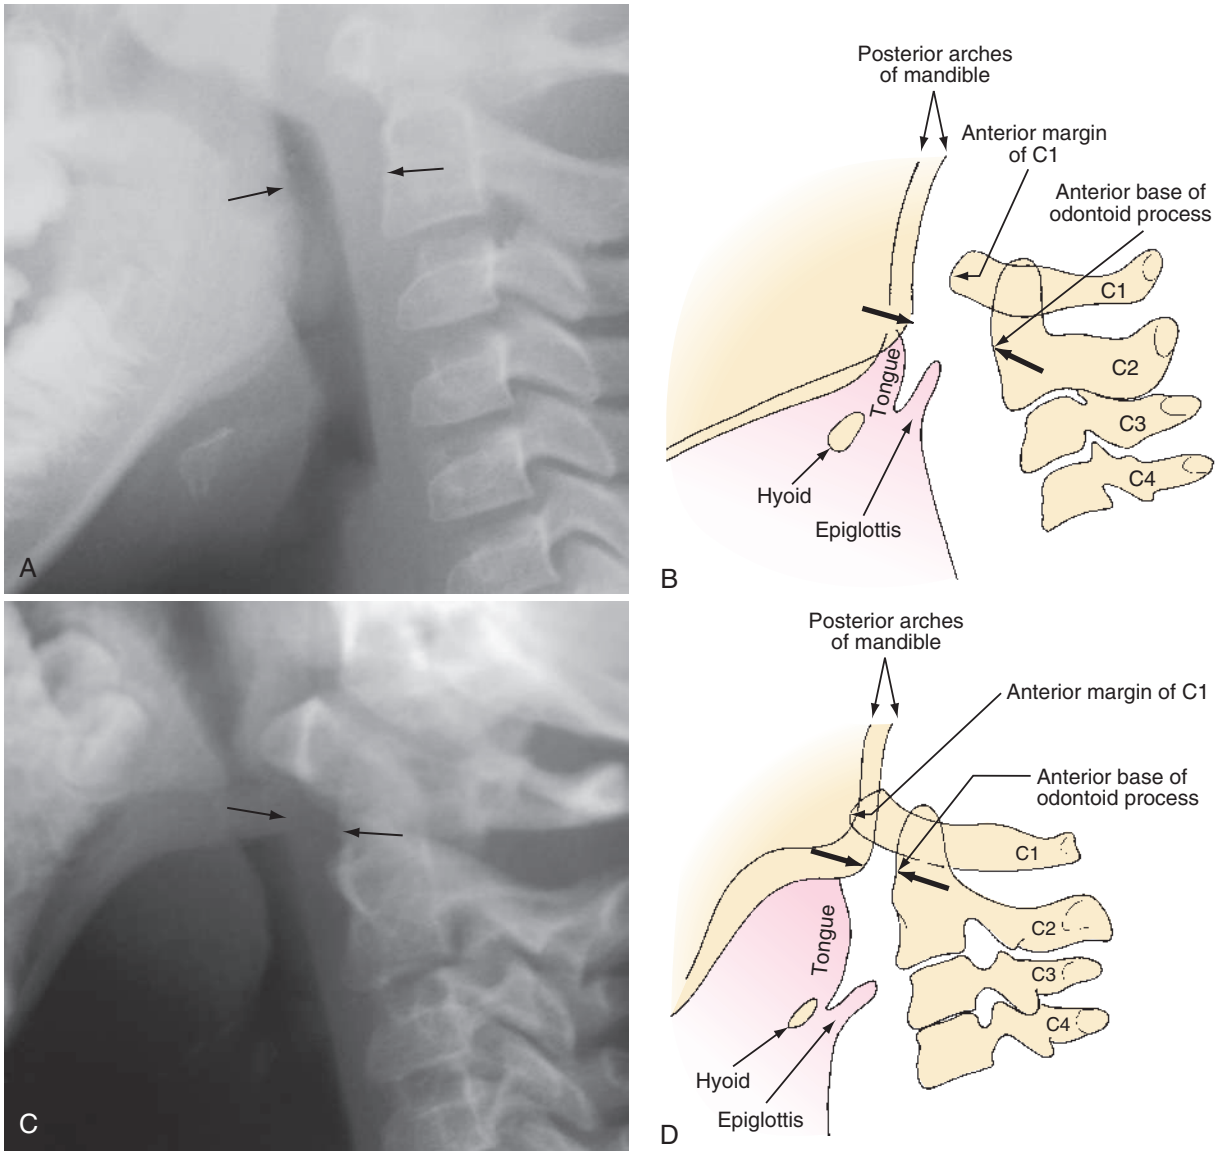

FIGURE 14.3 The larynx in children with mandibular hypoplasia is located more posteriorly than in children with normal anatomy. **A,** Lateral radiograph of the upper airway including the base of the skull and cervical spine of a normal 7-year-old child; the *arrows* denote the posterior border of the ramus of the mandible and the anterior border of the second cervical vertebra. **B,** Diagrammatic representation of the normal anatomy in **A**. **C,** The same radiographic projection in a 6-year-old child with Treacher Collins syndrome; the *arrows* again denote the posterior border of the ramus of the mandible and the anterior margin of the second cervical vertebra. **D,** Diagrammatic representation of the anatomy in **C**. Notice the significantly smaller space between the ramus of the mandible and the second cervical vertebra, compared with the normal anatomy; the anterior margin of the first cervical vertebra overlaps the posterior margin of the mandible. This extreme posterior location of the tongue and larynx makes direct visualization of the laryngeal inlet almost impossible in many children with this anomaly because of the acute angulation between the base of the tongue and the laryngeal inlet. (Radiographs courtesy Donna J. Seibert, MD; John A. Kirkpatrick, Jr., MD; and Robert H. Cleveland, MD.)

children and adults should be considered funnel-shaped, although this configuration is exaggerated and is of greater importance in infants and young children than in adults.

The cricoid is the only complete ring of cartilage in the laryngotracheobronchial tree; as such it is nondistensible. Because the mucosa that lines the upper airway is loose-fitting pseudostratified columnar epithelium, pressure on the mucosa may cause reactive edema that encroaches on the diameter of the lumen. A tight-fitting ETT that compresses the tracheal mucosa at this level may cause inflammation and edema when it is removed, reducing the luminal diameter and increasing the airway resistance at the time of extubation (e.g., postextubation croup). Because the subglottic region in the infant is smaller than in the adult, the same degree of airway edema results in greater resistance in the infant. For example, assuming that the diameter of the cricoid ring in the infant is 4 mm and the diameter of the adult cricoid ring or trachea is 8 mm, 1 mm of edema circumferentially within the airway (i.e., reduction of the diameter of the airway by 2 mm) would decrease the cross-sectional area of the airway in the infant by approximately 75% (to 2 mm), whereas the area in the adult

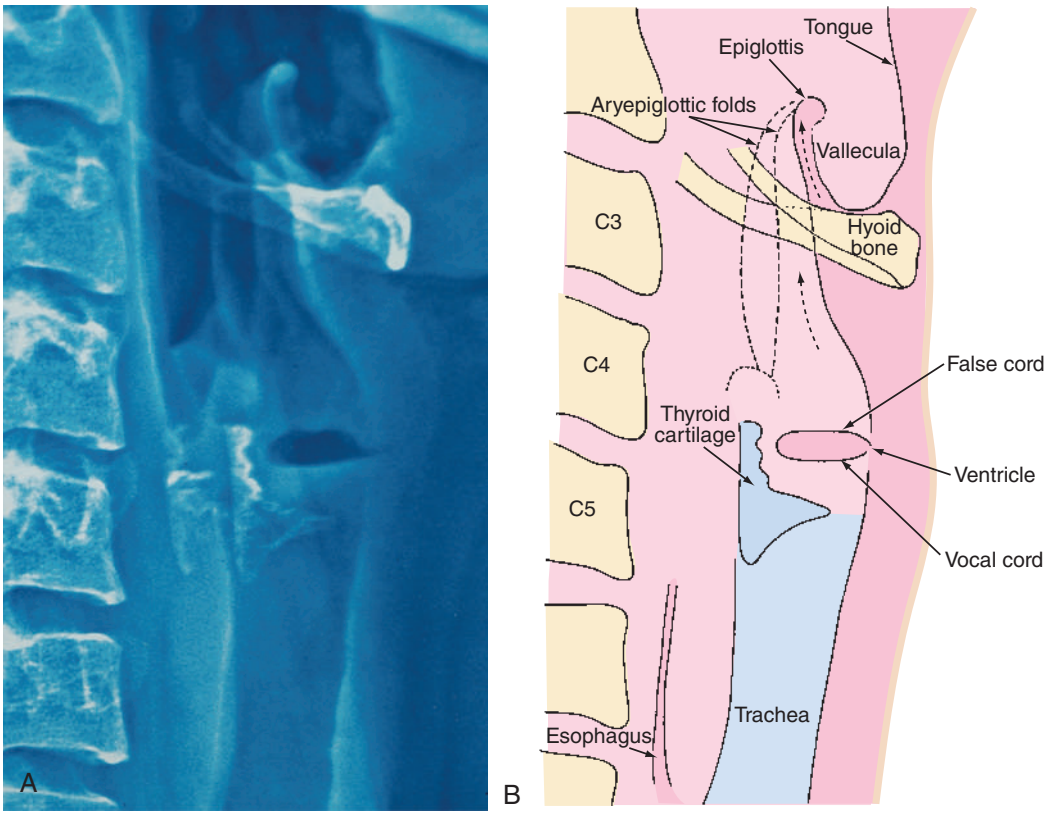

FIGURE 14.4 Lateral neck xerogram **(A)** and schematic diagram **(B)** of the larynx in an adult. Notice the relatively thin, broad epiglottis, the axis of the epiglottis which is parallel to the trachea. The hyoid bone "hugs" the epiglottis; there is no subglottic narrowing. Also note how the vocal cords are perpendicular to the axis of the trachea.

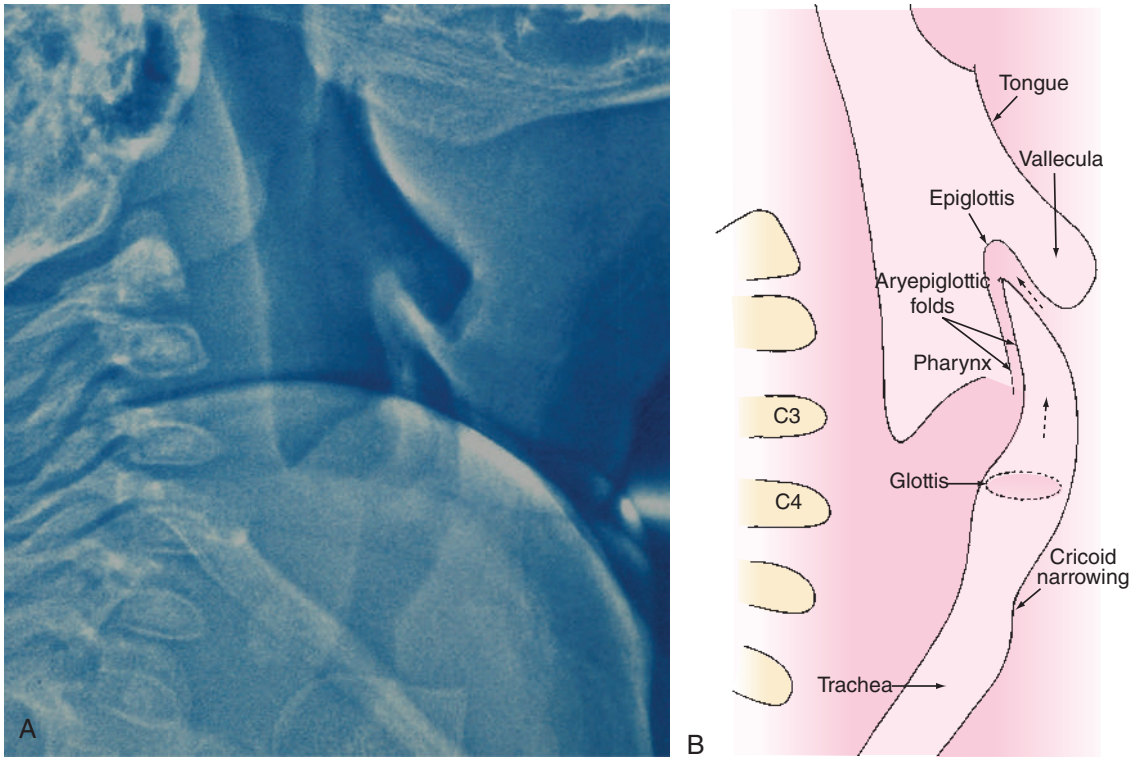

FIGURE 14.5 Lateral neck xerogram **(A)** and schematic diagram **(B)** of an infant's larynx. Notice the angled epiglottis and the narrow cricoid cartilage. Also note that the vocal cords are angled with a higher attachment anteriorly than posteriorly compared with the perpendicular position of the vocal cords in adults.

would decrease by only 44% (to 6 mm). Physiologically, because the resistance to airflow in the upper airway is turbulent, this reduction in diameter of the upper airway would increase the resistance to flow by the *radius to the fifth power*, or 32-fold, in the infant, compared with 5-fold in the adult. (Fig. 14.7).[2]

The Larynx

Understanding the anatomy and function of the larynx is critical to knowledgeable, safe, and successful airway management.

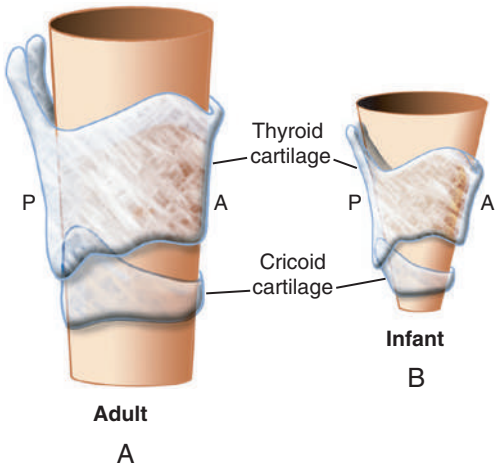

FIGURE 14.6 Configuration of the larynx of an adult **(A)** and an infant **(B)**. Notice that both larynxes are somewhat funnel shaped, but this shape is exaggerated in the infant and toddler. The adult laryngeal structures are of such size that most endotracheal tubes pass easily into the trachea. In infants and toddlers, it is common for the endotracheal tube (ETT) to pass easily through the vocal cords but to become snug at the level of the nondistensible cricoid cartilage. Concern for causing edema at this point resulted in the classic teaching that uncuffed ETTs should be used in young children (see text for more details). *A,* anterior; *P,* posterior.

ANATOMY

Structure

The larynx is composed of 1 bone (hyoid) and 11 cartilages (the single thyroid, cricoid, and epiglottic cartilages and the paired arytenoid, corniculate, cuneiform, and triticeal cartilages). These cartilages are suspended by ligaments from the base of the skull. The body of the cricoid cartilage articulates posteriorly with the inferior cornu of the thyroid cartilage. The paired triangular arytenoid cartilages rest on top of, and articulate with the superoposterior aspect of the cricoid cartilage. The arytenoid cartilages are protected by the thyroid cartilage (Fig. 14.8). The triticeal cartilages are rounded nodules of cartilage, approximately the size of a pea in adults, located in the margins of the lateral thyrohyoid ligament.

Tissue folds and muscles cover these cartilages. In contrast to adults, but comparable to most mammals, the cartilaginous glottis accounts for 60% to 75% of the length of the vocal folds in children younger than 2 years of age.[17] Contraction of the intrinsic laryngeal muscles alters the position and configuration of these tissue folds, thus influencing laryngeal function during respiration, forced voluntary glottic closure (Valsalva maneuver), reflex laryngospasm, swallowing, and phonation (Fig. 14.9).

The laryngeal tissue folds consist of the following:

- Paired aryepiglottic folds extending from the epiglottis posteriorly to the superior surface of the arytenoids (the paired cuneiform and corniculate cartilages lie within for support and reinforcement, much like the metal stays in a shirt collar)
- Paired vestibular folds (false vocal cords) extending from the thyroid cartilage posteriorly to the superior surface of the arytenoids
- Paired vocal folds (true vocal cords) extending from the posterior surface of the thyroid plate to the anterior projection or vocal process of the arytenoids
- A single interarytenoid fold (composed of the interarytenoid muscle covered by tissue) bridging the arytenoid cartilages
- A single thyrohyoid fold extending from the hyoid bone to the thyroid cartilage

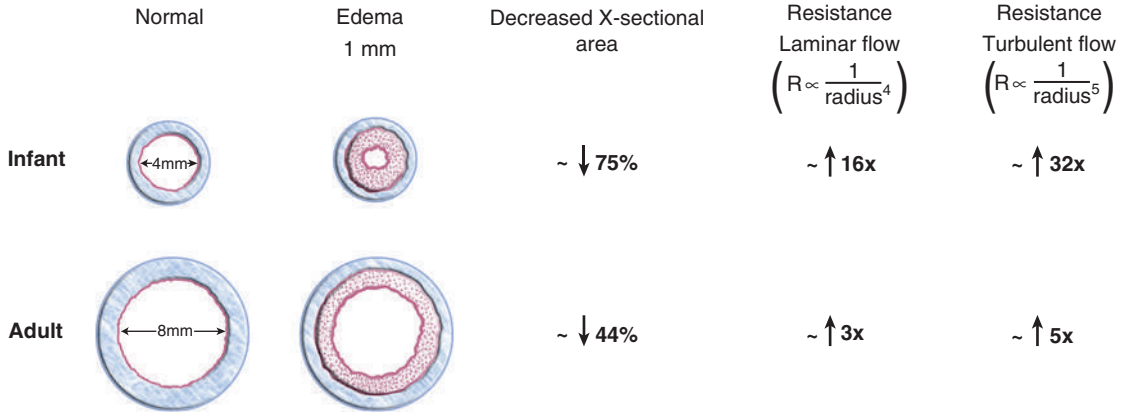

FIGURE 14.7 Relative effects of airway edema in an infant and an adult. The normal airways of an infant and an adult are presented on the left. Edematous airways display 1 mm of circumferential edema, reducing the diameter of the lumen by 2 mm. Notice that resistance to airflow is inversely proportional to the radius of the lumen to the fourth power for laminar flow (beyond the fifth bronchial division) and to the radius of the lumen to the fifth power for turbulent flow (from the mouth to the fourth bronchial division). The net result in an infant with a 4-mm diameter airway is a 75% reduction in cross-sectional area and a 16-fold increase in resistance to laminar airflow, compared with a 44% reduction in cross-sectional area and a 3-fold increased resistance in an adult with a similar 2-mm reduction in airway diameter. With turbulent airflow (upper airway), the resistance increases 32-fold in the infant but only 5-fold in the adult.

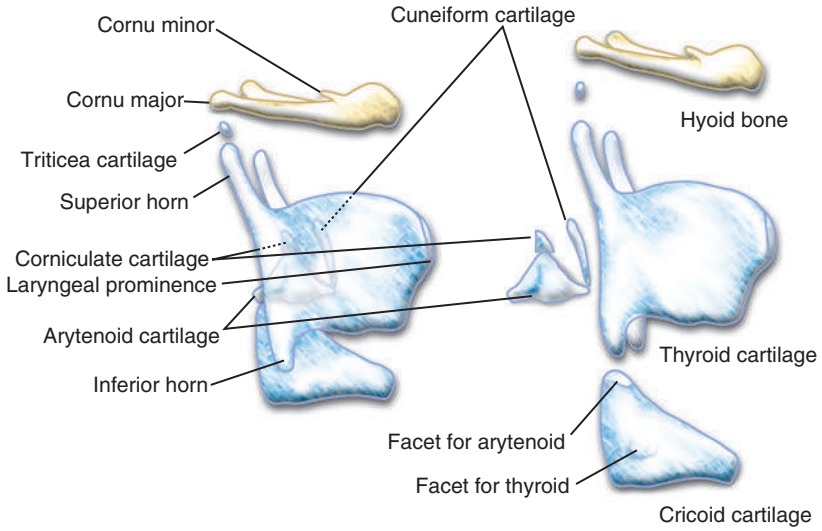

FIGURE 14.8 Laryngeal cartilages. The natural positions of the laryngeal cartilages are presented on the left, with the individual cartilages separated on the right. FIGURE 14.9 Photograph **(A)** and schematic diagram **(B)** of the larynx of a premature infant.

Histology

The highly vascular mucosa of the mouth is continuous with that of the larynx and trachea. This mucosa consists of squamous, stratified, and pseudostratified ciliated epithelium. The vocal cords are covered with stratified epithelium. The mucosa and submucosa are rich in lymphatic vessels and seromucous-secreting glands, which lubricate the laryngeal folds. The submucosa consists of loose fibrous stroma; therefore the mucosa is loosely adherent to the underlying structures in most areas. However, the submucosa is scant on the laryngeal surface of the epiglottis and the vocal cords, so the mucosa is tightly adherent in these areas.[20,21] Most inflammatory processes of the airway above the level of the vocal cords are limited by the barrier formed by the firm adherence of the mucosa to the vocal cords.[21] For example, the inflammation of epiglottitis is usually limited to the supraglottic structures, and the loosely adherent mucosa explains the ease with which localized swelling occurs (see Figs. 33.22 and 33.23). In a similar manner, an inflammatory process of the subglottic region (laryngotracheobronchitis [croup]) results in significant subglottic edema in the loosely adherent mucosa of the airway below the vocal cords, but it does not usually spread above the level of the vocal cords (see Fig. 33.21C).[20]

Sensory and Motor Innervation

Two branches of the vagus nerve, the recurrent laryngeal and the superior laryngeal nerves, supply both sensory and motor innervation to the larynx. The superior laryngeal nerve has two branches: the internal branch, which provides sensory innervation to the supraglottic region, and the external branch, which supplies motor innervation to the cricothyroid muscle. The recurrent laryngeal nerve provides sensory innervation to the subglottic larynx and motor innervation to all other laryngeal muscles.[21,22] Local anesthetic agents injected to block the superior laryngeal nerve result in anesthesia of the supraglottic region down to the inferior

margin of the epiglottis and motor blockade of the cricothyroid muscle, which causes relaxation of the vocal cords. Translaryngeal injection of local anesthetic through the cricothyroid membrane or a specific recurrent laryngeal nerve block is required for infraglottic and tracheal anesthesia.[23–25]

Blood Supply

Laryngeal branches of the superior and inferior thyroid arteries provide the blood supply to the larynx. The recurrent laryngeal nerve and artery lie in close proximity to each other, which accounts for the occasional vocal cord paresis after attempts to control bleeding during thyroidectomy.[26]

FUNCTION

Inspiration

During inspiration, the larynx is pulled caudad by the negative intrathoracic pressure generated by the descent of the diaphragm and contraction of the intercostal muscles. Thus, the larynx is stretched longitudinally, increasing the distance between the aryepiglottic and vestibular folds as well as between the vestibular and vocal folds. When the intrinsic muscles within the larynx contract, the arytenoids move laterally and posteriorly (rocking backward and rotating laterally), increasing the interarytenoid distance and separating as well as stretching the paired aryepiglottic, vestibular, and vocal folds. Overall, inspiration enlarges the laryngeal inlet, both longitudinally (like opening a telescope) and laterally, allowing the passage of greater quantities of air through the airway per unit time.

Expiration

At the end of expiration, the larynx reverts to its resting position, with longitudinal shortening of the distance between the aryepiglottic, vestibular, and vocal folds (like closing of a telescope). The arytenoids return simultaneously to their resting position by rotating medially and rocking forward, thus decreasing the interarytenoid distance and reducing the tension on the paired aryepiglottic, vestibular, and vocal folds and causing them to thicken.

Forced Glottic Closure and Laryngospasm

Glottic closure during forced expiration (forced glottic closure or Valsalva maneuver) is voluntary laryngeal closure and is physiologically similar to involuntary laryngeal closure (laryngospasm). Forced glottic closure occurs at several levels. Contraction of the intrinsic laryngeal muscles results in (1) marked reduction in the interarytenoid distance; (2) anterior rocking and medial movement of the arytenoids that causes apposition of the paired vocal, vestibular, and aryepiglottic folds; (3) longitudinal shortening of the larynx that obliterates the space between the aryepiglottic, vestibular, and vocal folds (like complete closing of a telescope). Contraction of an extrinsic laryngeal muscle, the thyrohyoid, pulls the hyoid bone caudad and the thyroid cartilage upward (cephalad), leading to further closure.[1,3,4,27–30]

Closure of the larynx during laryngospasm is similar to, but not identical to that described for voluntary forced glottic closure. There are two important differences. First, laryngospasm is accompanied by an inspiratory effort, which longitudinally separates the vocal from the vestibular folds. Second, in contrast to forced glottic closure, neither the thyroarytenoid muscle (an intrinsic muscle of the larynx) nor the thyrohyoid muscle contract; thus, apposition of the aryepiglottic folds and median thyrohyoid folds is minimal. These two differences allow the upper portion of the larynx to be left partially open during mild laryngospasm, resulting in the hallmark high-pitched inspiratory stridor (see Video 14.1).[1,27] Anterior and upward displacement of the mandible (jaw thrust applied at the condyle of the ascending ramus of the mandible) longitudinally separates the base of the tongue, the epiglottis, and the aryepiglottic folds from the vocal folds, helping to relieve laryngospasm.[28]

Swallowing

Glottic closure during swallowing is also similar to that which occurs during forced closure of the glottis. Protection of the glottic opening is achieved primarily by apposition of the laryngeal folds and secondarily by upward (cephalad) movement of the larynx. The upward movement of the larynx brings the thyroid cartilage closer to the hyoid bone, resulting in folding of the epiglottis over the glottic opening.[1,27,29,30] With loss of consciousness or deep sedation, the normal protective mechanism of the larynx may be lost or obtunded, thus predisposing to pulmonary aspiration of pharyngeal contents.

Phonation

Phonation is accomplished by alteration of the angle between the thyroid and cricoid cartilages (the cricothyroid angle) and by medial movement of the arytenoids during expiration.[1,22,31] These movements result in fine alterations in vocal fold tension during movement of air, causing vibration of the vocal folds. Lesions or malfunctions of the vocal folds (e.g., inflammation, papilloma, paresis) therefore affect phonation. Phonation is the only laryngeal function that alters the cricothyroid angle.[1] Therefore, despite significant airway obstruction during inspiration, it may still be possible to phonate.

Physiology of the Respiratory System

OBLIGATE NASAL BREATHING

Infants are considered obligate nasal breathers.[32,33] Obstruction of their anterior or posterior nares (nasal congestion, stenosis, choanal atresia) can cause asphyxia.[34–36] Immaturity of coordination between respiratory efforts and oropharyngeal motor and sensory input accounts in part for obligate nasal breathing.[37] Furthermore, because the larynx is more cephalad in the neck of an infant and oropharyngeal structures are closer together, the tongue rests against the roof of the mouth during quiet respiration, resulting in oral airway obstruction.[33] Multiple sites of pharyngeal airway obstruction may also contribute to airway obstruction when the infant attempts to breathe against a partially obstructed upper airway or with relaxation of upper airway muscle tone after sedation or induction of anesthesia.[38–42]

The ability to coordinate breathing and swallowing improves as the infant matures. The larynx enlarges and moves more caudad in the neck as the cervical spine lengthens and the infant begins to breathe adequately through the mouth. This matures by age 3 to 5 months. The ability to breathe through the mouth when the nares are obstructed is age dependent: 8% of preterm infants of 31 to 32 weeks postconception age were able to breathe through the mouth in response to nasal occlusion compared with 28% of more mature preterm infants of 35 to 36 weeks postconception age[43]; approximately 40% of full-term infants can switch from nasal to oral breathing.[44] However, the ability of premature neonates to breathe through the mouth may not be as poor as these early reports suggested. Slow and fast nasal occlusion applied to 17 healthy preterm infants (gestational age, 32 ± 1 weeks; postnatal age, 12 ± 2 days) led to a switch from nasal to oral breathing.

These improved results were attributed to the more extended observation period (>15 seconds) in the later study.[45] The presence of a nasogastric tube may also affect the infant's breathing if the "unobstructed" nasal passage has an existing underlying obstruction.

TRACHEAL AND BRONCHIAL FUNCTION

Tracheal and bronchial diameters are a function of elasticity and of distending or compressive forces (Fig. 14.10). The larynx, trachea, and bronchi in the infant are quite compliant compared with those in the adult and therefore are more subject to distention and compression forces.[32,46,47] The intrathoracic trachea is subject to stresses that are different from those in the extrathoracic portion.[46] During expiration, intrathoracic pressure remains slightly negative, maintaining patency of the intrathoracic trachea and bronchi (see Fig. 14.10B). During inspiration, a greater negative intrathoracic pressure dilates and stretches the *intrathoracic* trachea and bronchi.[48] The *extrathoracic* trachea at the thoracic inlet is slightly narrowed by dynamic compression that results from the differential between intratracheal and atmospheric pressures. However, the cartilages of the trachea, along with the muscles and soft tissues of the neck, maintain patency of the airway (see Fig. 14.10A).

Obstruction of the extrathoracic upper airway that can occur with epiglottitis, laryngotracheobronchitis, or an extrathoracic foreign body alters normal airway dynamics. Inspiration against an obstruction results in more negative intrathoracic pressure, further dilating the intrathoracic airways. Clinically, the net effect is a dynamic collapse of the extrathoracic trachea below the level of the obstruction. This collapse is maximal at the thoracic inlet, where the greatest pressure gradient exists between negative intratracheal and atmospheric pressures. As a result, inspiratory stridor is prominent (see Fig. 14.10C and Video 14.1).[46–53] With intrathoracic tracheal obstruction (e.g., foreign body, vascular ring) (see Video 14.1), stridor may occur during both inspiration and expiration.[54–57] In lower airway obstruction (e.g., asthma, bronchiolitis), significant intrathoracic tracheal and bronchial collapse may occur as a result of the prolonged expiratory phase and greatly increased positive extraluminal pressure (see Fig. 14.10D).[58] In addition, because the airways in children are very compliant, they may be more susceptible to closure during bronchial smooth muscle contraction (e.g., with reactive airway disease). Preterm and term infants may experience airway closure even during quiet respiration.

Avoiding dynamic airway collapse is particularly important. The very compliant trachea and bronchi of an infant or child are prone to collapse, particularly at the extremes of transluminal pressures that may occur when a child is crying vigorously. The susceptibility of a child to these dynamic forces on the airway is inversely related to age, with preterm infants being most susceptible and adults being least susceptible.[59] For this reason, it is essential that children with airway obstruction remain calm. Skill and understanding are required on the parts of the parents, nursing staff, and physicians. *Sedatives and opioids should be used with caution before insertion of an ETT, because they may depress or ablate the life-sustaining voluntary efforts to breathe, resulting in significant morbidity or mortality.*

WORK OF BREATHING

Work of breathing (WOB) may be defined as the product of pressure and volume. It may be analyzed by plotting transpulmonary pressure against tidal volume. The WOB per kilogram body weight is similar in infants and adults. However, the oxygen consumption of a full-term neonate (5–7 mL/kg per minute) is several times that of an adult (2-3 mL/kg per minute).[60] This greater oxygen consumption (and greater carbon dioxide production) in infants accounts in part for their increased respiratory frequency compared with older children. In preterm infants, the oxygen consumption related to breathing is three times that in adults.[61]

The location of airway resistance within the tracheobronchial tree differs between infants and adults. The nasal passages account for 25% of the total resistance to airflow in a neonate, compared with 60% in an adult.[33,62] In infants, most resistance to airflow occurs in the bronchi and small airways. This results from the relatively smaller diameter of the airways and the greater compliance of the supporting structures of the trachea and bronchi.[32,63,64] In particular, the soft cartilaginous chest wall of a neonate is very compliant; the ribs provide less support to maintain negative intrathoracic pressure. This lack of negative intrathoracic pressure combined with the increased compliance of the bronchi can lead to functional airway closure with every breath.[65–67] In infants and children, therefore, small-airway resistance accounts for most of the WOB, whereas in adults, the nasal passages provide the major proportion of flow resistance.[33,65,66,68–73]

In the presence of increased airway resistance or decreased lung compliance, an increased transpulmonary pressure is required to produce a given tidal volume, and therefore the WOB is increased. Any change in the airway that increases the WOB may lead to respiratory failure. Recall that the WOB (resistance to air flow) is inversely proportional to the fourth power of the radius of the lumen during laminar flow (beyond the fifth bronchial division) and to the fifth power of the radius during turbulent flow (upper airway to the fifth bronchial division). Because the diameter of the airways in infants is smaller than in adults, pathologic narrowing of the airways in infants exerts a greater adverse effect on the WOB. Increase in the WOB may also occur with a long ETT of small diameter, an obstructed ETT, or a narrowed airway. All of these situations increase oxygen consumption, which in turn increases oxygen demand.[74] The increased oxygen demand is initially addressed by an increase in respiratory rate, but the increased WOB may not be sustainable. The end result may be exhaustion, which leads to respiratory failure (CO_2 retention and hypoxemia) (Fig. 4.9).

The difference in histology of the diaphragm and intercostal muscles of preterm and full-term infants compared with older children contributes to increased susceptibility of infants to respiratory fatigue or failure. Type I muscle fibers permit prolonged repetitive movement; for example, long-distance runners through repeated exercise increase the proportion of type I muscle fibers in their legs. The percentage of type I muscle fibers in the diaphragm and intercostal muscles increases with age (preterm infants < full-term infants < 2-year-old children) (Fig. 14.11). Any condition that increases the WOB in preterm and full-term neonates may fatigue the respiratory muscles and precipitate respiratory failure more readily than in an adult.[75–77]

AIRWAY OBSTRUCTION DURING ANESTHESIA

Airway obstruction during anesthesia or loss of consciousness appears to be most frequently related to loss of muscle tone in the pharyngeal and laryngeal structures rather than apposition of the tongue to the posterior pharyngeal wall.[38,39,78,79] The progressive loss of tone with deepening anesthesia results in progressive airway obstruction primarily at the level of the soft palate and the epiglottis.[38,39,42,78,80,81] In children, the pharyngeal airway space decreases

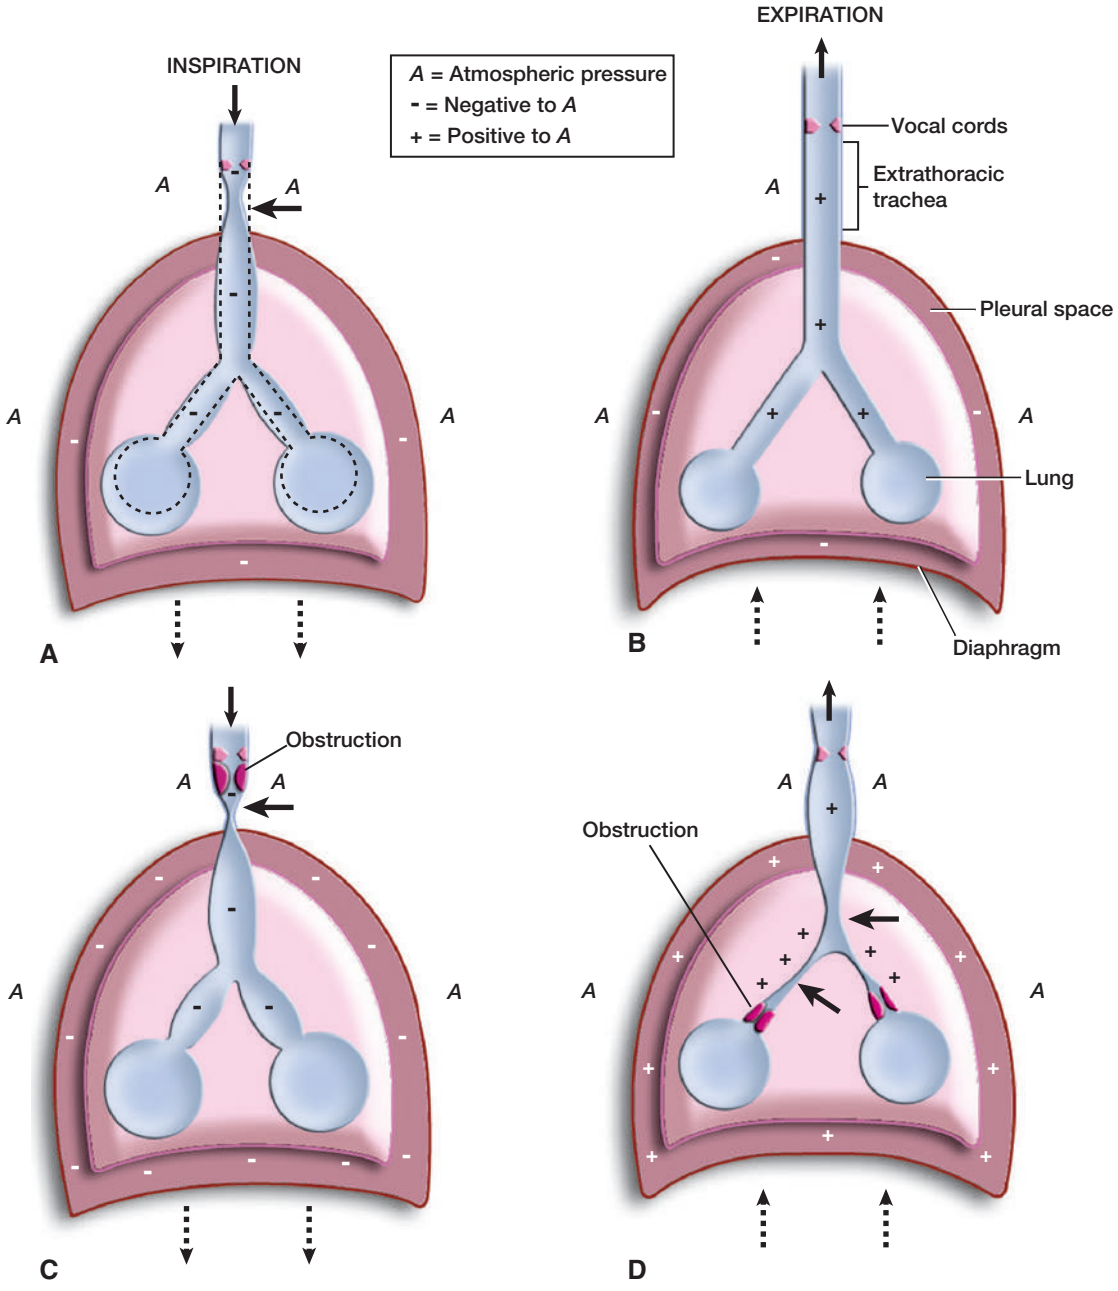

FIGURE 14.10 **A,** With descent of the diaphragm and contraction of the intercostal muscles, a greater negative intrathoracic pressure relative to intraluminal and atmospheric pressure is developed. The net result is longitudinal stretching of the larynx and trachea, dilatation of the intrathoracic trachea and bronchi, movement of air into the lungs, and some dynamic collapse of the extrathoracic trachea (*arrow*). The dynamic collapse is due to the highly compliant trachea and the negative intraluminal pressure in relation to atmospheric pressure. **B,** The normal sequence of events at end-expiration is a slight negative intrapleural pressure stenting the airways open. In infants, the highly compliant chest does not provide the support required; therefore airway closure occurs with each breath. Intraluminal pressures are slightly positive in relation to atmospheric pressure, with the result that air is forced out of the lungs. **C,** Obstructed extrathoracic airway. Notice the severe dynamic collapse of the extrathoracic trachea below the level of obstruction. This collapse is greatest at the thoracic inlet, where the largest pressure gradient exists between negative intratracheal pressure and atmospheric pressure (*arrow*). (Extrathoracic upper airway obstruction is characterized by inspiratory stridor.) **D,** Obstructed intrathoracic trachea or airways. Notice that breathing against an obstructed lower airway (e.g., bronchiolitis, asthma) results in greater positive intrathoracic pressures, with dynamic collapse of the intrathoracic airways (prolonged expiration or wheezing [*arrows*]).

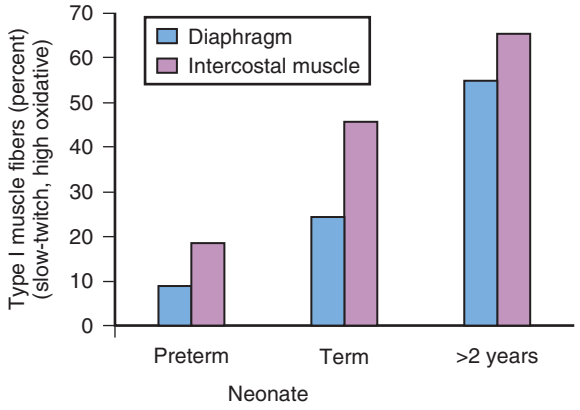

FIGURE 14.11 Muscle fiber composition of the diaphragm and intercostal muscles related to age. Note that a preterm infant's diaphragm and intercostal muscles have fewer type I fibers compared with term newborns and older children. The data suggest a possible mechanism for early fatigue in preterm and term infants when the work of breathing is increased. (Data from Keens TG, Bryan AC, Levison H, Ianuzzo CD. Developmental pattern of muscle fiber types in human ventilatory muscles. *J Appl Physiol.* 1978;44:909–913.)

in a dose-dependent manner with increasing concentrations of both sevoflurane and propofol anesthesia.[82–84] This reduction in pharyngeal space has been observed mainly in the anteroposterior dimension. As the depth of propofol anesthesia in children increases, upper airway narrowing occurs throughout the entire upper airway but is most pronounced in the hypopharynx at the level of the epiglottis. Extension of the head at the atlantooccipital joint with anterior displacement of the cervical spine (sniffing position) improves hypopharyngeal airway patency but does not necessarily change the position of the tongue. This observation supports the concept that upper airway obstruction is not primarily caused by changes in tongue position but rather by collapse of the pharyngeal structures.[40–42]

Pharyngeal airway obstruction also occurs during obstructive sleep apnea in children and adults.[37,85] The sniffing position increases the cross-sectional area and decreases the closing pressure of both the retropalatal and the retroglossal space in anesthetized adults with obstructive sleep apnea.[86] The application of continuous positive airway pressure (CPAP) is a common method to overcome such airway obstruction (see Figs. 33.10 and 33.11). During propofol anesthesia in children, CPAP works primarily by increasing the transverse dimension of the airway.[83] This occurs despite the fact that anesthesia obstructs the airway mostly by narrowing the anteroposterior dimension. Chin lift and jaw thrust also improve airway patency in anesthetized children with adenotonsillar hypertrophy.[87–89] Lateral positioning (also known as the "recovery or tonsillectomy position") dramatically enhances the effects of these airway maneuvers[88,89]; lateral positioning alone improves airway dimensions.[6] Compared with chin lift and CPAP, the jaw thrust maneuver is the most effective means to improve airway patency and ventilation in children undergoing adenotonsillectomy[87] (see Video 14.2).

Evaluation of the Airway

A history and physical examination with specific reference to the airway should be performed in all children who require sedation or anesthesia. In particular, a history of a congenital syndrome or physical findings of a congenital anomaly (e.g., microtia, which has been associated with difficult laryngoscopy)[90] should alert the practitioner to the possibility of difficulties with airway management. In special situations, radiologic and laboratory studies are required to further evaluate and clarify a disorder revealed by the history and physical examination. Although many methods exist for evaluating and predicting the difficult airway in adults,[91–95] no comparable methods have been forthcoming in children.[96,97] Large neck circumference correlated with other issues, such as snoring, asthma, hypertension, and diabetes in children as well as adverse perioperative respiratory events, but not with difficult laryngoscopy.[98] Routine evaluation of the airway in all children often sheds insight into the risk of a difficult airway. Characteristics that portend a difficult laryngoscopy and intubation include diagnosis of a specific syndrome associated with a difficult intubation (e.g., Treacher Collins syndrome), the inability to open the mouth (e.g., temporomandibular joint ankylosis, micrognathia Pierre Robin sequence or first arch syndrome), massive glossoptosis (e.g., Beckwith-Wiedemann syndrome), fused cervical spine (e.g., Klippel-Feil syndrome), or oropharyngeal space occupying lesions (e.g., cystic hygroma or glossopharyngeal tumors). For some syndromes, the airway improves with age (e.g., Pierre Robin sequence), whereas with others (e.g., Treacher Collins), the airway becomes progressively more difficult with age.

CLINICAL EVALUATION

Medical History

The *medical history* (both present and past) should investigate the following signs and symptoms; a positive history should alert the practitioner to the potential problems noted in parentheses.

- Presence of an upper respiratory tract infection (predisposition to coughing, laryngospasm, bronchospasm, and desaturation during anesthesia or to postintubation subglottic edema or postoperative desaturation)[99–104]
- Snoring, noisy breathing, obesity (adenoidal hypertrophy, upper airway obstruction, obstructive sleep apnea, pulmonary hypertension)[105]
- Presence and nature of cough ("croupy" cough may indicate subglottic stenosis or previous tracheoesophageal fistula repair; productive cough may indicate bronchitis or pneumonia; chronicity affects the differential diagnosis [e.g., the sudden onset of a persistent cough may indicate foreign-body aspiration; a night cough may indicate tracheal compression from a thoracic mass])
- Past episodes of croup (postintubation croup, subglottic stenosis)
- Inspiratory stridor, usually high-pitched (subglottic narrowing [see Video 14.1], laryngomalacia [see Video 14.1], macroglossia, laryngeal web [Video 14.3], extrathoracic foreign body or extrathoracic tracheal compression)
- Hoarse voice (laryngitis, vocal cord palsy, papillomatosis [see Video 14.1], granuloma [see Video 14.1])
- Asthma and bronchodilator therapy (bronchospasm)
- Repeated pneumonias (incompetent larynx with aspiration, gastroesophageal reflux, cystic fibrosis, bronchiectasis, residual tracheoesophageal fistula, pulmonary sequestration, immune suppression, congenital heart disease)
- History of foreign-body aspiration (increased airway reactivity, airway obstruction, impaired neurologic function)
- History of aspiration (laryngeal edema [Video 14.3], laryngeal cleft)
- Previous anesthetic problems, particularly related to the airway (difficult intubation, difficulty with mask ventilation, failed or problematic extubation)

- Atopy, allergy (increased airway reactivity)[104]
- History of smoking by primary caregivers (increased airway resistance, increased propensity to desaturation)[104,106]
- History of a congenital syndrome (many are associated with difficult airways)
- History of prematurity (subglottic stenosis, bronchopulmonary dysplasia, apnea, desaturation)

Physical Examination

The *physical examination* should include the following observations:

- Facial expression
- Presence or absence of nasal flaring
- Presence or absence of mouth breathing
- Color of mucous membranes
- Presence or absence of retractions (suprasternal, intercostal, subcostal [see Video 14.1])
- Respiratory rate
- Presence or absence of voice change
- Mouth opening (Fig. 14.12A)
- Size of mouth
- Size of tongue and its relationship to other pharyngeal structures (Mallampati Score)[107]
- Loose or missing teeth (see Fig. 14.12B)
- Size and configuration of palate
- Size and configuration of mandible
- Location of larynx in relation to the mandible (see Fig. 14.12C)
- Presence of stridor and, if present:
  - Is stridor predominantly inspiratory, suggesting an upper airway (extrathoracic) lesion (epiglottitis, croup, extrathoracic foreign body)?
  - Is stridor both inspiratory and expiratory, suggesting an intrathoracic lesion (aspirated foreign body, vascular ring, or large esophageal foreign body)? (see Video 14.1)
  - Is the expiratory phase prolonged or stridor predominantly expiratory, suggesting lower airway disease?
- Baseline oxygen saturation in room air
- Microtia (underdeveloped pinna): bilateral but not unilateral microtia is associated with difficulty in visualizing the laryngeal inlet (grade 3 or 4 in the Cormack-Lehane classification, see Fig. 14.22 later).[90] Five (42%) of 12 children with bilateral microtia were found to have a difficult laryngeal view compared with 2 (2.5%) of 81 children with unilateral microtia and 0 of 93 children without microtia.[90] Microtia may represent a mild form of hemifacial microsomia and its associated mandibular hypoplasia. The advantage of understanding this association is that ear deformity is often a more easily recognized clinical finding than mandibular hypoplasia.
- Global appearance: Are there congenital anomalies that may fit a recognizable syndrome? *The finding of one anomaly mandates a search for others.* If a congenital syndrome is diagnosed, specific anesthetic implications must be considered (see E-Table 14.1).

DIAGNOSTIC TESTING

Routine evaluation of the airway usually requires only a careful history and physical examination. In the presence of airway pathology, however, laboratory and radiologic evaluation can be extremely valuable. Radiographs of the upper airway (anteroposterior and lateral films and fluoroscopy) may provide evidence about the site and cause of airway obstruction. When necessary, MRI, CT, and three-dimensional (3-D) modeling provide more detailed information.[108–129] *Radiologic airway examination in a child with a compromised airway may be undertaken only if there is no immediate threat to the child's safety and only in the presence of skilled and appropriately equipped personnel able to manage the airway.* Securing the airway through tracheal intubation must not be postponed to obtain a radiologic diagnosis when the child has severely compromised air exchange. Blood gas analysis is occasionally of value for assessing the degree of physiologic compromise, especially with chronic airway obstruction and compensated respiratory acidosis. Performing an arterial (or venous) puncture for blood gas analysis may provide helpful information, but it is often upsetting to the child and may risk aggravation of the underlying airway obstruction through dynamic airway collapse. Candidates for blood gas analysis must be carefully selected and the procedure skillfully performed.

Endoscopic evaluation (flexible fiberoptic endoscopy) of the airway before tracheal intubation can be useful in infants and in cooperative older children if a glottic pathologic process is suspected or if difficulty is anticipated when visualizing the glottis. Ultrasound can also be used to examine the airway. It can be used to determine the internal diameter of the trachea, which can help with the selection of the optimal ETT size.[130]

Airway Management: The Normal Airway

MASK VENTILATION

Face masks are available in many sizes and shapes. We commonly use disposable, clear plastic masks with an inflatable cushioned

FIGURE 14.12 A, How far can a child open his or her mouth? Are there any abnormalities of the mouth, tongue, palate, or mandible? **B,** Are any teeth loose or missing? **C,** Is the mandible of normal configuration? How much space is there between the genu of the mandible and the thyroid cartilage? This space is an indication of the extent of the superior and posterior displacement of the larynx; there should normally be at least one finger breadth in a newborn and three finger breadths in an adolescent.

E-TABLE 14.1 Syndromes and Disease Processes With Associated Airway Difficulties

Syndrome	Airway	Cerebral	Cardiac	Renal	Gastrointestinal	Endocrine Metabolic	Musculoskeletal	Anesthetic Considerations
Achondroplasia[564–788, 959–963]	Midfacial hypoplasia, small nasal passages and mouth	Megacephaly ± hydrocephalus due to narrow foramen magnum					Dwarfism; odontoid hypoplasia with atlantoaxial instability	DI; difficult mask airway, ± hydrocephalus
Apert syndrome[564,785–788,802]	Maxillary hypoplasia, narrow palate ± cleft palate	Craniosynostosis, flat facies, hypertelorism	± Congenital heart disease	± Hydronephrosis, ± polycystic kidney	± Esophageal atresia		Syndactyly	DI; associated cardiac and renal problems
Arthrogryposis multiplex congenita (multiple congenital contractures)[964–968]	Associated hypoplastic mandible, cleft palate, Klippel-Feil syndrome, torticollis		± Ventricular septal defect				Thoracolumbar scoliosis	DI; associated cardiac disease; minimal muscle relaxant required, ± malignant hyperthermia
Beckwith-Wiedemann syndrome (visceromegaly)[585,690–695]	Macroglossia: regresses with age; may require partial glossectomy	± Mental handicap due to hypoglycemia	Large heart	Enlarged kidneys	Omphalocele, hepatosplenomegaly	Hypoglycemia up to 4 months of age, polycythemia	Eventration of diaphragm	DI; asymptomatic hypoglycemia; omphalocele; neonatal polycythemia
Cherubism (fibrous dysplasia of jaw)[815,816]	Bilateral painless mandibular and maxillary swelling may progress to airway obstruction							DI due to intraoral masses
Congenital hypothyroid	Large tongue	May be mentally handicapped				Hypothermia, hypometabolic	Umbilical hernia	DI; hypothermia; decreased drug metabolism
Cornelia de Lange syndrome[794–796]	High-arched palate, micrognathia, spurs at anterior angle of mandible, large tongue, ± cleft palate, short neck	Mental handicap	± Congenital heart disease					DI; associated cardiac disease
Craniofacial dysostosis of Crouzon (Crouzon syndrome)[802]	Maxillary hypoplasia with inverted V-shaped palate, ± large tongue	Ocular proptosis due to shallow orbits, craniosynostosis						DI; eye injury
Epidermolysis bullosa[876–884]	Pressure lesions to mouth and airway							Need gentle intubation with small tube; postoperative laryngeal obstruction due to bulla formation

E-TABLE 14.1 Syndromes and Disease Processes With Associated Airway Difficulties—cont'd

Syndrome	Airway	Cerebral	Cardiac	Renal	Gastrointestinal	Endocrine Metabolic	Musculoskeletal	Anesthetic Considerations
Freeman-Sheldon syndrome (whistling face)[822–833]	Small mouth, high palate	Hypertelorism, ± increased intracranial pressure, ± mental deficiency, ± microcephaly					Craniocarpotarsal dysplasia; strabismus; kyphoscoliosis; hip/knee contractures	DI; ± malignant hyperthermia[509,510]
Goldenhar syndrome (oculoauriculovertebral syndrome)[390,481,614,773–779]	Hypoplastic zygomatic arch, mandibular hypoplasia, macrostomia, ± cleft tongue, palate, tracheoesophageal fistula	Hydrocephalus					Occipitalization of atlas, cervical vertebral defects	DI; cervical spine defects
Hallermann-Streiff syndrome (oculomandibulodyscephaly)[801]	Malar hypoplasia, micrognathia, hypoplasia of rami and anterior displacement of TMJ, narrow high-arched palate							DI
Marfan syndrome[969,970]	Narrow facies with narrow palate		Dissecting aortic aneurysm, aortic insufficiency				Scoliosis, kyphosis	DI; associated cardiac and pulmonary disease
Mucopolysaccharidoses[628,700–702,707–710,714,715]								
Type IH (Hurler)[705]	Coarse facial features, macroglossia, short neck, tonsillar hypertrophy, narrowing of laryngeal inlet and tracheobronchial tree	± Increased intracranial pressure	Severe coronary artery and valvular heart disease, cardiomyopathy		Hepatosplenomegaly		Joint stiffness, kyphosis, contractures, odontoid hypoplasia, and atlantoaxial subluxation	DI; cervical spine instability; postobstructive pulmonary edema
Type IH/S (Hurler-Scheie)[711]	Macrocephaly, micrognathia	Mild mental deficiency to normal intelligence	± Valvular disease		± Hepatosplenomegaly		Mild joint stiffness	± DI
Type IS (Sheie) or type V[712]	Mandibular prognathism	Normal intelligence, corneal clouding	Aortic insufficiency				Joint stiffness	± DI
Type II (Hunter)[713]	Coarse facial features, tracheomalacia, macrocephaly, macroglossia	Increased intracranial pressure, severe mental deficiency	Valvular heart disease, cardiomyopathy		Hepatosplenomegaly		Joint stiffness, dwarfism, kyphoscoliosis	DI
Type III (Sanfilippo)	Mildly coarse facial features	Severe mental deficiency						± DI

E-TABLE 14.1 Syndromes and Disease Processes With Associated Airway Difficulties—cont'd

Syndrome	Airway	Cerebral	Cardiac	Renal	Gastrointestinal	Endocrine Metabolic	Musculoskeletal	Anesthetic Considerations
Type IV (Morquio)[698,699,706]	Mildly coarse facial features, prominent mandible, short neck		Late-onset aortic regurgitation				Joint laxity, kyphoscoliosis, odontoid hypoplasia with atlantoaxial instability	DI; cervical spine instability; restrictive pulmonary disease
Nager syndrome[661,971]	Micrognathia, cleft palate	Low-set ears, atresia of external auditory canal					Radial limb defects	DI
Papillomatosis larynx and trachea[899–904]	Difficult laryngoscopy		Pulmonary hypertension					DI; care not to seed papilloma into trachea
Pierre Robin syndrome (Robin sequence)[485,560,562,600,740–753]	Hypoplastic mandible; pseudomacroglossia; ± high-arched, cleft palate							DI
Pompe disease (cardiomuscular glycogen storage disease)[720–728]	Large tongue		Cardiomyopathy				Muscle weakness	DI; muscle weakness, sensitive to muscle relaxants; congestive heart failure, sensitive to myocardial depressants
Rheumatoid arthritis[808–814]	TMJ mobility limited, hypoplastic mandible, cricoarytenoid arthritis with narrow larynx		Myocarditis, valvular disease, especially aortic insufficiency			Steroid therapy, anemia	Cervical spine subluxation, rigid cervical spine	DI; cervical spine instability; associated heart disease; problems with positioning; steroid therapy
Rubinstein-Taybi syndrome[972–975]	Maxillary hypoplasia, narrow palate	Mental handicap	± Congenital heart disease				Associated cervical vertebral anomalies	DI; cervical spine instability; associated cardiac disease
Scleroderma[976,977]	Extensive scarring of mouth, face, body					Steroid therapy		DI; decreased pulmonary compliance; steroid therapy
Smith-Lemli-Opitz syndrome[798–800]	Micrognathia, ± cleft palate, recurrent pneumonia	Moderate mental handicap, microcephaly	± Congenital heart disease					DI; associated cardiac disease
Stevens-Johnson syndrome[978,979]	Laryngeal, tracheal, bronchial, bullae, pneumothorax, pleural effusion		Myocarditis	Urethritis	Esophagitis, fluid shifts	Temperature elevations		DI; fluid balance; myocarditis; temperature control; avoid intubation if possible

E-TABLE 14.1 Syndromes and Disease Processes With Associated Airway Difficulties—cont'd

Syndrome	Airway	Cerebral	Cardiac	Renal	Gastrointestinal	Endocrine Metabolic	Musculoskeletal	Anesthetic Considerations
Thalassemia major (Cooley anemia)[980–983]	Malar hypoplasia causes relative mandibular hypoplasia		Hemosiderosis					May be DI; anemia; associated cardiac disease
Treacher Collins syndrome[411,561,586,758–769]	Malar, mandibular hypoplasia, ± cleft lip, ± choanal atresia, ± macrostomia or microstomia		± Congenital heart disease				± Cervical spine deformity	DI; associated cardiac disease
Trisomy 21 (Down syndrome)[840,935–941,984–987]	Small mouth, hypoplastic mandible, protruding tongue	Mental handicap	Atrioventricular communis, ventricular septal defect, atrial septal defect		Duodenal atresia		Hypotonia, cervical spine subluxation	May be DI; associated cardiac disease; require less muscle relaxant; increased risk of postintubation stridor
Turner syndrome (Noonan syndrome)[789–792]	Narrow maxilla, small mandible, short neck	Mental handicap	Coarctation of aorta in females, pulmonary artery coarctation in males	Idiopathic hypertension		Hypogonadism		DI; associated cardiac disease; hypertension

CHD, congenital heart disease; *DI*, difficult intubation; *TMJ*, temporomandibular joint; ±, may or may not have the problem.

rim. The inflatable rim molds to the contour of the face to provide an atraumatic seal. The use of clear plastic in the cone of the mask allows visualization of humidity (indicating air exchange), secretions, vomitus, and lip color. The appropriately sized mask should rest on the bridge of the nose (avoiding the eyes) and extend to the mandible. Although mask anesthesia appears to be easy, it is one of the most difficult skills to master. The most common error during mask ventilation is to tightly compress the submental triangle with fingers placed below the mandibular ridge, thereby partially occluding the airway. Minimal pressure is required, and the fingers should rest on the mandible. Another common problem arises when the mouth is completely closed while the face mask is being applied. The upper airway may become completely obstructed, with ventilation becoming impossible both spontaneously and by manual control. In such a circumstance, the fingers should be removed from the mandible and face and a single digit applied gently to the condyles of the mandible (for a brief period), while lifting toward the hairline, until a patent upper airway is established.[131] This maneuver subluxes the temporomandibular joint, thereby opening the mouth and pulling the tongue and other soft tissues off the posterior pharyngeal wall. A hand should be on the reservoir bag at all times to monitor the effectiveness of ventilation and to provide CPAP if needed to maintain a patent airway. An alternative method is to partially close the adjustable pressure-limiting valve to inflate the reservoir bag and provide CPAP. Insertion of an oral airway may also relieve upper airway obstruction (although care must be taken as the inserted airway may also obstruct breathing if the size is excessive or too small; Figs. 14.13D and F.). If these maneuvers do not clear the upper airway, then the vocal cords may be closed or the child is apneic. Additional interventions may then be required.

Admonitions against extreme positions of the infant's head during bag-and-mask ventilation are intended to minimize the risk of stretching and thus narrowing and obstructing the very compliant infant trachea. However, a study of 18 healthy, full-term infants younger than 4 months of age showed that the tracheal dimensions did not change when the head position changed.[132] Therefore, stretching of the trachea may not result in narrowing of the tracheal lumen in otherwise healthy infants (Video 14.4). This study did not examine the effects of these head positions on the supraglottic airway or in the preterm infant. It is possible that these maneuvers (head extension) could result in supraglottic airway obstruction in some children. One study investigated the incidence of unanticipated difficult mask ventilation in children from birth to 8 years and reported an incidence of 6.6%.[133]

OROPHARYNGEAL AIRWAYS

An infant's tongue may obstruct the airway during induction of anesthesia or loss of consciousness. An oropharyngeal airway of appropriate size (or a supraglottic airway [SGA] such as the laryngeal mask airway [LMA; LMA North America, San Diego, CA]) may be inserted to relieve the obstruction. By holding the oral airway as shown in Fig. 14.13, one can estimate the appropriate size for the child; airways one size larger and one size smaller should be readily available as well. A tongue depressor may be inserted over the tongue to facilitate insertion of an oral airway and prevent downfolding of the tongue, which could impair venous and lymphatic drainage, causing tongue swelling and airway obstruction. If the airway device is too long, it may push the epiglottis into the glottic aperture, creating an additional site of airway obstruction or causing traumatic epiglottitis, or the tip may impinge on the uvula, causing uvular swelling and airway obstruction (see Fig. 14.13C, D).[134,135] If the airway device is too short, it may rest against the base of the tongue, forcing it posteriorly against the roof of the mouth, further aggravating airway obstruction (Fig. 14.13E, F). Oral airways should not be considered panaceas for upper airway obstruction. Care must be taken to avoid trauma to the lips and tongue, which may be caught between the teeth and the flange of the airway. An oral airway is also used to protect an ETT from compression by the child's teeth, and it serves to separate the mandible and maxilla to facilitate oropharyngeal suctioning.

NASOPHARYNGEAL AIRWAYS

Nasopharyngeal airways (also known as Robertazzi nasopharyngeal airways [SunMed, Grand Rapids, MI]) are occasionally used in children to relieve upper airway obstruction; the distance from the naris to the angle of the mandible approximates the proper length. Commercial airways are available in sizes 12F to 36F (Rüsch Inc., Duluth, GA). Some have an adjustable flange that enables manipulation of the airway to the appropriate length. Alternatively, for infants and small children, a shortened ETT may be used, although this is not as soft and pliable as a commercially available non-latex nasopharyngeal airway and may be more likely to cause trauma with insertion. Softening the tip of the ETT by immersion in hot water before insertion has not been shown to reduce the incidence of bleeding during nasotracheal intubation in children.[136] The nasopharyngeal airway may be better tolerated in the lightly anesthetized child than an oropharyngeal airway. Nasopharyngeal airways are usually avoided to prevent trauma to, and bleeding from, hypertrophied adenoids, and they are more commonly used to relieve residual airway obstruction on emergence from anesthesia.

TRACHEAL INTUBATION

Technique

The techniques used to intubate the trachea in infants and children differ from those in adults.[1–4,28–30,113,137,138] The risk of obstruction with trauma to the airway structures is increased in infants because the dimensions of the pediatric airway are smaller in children. Advancing the blade into the esophagus and then slowly withdrawing it to visualize the larynx is a technique that should be avoided if possible. *This maneuver may result in laryngeal trauma when the tip of the blade scrapes the esophageal mucosa, arytenoids, and aryepiglottic folds.*

There are several approaches to exposing the glottis in infants with a Miller blade. One approach consists of advancing the laryngoscope blade under constant vision along the surface of the tongue, placing the tip of the blade directly in the vallecula, and then using this location to pivot or rotate the blade to the right to sweep the tongue to the left and adequately lift the tongue to expose the glottic opening. This technique avoids trauma to the arytenoid cartilages. Lifting the base of the tongue lifts the epiglottis, exposing the glottic opening. If this technique is unsuccessful, the epiglottis may be lifted directly with the tip of the blade (see Video 14.1). Another approach is to insert the Miller blade into the mouth at the right commissure over the lateral bicuspids/incisors as originally described by Miller (now known as the paraglossal approach).[139,140] The blade is advanced down the right gutter of the mouth, aiming the blade tip toward the midline while sweeping the tongue to the left. Once the blade is under the epiglottis, the epiglottis is lifted with the tip, exposing the glottic aperture. By

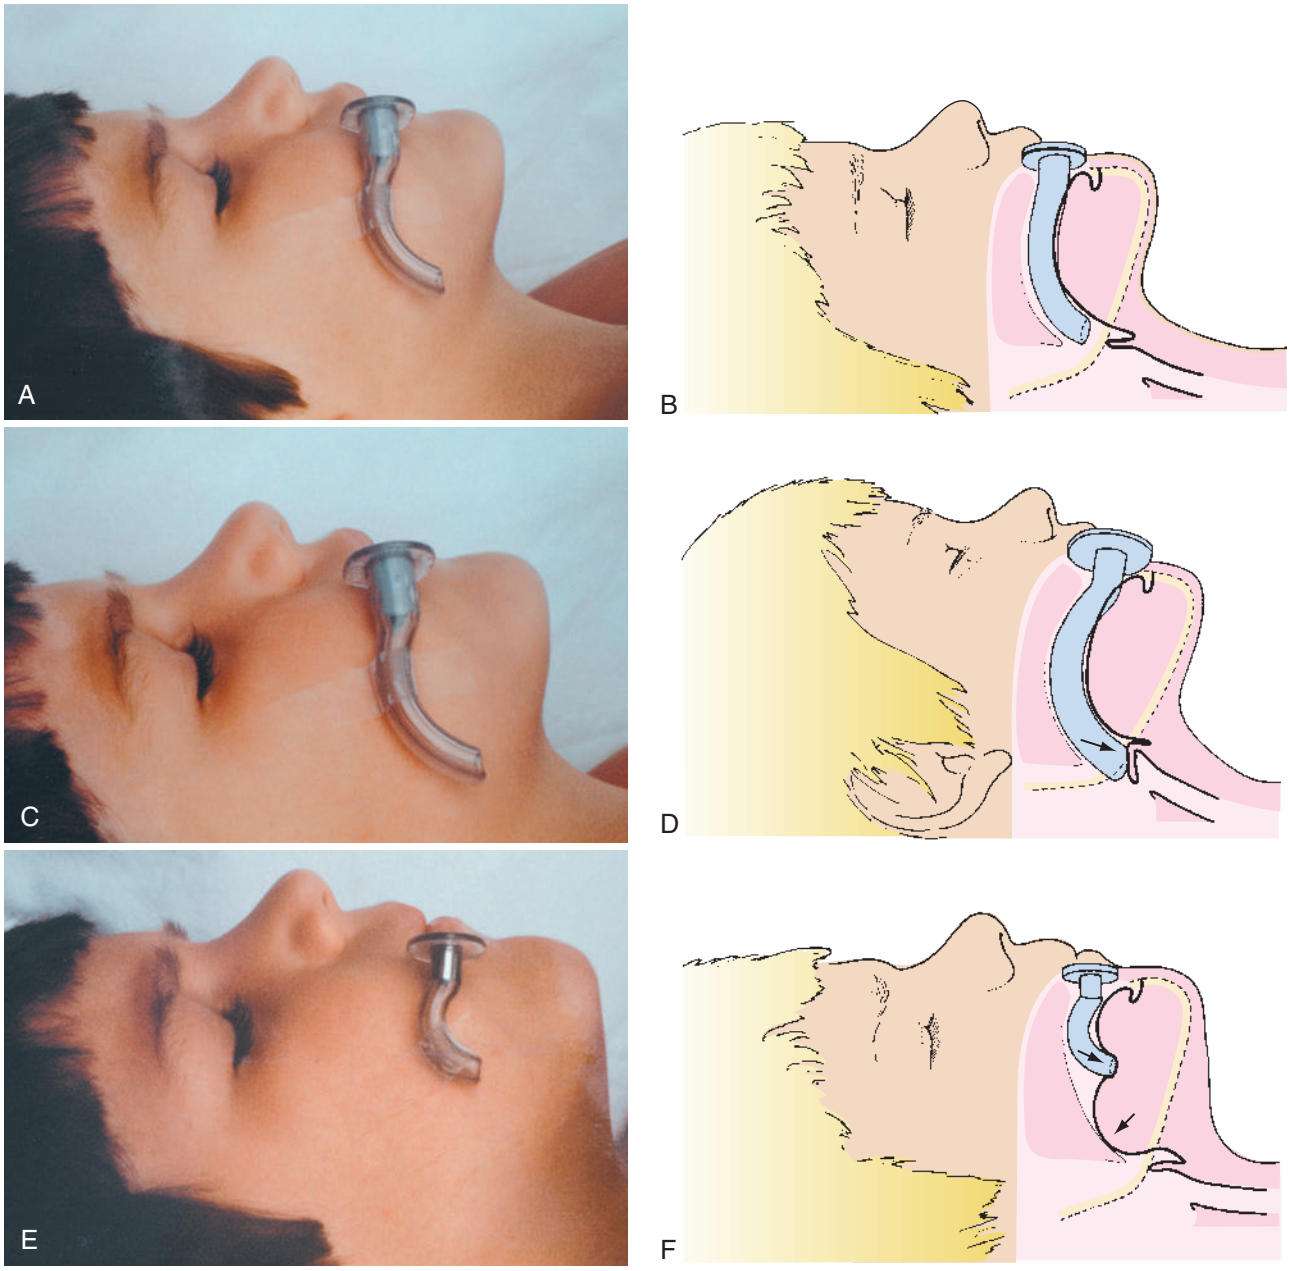

FIGURE 14.13 Correct airway selection. An artificial airway of proper size should relieve airway obstruction caused by the tongue without damaging laryngeal structures. The appropriate size can be estimated by holding the airway against the child's face: the tip of the airway should end just cephalad to the angle of the mandible **(A)**. Use of the correct size should result in proper alignment with the glottic opening **(B)**. If too large an oral airway is inserted, the tip will line up posterior to the angle of the mandible **(C)** and obstruct the glottic opening by pushing the epiglottis down (**D**, *arrow*). If too small an oral airway is inserted, the tip will line up well above the angle of the mandible **(E)** and exacerbate airway obstruction by kinking the tongue (**F**, *arrows*).

approaching the mouth over the bicuspids/incisors, damage to the maxillary central incisors is precluded. This is a particularly effective approach for the infant or child in whom intubation appears to be difficult. Whichever approach is used, care must be taken to avoid using the laryngoscope blade as a fulcrum through which pressure is applied to the teeth or alveolar ridge. If there is a substantive risk that pressure will be applied to the teeth, a plastic tooth guard may be applied to cover the teeth at risk (the central incisors of the maxilla).

Optimal positioning for laryngoscopy changes with age. The trachea of older children (≥6 years) and adults is most easily exposed when a folded blanket or pillow is placed beneath the occiput of the head (5- to 10-cm elevation), displacing the cervical spine anteriorly.[141] Extension of the head at the atlantooccipital joint produces the classic sniffing position.[113,142,143] These movements align three axes: those of the mouth or oral (O), pharynx (P), and trachea (T). Once aligned, these three axes permit direct visualization of laryngeal structures. They also result in improved

hypopharyngeal patency.[40,42,78,86,142,143] Fig. 14.14 demonstrates maneuvers for positioning the head during airway management. In infants and younger children, it is usually unnecessary to elevate the head because the occiput is large in proportion to the trunk, resulting in adequate anterior displacement of the cervical spine; head extension at the atlantooccipital joint alone aligns the airway axes. If the occiput is displaced excessively, exposure of the glottis may be hindered. In neonates, it is helpful for an assistant to hold the patient's shoulders flat on the operating room table with the head slightly extended. Some practitioners have adopted the practice of placing a rolled towel under the shoulders of neonates to facilitate tracheal intubation. This technique may be disadvantageous if the laryngoscopist stands but may be advantageous if he or she is seated.

The validity of the three-axis theory (alignment of the O, P, and T axes) to describe the optimal intubating position in adults has been challenged.[144–147] Some authors question the notion that elevation of the occiput improves conditions for visualization of the laryngeal inlet based on evidence from both MRI and clinical investigations.[144,146] However, one MRI study in children with an LMA in place found that slight head extension improved the alignment of the glottic and pharyngeal axes but worsened the alignment of the pharyngeal and laryngeal axes.[148] In a study of adults, neck extension alone was adequate for visualization of the larynx in most patients, but for obese patients and those with limited neck extension, an optimal intubating position was not determined.[144] Others favor the sniffing position but with varying support for the three-axis theory.[149–155] Even if the tracheas

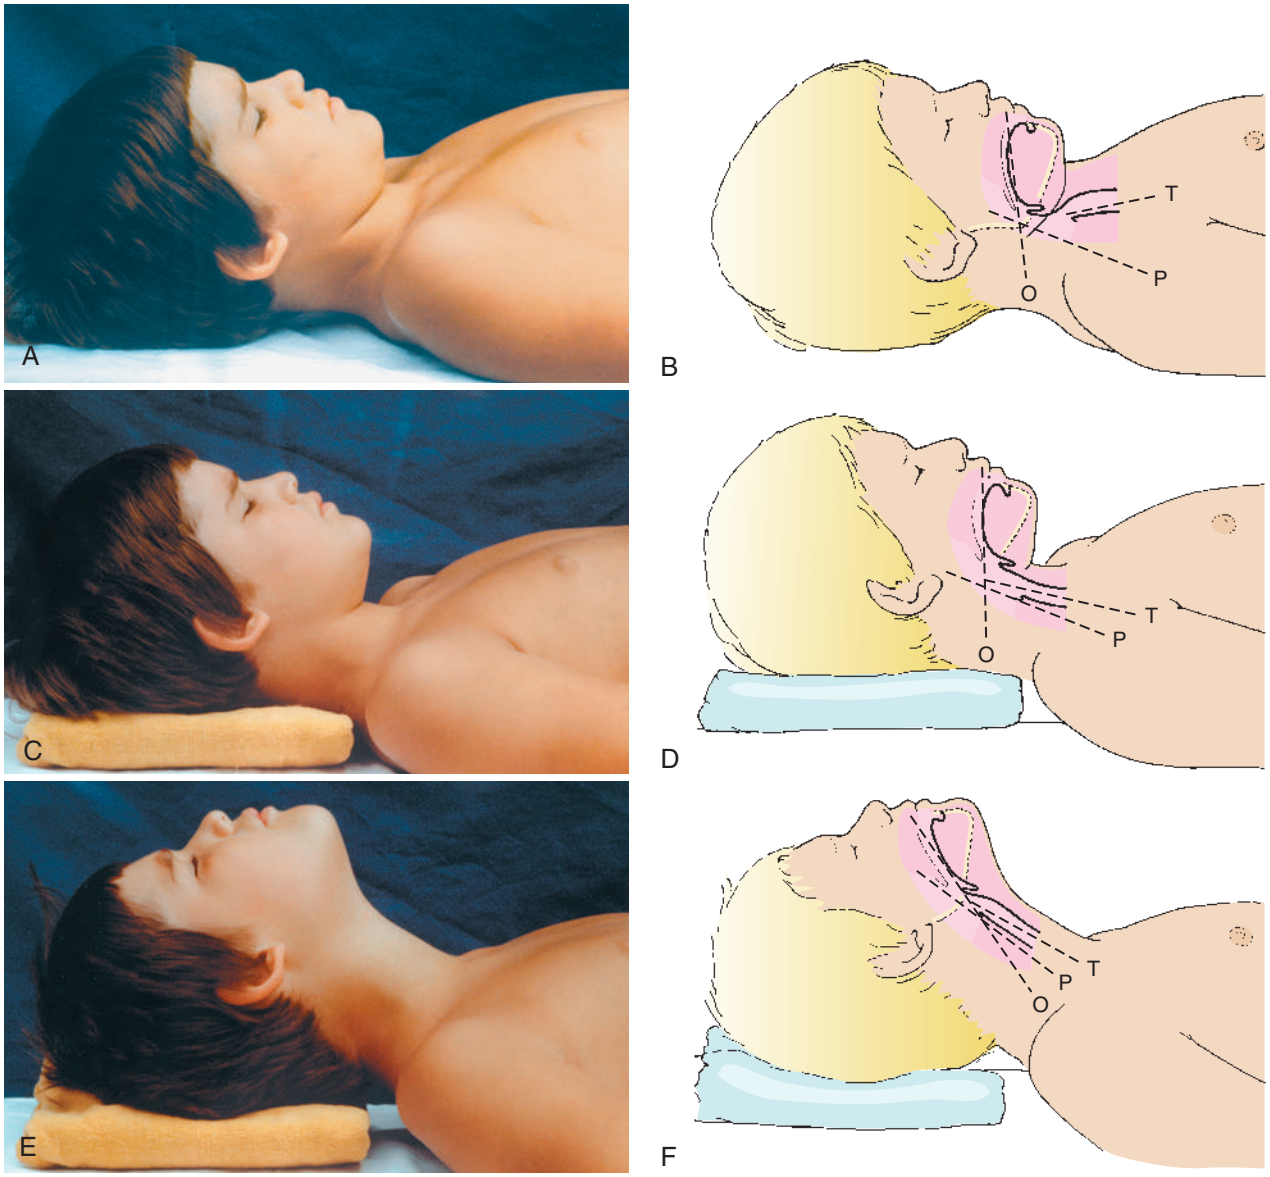

FIGURE 14.14 Correct positioning for ventilation and tracheal intubation. When a patient is lying flat on the bed or operating table **(A),** the oral (*O*), pharyngeal (*P*), and tracheal (*T*) axes pass through three divergent planes **(B)**. A folded sheet or towel placed under the occiput of the head **(C)** aligns the *P* and *T* axes **(D)**. Extension of the atlantooccipital joint **(E)** results in alignment of all three axes **(F)**.

of only a few patients are intubated more easily when placed in the sniffing position compared with simple head extension, the current routine application of the sniffing position appears to be the best clinical practice.[156]

Laryngoscopy can be performed while the child is awake, anesthetized, and breathing spontaneously, or anesthetized and paralyzed. Most tracheal intubations in children who are awake are performed in neonates, an approach that is not usually feasible or humane in older awake and uncooperative children. Awake intubation in the neonate is generally well tolerated if it is performed smoothly and rapidly; however, an international consensus group and others have cautioned against this practice unless intravenous (IV) access is not available or there is a life-threatening situation[157–160] Preterm and term infants are better managed with sedation and paralysis to minimize adverse hemodynamic responses.[161–165]

Selection of Laryngoscope Blade

A straight blade has been adopted for use in infants and young children for decades because it was thought to elevate the base of the tongue to expose the glottic opening better than a curved blade. However, the laryngeal view with the Miller blade was never compared with the curved blade. Recently, two studies demonstrated in young children younger than 2 years of age that both the Miller and Macintosh blades provide excellent laryngeal views if the former is used to elevate the epiglottis, and the latter to elevate the tongue. However, if the Macintosh blade is used to lift the epiglottis, the laryngeal view is inferior because the curve of the Macintosh blade partially obscures the view of the vocal cords.[166,167] The blade size chosen depends on the age and body mass of the child and the preference of the anesthesiologist; Table 14.1 presents the ranges commonly used.

Endotracheal Tubes

All materials used in the manufacture of ETTs have been subjected to rabbit muscle implantation testing in accordance with the standards promulgated by the Z79 Committee of American National Standards Institute since 1967.[168] If the material causes an inflammatory response in the rabbits, it cannot be used in the manufacture of ETTs. This has resulted in the elimination of organometallic constituents, which were used in the manufacture of red rubber ETTs.

Selection of the proper size of an ETT depends on the individual child.[169] The only size requirement for a manufacturer is a standardized inner diameter (ID). The external (outer) diameter (OD) varies among manufacturers, depending on the material from which the ETT is constructed. This diversity in OD mandates checking for proper ETT size and leakage around the tube. An appropriately sized uncuffed ETT may be approximated according to the child's age and weight (Table 14.2).[170]

ETTs sized 0.5-mm ID greater or less than the anticipated size should be available because of variability in the size of the airway. Use of the diameter of the terminal phalanx of either the second or fifth digit is unreliable.[171] Children with Down syndrome often require an ETT with a diameter smaller than that predicted by the child's age,[172] whereas children with cardiac disease often require a larger size cuffed ETT than that predicted by the child's age.[173] There are several means to identify whether the tube size is adequate. One holds that after using a standard formula to estimate the tube diameter, if the tube passes the subglottic region without meeting resistance, the tube size is not excessive. After the tube is stabilized, a sustained inflation pressure of 20 to 25 cm H_2O (short-term intubation perhaps as high as 35 cm H_2O) should be applied to detect an audible or auscultated air leak over the glottis. If no leak is detected, the ETT size is excessive and it should be exchanged for one with an ID 0.5 mm smaller. An air leak at this pressure is recommended because it is believed to approximate the capillary pressure of the adult tracheal mucosa. If lateral wall pressure exceeds this amount, ischemic damage to the subglottic mucosa may occur.[174] Be aware, however, that if the trachea has been intubated without neuromuscular blockade, laryngospasm around the ETT may prevent any gas leak and mimic a tight-fitting ETT.[175] If such a situation is suspected, the anesthetic depth should be increased before auscultating for an air leak. Changes in head position may also increase or decrease the leak.[175] These maneuvers are important for making the occasional diagnosis of unrecognized subglottic stenosis (see Fig. 37.8, and Video 14.1).

Traditional teaching has advocated the use of uncuffed ETTs for children younger than 8 years because an uncuffed ETT with an air leak exerts minimal pressure on the internal surface of the circular cricoid cartilage and thus poses potentially less risk for postextubation edema (croup).[170,174,176] An uncuffed ETT also allows insertion of a tube with a larger ID, resulting in less airway resistance, although this is only relevant for a spontaneously breathing child.[177] However, more recent clinical data and clinical practice have challenged these assumptions[178–187]; a number of studies demonstrated no differences in the incidence of postextubation complications after cuffed and uncuffed tubes when used for anesthesia,[178,183,188] except possibly with Microcuff tubes in neonates and former preterm infants.[189,190] Cited advantages of cuffed ETTs include decreased numbers of laryngoscopies and intubations to determine the appropriate size for the ETT, reduced

>2 years	(Age in years + 16)/4	(Age in years/4) +3

[a]In some neonates, a cuffed ETT may not have a leak below 30 cm H_2O, and therefore an uncuffed ETT may be more appropriate.
ID, inner diameter.

subglottic pressure, reduced operating room pollution and costs of anesthetic agents, decreased risk of aspiration, accurate control of carbon dioxide tension (P_{CO_2}), better ability to accurately measure the sophisticated physiologic respiratory functions of modern ventilators, absolute ability to deliver increased airway pressures in children with restrictive lung disease, the ability to control cuff pressure, and no or minimal increased risk of postextubation stridor.[178–184,188,191–193]

A drawback of cuffed tubes is the greater variability in functional OD compared with uncuffed tubes because of differences in cuff shape, size, and inflation characteristics.[194] In general, if a cuffed ETT is inserted, an ETT with a smaller ID should be selected to compensate for the ETT cuff. One study found a 99% rate of appropriate cuffed tube size selection for full-term infants through children 8 years of age using the following formula[183]:

$$\text{ID (mm)} = (\text{age [years]}/4) + 3$$

To overcome the shortcomings of the many pediatric cuffed tubes, the Microcuff ETT (Microcuff, PET, I-MPEDC; Microcuff GmbH, Weinheim, Germany, distributed by Kimberly-Clark USA) was designed with a high-volume/low-pressure elliptically shaped cuff that is more distally placed along the shaft of the ETT to better accommodate the anatomy of the airway in infants and children (Fig. 14.15).[195] The ultrathin polyurethane cuff (10 μm) allows tracheal sealing at low pressures and provides a uniform and complete surface contact with minimal formation of cuff folds.[185,191,195–198] At 20 cm H_2O inflation pressure, the cuffs have a cross-sectional cuff area of approximately 150% of the maximal internal tracheal cross-sectional area. Uninflated, the cuff adds only a minimal amount to the OD of the ETT. Shortened cuffs and the elimination of a Murphy eye allow a more distal position of the cuff, thereby theoretically reducing the risk of pressure being applied to the cricoid ring and adjacent mucosa.[199] The location of the cuff on the shaft of the tube helps to ensure cuff placement below the subglottis, perhaps with the advantage of less risk for endobronchial intubation or intralaryngeal cuff position. An anatomically based depth mark on the surface of the tube helps to guide correct placement. A report of neonatal stridor after Microcuff use in a neonatal intensive care unit has suggested previously unknown complications with this device.[190]

FIGURE 14.15 The MICROCUFF endotracheal tube (MICROCUFF, PET, I-MPEDC; MICROCUFF GmbH, Weinheim, Germany) (*right*) is designed with an ultrathin polyurethane (10 μm) high-volume/low-pressure cuff that has a more distal position along the shaft of the tube to better accommodate pediatric anatomy. In contrast to more traditional pediatric cuffed endotracheal tubes (*left*), the elimination of a Murphy eye allows a more distal position of the upper cuff border. The location of the cuff on the shaft of the tube helps to ensure cuff placement below the subglottis; perhaps with the advantage of less risk for endobronchial intubation or intralaryngeal cuff position. An anatomically based depth mark on the surface of the tube helps to guide correct placement.

An investigation of this specially designed ETT for children used the following guidelines to select cuffed ETT sizes[191]:

- For children ≥2 years, ID (mm) = (age [years]/4) + 3.5
- For children 1 to 2 years of age, ID 3.5 mm
- For neonates ≥3 kg and infants ≤1 year, ID 3.0 mm

Use of these formulas resulted in the need to reintubate to change tube size in 1.6% of children (6/500).[191] The incidence of postintubation croup was 0.4% (2/500 children). In a randomized, multicenter study of 2246 young children (mean age, 1.9 years), investigators reported similar findings for cuffed (Microcuff) and uncuffed tubes: postextubation stridor, 4.4% and 4.7%, respectively, and ETT exchange, 2.1% and 30.8%.[193] However, in a cost/benefit analysis of the Microcuff ETT (three to six times that of standard ETTs), the reduction in anesthetic cost offset the cost of the Microcuff ETT.[192]

As a rule, if a cuffed ETT is chosen, the cuff should be inflated to the minimal pressure that seals the air leak; with the Microcuff ETT, this is approximately 10.6 cm H_2O.[191,193,200,201] The cuff pressure should be reevaluated throughout the anesthetic if nitrous oxide is used because the latter may diffuse into the cuff, and with the Microcuff ETT, the ultrathin-walled cuff has greater permeability for nitrous oxide than conventional ETTs. The net effect may be excessive tracheal mucosal pressure, although this may be offset in part, as the cuff with Microcuff ETTs seals at a low pressure, ~10 cm H_2O.[200–202] The time interval to reach 25 cm H_2O cuff pressure with the Microcuff ETT is greater than with conventional cuffed ETT.[203] Routinely checking cuff pressure throughout the use of the anesthetic or filling the cuff with nitrous oxide is recommended.[204] A pressure relief valve that can be connected to the pilot balloon of a cuffed ETT to limit cuff pressures to 20 cm H_2O when nitrous oxide is used has been described.[205]

Endotracheal Tube Insertion Distance

The length of the trachea (vocal cords to carina) in neonates and children up to 1 year of age varies from 5 to 9 cm.[48] In most infants 3 months to 1 year of age, if the 10-cm mark of the ETT is placed at the alveolar ridge, the tip of the tube rests above the carina. In preterm and full-term infants, the distance is less. In children 2 years old, 12 cm is usually appropriate. An easy way to remember these lengths is 1**0** for a newborn, 1**1** for a 1-year old, and 1**2** for a 2-year old. After 2 years of age, the correct length of insertion (in centimeters) for oral intubation may be approximated by formulas based on age or weight (Table 14.3)[206–209]:

$$[\text{Age (years)}/2] + 12$$
$$[\text{Weight (kg)}/5] + 12$$
$$\text{ID of ETT} \times 3$$

TABLE 14.3 Distance for Insertion of an Oral Endotracheal Tube by Patient Age

Age	Approximate Distance of Insertion (cm) Even With Alveolar Ridge
Preterm <1000 g	6–7
Preterm 1000–2000 g	7–9
Term newborn	9–10
1 year	11–12
2 years	12–13
6 years	15–16
10 years	17–18
16 years	18–20
20 years	20–22

Some practitioners suggest using anatomic markers to choose the appropriate depth for the tube in the trachea in neonates.[210,211] An advantage of anatomic measurements is that the infant's weight may not be available immediately after birth or in sick neonates who present to the emergency department with urgent respiratory or cardiac compromise. One study that used chest radiographs to evaluate final ETT position determined that the length of the foot was as accurate as weight-based formulas to determine the depth of insertion for a nasotracheal tube (44% vs. 56% rate of optimal placement and 83% vs. 72% satisfactory placement).[211] Alternatively, the nasal-tragus length (the distance from the base of the nasal septum to the tip of the tragus) or the sternal length (the distance from the suprasternal notch to the tip of the xiphoid process) predicted the depth of insertion of the ETT. Either distance plus 1 cm accurately estimated oral ETT tube insertion distance; either distance plus 2 cm accurately estimated nasotracheal tube insertion distance.[210] Both measurements compared favorably with weight-based formulas when tube position was verified by chest radiography. It has also been suggested that a body surface area formula optimizes the position of the ETT. Chest radiography was used in that study to confirm the position of the ETT. The results showed that the depth of the tracheal tube had to be corrected in 20.3% of intubations when body surface area diagrams were used compared with 37% of intubations when an age-based formula was used for children older than 1 year of age and a weight-based formula was used for infants younger than 1 year of age.[212]

Preformed tracheal tube length often poorly matches the child's anatomy.[213] Seven brands of oral preformed ETTs were compared for the same size ID tube; the distance from the bend to the tip varied by 0 to 1 cm for cuffed tubes but 0 to 4 cm for uncuffed tubes. The greatest gap between cuffed and uncuffed oral preformed ETTs of the same size for a specific manufacturer was 2 to 3 cm for Portex (Smiths Medical, St. Paul, MN) sizes between 5.0 and 7.5 mm ID. Of greater concern was the variability in the distance from the bend to the tip of preformed nasal tubes; cuffed tubes varied by 0 to 5.5 cm and uncuffed varied from 2 to 9 cm (bend to tip) among manufacturers. The gap between cuffed and uncuffed nasal preformed ETTs of the same size ETT between 4.0 and 7.5 mm ID was 5 to 9 cm for all manufacturers. Thus the risk for endobronchial intubation varies substantively among manufacturers, and is greatest with nasal ETTs if they are inserted to the bend; some brands may be unsuitable for use in children.

After the ETT has been inserted and the first strip of adhesive tape has been applied to secure it, one must observe for symmetry of chest expansion and auscultate for equality of breath sounds in the axillae and apices (not on the anterior chest wall). The anterior chest wall in the child is not used to verify tracheal intubation because breath sounds may reverberate across the precordium in small children, obscuring the diagnosis of an endobronchial intubation. A CO_2 monitor confirms intratracheal positioning but does not confirm that the tip of the ETT is not in an endobronchial position. A capnogram that diminishes during the first few breaths suggests an esophageal intubation. Unexpectedly increased airway pressures, persistent desaturation, and asymmetrical chest wall movement all suggest an endobronchial intubation. Visible humidity on the walls of the ETT during expiration also confirms tracheal placement, but the humidity may not be visible in younger infants. It is also important to auscultate over the stomach and to observe for desaturation or cyanosis. Once a satisfactory position is achieved, a second strip of tape ensures secure fixation (Fig. 14.16).

We have observed a number of children whose ETT moved into a mainstem bronchus after initial correct position during repositioning for the surgical procedure; this manifested as a slight but persistent decrease in oxygen saturation (e.g., from 100% to a range of 93% to 95%). Several studies have demonstrated that simple flexion or extension of the neck can move the ETT sufficiently to cause an endobronchial intubation or dislodgment of the tube from the trachea, respectively.[214–216] *When a small but persistent decrease in oxygen saturation is noted, rather than increase the inspired oxygen concentration (FIO_2), one must first investigate the cause and reassess the position of the ETT.*[217]

Complications of Tracheal Intubation

Postintubation Croup

Perioperative postintubation croup (also referred to as postextubation croup) occurs in 0.1% to 1% of children.[184,191,218,219] Factors associated with increased risk of croup include an ETT with an OD that is too large for the child's airway (no leak at >25 cm H_2O pressure or resistance at the time of insertion), changes in position during the procedure, a position other than supine, repeated attempts at intubation, traumatic intubation, patient age between 1 and 4 years, duration of surgery greater than 1 hour, coughing on the ETT, and previous history of croup.[203,204] Concurrent upper respiratory infection has been variously reported as a risk factor and as unrelated.[99,219]

Treatment of postintubation croup consists of nebulized epinephrine and dexamethasone. The rationale for this treatment is based primarily on experience with the treatment of infectious croup.[220–229] Caution should be exercised when translating treatments from one type of croup to another, because the two types of croup are not identical processes, and efficacy of the interventions for the treatment of postintubation croup has not been proved in controlled trials.[230] Studies that examined the effect of dexamethasone given before extubation in children with prolonged intubation are conflicting.[231–234] Methylprednisolone given intramuscularly for the same indication has been reported to reduce postintubation stridor.[235]

Laryngotracheal (Subglottic) Stenosis

The frequency of subglottic stenosis has decreased over the past several decades to its current level of 0% to 2%.[236] Ninety percent of acquired subglottic stenoses are the result of tracheal intubation, particularly prolonged intubation (see Videos 14.1 and 14.5).[237–242] The incidence of subglottic stenosis after prolonged intubation in preterm neonates is reduced because the cricoid cartilage is relatively immature. At this age, the cartilage structure is hypercellular and

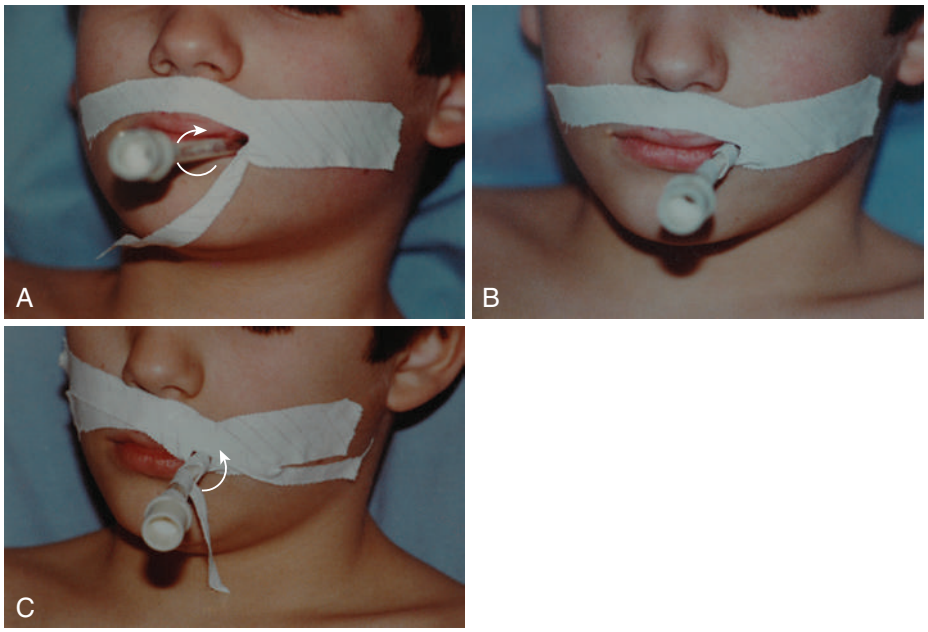

FIGURE 14.16 Securing the endotracheal tube (ETT). After insertion of the oral ETT and examination for proper position, the area between the nose and upper lip and both cheeks is coated with tincture of benzoin. **A,** After the benzoin is dry, tape that has been split up the middle is applied to the cheek, and the ETT is placed at the division of the split tape. **B,** One half is wrapped circumferentially around the tube, and the other half is applied to the space above the upper lip. **C,** A second piece of tape is applied in similar fashion from the opposite direction. A nasal ETT may also be secured with this technique.

the matrix has a large fluid content, making the structures more resilient and less susceptible to ischemic injury.[243]

The pathogenesis of acquired subglottic stenosis is ischemic injury secondary to lateral wall pressure from the ETT. Ischemia results in edema, necrosis, and ulcerations of the mucosa. Secondary infection results in exposure of the cartilage. Within 48 hours, granulation tissue begins to form within these ulcerations. Ultimately, scar tissue forms, resulting in narrowing of the airway (Fig. 14.17).[244–246] Specimens obtained from partial cricotracheal resection in children were found to have severe and sclerotic scarring with squamous metaplasia of the epithelium, loss of glands and elastic mantle fibers (tunica elastica), and dilation of the remaining glands with formation of cysts.[246] Also, the cricoid cartilage was affected on the internal and external side, with irreversible loss of perichondrium on the inside and resorption by macrophages of cartilage on both sides.[228]

Factors that predispose to subglottic stenosis include use of an ETT that is too large, laryngeal trauma (e.g., traumatic intubation, chemical or thermal inhalation, external trauma, surgical trauma, gastric reflux),[247–249] prolonged intubation (particularly greater than 25 days), repeated intubation,[250] hypotension, sepsis and infection, chronic illness, and chronic inflammatory disease.[240,251,252]

LARYNGEAL MASK AIRWAY

The LMA has become a standard alternative for airway management during general anesthesia.[253–258] A number of types of LMAs (also known as supraglottic devices [SGAs]) have been introduced into practice since the development of the original LMA, which is now referred to as the LMA Classic (Fig. 14.18).[259] These new types include the disposable LMA Unique, the ProSeal LMA (PLMA, described later), the Flexible LMA, the LMA Supreme (discussed later), and the intubating LMA Fastrach. The Fastrach is available only in sizes 3, 4, and 5 and is described for use in children who weigh more than 40 kg.[260] The LMA Classic is made of medical-grade silicone and consists of a large-bore tubular structure (barrel) with a 15-mm adapter at its proximal end and an elliptical, mask-like device that fits over the laryngeal inlet at its distal end. All masks are inflated by means of a valved pilot tube and balloon. The LMA Classic and the PLMA can be sterilized for reuse up to 40 times. The LMA Classic is available in eight sizes. Guidelines for selecting the appropriate mask for children are based on weight (see Table 14.4). A number of other manufacturers have developed similar devices; however, there is a dearth of comparative data available for children,[259] although there are numerous studies comparing one device with another.[261–266]

The LMA has been used for many different surgeries but it was developed to replace the face mask in adults during maintenance of anesthesia.[267] Some suggest that an LMA can be used for any case in which spontaneous ventilation is appropriate or any case that might reasonably be managed by face mask. The LMA offers several advantages over the face mask including that it frees the anesthesiologist's hands for other tasks and that it may be associated with less operating room pollution compared with mask ventilation.[268,269] The use of controlled ventilation with the LMA Classic has also been described.[270,271] However, this practice is more controversial than its use in spontaneously breathing children because of the risk of insufflation of ventilated gas into the stomach and resultant regurgitation.[272–274] Insufflation of gas into the stomach is more likely to occur when high ventilation pressures are used or required (i.e., pressures greater than the pressure that produces an audible air leak).[270,275] Clinically

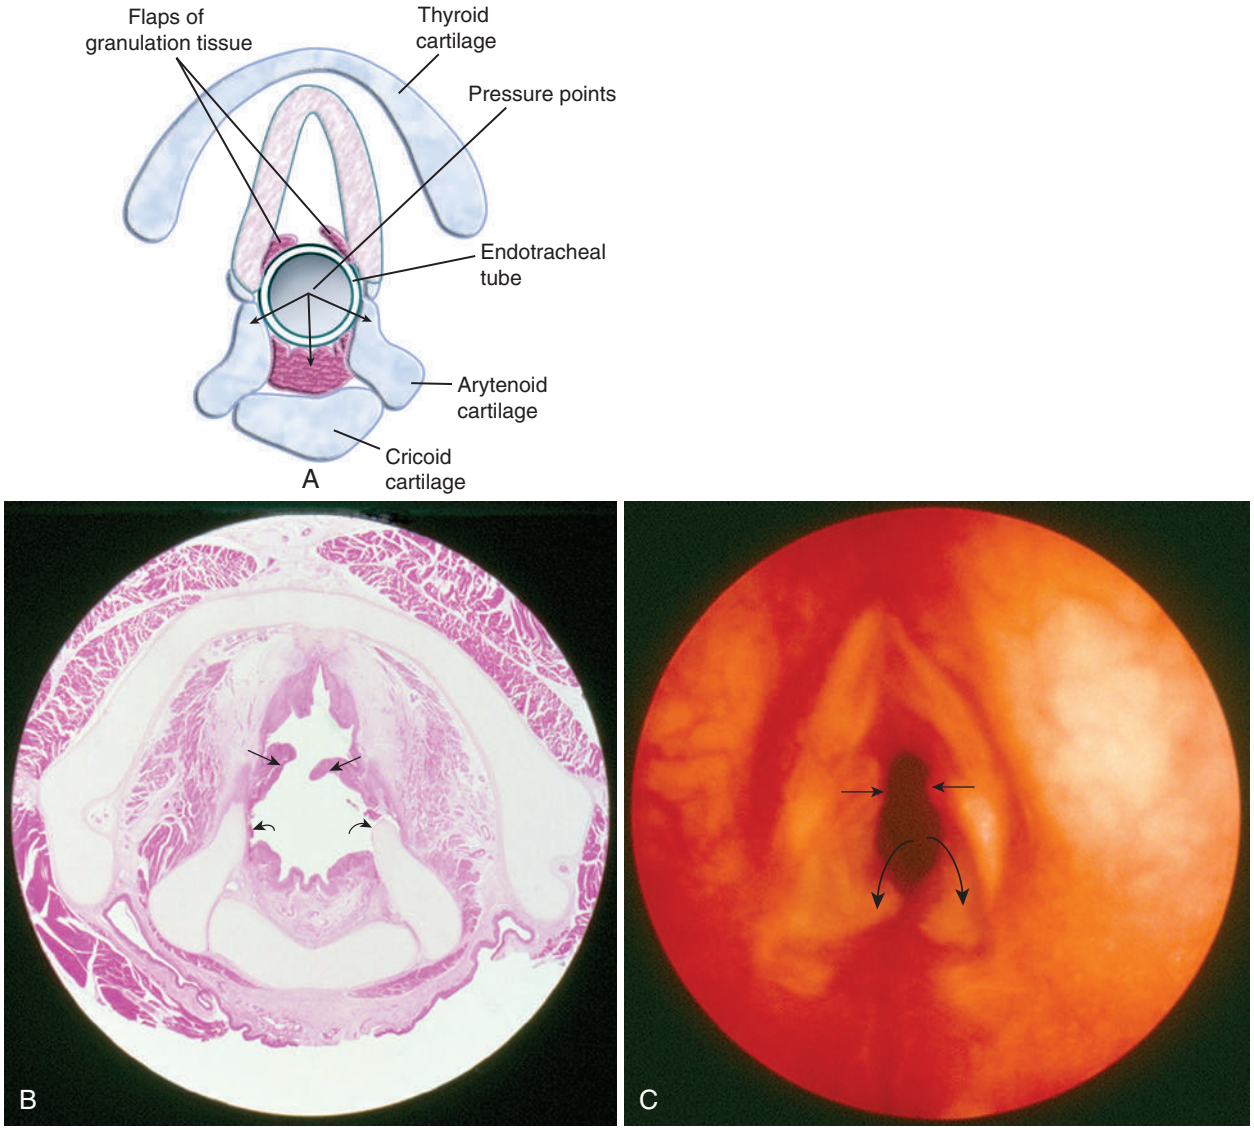

FIGURE 14.17 The pathogenesis of intubation injuries. **A,** Schemata of a cross section through the glottis. Pressure necrosis causes ulcerations at the vocal processes of the arytenoids with exposed cartilage. Flaps of granulation tissue are present anterior to these ulcerations. **B,** Cross section of the glottis at this same level; *straight arrows* indicate flaps of granulation tissue, and *curved arrows* indicate the absence of mucosa and ulcerations with exposed cartilage on the vocal processes of the arytenoids. **C,** Intubation injury to a 2-month-old infant; *straight arrows* indicate granulation tissue, and *curved arrows* indicate an area of ulcerations (*white area*). The most severe area of injury is usually at the level of the cricoid cartilage, resulting in subglottic stenosis. undetected LMA Classic malpositioning has been reported to be a significant risk factor for gastric air insufflation in children between 3 and 11 years of age undergoing positive-pressure ventilation, especially at peak inspiratory pressures greater than 17 cm H_2O.[276] Controlled ventilation with an LMA (with or without neuromuscular blockade) is easily accomplished and less likely to cause adverse events when the seal is relatively good and the lung inflation pressures are less than 17 cm H_2O.

The PLMA was designed to improve sealing pressures and to provide a conduit for evacuation of stomach contents and comes is seven sizes; these features make it more appealing for use with positive-pressure ventilation.[277] In sizes 3 and larger, there is a second dorsal cuff to increase the seal pressure of the glottic mask. The dorsal and ventral cuffs communicate, allowing simultaneous inflation by a single pilot balloon. In the smaller sizes, there is no second dorsal cuff but the profile of the mask has been altered to improve sealing. The PLMA is easy to insert, allows greater airway pressures with positive-pressure ventilation, and better protects against gastric insufflation.[278,279] A number of studies support the efficacy of the PLMA in children for both spontaneous and controlled ventilation.[279–283] In children, the PLMA and the LMA Classic are similarly easy to insert, have their proper position confirmed by fiberoptic visualization, and yield similar frequencies of mucosal trauma. The advantage is that

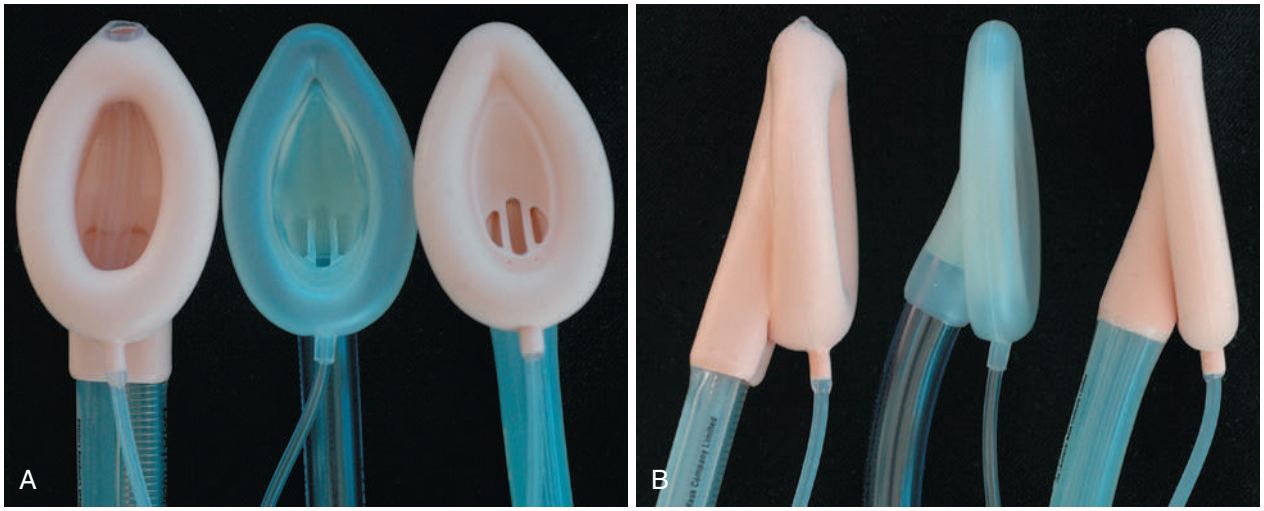

FIGURE 14.18 Three types of laryngeal mask airway (LMA) are available in pediatric sizes: the reusable LMA Classic, the disposable LMA Unique, and the ProSeal LMA (PLMA). Displayed are pediatric size 2 LMAs of each type. **A,** The transparent material of the disposable LMA Unique (*center*) is medical-grade polyvinylchloride (PVC), whereas the reusable PLMA (*left*) and LMA Classic (*right*) are made of medical-grade silicone. Notice the differences in structure. The drainage tube outlet of the PLMA can be seen at the most distal tip of the cuff. The PLMA uses the drain tube to elevate the epiglottis away from the larynx, whereas the Classic and Unique have aperture bars. In contrast to the Classic and Unique LMAs, the PLMA cuff is softer, has a special shape, and has a deeper mask bowl. These features of the PLMA allow for improved sealing for positive-pressure ventilation. **B,** In profile, the distinct shape of the PLMA (*left*) can be appreciated. The dual-tube structure (drainage and airway lumens) creates a larger tube profile (**A** *left*) that incorporates a bite block and improves stability.

oropharyngeal leak pressure is greater and gastric insufflation is less common with the PLMA.[279–283] In children, the ability to provide pressure support ventilation with the PLMA during anesthesia also improves gas exchange and reduces WOB compared with the application of CPAP.[284,285] The greater sealing pressure may also protect against aspiration, as reported in a 5-year-old child after inguinal hernia repair.[286] Pediatric gastroscopy is quicker and involves fewer airway complications when performed around the PLMA compared with nasal cannulas and with a conventional approach using an anesthetic technique in which children breathed a sevoflurane-air-oxygen mixture spontaneously with 1-mg/kg IV boluses of propofol.[287]

Flexible diagnostic and therapeutic bronchoscopy, radiation therapy, radiologic procedures, ear/nose/throat surgeries, and ophthalmologic procedures are the most commonly described pediatric indications for the LMA.[258,267,288–291] An advantage of the LMA for securing the airway in ophthalmologic surgery is that it is associated with no increase in intraocular pressure, in contrast to tracheal intubation.[292] The advantage of the LMA for diagnostic and therapeutic flexible bronchoscopy is that it provides a conduit for oxygenation and ventilation while allowing a larger bronchoscope to be used than can be passed through an age-appropriate ETT.[289,290,293,294] It also allows visualization and evaluation of the laryngeal structures. Some LMAs may provide better bronchoscopic conditions than others owing to their material or preconfigured shape.[295] For children who require frequent anesthetics over a brief period, as in radiation therapy, the LMA provides a secure airway without the trauma of repeated intubation.[258] The LMA has also been advocated for use in place of intubation in children who are at increased risk for bronchial airway reactivity (e.g., upper respiratory tract infection, history of reactive airway disease).[296–299] However, caution is required in children with an upper respiratory tract infection because the risk of laryngospasm remains substantive.

The LMA has also become an important tool in the management of the difficult airway, particularly in neonates (see later discussion) (Video 14.6). However, it should be noted that the LMA is an SGA device and, as such, does not reliably protect against pulmonary aspiration of gastric contents.[272–274] Because of their gastric access lumens, the PLMA and the LMA Supreme may be better alternatives in this setting, but formal study in children has not been performed.[300]

The recommended insertion technique for the LMA is the same for children as for adults (Video 14.6). The correct technique mimics deglutition or swallowing of food.[301] The cuff is completely deflated, and the posterior surface of the mask is well lubricated. These actions mimic lubrication of a food bolus with saliva and formation of a soft, flattened, wedge-shaped bolus. The child is placed in the age-appropriate intubating position. Induction may proceed by inhalation of halothane or sevoflurane or by IV propofol (3 to 5 mg/kg).[267,302] The nondominant hand is used to extend the head and flex the neck (sniffing position). This head position mimics the elevation of the larynx, neck flexion, and head extension that occurs with swallowing. The LMA is inserted with the mask aperture facing anteriorly (toward the tongue). The index finger of the insertion hand should be placed in the cleft between the mask and the barrel. With the index finger, the LMA is pushed upward and backward, toward the top of the child's head. This flattens the mask against the palate. Continued backward pressure (toward the top of the child's head) guides the LMA along the palate and down into the upper esophageal sphincter. It is essential that pressure be applied to force the LMA against the roof of the mouth. The mask is advanced along the palate until some resistance is felt. These actions mimic the propulsion of a food bolus into

TABLE 14.4 Size Selection and Recommended Cuff Volumes for the Laryngeal Mask Airway

Mask Size	Patient's Weight	Maximum Cuff Volume (mL)	Largest Endotracheal Tube (ID, mm), LMA Classic	Largest Endotracheal Tube (ID, mm), LMA Unique[a]	Largest Endotracheal Tube (ID, mm), ProSeal LMA[a]
1	Neonate/infants up to 5 kg	4	3.5	3.5	N/A
1.5	Infants 5–10 kg	7	4.0	4.0	4.0, some manufacturers 3.5
2	Infants/children 10–20 kg	10	4.5	4.5	4.0
2.5	Children 20–30 kg	14	5.0	5	4.5
3	Children/small adults 30–50 kg	20	6.0, cuffed	5.0, cuffed	5.0
4	Adolescents/adults 50–70 kg	30	6.0, cuffed	5.5, cuffed	5.0, cuffed
5	Large adolescents/adults 70–100 kg	40	7.0, cuffed	6.0, cuffed	6.0, cuffed
6	Anyone >100 kg	50	7.0 cuffed	N/A	N/A

[a]These sizes differ from the manufacturers' recommendations but have been found by the authors to be the better alternatives to ensure easy passage of the endotracheal tube through the LMA. In some cases the tubes listed are smaller; in some cases a cuffed alternative is given as an option rather than an uncuffed tube.
ID, inner diameter; *LMA,* laryngeal mask airway; *N/A,* not applicable.

the hypopharynx caused by tongue pressure, first upward and backward, then downward in an arc. When resistance is felt, air is injected into the mask cuff (see Table 14.4 for size recommendations and maximum recommended inflation volumes).

Inflation of the cuff causes the end of the airway to move out of the mouth about 1 cm and forms a loose seal around the esophageal inlet, thereby directing gas flow into the trachea. *If no outward movement is observed with inflation of the mask, the LMA may not be properly positioned.* Proper position can be ascertained further by auscultation of breath sounds, movement of the anesthesia bag, measure of expired CO_2, the ability to provide gentle assisted ventilation, and, if necessary, by direct visualization with rigid or fiberoptic laryngoscopy. If the lungs cannot be gently ventilated (peak airway pressure <20 cm H_2O) or no breath sounds are heard, the LMA must be immediately removed because it has not been properly positioned, or the child's airway might be obstructed. After proper placement is confirmed, the LMA may be secured with tape and a soft bite block (e.g., a rolled gauze) inserted.

Several reports claim that when the traditional insertion technique is used in children, the LMA frequently hangs up in the posterior pharynx, making proper positioning difficult.[303,304] Therefore other insertion techniques have been described. The rotational or reverse technique for children has been advocated to be simpler and more successful than the traditional placement technique.[305] The LMA is placed in the mouth with the cuff facing the hard palate (the opposite of the traditional technique). It is then advanced and rotated into position simultaneously (Video 14.7).[303,304,306] A partial mask inflation technique has also been advocated as more successful than the traditional (mask-deflated) technique.[306–309] The LMA is left partially inflated to smooth the edges of the mask and then is inserted in the usual manner,[307,308] or in a lateral manner and then rotated and advanced,[309] or with a complete 180-degree rotation.[306] For placement of the PLMA, the rotational technique was found to have no advantage over the standard technique in children.[310] A jaw thrust maneuver and the use of a rigid laryngoscope have also been advocated to assist in placement of the LMA Classic.[311]

Regardless of insertion method, the most common cause of failure is use of a wrong size LMA. An LMA that is too large will not pass beyond the posterior pharynx. An LMA that is too small will pass easily but may not seal against the laryngeal inlet. Another common mistake when using the traditional insertion method is to try to press the LMA *down* into the pharynx. Pressure should be directed *back,* toward the pharyngeal wall, so that the airway will follow the natural curve of the pharynx and seat correctly in the esophageal sphincter without kinking. Attempting to place the LMA when the child is inadequately anesthetized may make advancement impossible or result in laryngospasm.

LMA use can result in injuries to upper airway structures[312–314] and in damage to the recurrent laryngeal[315] or the hypoglossal nerves.[316] The incidence of sore throat may be equal to or greater than that seen with tracheal intubation.[317–319] LMA use in infants requires special caution. A review of the use of the size 1 LMA in 50 infants found that the LMA sometimes migrated over time, even after apparent correct initial placement; delayed airway obstruction occurred in 12 infants after apparent successful placement.[320] Vigilance is required to prevent loss of the airway.

Evaluation of a large dataset determined factors associated with LMA failure in children.[321,322] They included prolonged surgical duration, procedures of the head and neck, non-outpatient admission status, congenital airway abnormalities, and a category the authors called "patient transport," which consisted primarily of moving a patient's position or anesthetizing location with the laryngeal mask in situ.

LMA placement has been used successfully for neonatal resuscitation[323–325]; it may be an easier skill to acquire than bag-and-mask ventilation.[326,327] Given the recognition[328] that chest compressions are the most important factor in successful outcomes after cardiac arrest and the need to avoid interrupting compressions during cardiopulmonary resuscitation, the LMA may assume a greater role in airway management in cardiac arrest in the neonate.[329] The LMA has also been used to deliver surfactant to neonates with respiratory distress syndrome,[330] for longer-term intensive care management of neonates with difficult airways,[331–333] and for intrahospital transport of neonates with difficult airways.[334]

The LMA Fastrach was specifically designed to allow the blind passage of an ETT in an emergent situation in which direct laryngoscopy is not possible or in patients with cervical spine immobilization.[210,335–337] This is a rigid device with a fixed angulation designed primarily for adults (available in sizes 3, 4, and 5). It requires special, flexible ETTs with an ID of 6.0 to 8.0 mm.

The timing for removal of the LMA in children is controversial. Both "awake" and "deep" removal has been advocated.[338–343] Awake removal ensures return of protective reflexes but with the attendant

problems of airway reactivity. Deep removal avoids excessive airway reactivity and potential laryngospasm but may increase the risk of aspiration or airway obstruction (or both) as the child emerges from anesthesia later in the recovery room. One author suggested leaving the cuff inflated until the child begins swallowing or is able to open the mouth on command as a means for reducing the potential for laryngospasm. The proposed mechanism is that secretions are swept away from the larynx, reducing the stimulus for laryngospasm.[343] Lubrication of the cuff with 2% lidocaine jelly or the addition of an intravenously administered opioid to the anesthetic may reduce coughing and laryngeal stimulation on emergence.[307]

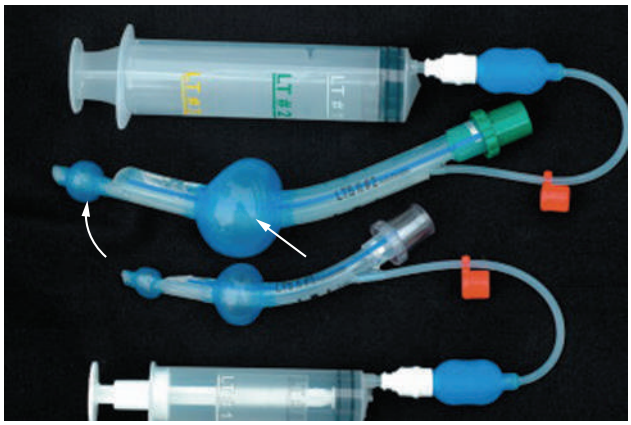
The LMA Supreme is a single-use, curved laryngeal mask with an elliptical airway tube and an integrated drain tube that extends to the tip of the mask bowl. The proximal end of the airway tube consists of a bite block, which should lie between the teeth when the mask is properly positioned. A fixation tab allows the mask to be secured to the face (Fig. 14.19). The deflated mask is held at the fixation tab and is inserted along the palate into the pharynx in a fashion similar to that used for the LMA Classic. Once in place, the cuff is inflated and the mask position is confirmed to be appropriate with the use of simple confirmatory tests. An appropriately positioned mask forms a leak-free seal with the glottis, and the mask tip is embedded in the upper esophageal sphincter. A simple test to confirm the position of the mask is the suprasternal notch test, wherein a small amount of water-soluble lubricant is applied to the drain tube of the airway. Application of slight pressure in the suprasternal notch should result in a slight up-and-down movement of the applied lubricant on the drain tube. This confirms that the drain tube is contiguous with and adequately sealed in the upper esophageal sphincter. The ability to easily place a gastric tube through the drain tube further confirms correct positioning of the airway. Suction should not be applied to the gastric tube until it has been advanced into the stomach; this prevents collapse of the drain tube and potential injury to the upper esophageal sphincter. The LMA Supreme is available in all pediatric sizes. A study comparing the LMA Supreme with the PLMA and the Classic LMAs in a neonatal manikin model demonstrated higher inflation pressures and shorter insertion times with the LMA Supreme.[344] Although the LMA Supreme has been found to be effective in adult populations,[345–348] there are few evaluations of the pediatric sizes.[349,350]

FIGURE 14.19 The LMA Supreme offers the advantages of a built-in suction port and a built-in bite block. This design may be particularly useful for tonsillectomy, because the ventilating tube is molded in a caudad direction and the bite block offers protection against distortion by a mouth gag or the child's biting on it during emergence.

OTHER SUPRAGLOTTIC AIRWAY DEVICES

Many other manufacturers have created their own versions of an SGA device similar to the LMA Classic. Some of these devices have design features that make them better conduits for tracheal intubation than the LMA Classic. Some have larger-diameter airway tubes that allow passage of larger (and cuffed) ETTs, lack glottic aperture bars (which can impede ETT advancement during an intubation attempt), and shorter airway tubes. Some devices also offer advantages in terms of cost.[351–353] Since there are now so many variations available, below we discuss only those SGAs with a different design and different mechanism for maintaining the airway.

The Laryngeal Tube



The Laryngeal Tube (LT; VBM Medizintechnik GmbH, Sulz, Germany) is designed to secure a patent airway during either spontaneous breathing or controlled ventilation. This device is available with a single lumen for ventilation only or with a double-lumen tube that also allows suction of gastric contents. This system seals the esophagus at the distal end with a small cuff attached at the tip (distal cuff), and a larger balloon cuff at the middle part of the tube (proximal cuff) stabilizes the device and blocks the oropharynx and nasopharynx. The two openings that lie between the cuffs are positioned so that the more distal opening faces the glottis. The cuffs are inflated through a single pilot tube and balloon, through which cuff pressure can be monitored. There are three black lines on the tube near a standard 15-mm connector that indicate adequate depth of insertion when aligned with the teeth. The nondisposable device is made of silicone (latex-free) and is reusable up to 50 times after sterilization in an autoclave. There are four variations: (1) standard single-lumen, reusable (LT); (2) single-lumen, disposable (LT-D); (3) double-lumen with drain tube, reusable (LT-suction II, or LTS II); and (4) double-lumen with drain tube, disposable (LTS-D) (E-Fig. 14.1).[354] It is available in six sizes, suitable for neonates up to large adults (Table 14.5).

The LT should be inserted while the child's head and neck are placed in the sniffing or neutral position. The tip of a well-lubricated LT is placed against the hard palate behind the upper incisors. The device is then slid down the center of the mouth until resistance is felt or the device is almost fully inserted. After connection to the anesthesia circuit, proper placement is confirmed by assessing ease of ventilation. Some adjustment (usually slight withdrawal) may be required to provide optimal ventilation. Care should be taken not to push the tongue backward into the posterior pharynx.

TABLE 14.5 Size Selection and Recommended Cuff Volumes for the Laryngeal Tube

Tube Size	Body Weight or Height	Recommended Cuff Volume (mL)	Connector Color
0 Newborn	<5 kg	10	Clear
1 Infants	5–12 kg	20	White
2 Children	12–25 kg	35	Green
3 Adults: small	<155 cm	60	Yellow
4 Adults: medium	155–180 cm	80	Red
5 Adults: large	>180 cm	90	Purple

14

E-FIGURE 14.1 The Laryngeal Tube (LT; VBM Medizintechnik GmbH, Sulz, Germany) is a single-lumen tube closed at the distal end with a small cuff attached at the tip (distal cuff, *curved arrow*) and a larger balloon cuff at the middle part of the tube (proximal cuff, *straight arrow*). The proximal cuff provides a seal in the upper pharynx, and the distal cuff seals the esophageal inlet. Two openings lie between the two cuffs, and the device is positioned so that the more distal opening faces the glottis. The cuffs are inflated through a single pilot tube and balloon, through which cuff pressure can be monitored. There are three black lines on the tube, near a standard 15-mm connector, that indicate adequate depth of insertion when aligned with the teeth. The LT is available in four types (standard LT, disposable LT, LT-suction II, and disposable LT-suction II) and in six sizes, including those designed for children. Specially marked and color-coded syringes are supplied to ensure proper cuff inflation. Two different sizes of the Laryngeal Tube are shown.

Ease of insertion of the standard LT is reported to be comparable to that of the LMA Classic, although the LT may require more readjustments of its position to obtain a clear airway.[355,356] The incidence of complications with the two devices appears to be similar.[355] The LT may provide a better seal than the Classic LMA.[357] Compared with the PLMA, the LT may be less effective and more difficult to insert.[358–360] Although the LT-suction device may have similar success to the PLMA,[361] there are scant data in children.[362–367] An initial report of its use in children ages 2 to 12 years found a successful placement rate of 96% (77/80 children). Complications occurred in two children; one had laryngospasm that resolved with deepening of the anesthetic, and the other complained of mild difficulty with swallowing postoperatively.[363] A study comparing the LT with the LMA found it to be less effective for either spontaneous or assisted ventilation and for fiberoptic evaluation of the airway in children younger than 10 years of age.[362] A study of 70 children using sizes 0 to 3 reported failure to place the LT in 12% of children. Failures were caused by inability to ventilate, hypoxemia, gastric insufflation, cough, and laryngospasm or stridor, particularly for children weighing less than 10 kg; therefore, the LT was not recommended for children of this size.[364] Although the manufacturer states that a flexible fiberoptic bronchoscope (FOB) may be passed through the device, the openings are of insufficient size to permit passage of an ETT.

The Cobra Perilaryngeal Airway

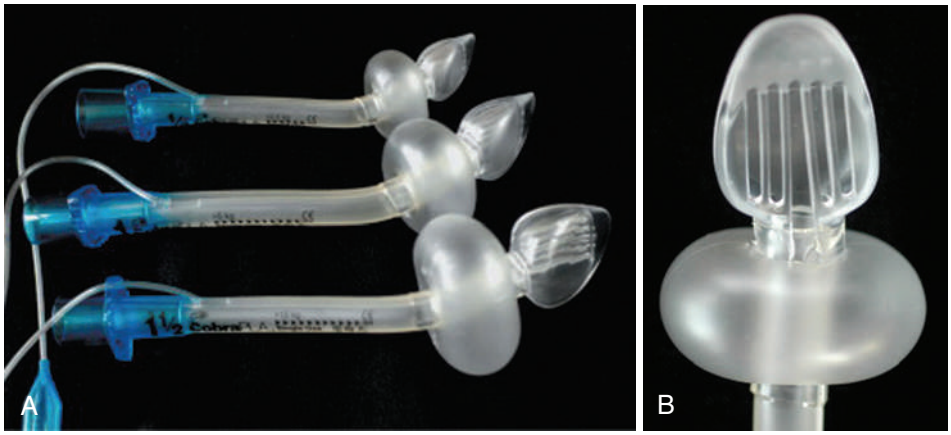
The Cobra Perilaryngeal Airway (CobraPLA; Engineered Medical Systems, Indianapolis, IN) is a disposable SGA that is marketed for the same indications as the LMA Classic but creates a seal more cephalad in the hypopharynx using a cylindrical inflatable cuff. The distal end of the device sits over the larynx, but the distal end is not inflatable (E-Fig. 14.2).[352,368,369] An initial report that compared the CobraPLA with the LMA Classic reported that the insertion time, airway adequacy, and number of repositioning attempts were similar. Peak airway sealing pressure was significantly greater with the CobraPLA; the authors concluded that the CobraPLA has better airway sealing capabilities than the LMA Classic.[370] A more recent group of investigators studying the CobraPLA in adults raised concerns about both the design and the safety of this device, particularly during controlled ventilation. After studying 29 patients, investigations were suspended and later stopped after two cases of significant pulmonary aspiration occurred in patients while using the CobraPLA.[371] The device is available in eight sizes and can be used in infants as small as 2.5 kg (Table 14.6).[368] The distal grill has a long center slit that is specifically designed to allow passage of an FOB and ETT (the size 0.5 neonate CobraPLA allows easy passage of a 3.5 uncuffed ETT). In a pediatric study, the orientation of the larynx as viewed through the CobraPLA using video was obtained in 45 infants and children. An acceptable view of the airway was obtained in all subjects, but the laryngeal view was mostly obstructed or completely obstructed by the folding of the epiglottis over the glottic opening in 77% of children weighing less than 10 kg; a similar problem was encountered in approximately 80% of children managed with the LMA Classic.[372] The investigators suggested extra vigilance to prevent airway obstruction in small children. Also, because the grill bars of the CobraPLA were closely opposed to the epiglottis and supraglottic structures in almost all subjects, it was suggested that removal of the device in a deeper plane of anesthesia may minimize laryngeal stimulation. In a comparison of the Cobra device with the Air-Q (Cookgas LLC, Mercury Medical, Clearwater, FL) for fiberoptic intubation in children 1 to 6 years of age, the fiberoptic view was comparable with both devices. The researchers also reported that the time to achieve intubation was greater, the seal was better, and the incidence of bleeding and sore throat were greater with the Cobra.[373] Further study of this device in children, particularly infants, is needed to define its role compared with various LMAs.[374–376] The Cobra-PLUS has a distal curve for easier placement and a thermistor on the pharyngeal cuff to measure temperature that reliably trends intraoperative temperatures.[377]

TABLE 14.6 Suggested CobraPLA Size, Weight, Cuff Volume, and Endotracheal Tube Sizes

Size	Patient Weight (kg)	Cuff Volume (mL)	Inner Diameter (ID, mm)	Maximal Size of Endotracheal Tube (mm ID)
0.5	>2.5	<8	5.0	3.0
1	>5	<10	6.0	4.5
1.5	>10	<25	6.0	4.5
2	>15	<40	10.5	6.5
3	>35	<65	10.5	6.5
4	>70	<70	12.5	8.0
5	>100	<85	12.5	8.0
6	>130	<85	12.5	8.0

The i-gel

The i-gel SGA (Intersurgical, Liverpool, NY) consists of a dual-channeled, noninflatable laryngeal mask made from a gel-like thermoplastic elastomer (Fig. 14.20). It has a built-in bite block and is available in sizes 1, 1.5, 2, 3, 4, and 5 (Table 14.7). One channel functions as the airway tube while the second channel exits at the tip of the device and provides gastric access when seated properly. The lubricated posterior surface of the i-gel is inserted along the palate into the posterior pharynx. An observational study in 50 children reported easy insertion in all patients with a mean leak pressure of 25 cm H_2O; gastric access was successfully obtained in all children.[378] When the i-gel was compared with the Ambu AuraOnce laryngeal mask (Ambu, Glen Burnie, MD), the leak pressures were greater and the times to insert the device greater with the i-gel. The authors noted a tendency for the i-gel to slide out and recommended taping it in place to prevent dislodgment intraoperatively.[379] When compared with the LMA Supreme, the airway leak pressures were greater with the i-gel.[380]



Summary

A variety of SGAs are currently available. Some are imitators of the LMA Classic but they are available at a reduced cost, whereas others are completely new designs. Many of the new devices have designs that assist in the management of normal and difficult airways in children, but there are insufficient data to clearly declare one device or one manufacturer superior to the other. Each institution must determine which devices fit best in its practice to assist in managing the pediatric airway.

Airway Management: The Abnormal Airway

CLASSIFYING THE ABNORMAL PEDIATRIC AIRWAY

It is important to recognize circumstances that may cause airway obstruction or difficult laryngoscopy. Conditions that predispose

E-FIGURE 14.2 The CobraPLA (perilaryngeal airway; Engineered Medical Systems, Indianapolis, IN) is a disposable supraglottic device that is marketed for the same indications as the laryngeal mask airway but creates a seal higher in the hypopharynx using a cylindrical inflatable cuff. Three different sizes are shown **(A)**. The distal end of the device sits over the larynx but is not inflatable. A long midline slit in the distal end of the device allows passage of a fiberoptic scope and endotracheal tube **(B)**.

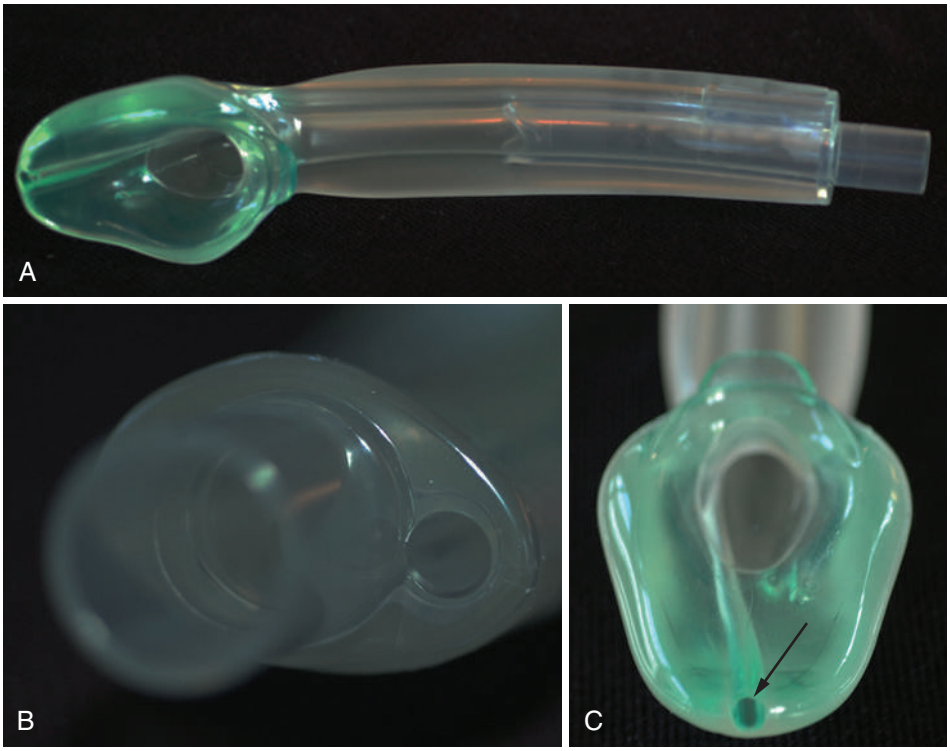


FIGURE 14.20 The i-gel supraglottic device **(A)** consists of a malleable non–latex-containing, noninflatable cuff that is designed to seal over the laryngeal inlet after insertion. The stem of the i-gel contains a "buccal cavity stabilizer," which is designed to resist accidental rotation after insertion and is made from a hard polymer that resists biting. The i-gel also contains a gastric suction channel next to the 15-mm connector **(B),** with which practitioners may evacuate gastric contents when the device is in the correct inserted position. **(C),** The distal position of the suction port *(arrow).*

TABLE 14.7 Suggested i-gel Supraglottic Device Size, Inner Diameter, Endotracheal Tube Size, and Nasogastric Tube Size

Size	Patient Weight (kg)	ID (mm)	Maximal Size of Endotracheal Tube (mm ID)[a]	Maximal Size of Nasogastric Tube (Fr)

to airway problems may be grouped according to anatomic location and may result from congenital, inflammatory, traumatic, metabolic, or neoplastic disorders. Tables 14.8 and 14.9 list the more common pediatric airway problems according to anatomic location. E-Table 14.1 lists the more common pediatric syndromes and associated anesthetic considerations; more complete information may be obtained elsewhere.[381–384] For optimal management of the airway in obese children, the reader is referred to Chapter 29.

MANAGEMENT PRINCIPLES

For any laryngoscopy, but in particular for the difficult airway, an extensive array of equipment to assist with the difficult airway must be available. We advocate the creation of a difficult airway cart stocked with equipment useful in the management of the difficult airway for children of all sizes and ages. Suggestions for contents are listed in Table 14.10. The approach to a difficult airway, as described earlier, must include a careful history and physical examination and, when indicated, radiologic evaluation. In the past, lateral neck xerograms were useful in delineating anatomic aberrations; however, ultrasound, MRI, and CT imaging have supplanted this modality.[109–111,113–124,143,385–390] Ultrasound can be useful in the identification of subglottic stenosis; there may also be a role for use of ultrasound to help with the prediction of difficult tracheal intubations and for the examination of children with known difficult airways.[130] Ultrasound can also be used to intubate the trachea quickly as it can be used as a visualization tool for the lighted stylet technique and may be particularly beneficial when blood or secretions impair visualization with traditional methods.[391]

In addition to the airway pathology, the pathophysiology of the congenital syndrome or associated disease process must be fully evaluated. The safest approach to managing a difficult airway is to formulate a plan that includes several contingencies for failure or loss of the airway and to have skilled help available, especially a surgeon who is experienced in performing pediatric bronchoscopy and tracheostomy. To maximize success and safety, a skilled assistant should help to position the child, facilitate

TABLE 14.8 Pediatric Airway Pathology Related to Anatomic Site

Anatomic Site	Etiology	Clinical Condition
Nasopharynx	Congenital	Choanal atresia, stenosis,[34,35,664–668] encephalocele[669–675]
	Traumatic	Foreign body, trauma[676–678]
	Inflammatory	Adenoidal hypertrophy,[676–678] nasal congestion[36]
	Neoplastic	Teratoma[679–681]
Tongue	Congenital	Hemangioma, Down syndrome, glossoptosis[682]
	Traumatic	Burn, laceration, lymphatic/venous obstruction[134,135,676,683–689]
	Metabolic	Beckwith-Wiedemann syndrome[585,690–696] hypothyroidism,[697] mucopolysaccharidosis,[628,698–719] glycogen storage disease,[720–730] gangliosidosis,[731–734] congenital hypothyroidism
	Neoplastic	Cystic hygroma,[735–739] cystic teratoma
Mandible/ maxilla	Congenital hypoplasia	Pierre Robin syndrome,[485,560,562,600,740–757] Treacher Collins syndrome,[411,561,586,758–772] Goldenhar syndrome,[390,481,614,773–780] Apert syndrome,[781–783] achondroplasia,[564,784–788] Turner syndrome,[789–793] Cornelia de Lange syndrome,[794–797] Smith-Lemli-Opitz syndrome,[798–800] Hallermann-Streiff syndrome,[801] Crouzon syndrome[802,803]
	Traumatic	Fracture,[804–806] neck burn with contractures[688,689,807]
	Inflammatory	Juvenile rheumatoid arthritis[808–814]
	Neoplastic	Tumors, cherubism[815–817]
Pharynx/ larynx	Congenital	Laryngomalacia (infantile larynx) (see Video 14.1),[676,818–821] Freeman-Sheldon syndrome (whistling face),[822–835] laryngeal stenosis,[676,836] laryngocele,[818] laryngeal web,[818,837–839] hemangioma[840,841]
	Traumatic	Dislocated/fractured larynx,[676,806,842–849] foreign body,[54,55,676,850–858] inhalation injury (burn),[683–686,688,807,859] postintubation edema/granuloma/stenosis,[860–874] swelling of uvula,[134,875] soft palate trauma, epidermolysis bullosa[876–888]
	Inflammatory	Epiglottitis,[50–52,889–894] acute tonsillitis,[895] peritonsillar abscess,[896,897] retropharyngeal abscess,[898] diphtheritic membrane, laryngeal papillomatosis[899–907]
	Metabolic	Hypocalcemic laryngospasm[47]
	Neoplastic	Tumors
	Neurologic	Vocal cord paralysis, Arnold-Chiari malformation[908–911]
Trachea	Congenital	Vascular ring,[56,57,912,913] tracheal stenosis or complete tracheal rings (Video 14.18),[914–916] tracheomalacia (see Video 14.1)[818,836,870,917–919] congenital tracheal web, hemangioma[920–923]
	Inflammatory	Laryngotracheobronchitis (viral),[49,52,53,219,924–926] bacterial tracheitis
	Neoplastic	Mediastinal tumors: neurofibroma,[927] paratracheal nodes (lymphoma)[928–934]

TABLE 14.9 Cervical Spine Anomalies[a]

Etiology	Clinical Condition
Congenital	Down syndrome,[935–944] Klippel-Feil malformation,[945–950] Goldenhar syndrome,[390,481,614,773–779,951] Pierre Robin,[952] torticollis
Traumatic	Fracture, subluxation,[805,806,842–846,953–956] neck burn contracture[689]
Inflammatory	Rheumatoid arthritis[808–814]
Metabolic	Mucopolysaccharidosis (Morquio syndrome)[698–713,957]

[a]Abnormalities of the cervical spine may limit extension and flexion, thereby contributing to the difficulties of airway management; a significant percentage of infants with Down syndrome have atlantoaxial instability.[958]

airway management, and observe the monitors and the child's vital signs. To direct an assistant, there should be clear communication about the airway management plan and specific details about maneuvers needed to facilitate the process. Familiarity with difficult airway algorithms and difficult airway management reviews can help the practitioner formulate a reasonable plan and ensure that no viable management options are missed.[392–398]

Certain principles apply to the care of any child in whom difficulty with airway management is anticipated. In most circumstances, an awake or mildly sedated approach would be the primary management strategy for the anticipated difficult airway if airway concerns were considered in isolation. However, often a practitioner using the awake approach may encounter difficulty in obtaining the child's cooperation. Assisted spontaneous ventilation during general anesthesia is the preferred technique when abnormal airway anatomy is present and difficulty with patient cooperation is anticipated; it provides adequate oxygenation while the airway is evaluated for the appropriate approach to tracheal intubation. Therefore the first choice for management of a potential difficult airway, whether the child is sedated or under general anesthesia, is to *maintain spontaneous ventilation*.[393,398] There are two reasons for maintaining spontaneous gas exchange. First, neuromuscular blockade may result in total airway obstruction owing to loss of tone of the tongue, pharyngeal and laryngeal muscles, and suspensory ligaments. This obstruction may not be easily alleviated with manual ventilation of the lungs. Neuromuscular blockade should not be used if airway obstruction or the potential for airway obstruction exists.[42] Second, if a child is paralyzed, the loss of spontaneous breath sounds eliminates a valuable guide to locating the glottis. For example, in children with craniofacial anomalies or cervical burn contractures, one may be able to visualize only the tip of the epiglottis with standard rigid laryngoscopy. In such cases, if specialized airway management equipment is unavailable, shaping the ETT tip into a 90-degree angle with a stylet (Fig. 14.21), placing the tip behind the epiglottis (or the center of the base of the tongue if the epiglottis is not

TABLE 14.10 Items to Consider for an Emergency Intubation Cart

Drawer 1	Lens paper
LMA Classic (disposable)—sizes 1, 1.5, 2, 2.5, 3, 4, 5	Surgical lubricant
LMA ProSeal (disposable)—sizes 1.5, 2, 2.5, 3, 4, 5	2% Lidocaine jelly[a]
LMA Fastrach—sizes 3, 4, 5	4% Lidocaine solution[a]
ETTs for Fastrach—sizes (mm ID) 6, 6.5, 7, 7.5, 8	Atomizer to spray topical lidocaine
ETT stabilizers for Fastrach	Suction catheters—sizes 8, 10, 14F
Size or weight charts for LMA	Yankauer suction tubes—pediatric and adult sizes
	Defogger
Drawer 2	Silicone spray
Transtracheal jet-ventilation catheters[a] (VBM)—infant (16 gauge), child (14 gauge), adult (13 gauge)	Halogen light bulb
Emergency Transtracheal Airway Catheter (Cook)	Disposable teeth guards
Magill forceps—adult and pediatric sizes	
Aillon tube bender	**Drawer 4**
Miller blades—sizes 0, 1, 2, 3, 4	Face masks—neonate, infant, toddler, child, adult (small/medium/large)
Macintosh blades—sizes 1, 2, 3, 4	Frie endoscopy mask—infant, child, adult
Phillips blades—sizes 1, 2	Bronchoscopy airways[a]—infant, child, adult
Wis-Hipple blades—sizes 1, 1.5	Bite blocks—infant, child, adult
Oxyscope blades—sizes 0, 1 (with oxygen tubing)	Ovassapian airways (2)
	Nasal trumpets[a]—sizes 2 to 34 F
Handles (Medium and Short)	Oral airways—sizes 90, 80, 70, 60, 50, 00, 000
C batteries × 2	
Oxygen Y-connector	**Drawer 5**
Albuterol adapters for metered-dose administration (3)	Self inflating bag (Ambu) with reservoir
Syringes (5 each)—5 mL, 10 mL	Enk Oxygen Flow Modulation set (Cook, Inc.)
Intravenous catheters, 10 of each commonly used sizes (24 ga, 22 ga, 20 ga, 18 ga, 16 ga)[a]	Jet ventilator
	Stylets—pediatric and adult
Swivel adapters (Portex, Sontex)	ETT exchange catheters with both Luer-Lok and 15-mm OD adapters—sizes (mm OD) 3, 4, 5, 7
No. 3 straight connectors × 2	Retrograde catheter with extra guidewire
	Extension cord with converter from Hubble to three-prong plug
Drawer 3	Other equipment to consider: lighted stylets and optical stylets (see text)
Preparation forceps or tongue-grabbing forceps	
Safety glasses	

[a]Items with outdates.

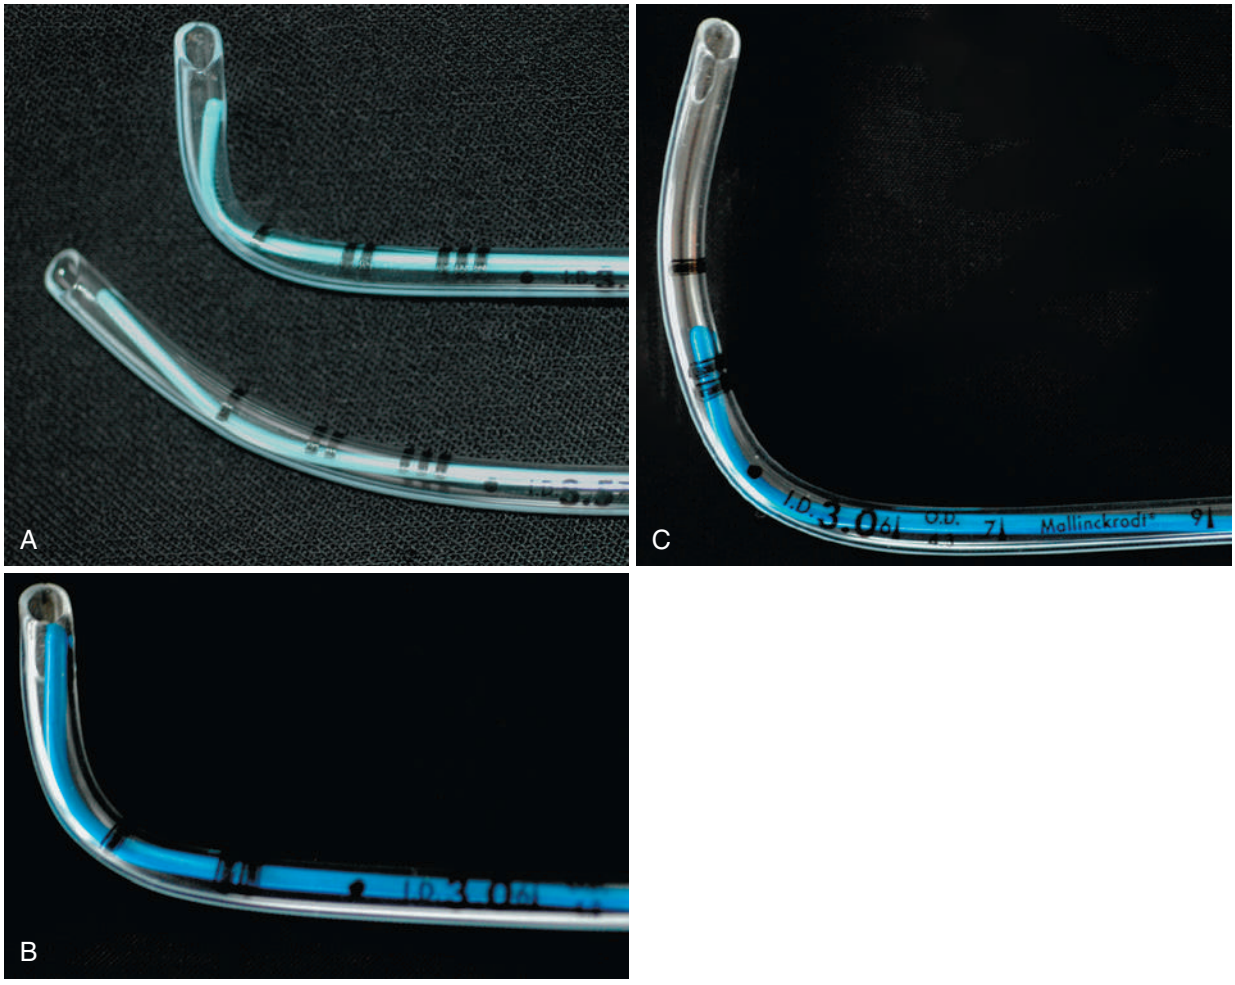
visible), and then listening for breath sounds with the ear near the proximal end of the ETT or tracking the capnogram often allows the practitioner to "blindly" locate the glottic opening and trachea. Despite the rich history of the "spontaneous ventilation" approach to the difficult airway, there has been a shift in practice of late to paralyzing children with difficult airways with nondepolarizing muscle relaxants, particularly with rocuronium because of the availability of sugammadex to reverse the paralysis should an emergency situation arise (see airway registry below).

If the child is able to cooperate while mildly sedated, there are several options for airway management. An opioid-benzodiazepine combination will blunt airway reactivity, decrease discomfort, and provide anxiolysis and amnesia. These combinations, particularly fentanyl and midazolam, are effective for sedation of adolescents and mature preteens.[399] Dosing is based on weight and is guided by clinical parameters, including preexisting medical conditions. However, benzodiazepine-opioid sedation may not suffice for a frightened young child because the dose requirement for sedation may exceed the dose that causes apnea. Alternatively, ketamine, which provides both hypnosis and analgesia, may be used alone or in conjunction with midazolam.[399] Ketamine usually preserves adequate spontaneous ventilation and upper airway patency[400] while preventing laryngeal reactions to airway manipulation. Ketamine and midazolam should be slowly titrated to effect to avoid oversedation and apnea.[401] Midazolam takes almost 5 minutes to achieve peak electroencephalographic effects, necessitating adequate time between incremental doses (see Fig. 48.7).[402,403] Ketamine is usually titrated in doses of 0.25 to 0.5 mg/kg IV every 2 minutes. Although there is a large incidence of psychomimetic emergence reactions in adults, these reactions are less common in children, particularly if ketamine is combined with midazolam. Ketamine may increase secretions that enhance airway reactivity and interfere with video-based airway management; antisialagogue administration may mitigate these effects. In addition, the anticholinergic effect of atropine or glycopyrrolate will blunt reflex bradycardia that can occur with airway manipulation. Dexmedetomidine may be administered as the sole sedating agent or combined with reduced doses of other sedatives or opioids to be effective for sedation while maintaining spontaneous respirations during fiberoptic intubation in adults and children.[404–411]



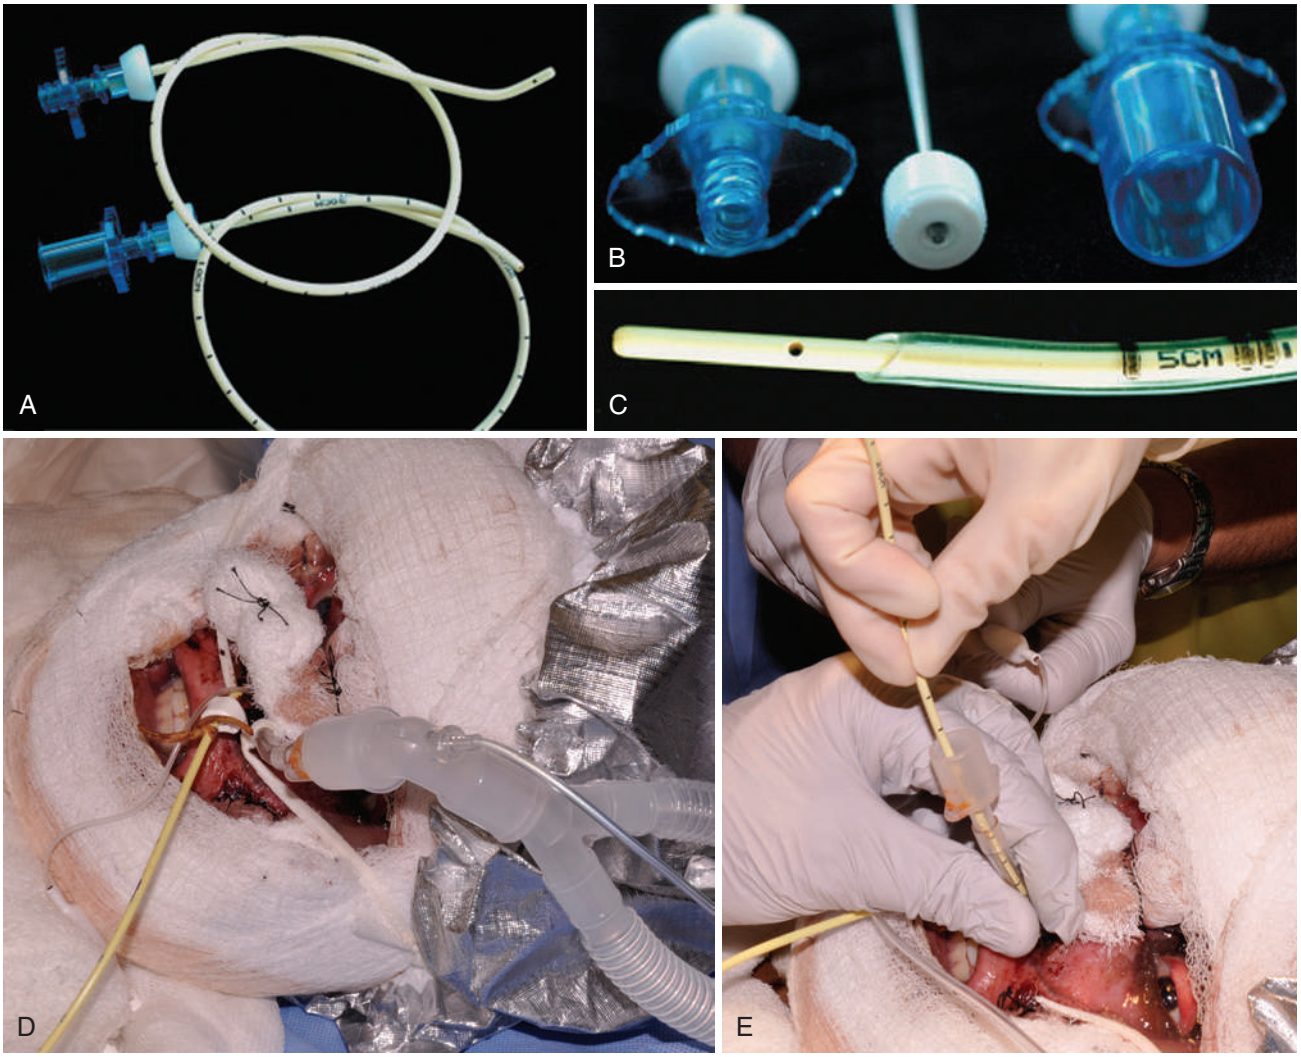


FIGURE 14.21 A stylet placed within an endotracheal tube (ETT) often facilitates placement. **A,** The "hockey-stick" configuration. **B,** In children with midfacial hypoplasia syndromes, in which the anatomic relation of the base of the tongue to the laryngeal inlet is abnormal, a stylet with a 90-degree bend 1 to 2 cm from the tip allows placement of the ETT behind the epiglottis and at the laryngeal inlet. Breath sounds audible at the 15-mm connector confirm appropriate location. **C,** Maintaining the position of the stylet while advancing the ETT frequently allows successful "blind" endotracheal intubation around the base of the tongue even without the use of special airway equipment.

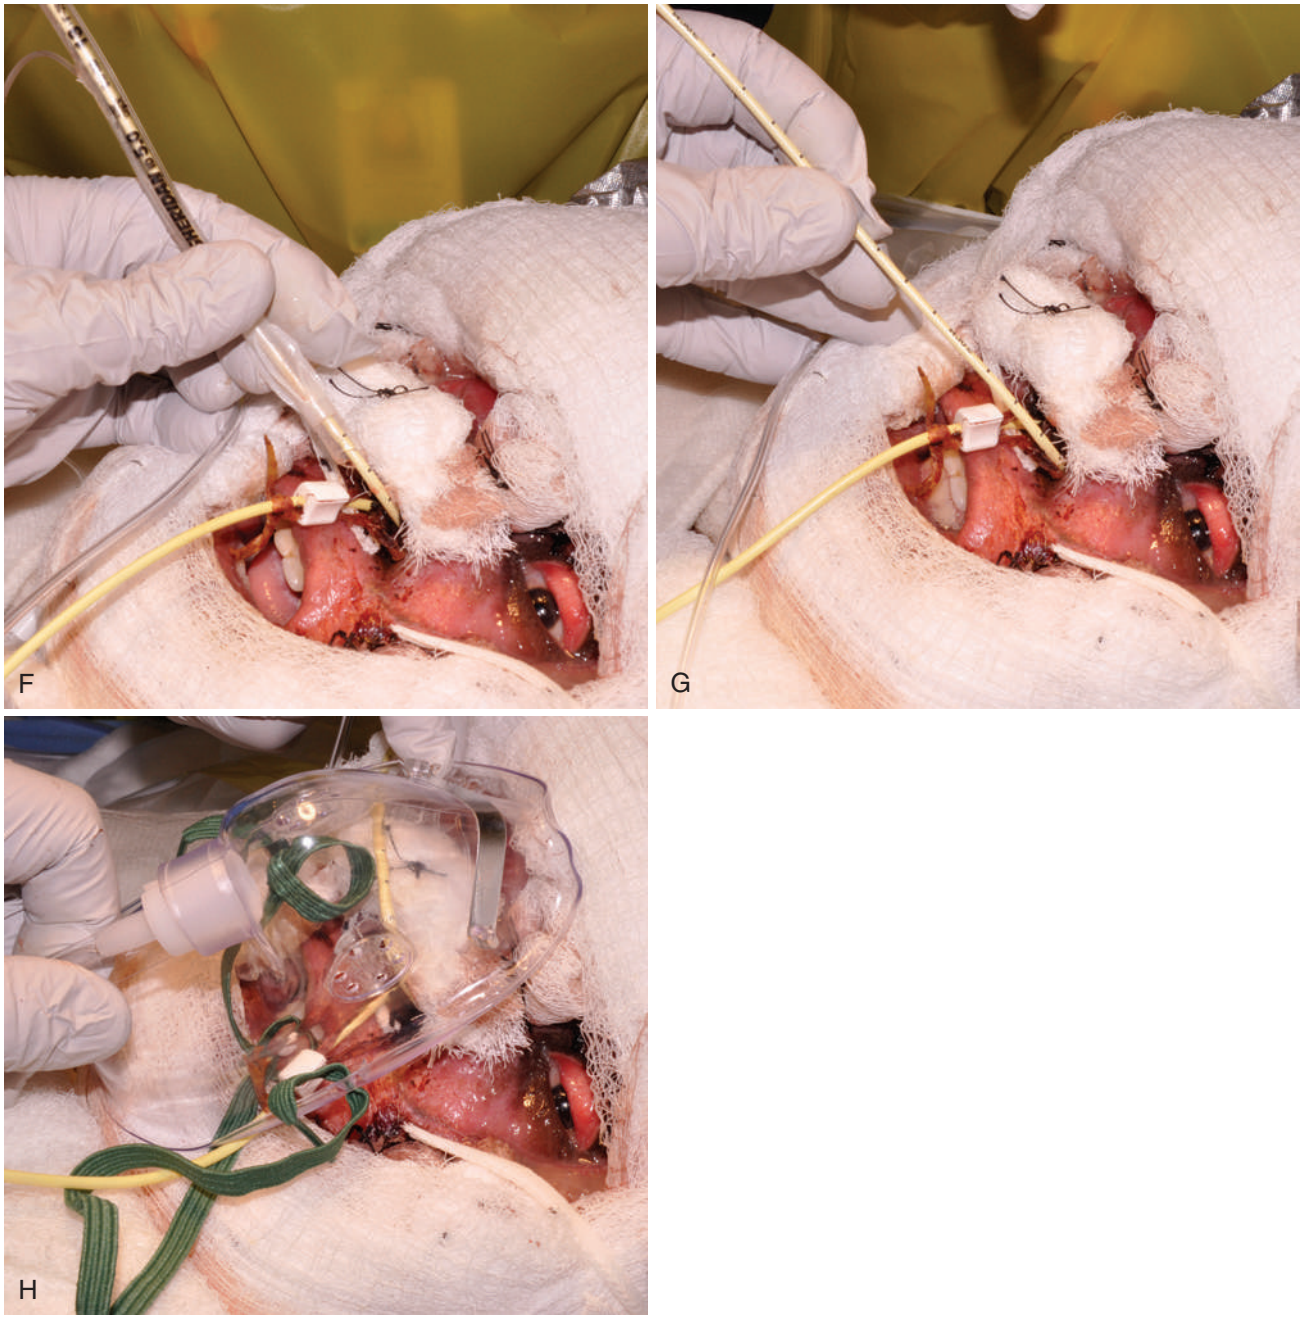
A multicenter registry, the Pediatric Difficult Intubation (PediDI) registry,[412] was developed to examine the risk factors for a difficult intubation, examine the success rates of various intubation techniques, and assess the complications that occur in children with difficult tracheal intubations. Data from this registry demonstrate that children with difficult airways were often paralyzed for their airway management after confirming easy mask ventilation. This is likely because of the fear of airway activation (laryngospasm, bronchospasm, coughing) during the airway management. Performing a 5-second jaw thrust in an unparalyzed anesthetized child is a reliable test to assess the risk of airway activation when the airway is instrumented. Absence of movement, tachypnea, and tachycardia in response to the jaw thrust suggests a small risk of triggering a response to airway instrumentation. The depth of anesthesia, however, needs to be maintained during the airway manipulation, particularly if the intubation attempt is prolonged.



Topical anesthesia may be used in conjunction with sedation or general anesthesia to blunt airway reactivity in those children in whom spontaneous ventilation is preserved. Useful methods for providing topical anesthesia to the airway include (1) nebulized lidocaine; (2) topical application of local anesthetic sprays, jellies, or ointments; (3) translaryngeal delivery of lidocaine; (4) "spray as you go" with lidocaine injected onto the surface of the larynx and vocal cords through the channel of an FOB usually used for suctioning or administering oxygen; and (5) superior laryngeal nerve block.[399] Caution is required to avoid delivering a toxic dose of local anesthetic. Maximum doses of the local anesthetic are based on the patient's weight and should be calculated in advance (see Table 42.2). Lidocaine seems to have the best safety profile; we limit our maximum dose to 4 mg/kg.[412a] We do not recommend the use of benzocaine (Cetacaine) local anesthetic spray in children weighing less than 40 kg, because it is associated with methemoglobinemia and it is difficult to titrate or limit the administered dose.[96,413]

Strategies to maintain oxygenation vary according to the technique (spontaneous respiration vs. paralyzed). For infants who are breathing spontaneously, the Oxyscope (Heine Optotechnik, Herrsching, Germany) is a Miller 1 laryngoscope blade with an insufflation channel along its length so that it may be attached to an oxygen source (E-Fig. 14.3).[414–416] Other strategies include

E-FIGURE 14.3 Endotracheal tube exchangers are available that will fit an endotracheal tube (ETT) with a 3.0-mm ID. These have side holes at the tip that allow delivery of oxygen **(A)** and may be attached to either a jet ventilation system or a standard 22-mm OD adapter **(B)**. This device is also available with a stylet and slight bend to be used as an intubation bougie **(C)**. This device can be used to successfully reinsert the ETT should the patient fail extubation criteria. **D,** This child had a very severe facial burn and was intubated by the nasal route because he had such severe trismus that we were not able to open his mouth. Several days after grafting, he appeared to have satisfactory conditions for extubation. Given the degree of difficulty in placing the mask on his face, extubation was planned using an airway exchange catheter (RapiFit; Cook Critical Care, Bloomington, IN). E, After preoxygenation and sedation with intravenous ketamine and midazolam in low doses, 1 mg/kg of lidocaine was sprayed down the ETT and the airway exchange catheter was advanced into the trachea.

Continued

E-FIGURE 14.3, cont'd F, The ETT was then removed, leaving the airway exchange catheter in place **(G)**. **H,** The child was then administered oxygen by face mask and observed for satisfactory ventilation and oxygenation, after which the airway exchange catheter was removed.

the use of high-flow nasal cannula,[417] insufflation into the hypopharynx via a nasal trumpet or shortened preformed airway RAE tracheal tube, or intubation through an LMA. For the nonbreathing patient preoxygenation with 100% oxygen is vital.

Many techniques and devices for managing a difficult airway have been recommended; these are reviewed in detail later. Previous experience in normal airways can render these devices valuable adjuncts in difficult airway management. *If one is unable to secure tracheal intubation, it is important to recognize the limits of one's ability. Do not hesitate to seek assistance from a colleague or request the surgeon to perform a tracheostomy or bronchoscopy. As an alternative, the child can be awakened and referred to a major pediatric center. In an urgent, life-threatening situation, placement of an SGA device or percutaneous cricothyroidotomy can be lifesaving* (see "The Unexpected Difficult Intubation").[255,293,294,418,419]

Cognitive biases may play a role in airway management and knowledge of these thinking patterns may help clinicians select the appropriate choices when things go wrong. Some examples of biases that may occur with airway management include loss aversion, framing, and anchoring. Loss aversion is the idea that we dislike a loss more than we like an equivalent gain, which leads us to make irrational choices. An example would be a patient with a recognized difficult airway and a known history of difficult mask ventilation. A clinician may recognize the need for an awake or sedated approach but because of a lack of familiarity with performing the awake technique and fear of failure and the associated negative perception from peers, they may decide to proceed with inhaled induction. The loss of reputation and negative perception (loss aversion) influenced the clinician to make an inappropriate choice for the patient. Anchoring occurs when a starting point influences or biases subsequent decisions; an example would be a patient who is easy to mask ventilate after induction of anesthesia but subsequently becomes impossible to ventilate. A clinician may fixate on the fact that ventilation was easy before and continue to try interventions to improve ventilation and delay definitive treatment such as a surgical airway because of anchoring to the previous condition. The cognitive frame of the clinician plays a critical role in his or her next steps and framing has been shown to influence choices in many situations. A lay example is labeling of food as 90% fat-free versus 10% fat. Though both labels communicate the same information, the former is more desirable and consumers choose that option more often. In the patient described earlier who went from being easy to mask ventilate to becoming impossible to ventilate, two thinking patterns are common in the clinician's mind. One frame could be *"This is very bad, this patient may need a surgical airway, I will be sued."* Another frame could be *"This patient needs a surgical airway, this will be lifesaving."* Clearly the latter frame results in the most favorable action, whereas the former may lead to inaction or delays.[420]

Documentation

Documentation of the difficult airway and its management is essential to provide useful information for the next time that the child requires sedation or anesthesia. A note in the anesthesia record should clearly address the following issues:

1. Whether mask ventilation was attempted, and if so, whether there was any difficulty
2. Special maneuvers that were required for successful mask ventilation
3. Special maneuvers that were not helpful with mask ventilation
4. Any difficulty with tracheal intubation
5. Special techniques that were required for successful intubation
6. Special techniques that were not helpful for intubation
7. Grade of the laryngoscopic view of laryngeal structures during direct laryngoscopy (Fig. 14.22)

In addition to discussion with the family and the child (when age appropriate), a letter should be given to the family and child outlining the difficulties with the airway, describing how the airway was managed, and referring them to the MedicAlert Foundation registry.[371] This should be copied and circulated to the medical record and to the MedicAlert registry. In the United States, the MedicAlert registry for difficult airway/difficult intubation can be reached by telephone at 1-888-633-4298. Similar registries are also being formed internationally.[421] The MedicAlert registration form asks for clinical details about the type of airway difficulty, as well as which maneuvers were successful in management and those which were not. Any practitioner who provides airway management to the registered patient can update this information

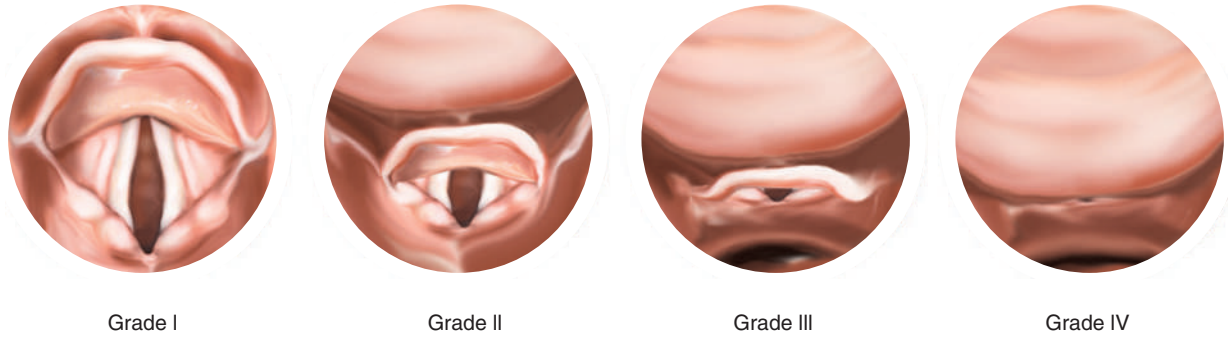


FIGURE 14.22 The laryngoscopic grading system of Cormack and Lehane offers a reasonable means of describing visualization of the larynx. It is useful to grade the degree of visualization during laryngoscopy and how that visualization was achieved (e.g., external cricoid pressure or laryngeal manipulation, the size and configuration of the laryngoscope blade). This provides useful information for the next person attempting laryngoscopy so that he or she has some degree of knowledge regarding what to expect. Grade I is visualization of the complete laryngeal opening; grade II, visualization of just the posterior area; grade III, visualization of just the epiglottis; and grade IV, visualization of just the soft palate. (Reproduced with permission from Cormack RS, Lehane J. Difficult tracheal intubation in obstetrics. *Anaesthesia* 1984;39:1105–1111.)

at any time. Although scoring systems used in adults[91–95] have not been thoroughly investigated in all age groups,[96,422] it is useful to describe in detail the view of the larynx that was achieved and how it was achieved (e.g., blade type, size, external laryngeal manipulation, GlideScope [Verathon, Seattle, WA]).

The Unexpected Difficult Intubation

With careful preoperative evaluation and planning, the unexpected pediatric difficult airway should be a rare occurrence. However, the practitioner should always be prepared for this potentially life-threatening event. Because the unexpected difficult airway occurs after the anesthesia (plan A) has been initiated, many of the management decisions required for the anticipated difficult airway have already been made. Of primary importance is maintaining adequate oxygenation while a definitive course of action is pursued (i.e., plan B, plan C, and so on). A reasonable pediatric decision tree, based on the difficult airway algorithm of the American Society of Anesthesiologists (ASA), is presented in Fig. 14.23. An

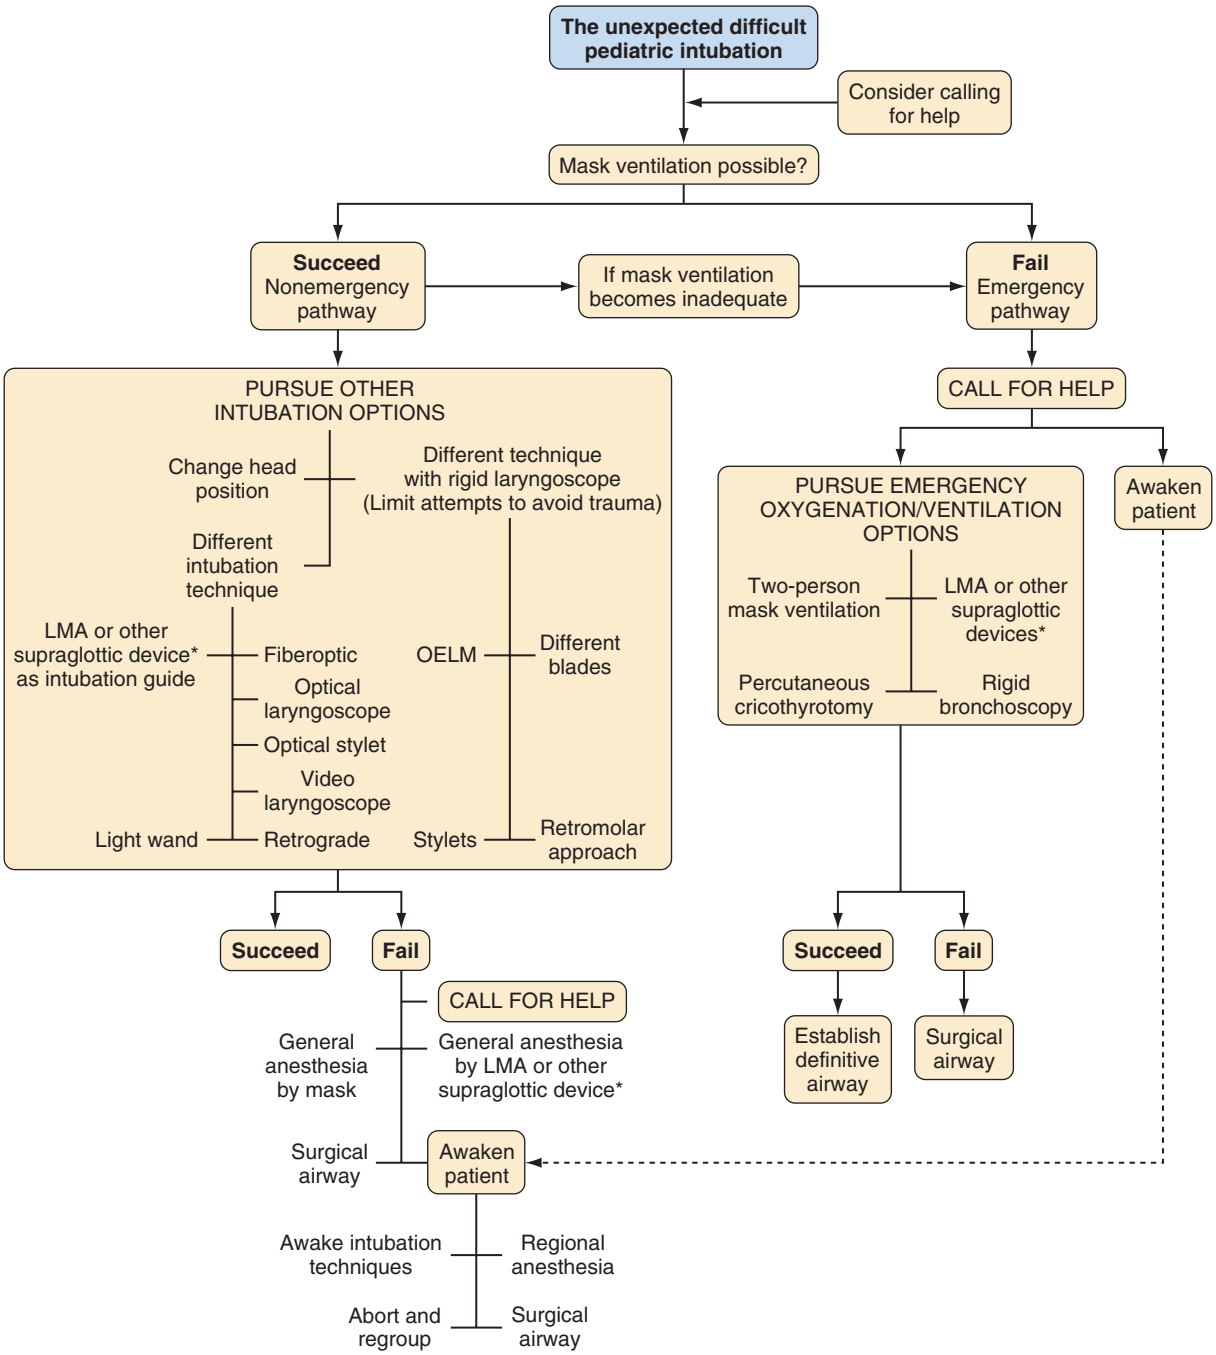

FIGURE 14.23 A proposed algorithm for management of the unexpected difficult pediatric airway. *LMA,* laryngeal mask airway; *OELM,* optimal external laryngeal manipulation; *PLMA,* ProSeal LMA. *Consider using PLMA if the child is at risk for aspiration or if high inflation pressures are needed. (Modified with permission from Wheeler M. Management strategies for the difficult pediatric airway. *Anesth Clin North Am.* 1998;16:743–761.)

important difference between infants and adults should be noted in this scenario. Because infants have an increased metabolic rate and decreased functional residual capacity, the time between the loss of the airway and resultant hypoxemia with potential secondary neurologic injury is significantly diminished compared with adults.[423] In a mathematical model, the approximate time to zero oxygen saturation from an FIO_2 of 90% is 4 minutes in a 10-kg child, whereas the same process in a healthy 70-kg adult takes almost 10 minutes.[421,424]

The PediDI registry demonstrated that more than two direct laryngoscopy attempts in children with difficult tracheal intubation was associated with a high failure rate and an increased incidence of severe complications.[412] These findings suggest that the following strategies should be considered: (1) minimize the number of direct laryngoscopy attempts, and transition to an indirect technique (videolaryngoscope/fiberoptic bronchoscope) when direct laryngoscopy fails, and (2) consider a means for passive oxygenation of the lungs during tracheal intubation attempts such as high-flow nasal cannula and the modified nasal trumpet (Video 14.8).[425] A similar registry of pediatric intensive care units confirmed the association between multiple tracheal intubation attempts and associated adverse events.[426]

SGAs can be effectively used and are often the key initial step for safe management of the difficult airway. The pediatric airway guidelines published by the Difficult Airway Society/Association of Paediatric Anaesthetists of Great Britain and Ireland (APAGBI) suggest the use of an SGA, if feasible, when failed tracheal intubation occurs in the pediatric difficult airway population (APAGBI Paediatric Airway Guidelines, available from http://www.apagbi.org.uk/publications/apa-guidelines). A retrospective study that examined the elective use of SGAs as the primary airway management in children with difficult airways concluded that they could be effectively used. In this study, 77,272 children received general anesthesia at a pediatric institution; 459 of these patients (0.6%) were reported to have a difficult airway (defined as either a history of a difficult direct laryngoscopy, a history of difficult mask ventilation, or both) and 109 of those patients received general anesthesia with an SGA for primary management with a success rate of 96%. (In four patients, an alternative airway was required.)[427]

Extubation of the Child With the Difficult Airway

Preparation for extubation begins shortly after the airway is secured. Equipment used to secure the airway should be rechecked, quickly returned to functional status, and then left in the operating room until successful safe extubation. Children who had prolonged attempts at intubation or who will have procedures that may lead to airway edema may benefit from IV dexamethasone (0.5 to 1 mg/kg, up to 20 mg).[232–234] If significant airway edema is suspected, consider leaving the child intubated postoperatively until it resolves. The child must be fully awake and have full return of strength and adequate ventilatory effort before extubation is attempted.

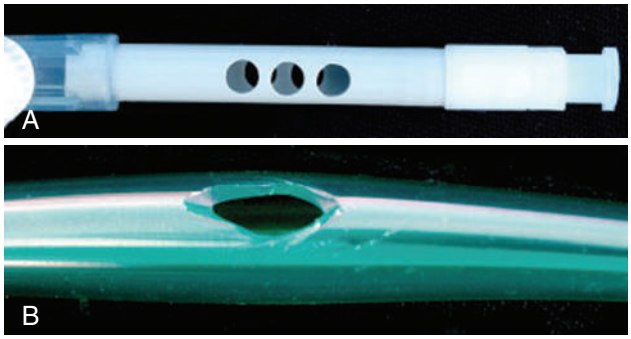
A Cook airway exchange catheter with Rapi-Fit adapter (Cook Critical Care, Bloomington, IN) is a hollow plastic guide with holes on its distal end that may be useful as a bridge to extubation because the adapter on its proximal end allows the placement of either a Luer-Lok connector for connection to a jet ventilator or a 15-mm adapter for connection to a standard anesthesia ventilating system (E-Fig. 14.4)[428–431] It is available in a variety of sizes to allow the exchange of ETTs with 3.0-mm ID or larger. This can be used for oxygenation and ventilation and as a guide to reinsertion of the ETT if the child's ventilatory efforts are inadequate or if airway obstruction occurs.[432] However, caution is required when using this device for jet ventilation, because significant barotrauma has been reported.[433,434]

An alternative to jet ventilation is the Enk Oxygen Flow Modulation set (Cook Critical Care), which allows flow from a standard low-pressure flow meter to be adjusted by occluding holes in the delivery system with the thumb and forefinger (E-Fig. 14.5, Top). As a potential substitute for the Enk device, one could cut a side hole in the plastic oxygen delivery tubing to create a similar low-pressure oxygen delivery system (see E-Fig. 14.5, Bottom). Pneumothorax, pneumomediastinum, and deaths have occurred when jet ventilation was used with an airway exchange catheter.[435] One report suggested that only insufflation or gentle manual ventilation should be used initially and that jet ventilation should be reserved for situations in which these techniques are ineffective. These authors also recommended that the optimal management was reintubation.[436]

If the child remains intubated for a prolonged period of time after surgery, it is advisable to return the child to the operating room for extubation. A surgeon who is prepared to perform rigid bronchoscopy and tracheostomy and an anesthesiologist who is familiar with the techniques used for the previously successful airway management should be in attendance.

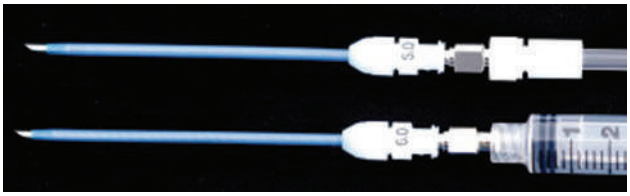
SPECIAL TECHNIQUES FOR VENTILATION

Multi-Handed Mask Ventilation Techniques



Multi-handed mask ventilation techniques can provide an effective temporizing measure until the airway is secured or the child is awakened. One person uses both hands to maintain an adequate mask fit, and a second person compresses the reservoir bag (Fig. 14.24). This can also be accomplished by having a single provider use two hands on the mask while the anesthesia ventilator is activated.[437] Occasionally, a second person is required to perform a jaw thrust with one hand while compressing the anesthesia bag with the other. Rarely, a third person may be required to compress the anesthesia bag with two hands (to generate a greater peak inflation pressure) while the first person holds the mask with two hands and the second person performs a two-handed jaw thrust.[437]

Laryngeal Mask Airway



The LMA has revolutionized difficult airway management in children. Numerous case reports and extensive clinical experience attest to the value of the LMA for establishing an airway when both ventilation and intubation are extremely difficult or impossible.[395,438–440] The LMA has been described as a tool for use in both the nonemergency pathway (*cannot intubate, can ventilate*) and the emergency pathway (*cannot intubate, cannot ventilate* [CICV]) of the ASA difficult airway algorithm.[393,395] Use has been described in the awake child (LMA insertion in awake infants with Pierre Robin syndrome [Robin sequence])[441,442] (Video 14.9) and in the anesthetized child with a known or suspected difficult airway. It can be used as the definitive airway in some circumstances, as a conduit for intubation, or as a temporizing airway while other options are pursued (e.g., a surgical airway). There are now many other SGA devices reported to be useful in the management of the child with a difficult airway (see above discussion), but comparative studies in pediatrics are lacking.[300,443]

Percutaneous Needle Cricothyroidotomy

The American Heart Association changed its recommendations for emergency airway management to a percutaneous needle

E-FIGURE 14.4 A, A device that may be substituted for a jet ventilation system that allows delivery of oxygen at low flows is the Enk Oxygen Flow Modulation set (Cook Critical Care, Bloomington, IN.). Occlusion of the side holes with the thumb and first finger allows diversion of flow into a transtracheal or translaryngeal cannula, and removal of the occlusion allows flow to exit the side of the device. **B,** A low-cost alternative is to simply cut a side hole in the oxygen delivery tubing and use it in the same way as the Enk system.

E-FIGURE 14.5 *Top,* A transtracheal kink-resistant catheter is available in a 6F external diameter (Emergency Transtracheal Airway Catheter; Cook Critical Care, Bloomington, IN). The system is similar to a simple intravenous catheter device inserted percutaneously with a syringe (*bottom*). Aspiration of air confirms tracheal position, and the catheter is advanced as described in Fig. 14.25. The catheter can be attached to either a jet ventilation system (*top*) or the system described in Fig. 14.25.

FIGURE 14.24 **A,** The two-handed technique for mask ventilation may be useful to improve mask fit and therefore ventilation when the traditional technique is inadequate. One person holds the mask while a second person squeezes the ventilation bag. **B,** Occasionally, a third person is required to perform a two-handed jaw thrust (see text for details).

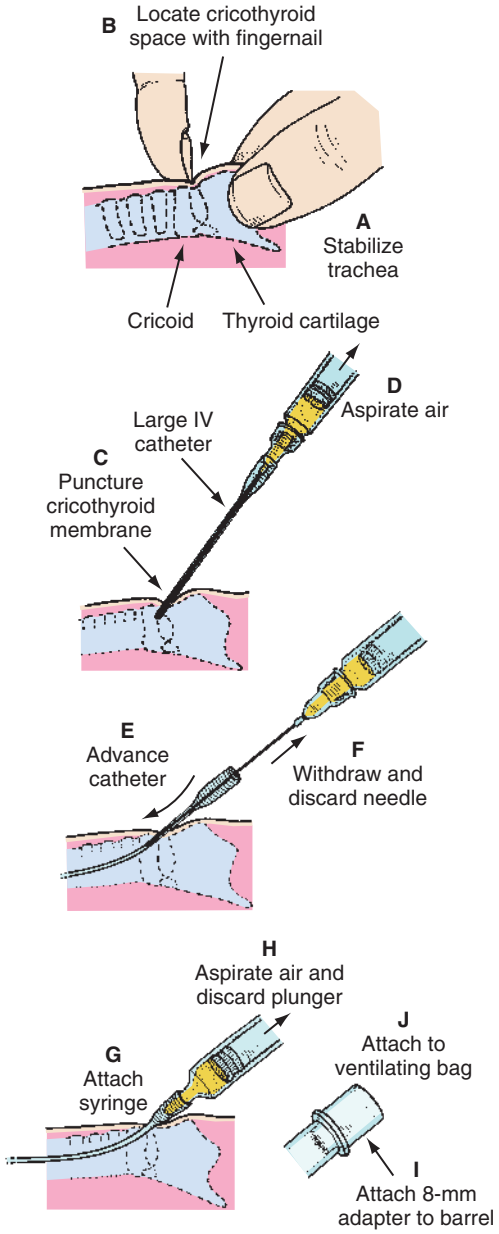


FIGURE 14.25 Percutaneous cricothyroidotomy. Extend the head in the midline with a rolled towel or folded sheet beneath the shoulders. **A,** Standing to the left of the child, stabilize the trachea with the right hand. **B,** The cricothyroid membrane is located with the index fingertip of the left hand between the thyroid and cricoid cartilages. This space is so narrow (1 mm) in an infant that only a fingernail can discern it. The trachea is then stabilized between the middle finger and thumb of the left hand while the fingernail of the index finger marks the cricothyroid membrane. **C,** A large intravenous (IV) catheter (12- to 14-gauge) is then inserted through the cricothyroid membrane, and air is aspirated **(D)**. The catheter is advanced into the trachea through the membrane, and the needle is discarded; an intraluminal position is reconfirmed by attaching a 3-mL syringe **(E)** and aspirating for air **(F)**. A 3-mm adapter from a pediatric endotracheal tube can be attached to any intravenous catheter **(G)**. Ventilation is accomplished by attaching to a breathing circuit with a standard 22-mm connector **(H)**. An alternative would be to leave the barrel of the 3-mL syringe attached to the IV catheter, insert an 8-mm endotracheal tube adapter to the syringe barrel **(I),** and then attach to a ventilating system with a standard 22-mm adapter **(J)**. (From Coté CJ, Eavey RD, Todres ID, Jones DE. Cricothyroid membrane puncture: oxygenation and ventilation in a dog model using an intravenous catheter. *Crit Care Med*. 1988;16:615–619, © by Williams & Wilkins.)

cricothyroidotomy over a surgical cricothyroidotomy in 1992 because it was believed that the former entails less risk of injury to vital structures such as the carotid arteries or jugular veins, particularly in the hands of nonsurgical trained practitioners. In addition, most practitioners can more rapidly perform the percutaneous procedure. However, the cricothyroid membrane has a relatively small width in infants and children younger than 5 years of age. Attempts at cricothyroidotomy may readily damage cricoid and thyroid cartilages, resulting in laryngeal stenosis and permanent damage to the speech mechanism. Therefore, this procedure should be reserved for use only under emergency circumstances.[444,445] More studies are needed but at this time, needle cricothyroidotomy is still the technique of choice in the "*cannot intubate, cannot oxygenate*" (CICO) situation in infants (APAGBI Pediatric Airway Guidelines [see discussion below] available from http://www.apagbi.org.uk/publications/apa-guidelines).

Because percutaneous needle cricothyroidotomy is rarely used in infants and children, it is recommended that experience be gained with patient simulators or in animal models, because success in the hands of the inexperienced is not assured.[446–449] A schema of this procedure is presented in Fig. 14.25. A commercial product called the Jet-Ventilation-Catheter (VBM Medizintechnik GmbH) is available in three sizes: 16, 14, and 13 gauge. It consists of a slightly curved puncture needle within a Teflon, kink-resistant cannula nearly identical to an IV catheter (Fig. 14.26A). This cannula has two lateral eyes at its distal end and a combined Luer-Lok and

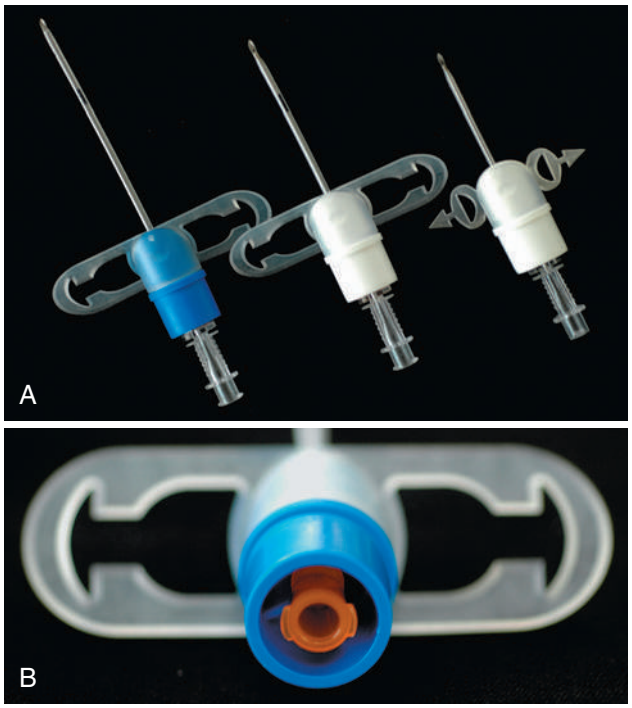

FIGURE 14.26 A, The Jet-Ventilation-Catheter (VBM Medizintechnik GmbH, Sulz, Germany) is available in three sizes: From left to right: 13 gauge (adult), 14 gauge (child), and 16 gauge (infant). It consists of a slightly curved puncture needle within a Teflon, kink-resistant cannula. The procedure for insertion is similar to that described in Fig. 14.25. **B,** This cannula has two lateral eyes at its distal end and a combined Luer-Lok and 15-mm adapter (surrounding the Luer-Lok) at its proximal end, allowing either jet or standard ventilation. It also has a fixation flange and foam neck tape to secure the airway.

15-mm adapter at its proximal end (see Fig. 14.26B). It also has a fixation flange and foam neck tape to secure the airway.

Percutaneous needle cricothyroidotomy provides only a means for oxygen insufflation and does not reliably provide adequate ventilation. In the spontaneously breathing patient, simple delivery of intratracheal oxygen (1 to 2 L/minute) may be sufficient in the short term, because hypercarbia is generally well tolerated by healthy children.[444,450,451] A number of children with arterial CO_2 values well above 150 mm Hg have survived neurologically intact when adequate oxygenation was maintained.[451] Therefore simple oxygenation without attempts at ventilation may be all that is required to sustain life (Fig. 14.27). For the child without respiratory effort, there is a need to provide ventilation in addition to oxygenation. An Ambu bag with the pop-off disabled can provide limited ventilation through a percutaneous catheter, but these devices will be ineffective at standard pop-off pressures.[444,452] Extremely high ventilating pressures are required, but mid-tracheal pressures are significantly less (10 to 16 cm H_2O).[444] A percutaneous cricothyroidotomy catheter can also be used with a jet ventilation system. Jet ventilation via a catheter passed through a narrow glottic opening has also been described.[453–456]

If upper airway obstruction is present (e.g., after multiple unsuccessful attempts at rigid laryngoscopy), there will be a limited pathway for the egress of air and oxygen, and barotrauma may result from insufflation of oxygen or attempts at ventilation. Very serious morbidity and mortality may result from massive subcutaneous emphysema or tension pneumothorax.[457,458] Therefore,

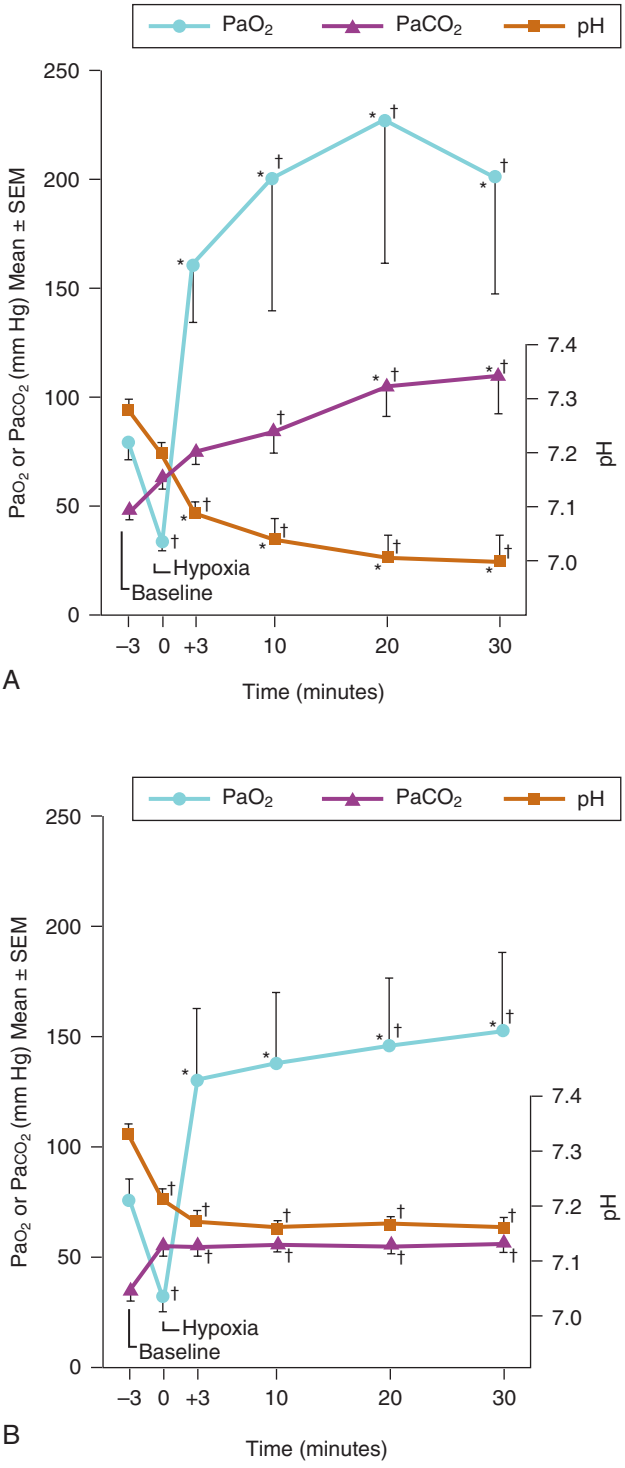

FIGURE 14.27 A, Changes in arterial blood gases and pH are plotted over time for six dogs with spontaneous ventilation; baseline values in room air are plotted at time –3; values after 2 to 3 minutes of hypoxemia as a result of airway obstruction are plotted at time 0. Marked, sustained increases in arterial oxygen tension (Pa_{O_2}) follow cricothyroid membrane puncture with delivery of only 1.0 L/minute oxygen. **B,** Changes in arterial blood gases and pH are plotted over time for five dogs that were not making spontaneous ventilatory efforts. Both oxygenation and ventilation were achieved with a self-inflating bag attached via a 3.0 ID adapter to an IV cannula introduced through the cricothyroid membrane. Pa_{CO_2}, carbon dioxide tension; *SEM,* standard error of the mean; *Sig.*, significant difference. (From Coté CJ, Eavey RD, Todres ID, Jones DE. Cricothyroid membrane puncture: oxygenation and ventilation in a dog model using an intravenous catheter. *Crit Care Med.* 1988;16:615–619, © by Williams & Wilkins.)

jet ventilation must be used with extreme caution in infants and children.[459]

Another IV catheter–type emergency airway device is the Emergency Transtracheal Airway Catheter (Cook Critical Care), which consists of a 6F reinforced catheter that is advanced over a 15-gauge needle similar to the devices described earlier (E-Fig. 14.6). One study simulated use of the Enk Oxygen Flow Modulation set with a variety of IV cannulae and the Emergency Transtracheal Airway Catheter. The investigators concluded that the device worked best when all holes on the Enk device were occluded simultaneously and that minimum flow should never be less than 1 L/minute. They also suggested that initial fresh gas flow be set to 1 L/minute and then adjusted up or down to effect.[460] Successful ventilation with uncuffed devices may depend on the patency of the upper airway (i.e., the greater the patency, the less the effectiveness of ventilation in the nonbreathing patient).[461] None of these devices has been examined in controlled trials to confirm efficacy, in part because these events are so rare. Therefore, we recommend training on simulators so that each practitioner can determine what device is best in his or her hands.

Several percutaneous emergency airway devices are available that use a short but large-diameter needle or a needle, guidewire, and dilator to aid insertion of a percutaneous airway.[446,462–464] The Quicktrach (Rüsch) is a device that consists of a tapered 2- or 4-mm catheter with a fixation flange for securing with cloth tape. A removable plastic stopper is designed to limit the depth of needle insertion. This device requires several steps: puncture of the skin, aspiration for air, removal of the stopper, removal of the needle/syringe, and attachment to standard 22-mm connector. A flexible connector is also provided (E-Fig. 14.7). A rabbit model to simulate infant cricothyroidotomy found success in all attempts but 2 of 10 attempts resulted in fracture of the cricoid cartilage and 1 resulted in damage to the mucosa of the posterior tracheal wall.[465] Conversely, this device has been shown to allow more rapid establishment of an airway than other devices that use a Seldinger technique[466,467]; a larger, cuffed adult model is now available (E-Fig. 14.8).

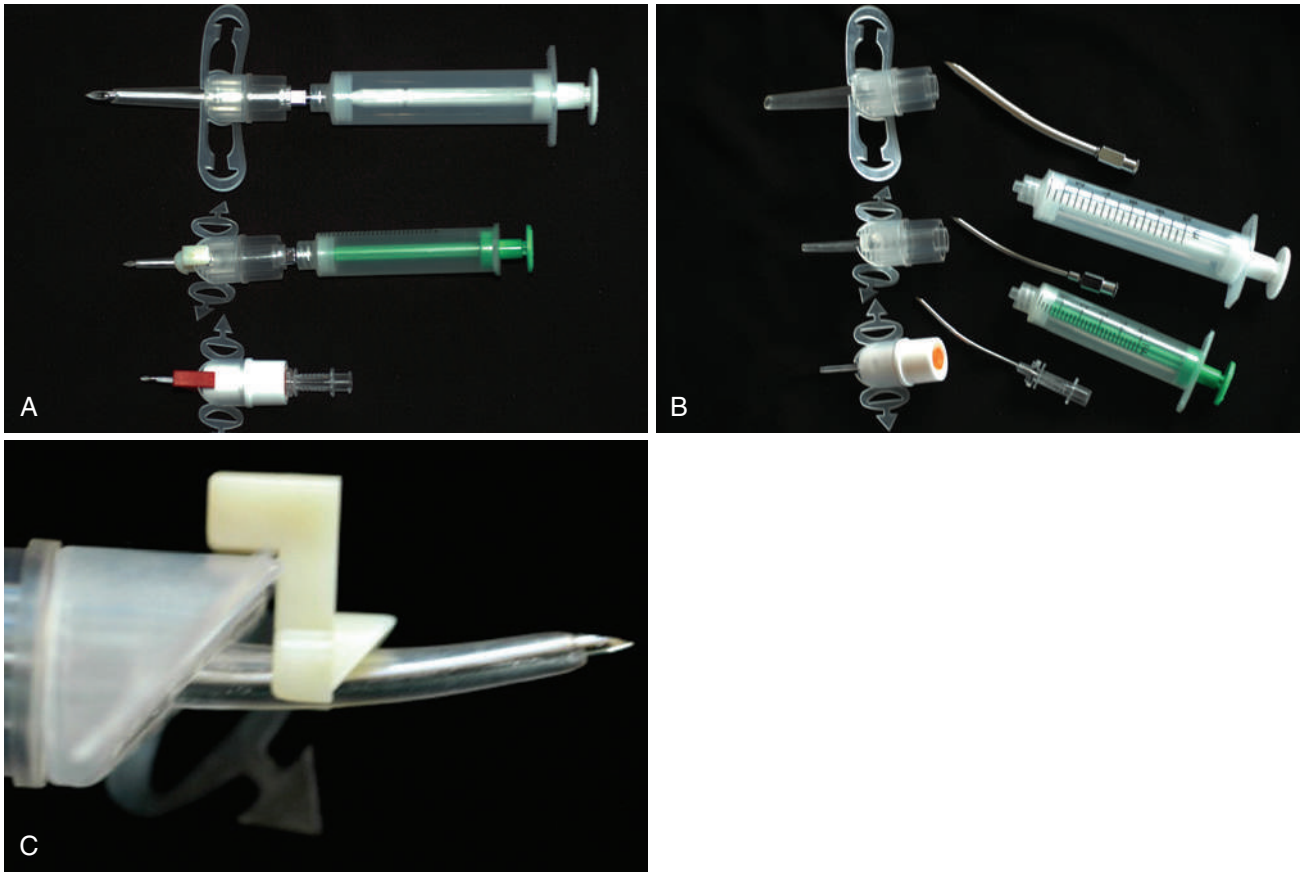
Other devices that use the Seldinger technique (i.e., needle, guidewire, scalpel incision of the skin, and passage of a dilator and tracheostomy tube) are the Arndt and Melker devices (Cook Critical Care).[468] These devices provide a 3.0-mm ID airway that is sufficient for ventilation as well as oxygenation (E-Fig. 14.9). However, the time required to insert such devices may be longer than for simpler devices and may be inappropriate for immediate rapid establishment of an airway.[446,466,467] In contrast, a porcine cadaver study found greater comfort with this technique compared with a scalpel technique.[469] These devices are useful for elective percutaneous tracheostomy.[470]

Another device, Pertrach (Engineered Medical Systems), uses a split needle on a syringe to puncture the cricothyroid membrane (E-Fig. 14.10). A skin incision is made, and an introducer with tracheostomy tube (3.0-mm ID) is directed into the trachea, splitting the needle, which is removed. The introducer is then removed and the airway is secured with tracheostomy tape. There are no case reports in the literature to determine the ease or difficulty of insertion in children, but the multiple steps required suggest that it may be a device for elective tracheostomy rather than emergent establishment of a surgical airway.

Another percutaneous tracheostomy device is the Bivona Pedia-Trake kit (Smiths Medical) (E-Fig. 14.11). A skin incision is made with a scalpel, and a large needle is introduced with a skin dilator, which in theory opens the incision sufficiently to allow passage of an obturator and a 3.0-, 4.0-, or 5.0-mm ID tracheostomy tube (with or without cuff). This device appears sufficiently complicated to not be useful in a CICV emergency; it might be better suited when there is an urgent but not emergent need to establish surgical access to the airway.

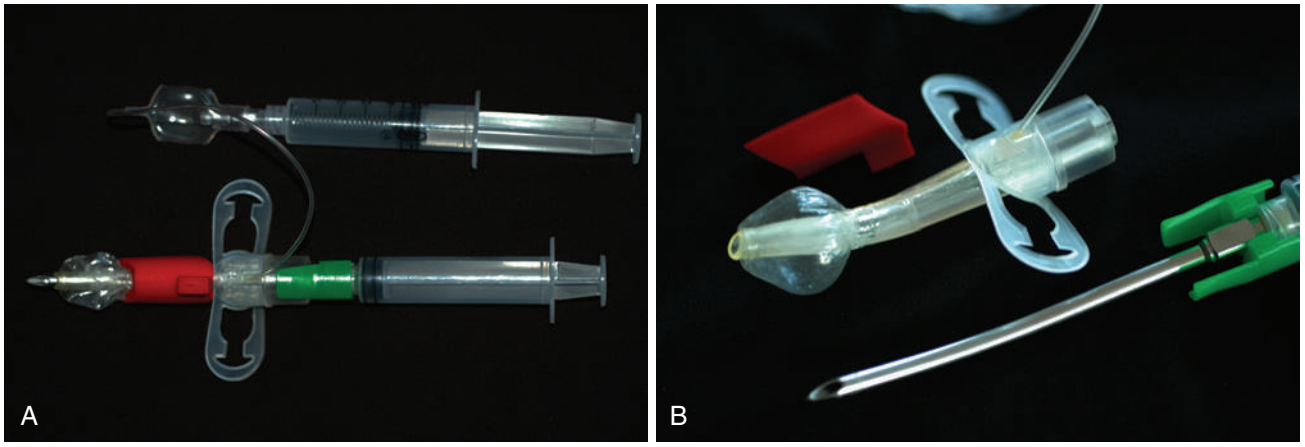
Other devices with limited pediatric use[462] are kits designed to place a full-sized tracheostomy tube, such as the Nu-Trake (International Medical Devices, Northridge, CA) and Abelson (Gilbert Surgical Instruments, Bellmawr, NJ) devices. They may potentially cause tracheal or laryngeal injury in small patients because of the relatively large size of the needle; again, little experience in children has been published.[463,464,471]

Laryngeal Mask Airway Versus Percutaneous Needle Cricothyroidotomy and Transtracheal Jet Ventilation



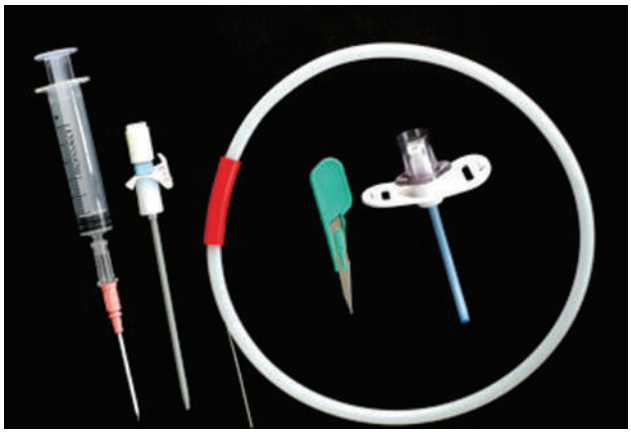
The LMA Classic has proved to be an extremely useful device in airway emergencies. In contrast to percutaneous needle cricothyroidotomy, it is an effective device for ventilation as well as a conduit for intubation.[472] The LMA is easily inserted and requires a relatively low level of skill, as demonstrated in numerous studies comparing this technique with other airway management skills (e.g., mask ventilation, endotracheal intubation). More importantly, in contrast to transtracheal jet ventilation, the complication rate with the LMA Classic is exceedingly low.[473] However, if glottic or subglottic obstruction to ventilation is present, the SGA will be ineffective and a surgical airway with or without transtracheal jet ventilation is still the emergency technique of choice. Since the introduction of the LMA, clinical experience suggests that if glottic or subglottic pathology is not suspected, LMA placement to establish ventilation may be appropriately attempted as the first step at airway rescue.[395]

Surgical Airway

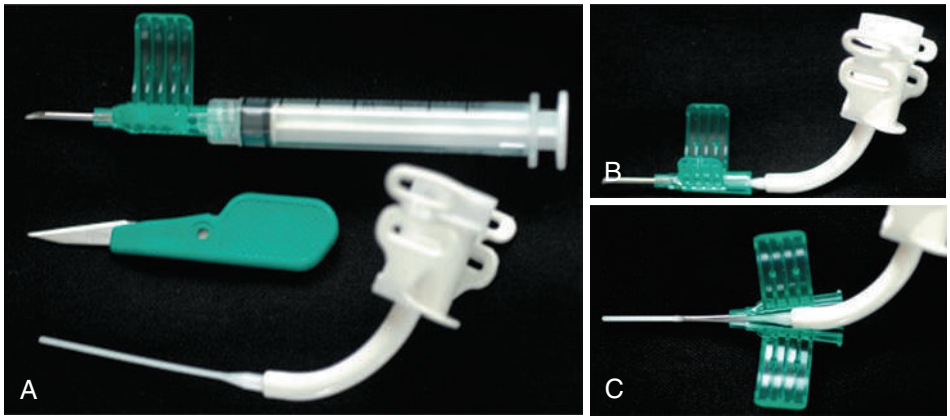


An emergent surgical airway is viewed by some as an alternative to needle cricothyroidotomy.[447,474] It previously fell under the purview of the surgeon, in particular the pediatric otolaryngologist.[447,448,474–476] However, with training, it can be performed quickly by anesthesiologists.[477,478] A CICO situation event in children is extremely rare. Very few practitioners have ever performed a surgical cricothyroidotomy in a child or an adult. There is very little clinical evidence to support any surgical versus needle technique. Randomized trials are ethically impossible and case series in children are not available because of underreporting. Guidelines are based largely on animal studies and expert opinion. Both needle cricothyroidotomy and the surgical scalpel bougie technique are difficult in infants because the trachea is small and mobile[474]; the surgical emergent airway is best performed in those older than 5 years. In nonemergent airway management for children, a tracheostomy is preferred to a cricothyroidotomy because of fewer long-term complications and better results with later decannulation of the airway.[446,479]

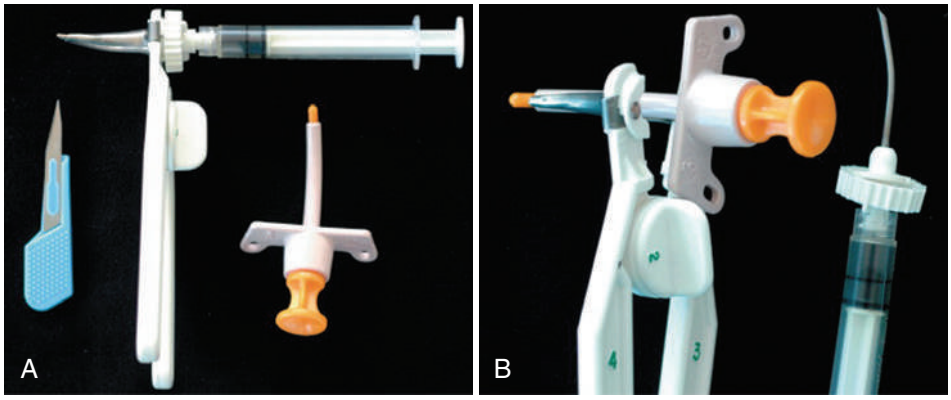
Anterior Commissure Scope and Rigid Ventilating Bronchoscope



Two pieces of equipment used by otolaryngologists that can assist in visualizing the larynx and providing a method of ventilation are the anterior commissure scope and the rigid ventilating bronchoscope. The anterior commissure scope is a rigid, tubular, straight-blade laryngoscope with a light at the tip. The technique to place the anterior commissure scope and the advantages for visualization are similar to those described later for the straight blade used with the retromolar approach.[140]



E-FIGURE 14.6 QuickTrach Emergency Cricothyrotomy Device (Rüsch Inc., Duluth, GA) is available in three sizes (**A, B,** and **C**), *bottom to top*): 1-mm neonatal, 2-mm toddler, and 4-mm older child. This device is similar to the devices presented in Fig. 14.25, but the diameter of the introducing needle is larger and the final size catheter also has a larger diameter. **(C)** A white plastic stopper is designed to prevent excessive depth of insertion and is removed after successful entry into the trachea. The fixed curve of the large needle requires a change in angle from 90 degrees with the skin at insertion to 60 degrees with the skin after entry into the trachea. The built-in flange and strap allow rapid fixation. The size of these devices would seem to limit their utility to larger children and adults, and it would appear that some training on a simulator would be advised.



E-FIGURE 14.7 A and B, QuickTrach Emergency Cricothyrotomy Device for older patients. The device is shown assembled **(A)** and disassembled **(B)**. The principles of insertion are similar to those described in Fig. 14.25, but this device provides a much larger airway with a cuff, allowing a better seal. It would appear that this device would only be appropriate for teenagers because of the size of the insertion needle.

E-FIGURE 14.8 The Arndt Emergency Cricothyrotomy Set (Cook Critical Care, Bloomington, IN) provides a 3.0-mm ID airway that is sufficient for ventilation as well as oxygenation. Percutaneous dilation cricothyroidotomy uses a five-step staged technique, similar to the Seldinger technique used for placement of central venous catheters, to place a secure airway. (1) A percutaneous needle cricothyroidotomy is performed, and negative pressure measured via a syringe and side port confirms aspiration of air. (2) A guidewire is then passed through the needle. The needle is removed, leaving the wire within the trachea. (3) A scalpel is used to puncture the skin. (4) A dilator and cricothyroidotomy tube together are threaded over the guidewire into the trachea. (5) The dilator and guidewire are removed, leaving the cricothyroidotomy tube (airway) in place. A connection for jet ventilation is also provided. There is limited experience with this device in children, particularly infants. Other similar devices are available (see text for details).

E-FIGURE 14.9 **A,** The Pertrach system (Pulmodyne, Indianapolis, IN) uses a split needle on a syringe to make a puncture through the cricothyroid membrane. **B,** An introducer/dilator is passed through the needle into the trachea. **C,** A skin incision is made and the introducer, together with a 3.0-mm ID airway, is advanced into the trachea while the needle is split and removed. The introducer is then removed, and the airway is secured with tracheostomy tape.

E-FIGURE 14.10 A, The Bivona Pedia-Trake percutaneous tracheostomy device (Smiths Medical, St. Paul, MN) uses a multiple-step technique that may not be appropriate for an emergent situation. A large-bore needle on a syringe is used to puncture the cricothyroid membrane (surrounding the needle is a sharp, tapered dilation system). **B,** After successful entry into the trachea, the syringe and needle are withdrawn, and the opening is dilated. A size 3-, 4-, or 5-mm ID tracheostomy tube is then inserted and secured with tracheostomy tape.

E-FIGURE 14.11 A gum elastic bougie may be used as a guide to pass the tracheal tube into the laryngeal inlet. A hockey-stick configuration is frequently useful, particularly when only the epiglottis or the most posterior portion of the glottis can be visualized. The gum elastic bougie has a preformed angled tip. When the bougie is successfully placed in the trachea, one can detect the subtle "bumpy" feel of the bougie making contact with the anterior tracheal rings. This device may also be used to facilitate intubation through a laryngeal mask airway or as an adjunct to other airway devices.

SPECIAL TECHNIQUES FOR INTUBATION

Rigid Laryngoscopy

The rigid laryngoscope is the most familiar and most universally available piece of airway equipment; therefore it is critical for the practitioner to become familiar with its use and to know a variety of techniques. Some suggestions are reviewed here. It is reasonable to take a second look with the rigid laryngoscope after an unexpected failed intubation; however, a good rule is to always change something about the approach that may improve visualization. In the past, awake rigid intubation was the traditional approach to the problematic neonatal airway, but this approach should be used only in an extreme emergency or when IV access is not available.[157–160] Some anatomic features are completely unfavorable for success with the rigid laryngoscope, regardless of technique. Repeated unsuccessful attempts should be avoided because this can lead to airway trauma and edema. Because infants and children already have smaller airway structures, they are uniquely susceptible to a rapid progression from "*cannot intubate, can ventilate*" to the CICV scenario.

Whether the child has a normal or an abnormal airway, it is essential to ensure correct positioning and to use age-appropriate equipment. The following maneuvers have been found to be helpful in achieving successful intubation of the child with a difficult airway.

Optimal External Laryngeal Manipulation

Pressure can be applied externally to the larynx during the intubation to maximize visualization of the larynx.[480] Optimal external laryngeal manipulation (OELM) is particularly helpful for children with immobile or shortened necks and for infants. Either an assistant or the laryngoscopist can perform OELM. When the laryngoscopist performs the maneuver, the assistant either can pass the ETT into the glottis while the laryngoscopist maintains OELM or OELM can be assumed by the assistant to allow the laryngoscopist to pass the ETT.[480] OELM may also be used in conjunction with other, more advanced airway devices such as the GlideScope (discussed later).[481–483]

Intubation Guides

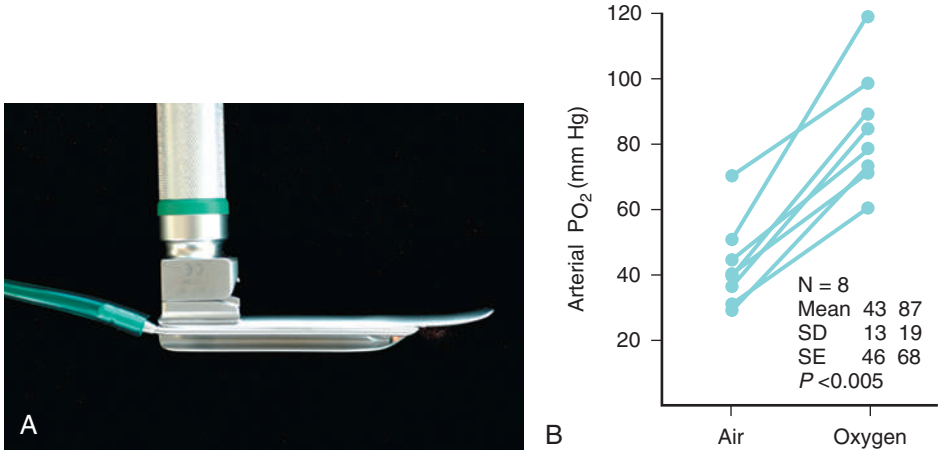
Intubation guides include plastic-coated, flexible metal stylets and the gum elastic bougie. These can be used for blind placement of the ETT under the epiglottis. A flexible stylet is placed inside the ETT and preformed to shape the ETT tip to one that will optimize intubation success (see Fig. 14.21). A hockey-stick configuration is frequently useful, particularly if only the epiglottis or the most posterior portion of the glottis can be visualized. The gum elastic bougie has a preformed, angled tip. It is placed alone and then the ETT is threaded over it and into the trachea (E-Fig. 14.12). When the bougie is successfully placed in the trachea, one can detect the subtle "bumpy" feel of the bougie making contact with the anterior tracheal rings. This device may also be used to facilitate intubation through an LMA or as an adjunct to other airway devices.[484–487]

Dental Mirror

The authors of one report used a short-handled dental mirror (no. 3, Storz Instrument Company, Manchester, England) to assist in the indirect visualization of the larynx of a 10-week-old infant. Laryngoscopy was impossible with a size 1 Miller blade. The infant was returned to spontaneous ventilation, a size 1 Macintosh blade was used to expose the pharynx, and the mirror was used to visualize the larynx. A styleted ETT was then passed into the glottis under indirect vision.[488]

Retromolar, Paraglossal, or Lateral Approach Using a Straight Blade

Use of a straight blade in a retromolar approach may allow glottic visualization when the classic rigid intubation technique fails, particularly if the difficulty is secondary to a large tongue or small mandible (Fig. 14.28).[140,482,485,489–493] With the child's head turned slightly to the left, a no. 1 Miller blade is introduced into the extreme right side of the mouth. It is advanced in the space between the tongue and the lateral pharyngeal wall; the tongue is swept completely to the left and is essentially bypassed. It is very helpful to have an assistant pull back the right corner of the mouth with a small retractor (e.g., Senn retractor) to increase the space for ETT placement. The blade is advanced while staying to the right, overlying the bicuspids and lateral incisors until the epiglottis or the glottis is visualized. When the epiglottis comes in view, it is lifted with the blade tip to expose the glottic opening. It is extremely unlikely that pressure from the laryngoscope blade on the bicuspids and lateral incisors could loosen these teeth, because they have two roots or their roots are deeper than the central incisors.



At this juncture in the laryngoscopy, it may be possible to move the proximal end of the blade toward the midline of the mouth to increase room for ETT placement and manipulation, although care must be taken to avoid applying pressure on the central incisors of the maxilla, lest they become loosened. If the glottis is not visualized, the head can be rotated farther to the left and the blade can be kept lateral to improve visualization. The ETT should be styletted and formed into a 90-degree bend configuration to assist in placement (see Fig. 14.21), particularly if the view of the glottis is only partial. A shorter-length blade (usually a size 1 Miller, even in older children) than that used in the traditional midline approach is chosen because the distance to the glottis with this method is greatly shortened.

Several mechanisms are responsible for the improved view of the glottis with the retromolar approach to laryngoscopy. First, there is a reduced need for soft tissue displacement and compression because the lateral placement of the blade bypasses the tongue. This approach to an improved view of the glottic opening is particularly useful for children with micrognathia.[482,485,490,492,493] In such children, the space available to displace the tongue is reduced compared with the traditional midline approach to rigid laryngoscopy. Second, there is an improved line of visualization because the incisors and maxillary structures are bypassed by lateral blade placement and by shifting of the head to the left. Third, the use of a straight blade avoids the possible intrusion of a curved blade into the line of sight.[140,489–491] Finally, both the angle and the distance from the insertion of the straight blade at the right commissure of the mouth are reduced, facilitating an easier view of the glottic opening, particularly during a difficult intubation, compared with inserting the blade in the midline.

Fiberoptic Laryngoscopy

An advantage of using the FOB for intubation of the child with a difficult airway is that it does not require extensive head or neck manipulation and is therefore useful in children who have cervical inflexibility (Klippel-Feil syndrome) or cervical instability (Down syndrome, achondroplastic dwarfism, trauma) (see Videos 14.10 and 14.11). The technique is also versatile because the flexible instrument conforms to a variety of abnormal airways; it is well tolerated by the sedated, spontaneously breathing child.[399,494–496]

Its disadvantage is that the fiberoptic bundle is small, permitting only a limited field of vision. For this reason, the presence of blood or copious secretions may render the FOB ineffective. In

E-FIGURE 14.12 A, The Oxyscope (Heine Optotechnik, Herrsching, Germany), a modified laryngoscope, delivers 2 L/minute of oxygen and, if connected to the anesthesia circuit, anesthetic agent at the tip of the blade during laryngoscopy. **B,** Increased levels of arterial oxygen tension (Po_2) were achieved during laryngoscopy of spontaneously breathing infants. (From Todres ID, Crone RK. Experience with a modified laryngoscope in sick infants. *Crit Care Med*. 1981;9:544–545, © Williams & Wilkins.)

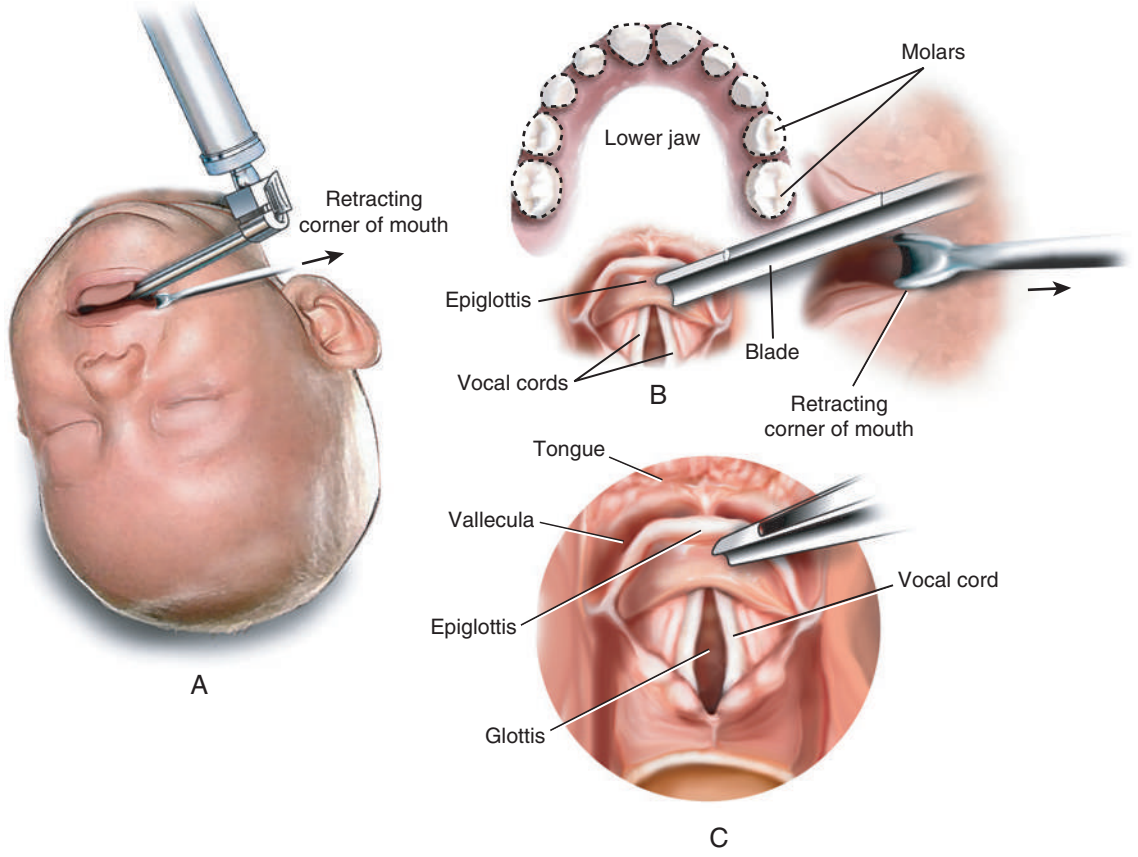


FIGURE 14.28 **A** through **C,** The retromolar, paraglossal, or lateral approach to rigid laryngoscopy using a straight blade. Notice that the child's head is turned to the left and that the laryngoscope blade is inserted over the molars toward the glottic opening (see text for details).

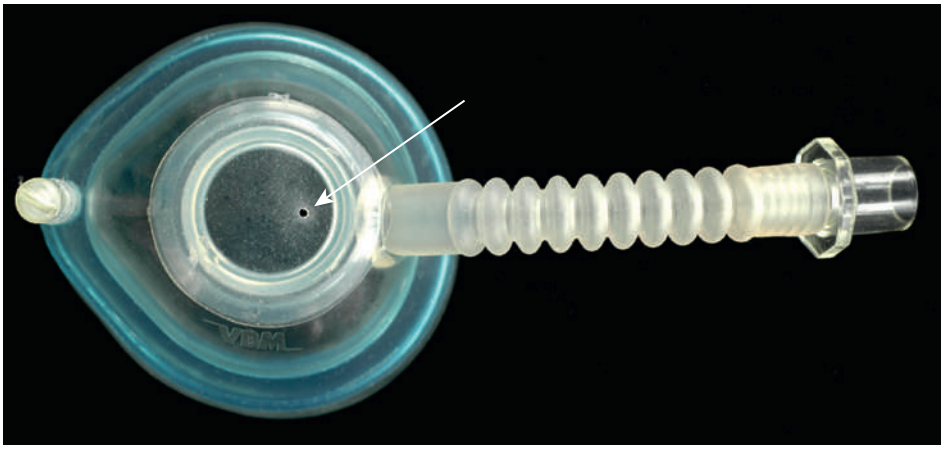
addition, use of the FOB requires extensive experience and practice in normal airways first. Our experience suggests that each size of available FOB should be used in at least 20 normal airways before use is attempted in an abnormal airway.[497] Practice with all available sizes of FOBs is important because the manual skills required for each size differ somewhat. Also, FOBs are fragile and expensive. Great care must be taken when using and storing FOBs to prevent breakage of the fiberoptic bundles and the adjustable tip mechanism. They must also be sterilized between uses to maintain the patency of the working channel and clear, bright vision through the fiberoptic bundles and to avoid transmission of infection.



Equipment

FOBs with directable tips are available in various sizes; the smallest, 2.2 mm in diameter (Olympus LFP; Olympus, Tokyo), can fit through a 2.5-mm ID ETT with or without the 15-mm adapter removed. However, unlike most of the larger FOBs, this scope has no working channel for suctioning or administration of oxygen or topical anesthesia. FOBs with the light source incorporated into the body of the scope are now available; these increase the portability of the instrument, making its use both outside and inside the operating room more simple and convenient.

Ancillary Equipment

Endoscopy masks can be used to provide oxygen to the spontaneously breathing child and to ventilate the paralyzed child during fiberoptic laryngoscopy. The Frei endoscopy mask (VBM Medizintechnik GmbH [E-Fig. 14.13]) and the Patil-Syracuse endoscopy mask (Anesthesia Associates, San Marcos, CA) are commercially available.[498,499] Patil-Syracuse masks are available in a child size but are too large for most children younger than age 4 years.[96] The Frei mask configuration allows the FOB to be placed in a central position, overlying the nose and mouth, which is more favorable for tracheal intubation. The clear membrane with the hole for the bronchoscope can be rotated to allow either oral or nasal approaches. Alternatively, a disposable facemask can be combined with a bronchoscopic swivel adapter.[500] The FOB can then be passed through the diaphragm of the adapter while ventilation is maintained via the anesthesia circuit. There are two types of commercially available adapters. One type attaches directly to an anesthesia mask. The other type is designed to attach to the ETT and can be modified to fit on the anesthesia mask using a 15- to 22-mm adapter.

Commercial oral airways designed for use in bronchoscopy are available for pediatric patients (IMD Inc., Park City, UT); however, there are only three sizes (infant, child, and adult), and no studies have evaluated their usefulness in assisting fiberoptic intubation in children. Guedel airways can also be modified for use as oral intubation guides.[500] A strip is cut from the convex surface of the airway to create a channel for placement of the FOB. This modified airway may be used to maintain a midline approach to the glottis; however, it is ineffective as a bite block.

E-FIGURE 14.13 The Frei endoscopy mask is used for oxygenation and ventilation of a patient. A fiberoptic laryngoscope with a softened endotracheal tube of appropriate size presoaked in warm sterile water (not shown) is passed through a membrane opening in the mask. This allows one to maintain a constant depth of anesthesia and continuous oxygenation while visualizing the airway with the fiberscope.

Direct Technique

The optimal position of the child for fiberoptic bronchoscopy is different from the position for rigid laryngoscopy. The head should be flat on the table and slightly extended at the atlantooccipital joint to prevent the epiglottis from obstructing a view of the glottic opening.[501] If an oral approach is selected, it is vital that the FOB pass in the midline. A nasal approach may make midline placement simpler and avoids the risk of the child biting the FOB or ETT. One useful technique is to apply a topical vasoconstrictor (e.g., oxymetazoline) to the naris, place a lubricated nasal trumpet into the naris, and then insert a 15-mm connector from a tracheal tube into the nasal trumpet (Video 14.8). This allows oxygen and inhalation agent to be delivered to the child while performing standard fiberoptic laryngoscopy (see Videos 14.10 and 14.11). However, the oral approach offers several advantages over the nasal approach, including avoidance of shearing adenoidal tissue and nasal bleeding. The oral approach may also be less stimulating and better tolerated than the nasal approach. If nasal intubation is chosen in a young child, a topical vasoconstrictor will reduce the risk of bleeding. With both approaches, an assistant should perform a jaw thrust to open the posterior pharyngeal and supraglottic spaces. Alternatively, a bite block or intubating airway may be used. Occasionally, the best view is obtained by direct traction on the tongue, which optimally opens the posterior pharynx. This can be accomplished by grasping the tongue with a gauze, plastic forceps, a stitch through the tongue, or application of high suction to the underside or tip of the tongue (Fig. 14.29).[502]

The tip of the FOB should be introduced behind the tongue and gradually advanced in the midline under direct vision until a recognizable structure is observed. It is essential that the FOB be kept rigid so that when the direction of the tip is altered, it remains in the same plane as the handle of the FOB. When the FOB is rotated, the tip should be slightly bent to provide a panoramic view. In general, the tip of the FOB is passed into the trachea before any attempts are made to pass the ETT through the nose or oropharynx. Because the distances in the oropharynx in children are less than in adults, the most common initial error when using this technique is to advance the FOB too deeply and into the esophagus. To avoid this pitfall, the FOB should be advanced only toward identifiable airway structures.

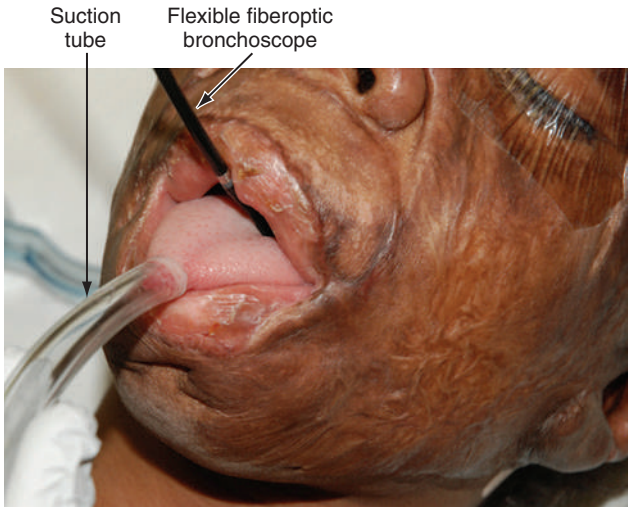


FIGURE 14.29 Suction can be applied to the tip of the tongue to facilitate pulling it forward to improve glottic visualization. This technique is particularly useful when the tongue is slippery due to secretions or if the mouth opening is small and prevents direct grasping of the tongue with a dry gauze.

Once the FOB is introduced into the airway, a common problem is resistance to passage of the ETT. To minimize this occurrence, the ETT should be loaded onto the scope with the bevel facing down (Murphy eye up) for oral intubation and bevel facing up for nasal intubation.[503,504] This can be remembered by the mnemonic *UNDO:* bevel **U**p for **N**asal intubation, **D**own for **O**ral intubation.[505] If persistent resistance is encountered while attempting to pass the ETT past the glottic opening, the ETT should be rotated 90 to 180 degrees to place the bevel in a more favorable orientation for passage through the vocal cords. One study demonstrated that a 90-degree counterclockwise rotation of the ETT before advancement resulted in a smooth passage of the ETT into the larynx.[506] The depth of anesthesia or sedation as well as oxygen saturation (pulse oximetry) must be carefully monitored throughout the procedure. Arrhythmias may be avoided by providing an adequate depth of analgesia/anesthesia and ensuring a patent airway.

Fiberoptic laryngoscopy techniques should be perfected on manikins and on children with normal anatomy before such techniques are attempted on children with difficult airways.[507–513] In a study that compared the time to intubation and complications in 40 infants with the Miller size 1 laryngoscope blade or the Olympus LFP FOB, the time to intubation was slightly greater with the FOB (22.8 vs. 13.6 seconds), whereas the complication rate was similar.[514] The authors concluded that routine use of the FOB for intubation in normal infants is a safe and reasonable method to gain and maintain skills with this technique.[514] For children, video-assisted fiberoptic intubation appears to offer advantages over fiberoptic intubation using a traditional eyepiece. These include faster mastering of this skill and an overall improved success rate when compared with the traditional method.[497,515]

Staged Techniques

Staged methods of fiberoptic intubation can be used in infants and small children when the available FOBs are too large to pass through the appropriately sized ETT.[516] One method requires an FOB with a working channel and a cardiac vascular catheter with guidewire. The guidewire is passed through the working channel of the FOB to within 1 inch of its tip. The FOB is then introduced into the mouth and positioned above the vocal cords. The guidewire is advanced under direct observation through the glottis into the trachea. The FOB is removed, leaving the guidewire in place. The lungs are ventilated by mask while an assistant passes the cardiac catheter over the guidewire (to stiffen the guidewire and facilitate passage of the ETT). The ETT is threaded over the catheter/guidewire combination, which is then removed, leaving the ETT in place.[516–518] Some authors report that threading of the cardiac catheter over the guidewire is unnecessary. A modification of this technique when the FOB has no working channel has also been described.[519] An 8F red rubber catheter was attached by waterproof tape to the insertion cord of the FOB proximal to the flexible tip. The larynx was visualized with the FOB, and a guidewire was threaded through the rubber catheter into the trachea. With the guidewire in position, the FOB (with the red rubber catheter) was withdrawn, and an ETT was passed over the guidewire into the trachea.

Another alternative for intubation when the FOB is too large to pass through the appropriately sized ETT is intubation under fiberoptic observation.[520–522] The FOB is introduced through one naris to visually aid the placement of the ETT that is passed

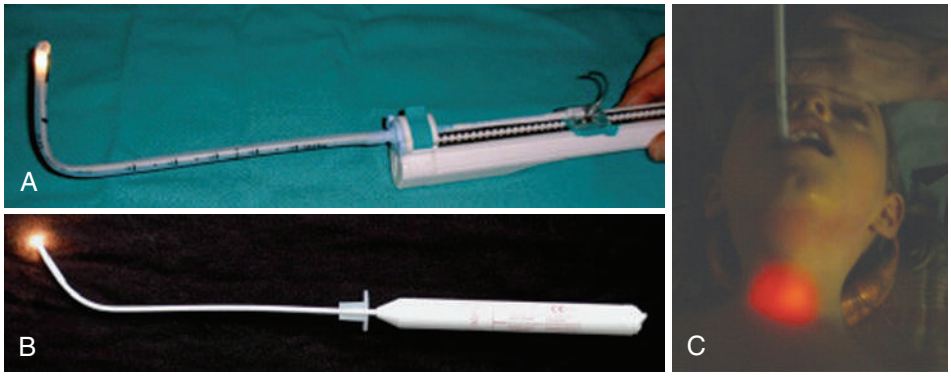
through the other naris and manipulated into the glottis. Alternatively, if the observed ETT is not easily passed into the glottis, a small catheter may be more easily manipulated into the glottis and used as a stylet to pass the ETT into the trachea. Spontaneous ventilation is preserved, and oxygen can be administered via the ETT during the intubation. This technique was used successfully in two neonates, one with congenital fusion of the jaws and a second with Dandy-Walker syndrome associated with Klippel-Feil syndrome, micrognathia, hypoplasia of the soft palate, and anteversion of the uvula.[520,521] More recently, an adult video-FOB was used to intubate the trachea of a toddler with temporomandibular joint ankyloses.[523] If the available FOB is both too large and lacks a working channel, another staged fiberoptic intubation technique can be used. The FOB is loaded with an ETT that is larger than the larynx of the infant. The larynx is visualized with the FOB, and the ETT is advanced and positioned just above the vocal cords. The FOB is then removed, and an ETT changer or catheter is advanced into the trachea through the larger ETT. The larger ETT is then removed, and the appropriately sized ETT for the child is threaded over the tube changer or catheter into the trachea. This technique was used successfully in a 6-month-old infant whose operation had previously been canceled because of failure to intubate.[524]

Lighted Stylet

A lighted stylet (Light Wand) is a useful adjunct for managing the pediatric difficult airway (E-Fig. 14.14).[525–529] A number of these devices are available: Surch-Lite Lighted Intubation Stylet (Bovie Medical Corporation, Purchase, NY), Light Wand (Vital Signs, Mexicali, Mexico), and Trachlite (Rüsch, Tuttlingen, Germany). These devices essentially comprise a malleable stylet with a high-intensity light at the tip; the stylet is shaped into a curve similar to that anticipated for successful passage into the laryngeal inlet (45 to 90 degrees). To begin, an ETT is passed over a well-lubricated lighted stylet. The tip of the stylet should remain within the tip of the ETT to minimize the potential for airway trauma. The room lights should be dimmed at this time to ensure that the stylet is visible when the wand is in the mouth. The lighted stylet is then introduced into the mouth while the proximal end of the stylet is flat against the cheek. As the stylet is inserted into the mouth, the proximal end of the handle is rotated counterclockwise until it is upright. The stylet continues to pass through the oropharynx, following the curvature of the tongue. If the tip of the lighted stylet is not in the proper position (e.g., in the esophagus), a diffuse light or no light will be observed on the surface of the neck. Proper position is usually ensured when a sharp, well-defined, bright circle or cone of light is observed transilluminating the neck directly in the midline at the level of the cricothyroid membrane (see E-Fig. 14.14). Once proper position is ensured, the ETT is gently advanced and the stylet is removed.[528,530]

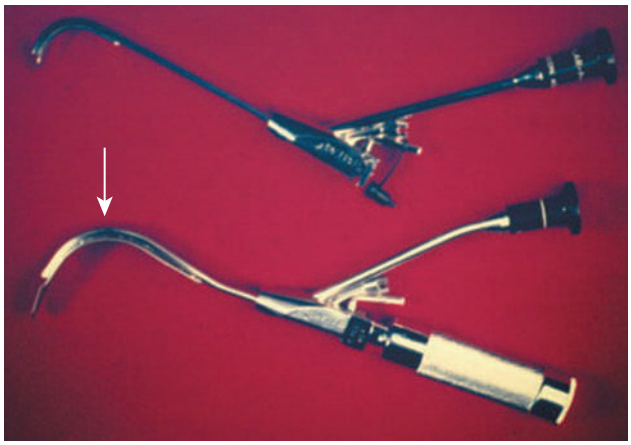
This technique is useful in those children in whom there is no intrinsic laryngeal or airway pathology but in whom visualization is anticipated to be difficult. The lighted stylet may also be of value in children with a fracture of the cervical spine, because tracheal intubation can be accomplished with minimal movement of the neck.[531] The hemodynamic response to intubation with this technique is similar to that observed with rigid laryngoscopy.[527] The limitations of this technique are that it is a blind technique, the diameter of the device limits it use to larger-sized ETTs, and it may require multiple attempts; however, the success rate markedly increases with experience.[528,530] The most common cause of difficulty in passing the ETT is that the tube hangs up on the epiglottis. When this occurs, the lighted stylet may be withdrawn and its position slightly adjusted more posterior to allow passage behind and beyond the epiglottis. Alternatively, the ETT can be rotated along the long axis of the stylet so that the bevel is facing up. Our advice for using this technique is similar to that for bronchoscopy: it should be used in children with normal anatomy to gain the necessary experience required for managing children with abnormal airway anatomy. This adjunct has also been combined with an LMA to guide the stylet into the trachea.[532]

Bullard Laryngoscope



The Bullard laryngoscope is now rarely used for direct visualization of the laryngeal inlet in children with airway pathology (E-Fig. 14.15). It is available in three sizes: adult, pediatric, and pediatric long. This instrument combines fiberoptic bundles and mirrors. It is positioned within the larynx like a laryngoscope blade, and the direction of force used to displace the tongue is similar to that used with a standard laryngoscope, although this is not intuitively obvious from its configuration. It is designed to provide visualization around a 90-degree bend at the tip (i.e., around the base of the tongue). This configuration may be helpful for direct visualization of the larynx in children with mandibular hypoplasia syndromes (e.g., Robin sequence, Treacher Collins syndrome,[533] Goldenhar syndrome, cervical fracture restricting motion), when the acute angulation of the base of the tongue to the glottic opening is exaggerated, and in children with congenital trismus (Hecht syndrome).[534] The technique used in children is different from that used in adults. Once the laryngeal inlet is visualized, a styleted ETT, with a bent configuration similar to the curve of the Bullard laryngoscope (see Fig. 14.21B), is inserted just to the side of the Bullard laryngoscope blade and advanced under direct vision into the trachea. Success with this instrument is directly proportional to the experience of the anesthesiologist, because the perspective seen through this laryngoscope, the method of visualization, and the indirect method of ETT placement are so different from standard laryngoscopy.[535,536]

Despite the availability of pediatric Bullard laryngoscopes,[537] adult scopes have also been successfully used in children.[538,539] Although tracheal intubation in children 1 to 5 years of age with a Bullard laryngoscope takes more time than with a Wis-Hipple 1.5 blade, the adult Bullard laryngoscope complements the Wis-Hipple 1.5 blade. Occasionally, the Bullard laryngoscope provides a superior laryngeal view and thus allows successful intubation when a failure with the Wis-Hipple blade occurs. When multiple passes of the tube off the adult Bullard laryngoscope were required, this is usually because of contact with the right aryepiglottic fold or anterior vocal cord. The latter appears to be more problematic when the adult laryngoscope is used in children.[538,539]



Additional limitations of the Bullard laryngoscope are that the ETT can partially obstruct the view of the larynx during insertion and that it can be used only for oral intubation.[537] An advantage is that there appears to be minimal motion of the cervical spine in patients with cervical spine disarticulations.[540–542]

Retrograde Wire-Guided Intubation

The technique of retrograde wire-guided intubation uses transtracheal passage of an IV catheter through the cricothyroid membrane into the larynx and retrograde passage of a guidewire from a Seldinger vascular cannulation set to create a guide for intubation.[416,543–549] A commercial kit is available for use with ETTs that are 5 mm ID or larger (Cook Critical Care). This

E-FIGURE 14.14 Lighted stylets are available from a number of manufacturers. **A,** Trachlight (Laerdol Medical Corporation, Wappingers Falls, NY). **B,** Surch-Lite Lighted Intubation Stylet (Aaron Medical Industries, St. Petersburg, FL). Also available are the Light Wand (Vital Signs, Mexicali, Mexico), and the Trachlite (Rüsch, Tuttlingen, Germany). These devices provide a blind method for placing larger-sized endotracheal tubes. **C,** A bright light on the surface of the neck at the level of the larynx indicates the correct location for passage into the trachea. If no light is visible, this usually indicates passage into the esophagus.

E-FIGURE 14.15 The Bullard laryngoscope is available in three sizes: adult, pediatric, and pediatric long. The device shown at the top is the adult version, which has an attached endotracheal tube guide; the pediatric versions do not have this guide. This instrument combines fiberoptic techniques and mirrors; the fiberoptic bundles are contained within an instrument that functions and is positioned within the larynx like a laryngoscope blade. It is designed to provide visualization around a 90-degree bend at the tip (*arrow*) (i.e., around the base of the tongue). This configuration may be helpful for direct visualization of the larynx in children with mandibular hypoplasia syndromes (e.g., Pierre Robin syndrome, Treacher Collins syndrome, Goldenhar syndrome, cervical fracture restricting motion) when the acute angulation of the base of the tongue to the glottic opening is exaggerated. Once the laryngeal inlet is visualized, a styleted endotracheal tube with a bent configuration similar to the curve of the Bullard laryngoscope (see Fig. 14.21B and C) is inserted just to the side of the Bullard laryngoscope blade and advanced under direct vision into the trachea.

technique is rarely used in children because of the greater compressibility of the trachea and the increased risk of posterior tracheal wall perforation by the catheter in children compared with adults.

Video and Indirect Intubating Devices

Advances in technology have led to the reduction in size of video cameras and optical lenses. The integration of these devices into various laryngoscopes and stylets has produced several enhanced tools for securing the airway in children.[550] Several of these new scopes improve visualization during laryngoscopy[484,551–557] and perform better than traditional laryngoscopy in children with difficult direct laryngoscopy.[558–564] However, they are often associated with prolonged time to intubation compared with direct laryngoscopy, and their utility is limited in the presence of blood and secretions. These new devices can be categorized as (1) video laryngoscopes, which incorporate a video camera into the tip of the device; (2) optical laryngoscopes, which use a series of mirrors, prisms, or both to transmit the image from the tip of the device; and (3) optical stylets, which incorporate video or optical systems into a rigid or malleable stylet.

Videolaryngoscopes

Videolaryngoscopes are quickly becoming ubiquitous in anesthesia practice and will inevitably become the standard of care. They offer unique advantages over standard direct laryngoscopy such as an improved view of the glottis, a shared view of the airway that facilitates guidance of a trainee and less force required to perform the intubation. Although the term videolaryngoscope is loosely used to describe a large number of laryngoscopes with video and optical cameras, these devices can be very different with unique design characteristics. Videolaryngoscopes can be classified in two broad categories–those with angulated blades and those with standard curved blades. The videolaryngoscopes with angulated blades may perform better in patients with difficult airways, while those with standard blades may be best suited for patients with normal airways. Although angulated blades offer a better view of an "anterior" airway, passing the tube may be more challenging because of the acute angles made between the camera line of sight and the plane of the trachea. Videolaryngoscopes with standard blades are less likely to be associated with this difficulty but may not offer as optimal a view as angulated blades in the difficult airway patient. Videolaryngoscopes with conventional blades can be used to teach traditional laryngoscopy and therefore help trainees to maintain their skill with that technique while having the advantage of direct feedback from an instructor monitoring the camera screen. Videolaryngoscopes have been associated with higher first-attempt success and success rates in adults compared with direct laryngoscopy and have been shown to have improved views of the airway in children as well.[552,565–567] A retrospective cohort study in a pediatric emergency department compared videolaryngoscopy with the C-MAC video laryngoscope (Karl Storz Gmbh & Co. KG, Tuttlingen, Germany) with direct laryngoscopy and found no differences in first-attempt intubation success (adjusted odds ratio = 1.23, 95% confidence interval [CI] = 0.78-1.94), complication rates, or intubation success rates.[568] A meta-analysis of randomized controlled trials in children (993 participants) that compared video laryngoscopes with direct laryngoscopes concluded that the use of videolaryngoscopy improved glottic visualization but prolonged the time to intubation and was associated with increased failures. They found similar first-attempt success between video laryngoscopy and direct laryngoscopy (relative risk 0.96; 95% CI 0.92-1.00; I^2 = 67%).[569] The report of increased failures is not consistent with our experience and is in fact doubtful with modern videolaryngoscopes. A careful examination of their meta-analysis shows that most of the failures occurred in a single study that examined the Bullard laryngoscope in which 50% of first attempts failed in a cohort of 2- to 10-year-old children with simulated restricted neck mobility.[569] Many evaluations of videolaryngoscopes are conducted in manikins; although this should be the first step to evaluate a new device, we encourage researchers to conduct clinical studies to expand our knowledge about the real-world performance of these devices. One study demonstrated that although trainees performed tracheal intubation with a variety of videolaryngoscopes expeditiously in a manikin, they took significantly longer in children younger than 2 years of age.[570]

GLIDESCOPE. The GlideScope (Verathon, Bothell, WA) (E-Fig. 14.16) consists of a hypercurved blade that incorporates a high-resolution camera with a built-in antifog system. It is available in six sizes (0, 1, 2, 2.5, 3, 4) that accommodate all sizes of patients, including as small as approximately 1 kg. Before clinical use, the GlideScope is switched on to allow the antifog system to warm up. A styletted ETT is necessary for successful intubation, and the stylet's curvature should mimic that of the selected GlideScope blade. The manufacturer markets a GlideScope-specific rigid stylet, but a standard malleable stylet has been shown to be equally effective.[571] Unlike traditional direct laryngoscopy, sweeping the tongue to the left of the blade is unnecessary because of the distally located camera. The GlideScope blade is ideally placed in the midline or slightly to the left in the pharynx (Video 14.12). This position maximizes the space available for introduction of the ETT. The blade tip is placed in the vallecula, and slight elevation of the blade exposes the glottis. The epiglottis may be elevated if placement of the blade tip in the vallecula does not result in optimal visualization. A poor view may occur if the blade size is inappropriate or if the blade is inserted too deeply in the pharynx. OELM may also be used to facilitate laryngeal visualization.[551,567]

Once the best view is obtained, the styletted ETT is inserted under direct vision alongside the GlideScope blade until it just passes the palatoglossal arches and is in full view on the GlideScope monitor. The technique of sequentially visualizing the ETT directly and then on the monitor and creating space by inserting the GlideScope slightly to the left in the pharynx helps minimize the risk of injury to the soft tissues of the airway during advancement of the ETT.[572–576] Children with severely obstructing tonsils may be vulnerable to injury if the laryngoscopist focusses their attention only on the screen and ignores the styletted tube as it is brought into view.[577]

When the ETT is visible on the monitor, the tip is directed into the glottic inlet. The stylet should be pulled back once the ETT tip is inserted through the cords, because this facilitates the advancement of the ETT down the trachea. Difficult ETT insertion despite a good view of the glottic opening is an occasional problem encountered with the GlideScope and other video and optical laryngoscopes. This is because of the indirect approach to intubation and the need for good hand-eye coordination. These skills can be acquired by frequent use of the device in children with normal airways.[578–582] The GlideScope Cobalt was successfully used for intubation in a cohort of 121 infants. The average intubation time was 30 seconds, and 95% of the intubations were successful on the first two attempts.[583] It has also been used to facilitate intubation in children with craniofacial abnormalities.[481,584–586] When compared with direct laryngoscopy, the GlideScope provided

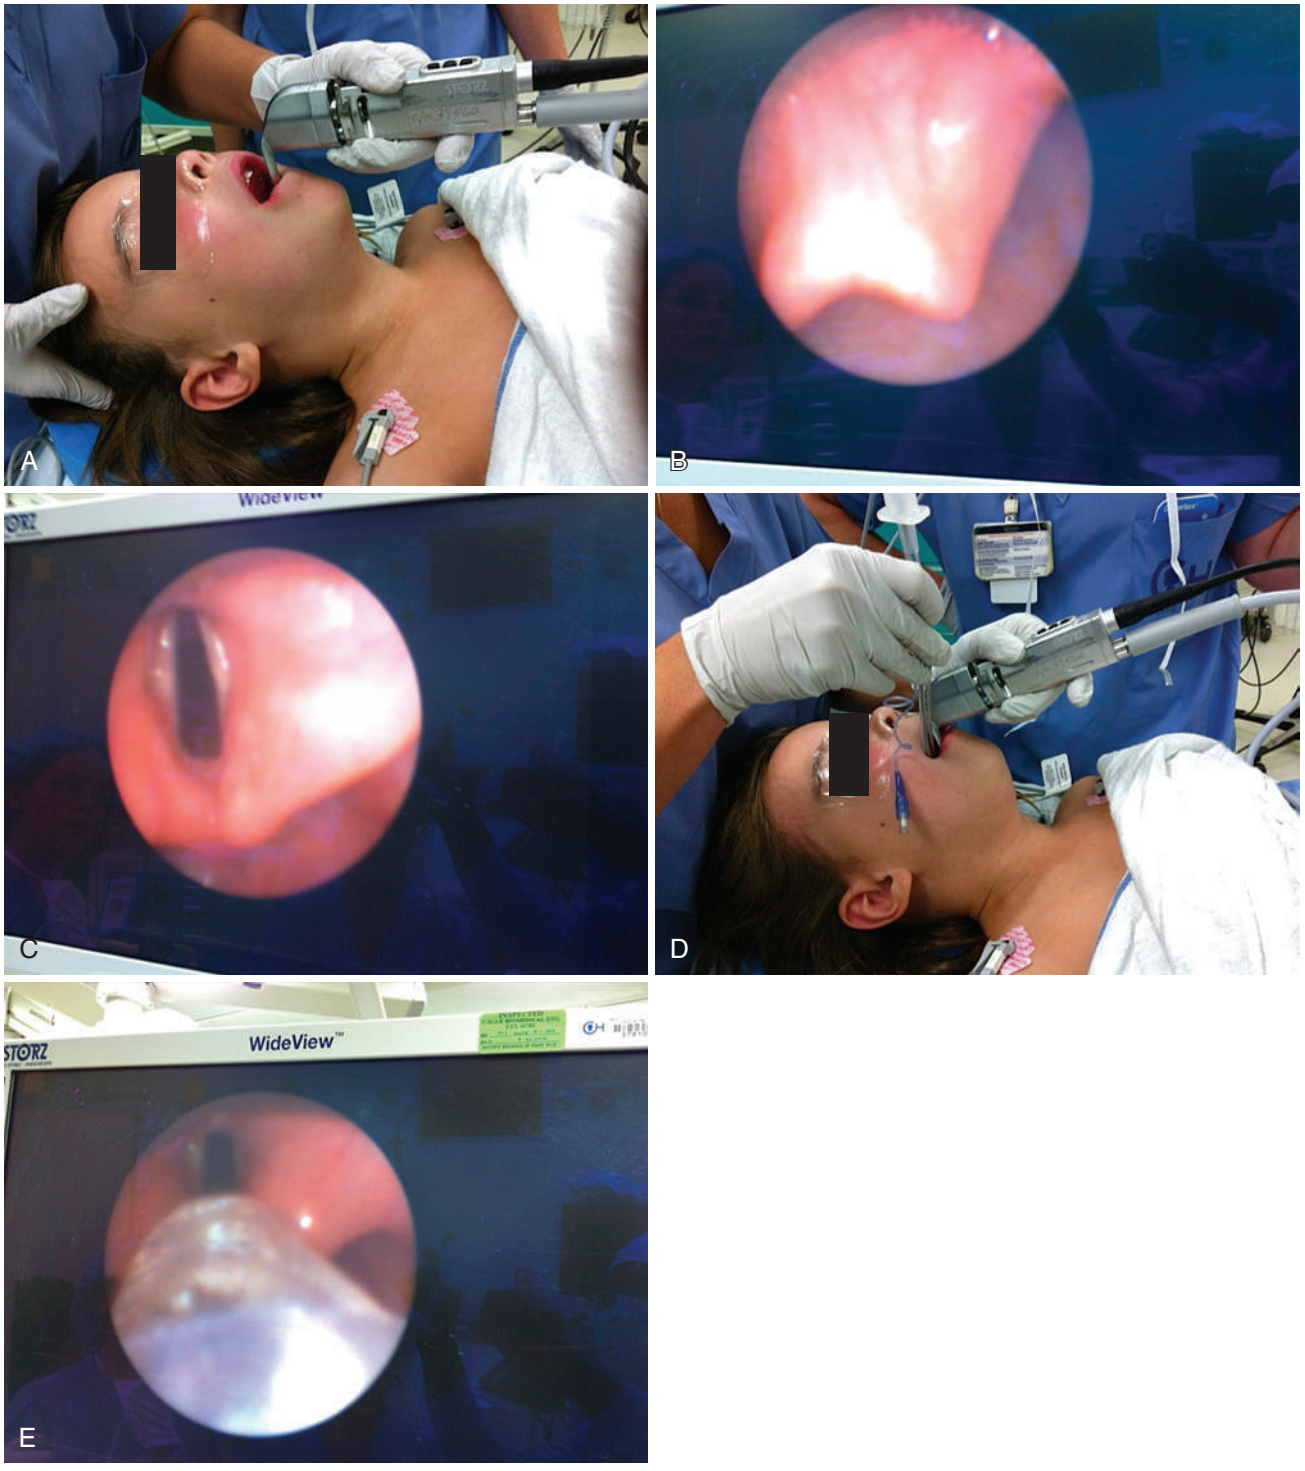
E-FIGURE 14.16 A, The GlideScope (Verathon, Bothell, WA) consists of an inner reusable video baton and an outer disposable plastic blade that is available in six sizes. The lubricated, styleted endotracheal tube (ETT) is formed into the same shape as the GlideScope blade before insertion. **B,** The laryngoscopist advances the GlideScope into the midline or left side of the pharynx to expose the glottic opening and then inserts the ETT alongside the scope while watching the video screen. **C,** The ETT is advanced into the glottic opening under direct vision.

superior laryngeal views in children with baseline limited views of the glottic opening.[587]

STORZ VIDEO LARYNGOSCOPE. The Storz Video Laryngoscope (Karl Storz GbmH) integrates a camera into Miller- and Macintosh-type blades. This design allows the operator to perform laryngoscopy in the traditional fashion as the Miller-type blade with the video view available if necessary. The video view has been shown to provide one Cormack-Lehane grade improvement over the direct line-of-sight view because of the angulation of the video camera at the tip.[588] It has no antifog mechanism, so use of an antifog solution is needed for unimpaired visualization. Intubation with the Miller video blade can be performed without a stylet, although a styleted ETT with a slight bend at the tip facilitates intubation (E-Fig. 14.17). The Storz Video Laryngoscope is inserted in a fashion similar to insertion of the GlideScope. The tip of the blade can be placed in the vallecula; however, because of the magnified lens of the camera, the epiglottis often obstructs the camera view. If this occurs, the blade tip is best used to lift the epiglottis to expose the glottis. Once optimal visualization is obtained, the ETT is placed directly along the shaft of the video blade, which guarantees immediate visualization of the ETT in the magnified field of view of the camera and avoids injury to airway soft tissues.

When the Storz Video Laryngoscope was compared with the GlideScope in a pediatric manikin model with normal and difficult airway configurations, the times to intubation and the visual analog scale scores for field of view and ease of use of the two devices were similar.[589] In a small trial of 10 children younger than 2 years of age, the time to successful tracheal tube positioning was greater with the Storz instrument compared with the Airtrach (Prodol Meditec, Guecho, Spain) but the success rate was similar.[590] In another infant manikin study, the Storz Video Laryngoscope was associated with better views, more successful intubations, and similar intubation times as the standard Miller laryngoscope.[588] The Storz Video Laryngoscope has been successfully used to intubate infants and newborns with difficult and normal airways.[588,591] As with all video laryngoscopes, good hand-eye coordination is necessary for successful intubation. In addition, the operator must develop the skills necessary to manipulate the ETT indirectly and on a magnified scale. This magnification effect makes subtle movements of the ETT appear large on the video monitor and adds an additional challenge to intubation with these devices. Practice on children with normal airway anatomy is recommended before use on children with abnormal airways.[550]

MULTIVIEW SCOPE. The MultiView Scope (Medical Products International, Tokyo) is a video laryngoscope system that integrates a camera into Miller- and Macintosh-style blades (E-Fig. 14.18). The handle of the device has a mounted video screen that displays the image from the blade tip. The image from the screen can be transmitted to an external monitor wirelessly, using a manufacturer-supplied attachment (AirView). Aside from being magnified, the direct line-of-sight view is identical to the camera view, making this an ideal tool for teaching direct laryngoscopy. The MultiView Scope also comes with a malleable stylet attachment that provides the ability to insufflate oxygen through the mounted ETT.

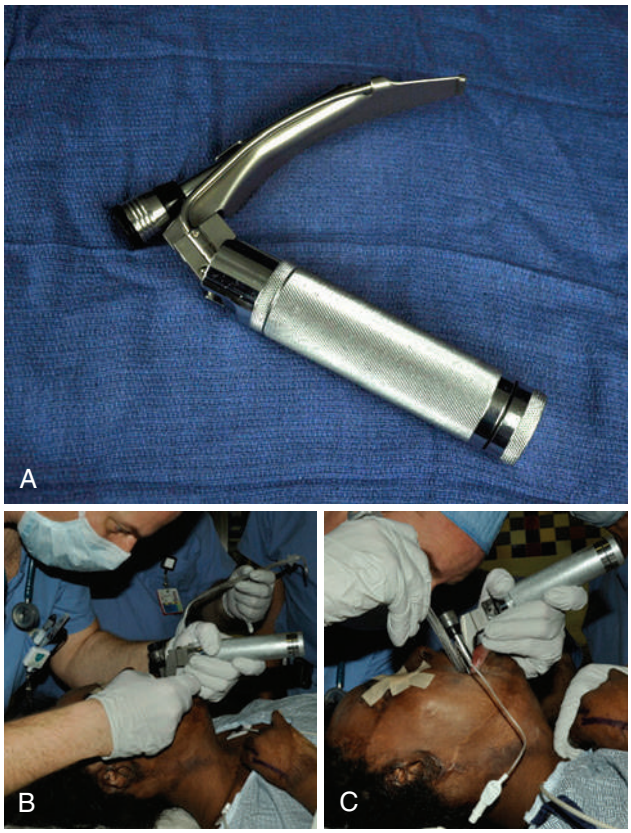


Optical Laryngoscopes

AIRTRAQ. The Airtraq (Prodol Meditec SA, Vizcaya, Spain) is a single-use, curved plastic laryngoscope that uses lenses and prisms to transmit the image from its distal tip to an eyepiece. It may reduce the incidence of esophageal intubation and may offer greater success rates, particularly in the hands of the inexperienced laryngoscopist.[592] It has a molded channel into which the ETT is inserted (Fig. 14.30), thereby eliminating the need to manipulate the ETT independently during intubation as is required with the GlideScope, Truview (Teleflex Medical, Netanya, Israel), and Storz Video Laryngoscope. The manufacturer offers a wireless monitor for use with the device. The device should be turned on 30 seconds before use to allow the built-in antifog system to warm up. A disadvantage is that a minimum mouth opening of 16 mm is required for insertion of the Airtraq.

The selected ETT and guide channel of the Airtraq are lubricated, and the cuff of the ETT is fully deflated to avoid cuff damage during advancement of the tube in the channel.[593,594] The appropriately sized ETT is loaded into the guide channel of the device, and the child's head is placed in a neutral position. The Airtraq is inserted in the midline in the pharynx and is advanced along the tongue base into the vallecula (Video 14.13). The epiglottis may be elevated to optimize the view, if necessary. Once in position, the Airtraq is gently lifted to obtain optimal glottic exposure, the glottis is centered in the viewfinder by rotating the entire device slightly clockwise or counterclockwise as necessary, and the ETT is advanced after the optimal centered view is obtained. On occasion, the ETT is directed below the glottic opening; if this occurs, the Airtraq should be withdrawn slightly and the advancement attempted again. The guide channel deflects the ETT slightly leftward (an effect that is more pronounced in infants and neonates); this tendency may be countered by rotating the device slightly clockwise as needed.[595,596] Once the trachea is intubated, the Airtraq is separated from the ETT by holding the tube at the mouth and moving it laterally from the guide channel. The Airtraq is then rotated gently out of the oropharynx.

A suboptimal view with the Airtraq is often a result of inserting the device past the glottis. If this happens, the device should be withdrawn slowly until the larynx comes into view. As with other optical and video-enhanced laryngoscopes, the Airtraq has been associated with airway soft tissue injury. A tonsillar injury in a 4-year-old child was attributed to the width of the guide channel of the device.[597] Care should be taken when using the device in small children, given its size relative to the pharyngeal space. An Airtraq devoid of the guide channel is available for nasal intubations; the intubation may be facilitated with the use of Magill forceps or a gum elastic bougie.[598] The Airtraq has been successfully used for intubation in children with normal and difficult airways; however, despite its having a guide channel, some reports have noted difficulty with directing the ETT in neonates and infants.[484,552–554,599–601] The Airtraq is easy to learn and use.[602,603] As with many optical and video devices, there remains a learning curve to using the device,[604] particularly the manipulation of the tracheal tube into the glottis in small patients.[550]



TRUVIEW. The Truview EVO2 Infant device (Teleflex Medical, Netanya, Israel) is an optical laryngoscope with an angulated, stainless steel blade that transmits a magnified image from the tip of the device to an eyepiece using lenses (E-Fig. 14.19). A camera is available for connection to the eyepiece to allow the image to be viewed on a monitor. A side port is integrated into the blade to allow oxygen insufflation to clear the lens during intubation; however, caution should be exercised when insufflating oxygen in neonates and infants because of the rare risk of gastric insufflation and rupture.[605–607] Because of the indirect view afforded by the device, a stylet is necessary for successful intubation; a preformed stylet is available from the manufacturer. As with the GlideScope, the ETT should be shaped in a curve similar to the

E-FIGURE 14.17 The Storz Video Laryngoscope system (Karl Storz GmbH, Tuttlingen, Germany) integrates a camera into Miller- and Macintosh-type blades. **A,** The blade is inserted in the usual fashion. **B,** The epiglottis often obstructs the camera view. **C,** The glottis is exposed by standard means of lifting or angling the blade. **D,** The styleted endotracheal tube is inserted in the usual fashion down the right side of the oropharynx along the shaft of the video blade. **E,** The laryngoscopist directs the endotracheal tube through the glottic opening while watching the video screen.

E-FIGURE 14.18 The MultiView Scope (Medical Products International, Tokyo) integrates a camera into Miller- and Macintosh-style blades with a mounted video screen on the handle. **A** and **B,** In infants, it may be used to get a better view of the endotracheal tube entering the glottic inlet. **C,** The attending anesthesiologist can monitor the trainee's technique by watching the view on the screen. **D,** The MultiView Scope also comes with a malleable stylet attachment that allows oxygen insufflation through the mounted endotracheal tube.

E-FIGURE 14.19 A, The Truview EVO2 Infant (Teleflex Medical, Netanya, Israel) is an optical laryngoscope with an angulated, stainless steel blade that transmits a magnified image from the tip of the device to an eyepiece using lenses. The device contains an integrated side port for oxygen insufflation. **B,** The device is inserted in a similar manner as for routine direct laryngoscopy. **C,** The endotracheal tube is inserted into the trachea with the use of the proximal eyepiece.

FIGURE 14.30 **A,** The Airtraq optical laryngoscope (Prodol Meditec SA, Vizcaya, Spain) is a plastic, curved laryngoscope with a distal video camera that allows improved laryngeal views. It is supplied with a portable monitor. **B,** The Airtraq with the endotracheal tube (ETT) loaded into the molded channel is inserted in the midline of the pharynx. **C,** The ETT is held laterally from the Airtraq after intubation, and the Airtraq is then rotated away from the operator and out of the pharynx.

Truview blade. The blade is placed centrally along the tongue in the pharynx to the vallecula, and slight elevation should expose the vocal cords. The ETT is then passed alongside the device, taking care to look in the mouth during initial insertion to make sure the airway soft tissues are not injured. The Truview EVO_2 has been compared to laryngoscopy with a Miller blade in children, with results showing improved views of the larynx but longer intubation times.[556] If the patient's head is in the neutral position as for cervical spine instability, application of OELM will improve the view.[608] A study in adults found an improved laryngeal view compared with standard laryngoscopy without the need to align the oral, pharyngeal, and tracheal axes.[609] Once again, there is a learning curve with this device, and practice should shorten intubation times and minimize injury to soft tissues.[550] The Truview PCD Pediatric is the most recent iteration of the original Truview design; it is available with four pediatric blade sizes (0, 1, 2, 3) for newborns from 800 gm to large teenagers. A recent assessment of the Truview PCD in 86 consecutive children with normal airways found that 79 patients were successfully intubated on the first attempt while 4 patients required 2 attempts. Tracheal intubation time was 30 (27.9–37) seconds.[610]

Optical Stylets

Use of optical stylets, unlike FOB intubation, allows the operator to visualize the ETT as it enters the glottis. This is because the stylet is located just within the distal tip of the ETT, providing the operator with a view of the leading edge of the ETT. This view allows immediate recognition of impediments to ETT advancement such as the right arytenoid and enables negotiation of the stylet around these obstacles. The Shikani and the Bonfils are two optical stylets available for pediatric use. Secretions, fogging, and airway soft tissue can impede intubation with optical stylets because of their small lenses and limited depth of view. Impairment of visualization by airway soft tissue can be addressed by combining these devices with direct laryngoscopy. The direct laryngoscope allows the creation of space for visualization with the optical stylet but may require two operators for successful intubation. Optical stylets may be easier to learn and maneuver than FOBs, although some have questioned the utility of these devices in the pediatric population, particularly in the presence of copious secretions.[611,612]

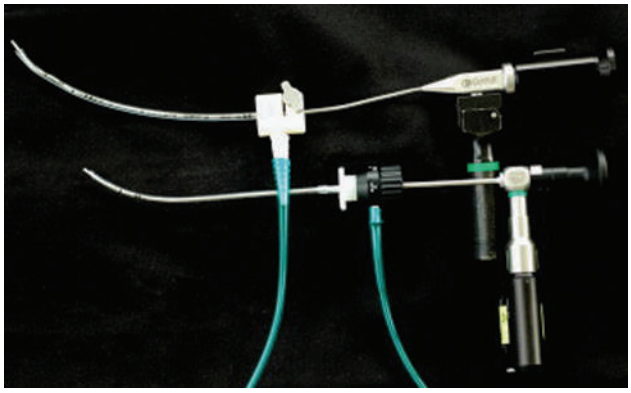
SHIKANI OPTICAL STYLET. The Shikani Optical Stylet (SOS; Clarus Medical, Minneapolis, MN) is a malleable, J-shaped

fiberoptic stylet that transmits the image from its distal tip to an eyepiece (E-Fig. 14.20). It has an adjustable tube stop to secure the tube and a port for oxygen insufflation, which should be used with caution in small children.[607,613] The nondominant hand is used to perform a jaw thrust, elevating the epiglottis from the posterior pharyngeal wall, and the stylet is then inserted in the midline in the pharynx (Video 14.14). The tongue base, uvula, and epiglottis are visualized in succession, and the tip is placed just above or just into the glottic inlet. The ETT is then advanced while the SOS is held steady. The SOS is a useful adjunct in the management of the pediatric difficult airway.[614,615]

STORZ BONFILS OPTICAL STYLET. The Bonfils Optical Stylet (Karl Storz) is a rigid fiberoptic stylet with a fixed 40-degree curvature (E-Fig. 14.21). It delivers a higher-quality image than the SOS but is not malleable. Although the manufacturer recommends a retromolar approach to intubation, a midline approach similar to that of the SOS has been found to be successful in children.[616] The Bonfils is available in pediatric and infant sizes and can be coupled to a portable monitor (available from the manufacturer). The use of an antisialagogue and suctioning greatly improves visualization when intubating with optical stylets. When the Bonfils was compared with direct laryngoscopy in a cohort of children with normal airways, the Bonfils was associated with better views but had a greater incidence of intubation failure.[611,612,617] In a comparison of the Bonfils, standard direct laryngoscopy, and GlideScope, the Bonfils resulted in a significantly improved laryngeal view and shorter intubation times.[618] Another study that compared the Bonfils with standard FOB found a shorter time to intubation (52 ± 22 seconds vs. 83 ± 24 seconds) and better image quality with the Bonfils, although all children were successfully intubated.[619] A case report describes its successful use in an infant with massive macroglossia and multiple hemorrhagic lymphangiomata compressing the airway, wherein it converted a grade 4 laryngoscopic view to a grade 1 view.[620]

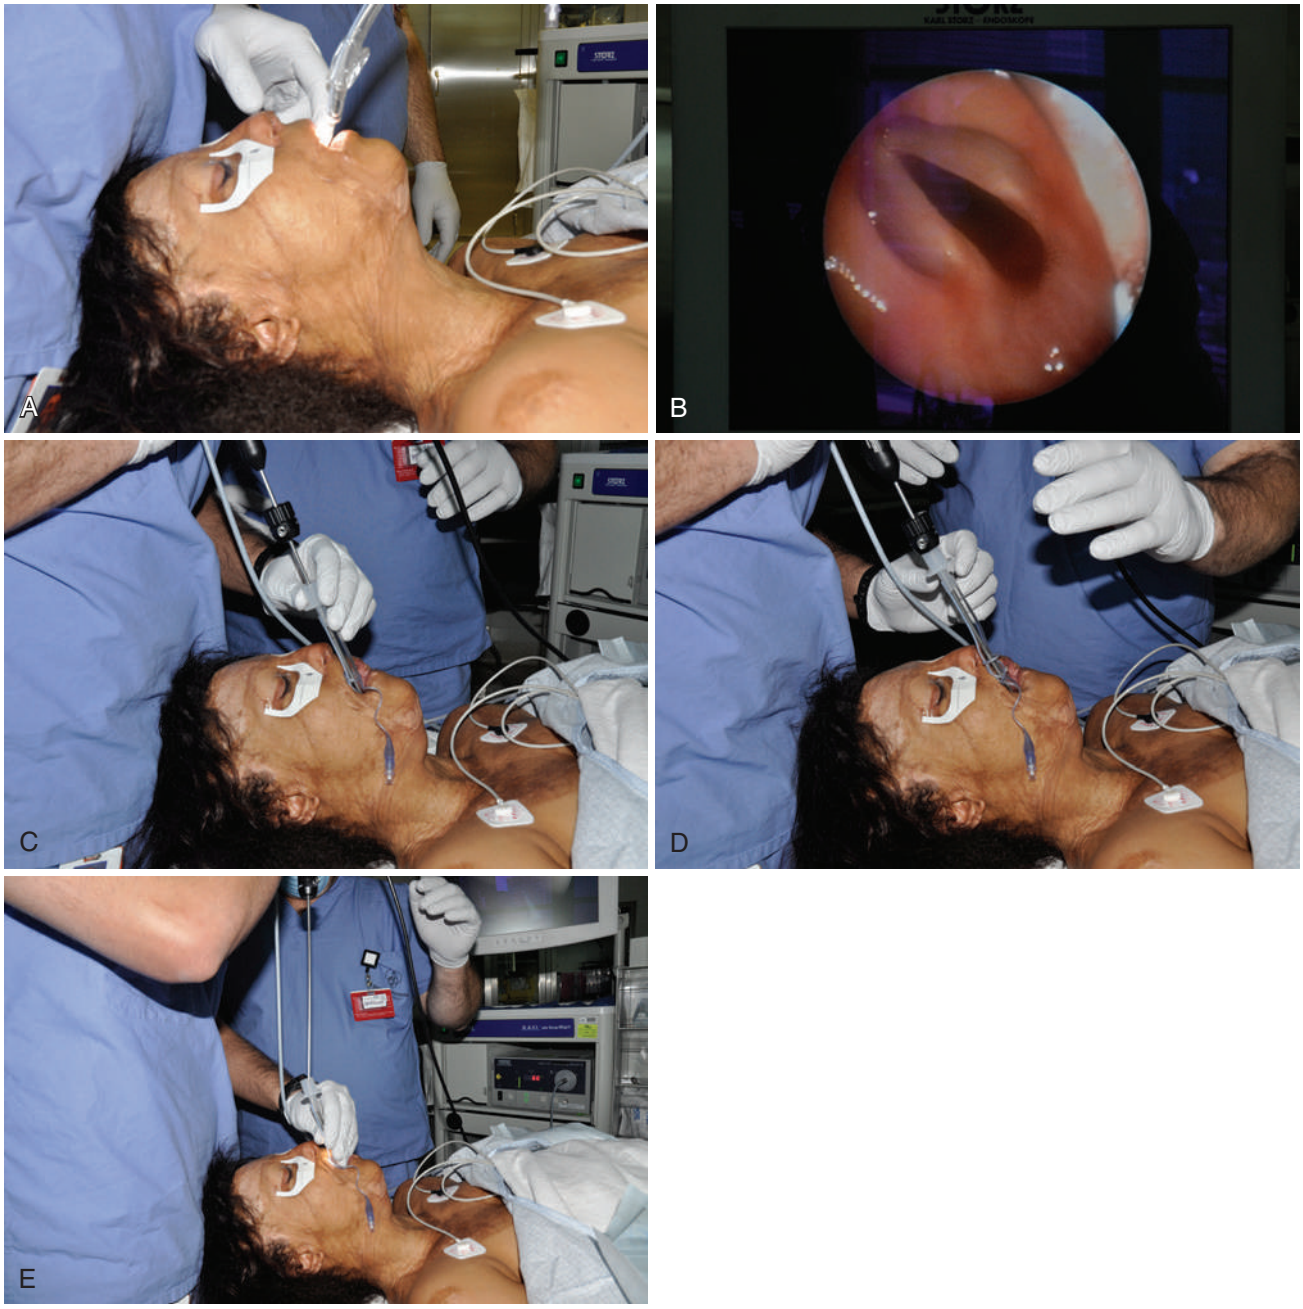
SHIKANI VERSUS STORZ BONFILS OPTICAL STYLETS. Both devices consist of a metal stylet containing a fiberoptic illumination fiber and a fiberoptic vision fiber that are connected to an eyepiece or a video monitor. The light source may be external or battery powered and attached to the housing at the base of the eyepiece; the latter version allows easy transport in an emergency outside the traditional operating room location (see E-Figs. 14.20 and 14.21).[621,622] These devices are described for use either with or without rigid laryngoscopy. There are slight differences between them. Both provide an adapter to hold the ETT that allows delivery of oxygen through the tip of the ETT, but the SOS requires removal of the 15-mm adapter, whereas the Storz Bonfils device uses the 15-mm adapter to hold the tube in place. The pediatric SOS is slightly malleable and can accommodate a 3.0-mm ID ETT; a 2.5-mm ID ETT fits but is tight. The Storz device is not at all malleable but readily accommodates a 2.5-mm ID ETT.[614,621,623,624] One further difference is that the quality of light (on battery mode) seems a bit brighter with the Storz device.

Laryngeal Mask Airway as a Conduit for Intubation



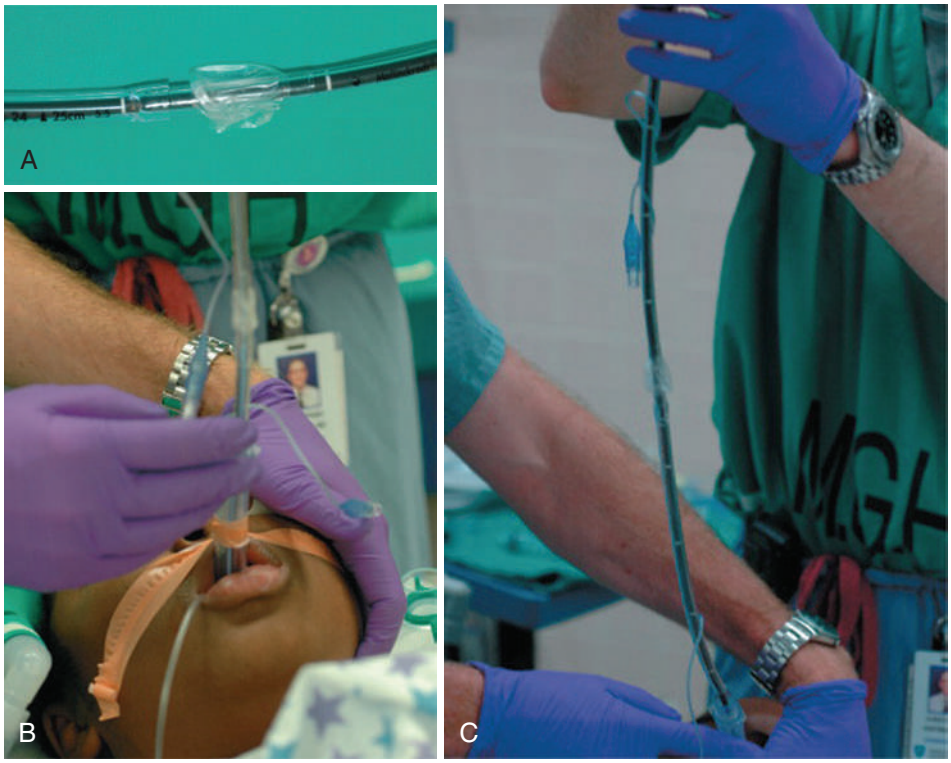
Numerous case reports affirm the usefulness of the LMA as a conduit for intubation.[472] Multiple methods for placing the ETT through the LMA have been described: blind, FOB assisted, stylet- or bougie-assisted, and retrograde-assisted.[419,625–631] Because of the high occurrence in children of the epiglottis overlying the laryngeal inlet,[372] even with apparently correct placement as judged by ability to ventilate, a visual technique for ETT placement (i.e., FOB-assisted) may be the best method. However, because the LMA and conventional ETTs have similar lengths, all intubation methods are complicated by the inability to stabilize the ETT position as the laryngeal mask is withdrawn; that is, LMA removal over the ETT may cause simultaneous withdrawal of the ETT.[632–635] Proposed solutions are leaving the LMA in place,[635–637] splitting the LMA,[335] cutting and shortening the LMA,[634,638,639] using longer ETTs,[640] and using two ETTs in sequence (tube on a tube), but each technique has disadvantages. Leaving the LMA in place makes securing the ETT difficult and precarious. Modifying the LMA may adversely affect its function, and removing a split LMA can easily dislodge the ETT. Longer ETTs may not be readily available. When an FOB is used to place the ETT, the LMA may be withdrawn first over the scope. The ETT is then grasped, passed through the LMA, and threaded over the FOB into the trachea.[628,641,642] An alternative is to telescope two identical ETTs end to end or to use two that differ in size by 0.5-mm ID, either larger or smaller (E-Fig. 14.22 and Video 14.15).[643–645] These ETTs are then threaded onto the FOB. The upper tube is used to maintain the lower tube in position as the LMA is withdrawn.[439,646] The upper ETT is then removed, the 15-mm adapter is replaced on the lower tube, and the correct position is confirmed by exhaled CO_2 and auscultation. Placing two ETTs on the FOB allows removal of the LMA, but the 15-mm adapter needs to be replaced, which can be difficult if the ETT is covered with lubricant. The apnea time from insertion of the fiberscope into the LMA until the ETT has been advanced into the trachea can be minimized by using continuous ventilation through a swivel adapter attached to the LMA or ETT.[632,647,648]

It has been suggested that smaller-sized, cuffed ETTs should be used for easier passage and then the cuff can be inflated to eliminate leaks. However, the pilot balloon of a cuffed ETT does not pass through the internal lumen of pediatric LMA sizes of 1.0 to 2.5 (Video 14.16). In larger LMAs, the ETT pilot balloon connection may be too short, so that the pilot balloon can become stuck within the LMA during withdrawal.[649] The largest ETT that will pass through each size of LMA is listed in Table 14.4. For the pediatric-sized LMA Unique and PLMA, even smaller ETTs must be used. The LMA Fastrach is available only in sizes 3, 4, and 5.



The air-Q

The air-Q Mask Laryngeal Airway (Mercury Medical, Clearwater, FL) is an oval-shaped laryngeal mask with a shortened, wide, hypercurved airway tube (Fig. 14.31). The air-Q intubating laryngeal mask is available in smaller sizes for younger children and offers some advantages over traditional laryngeal masks when used as an intubation conduit in children. It has a wider airway tube that accommodates cuffed ETTs and its length is shorter, facilitating removal of the mask after tracheal intubation. The air-Q performs well as a conduit for tracheal intubation and has been successfully used in children with difficult airways.[650–654] The air-Q is supplied with a red tag attached to the pilot balloon of the mask. This tag equalizes the pressure in the mask to atmospheric pressure, and the mask should be inserted with the tag attached. The manufacturer recommends light lubrication of the back of the mask and the tip of its inner surface.



The air-Q is held in the operator's dominant hand by its airway tube and is inserted into the pharynx at an angle (Video 14.17). The mask is advanced along the tongue base until slight resistance is encountered; a jaw thrust is then performed with the nondominant hand, and the mask is inserted slightly farther until it becomes seated in the airway. When the air-Q is used as a conduit for intubation, the ETT and its cuff should be checked

E-FIGURE 14.20 Optical stylets. *Top,* Shikani Optical Stylet (Clarus Medical, Minneapolis) is a malleable optical stylet capable of use with 3.0-mm ID endotracheal tubes (ETTs). The somewhat malleable tip allows the anesthesiologist to configure the shape as needed for each patient. This device provides another alternative for managing the difficult airway at a much lower cost than fiberoptic equipment. *Bottom,* Storz Bonfils Optical Stylet (Karl Storz GmbH, Tuttlingen, Germany) is a rigid device with a preformed 40-degree bend. This device allows passage of a 2.5-mm ID ETT. Both devices provide an adapter that allows administration of oxygen or oxygen and anesthetic gases at the tip of the ETT during airway manipulations (see text for details).

E-FIGURE 14.21 In this series of photographs, the Storz Bonfils Optical Stylet is used to accomplish tracheal intubation in a patient with extensive head and neck scar contractures. **A,** The endotracheal tube (ETT) is loaded into the Bonfils and introduced into the patient's mouth. **B,** The glottic inlet is identified, and the Bonfils is held directly in the opening. **C** and **D,** The ETT is advanced off the Bonfils into the trachea. **E,** The Bonfils is then carefully removed while the ETT is held in place.

E-FIGURE 14.22 The laryngeal mask airway (LMA) can be used as a conduit for fiberoptic intubation, allowing better control of the airway while locating the glottis. The LMA also helps to maintain the fiberoptic bronchoscope (FOB) in the midline. Two endotracheal tubes (ETTs) are wedged together end to end **(A)** after removal of the 15-mm adapter from the distal ETT (usually the proximal ETT is one-half size smaller than the distal tube). An assistant holds the LMA in place, and the FOB is introduced into the LMA **(B)**. When the tip of the FOB is located within the trachea, the double-length ETT is passed into the trachea **(C)**. The proximal ETT is used to hold the distal ETT in place while the LMA is threaded off the ETTs. The original 15-mm adapter is replaced, and the ETT is taped in place. With the appropriate size FOB, this technique may be used with ETT sizes of 3.5 mm ID or greater.

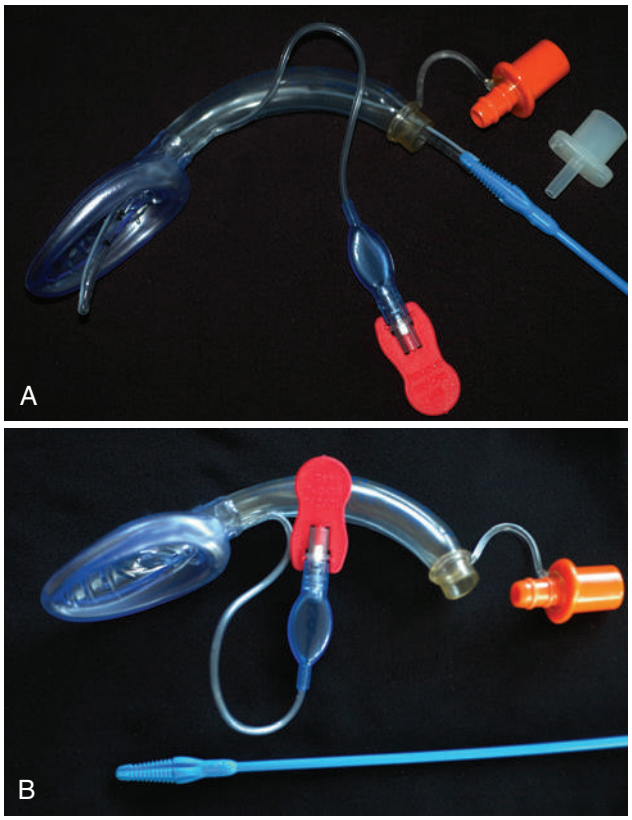


FIGURE 14.31 A, The air-Q Intubating Laryngeal Airway (Mercury Medical, Clearwater, FL) offers some advantages over traditional laryngeal masks when used as an intubation conduit in children. It has a wider airway tube that accommodates cuffed endotracheal tubes (ETTs), and its length is shorter, which facilitates removal of the mask after tracheal intubation. Before the intubation attempt, one should check that the ETT and its cuff will easily pass through the laryngeal airway size to be used. The 15-mm adapter of the air-Q is removed, the trachea is intubated with a bronchoscope, and the ETT is advanced into the trachea. **B,** When correct tracheal position is ensured, a special stylet (coudé-tip Tracheal Tube Introducer, available in three sizes for pediatric-sized ETTs) is inserted into the lumen of the ETT, the cuff of the air-Q is deflated, and with slight advancing pressure the ETT is held in place while the air-Q is gently withdrawn.

before the intubation attempt to be sure they will easily pass through the size to be used. The external surface of the ETT should be liberally lubricated. The 15-mm adapter of the air-Q is removed, the trachea is intubated with a bronchoscope, and the ETT is advanced into the trachea. When correct tracheal position is ensured, a special stabilizer (available in three sizes for pediatric-sized ETTs) is inserted into the lumen of the ETT. The cuff of the air-Q is deflated, and with slight advancing pressure the ETT is held in place with the stabilizer while the air-Q is gently withdrawn (Video 14.17). Proper ETT position is then reconfirmed, and the ETT is taped in place.

The air-Q was compared with the LMA Unique in a cohort of 50 children aged 6 to 36 months. The air-Q had higher airway leak pressure and a superior fiberoptic grade of view than the LMA Unique.[655] In another study that evaluated the air-Q as a conduit for tracheal intubation in infants, the mean oropharyngeal leak pressure was 18.5 ± 1.8 cm H_2O, and the mean insertion time was 13.3 ± 3.9 seconds; tracheal intubation was successful in 19 of 20 infants.[656] Another study compared the air-Q with an i-gel; the i-gel provided a greater leak pressure but the air-Q provided better fiberoptic views in children.[657] The successful use of the air-Q as a conduit for tracheal intubation has also been reported in infants with difficult direct laryngoscopy.[654,658]

Combined Techniques

Retrograde Wire and the Flexible Fiberoptic Bronchoscope

A case series reported the use of a combined retrograde wire and FOB technique in 20 children aged 1 day to 17 years.[659] Equipment required includes a ventilating endoscopic mask, equipment for retrograde wire intubation, an FOB with a working channel, and grasping forceps. The technique begins similarly to retrograde wire-guided intubation. A venous cannula is passed through the cricothyroid membrane in a cephalad manner. The needle is removed, and lidocaine is injected to provide topical anesthesia. Aspiration is done first; detection of air confirms correct placement of the cannula within the lumen of the trachea. A guidewire of suitable length is passed through the cannula and advanced cephalad into the pharynx until it can be retrieved with the forceps from the mouth. The wire is then passed into the working channel of an FOB in a retrograde manner starting at the tip of the FOB (some FOBs may require removal of tip components to allow the wire to pass). An appropriately sized ETT should already be threaded onto the FOB. The FOB is then advanced along the wire while the laryngoscopist looks for familiar anatomic structures. After placement of the FOB tip below the vocal cords is confirmed, the wire is removed in the caudad direction from the IV cannula. The FOB is further advanced to the mid-trachea, and the ETT is threaded into place.

Tips for success with this technique are to preserve spontaneous ventilation and to remove the guidewire in the caudad direction, because this tends to pull the FOB farther into the airway rather than out of the airway, which might occur if it is removed in the opposite direction. This technique may improve success over retrograde techniques alone, because the FOB allows direct visualization and is a stiffer guide for the ETT than the wire alone. It also may improve success over the FOB alone, because the glottis is more readily identified even in the presence of blood or secretions.

Rigid Laryngoscopy and the Flexible Fiberoptic Bronchoscope

The rigid laryngoscope blade may be used to facilitate exposure so that an FOB can be used to visualize the larynx.[660]

Flexible Fiberoptic Bronchoscope Used in a Retrograde Manner

An FOB was used in a retrograde manner in a 4-year-old child with Nager syndrome who presented for tracheocutaneous fistula closure after decannulation of a tracheostomy. After failed attempts at rigid and direct fiberoptic ETT placement, a FOB was placed in a retrograde fashion, using direct vision, through the fistula, past the vocal cords, into the nasopharynx, and out the naris. It was then used as a stylet for ETT placement.[661] The clinical scenario was unusual, but the technique was successful for this child.

Retrograde Light–Guided Laryngoscopy

Retrograde light-guided laryngoscopy (RLGL) describes a method by which a light-emitting diode flashlight is placed externally in the area of the cricothyroid membrane. Direct laryngoscopy is then performed with a laryngoscope blade with the light source switched off. The glottis is illuminated by the retrograde transmission of light and the vocal cords glow red. This bright intense light provides a discrete target for the laryngoscopist to insert the

breathing tube. When compared with traditional direct laryngoscopy, use of RLGL improved first-attempt intubation success rate, time to successful intubation, and incidence of sore throat.[662,663]

ACKNOWLEDGMENTS

We wish to thank Melissa Wheeler for her prior contributions to this chapter and I. David Todres posthumously.

Many manufacturers have graciously provided us samples of airway devices so that we could illustrate examples of commonly available equipment. There is insufficient room to illustrate all available devices. Lack of illustration of a device should not be construed as lack of efficacy, nor should illustration of a device be interpreted as endorsement. Practitioners are encouraged to use all equipment available and to make their own educated decision about what devices provide the greatest safety and efficacy in their hands.

ANNOTATED REFERENCES

Crawford MW, Rohan D, Macgowan CK, et al. Effect of propofol anesthesia and continuous positive airway pressure on upper airway size and configuration in infants. *Anesthesiology*. 2006;105:45-50.

These two papers by Crawford and colleagues clarify how anesthetics produce airway obstruction in children. Airway obstruction during anesthesia or loss of consciousness appears to be primarily related to loss of muscle tone in the pharyngeal and laryngeal structures rather than apposition of the tongue to the posterior pharyngeal wall. This reduction in pharyngeal airway space decreases in a dose-dependent manner with increasing concentrations of either sevoflurane or propofol anesthesia.

Fiadjoe JE, Nishisaki A, Jagannathan N, et al. Airway management complications in children with difficult tracheal intubation from the Pediatric Difficult Intubation (PeDI) registry: a prospective cohort analysis. *Lancet Respir Med*. 2016;4(1):37-48.

This registry reviewed 1018 difficult intubation encounters in children. Complications were associated with more than two attempts at tracheal intubation, weight less than 10 kg, short thyromental distance, and three direct laryngoscopy attempts before an indirect technique. The most frequent complication was temporary hypoxemia, but 15 children suffered cardiac arrest. The authors concluded that limiting the number of direct laryngoscopy attempts and quickly transitioning to an indirect technique when direct laryngoscopy fails would enhance patient safety.

This review paper is a comprehensive summary of the newer devices and techniques with which to manage the difficult pediatric airway.

Litman RS, McDonough JM, Marcus CL, et al. Upper airway collapsibility in anesthetized children. *Anesth Analg*. 2006;102:750-754.

This study used an innovative method to measure the propensity of the upper airway to collapse and demonstrated that halothane is a better anesthetic agent than sevoflurane for keeping the upper airway patent during general anesthesia.

Litman RS, Wake N, Chan LM, et al. Effect of lateral positioning on upper airway size and morphology in sedated children. *Anesthesiology*. 2005;103:484-488.

This study used cross-sectional magnetic resonance images of the upper airway to demonstrate that when sedated children are placed in the lateral position, upper airway patency improves, mainly at the level of the epiglottis.

Practice guidelines for management of the difficult airway: an updated report by the American Society of Anesthesiologists. Task force on management of the difficult airway. *Anesthesiology*. 2013;118(2):251-270.

The most recent guidelines from the American Society of Anesthesiologists for management of the patient with a difficult airway, whether anticipated and unanticipated. Although geared for adult anesthesia, the approach outlined in the algorithm may be applied to children.

Rolf N, Coté CJ. Diagnosis of clinically unrecognized endobronchial intubation in paediatric anaesthesia: which is more sensitive, pulse oximetry or capnography? *Paediatr Anaesth*. 1992;2:31-235.

This paper determined that pulse oximetry is more sensitive than capnography in detecting endobronchial intubation. It recommends that when a small but persistent change in oxygen saturation is noted, rather than increase the inspired oxygen concentration, one must first investigate the cause and reassess the position of the endotracheal tube.

Shi F, Xiao Y, Xiong W, et al. Cuffed versus uncuffed endotracheal tubes in children: a meta-analysis. *J Anesth*. 2016;30(1):3-11.

This meta-analysis of two randomized controlled trials and two prospective cohort studies including 1979 children intubated with cuffed endotracheal tubes versus 1803 with uncuffed endotracheal tubes. Cuffed endotracheal tubes reduced the need for tracheal tube exchanges and did not increase the risk for post extubation stridor.

Weiss M, Dullenkopf A, Gysin C, et al. Shortcomings of cuffed paediatric-tracheal tubes. *Br J Anaesth*. 2004;92:78-88.

This paper compares the physical characteristics of the most commonly available pediatric endotracheal tubes (ETTs). It also underscores the shortcomings in ETT design that may affect airway-related patient complications and that should be considered in choosing ETTs for children.

Wheeler M, Roth AG, Dsida RM, et al. Teaching residents pediatric fiberoptic intubation of the trachea: traditional fiberscope with an eyepiece versus a video-assisted technique using a fiberscope with an integrated camera. *Anesthesiology*. 2004;101:842-846.

Lack of proficiency using fiberoptic equipment for pediatric airway management remains a concern. This paper supports two important points: (1) one can achieve a satisfactory proficiency with a pediatric fiberoptic system with relatively few intubations, and (2) a video system can both improve the speed of skill acquisition and shorten the time required for successful intubation.

General Perioperative Considerations
Ventilation and Perfusion During Thoracic Surgery
Thoracoscopy
Techniques for Single-Lung Ventilation in Infants and Children
Surgical Lesions of the Chest
Summary

General Perioperative Considerations

A thorough preoperative evaluation is essential when caring for the child who is scheduled for thoracic surgery. Appropriate imaging and laboratory studies should be performed according to the lesion involved. Guidelines for fasting, choice of premedication, and preparation of the operating room (OR) are the same as for other infants and children scheduled for major surgery. After induction of anesthesia, placement of an intravenous (IV) catheter, and tracheal intubation, arterial catheterization should be considered for children undergoing thoracotomy as well as those with severe lung disease having thoracoscopic surgery. For thoracoscopic procedures of relatively brief duration in children without significant lung disease, an arterial catheter may not be required. The arterial catheter facilitates monitoring of systemic blood pressure during manipulation of the lungs and mediastinum as well as arterial blood gas tensions during single-lung ventilation (SLV). Placement of a central venous catheter is generally not indicated if peripheral IV access is adequate for projected fluid and blood administration.

Inhalational anesthetic agents are commonly administered in 100% O_2 during maintenance of anesthesia. The delivery of high concentrations of oxygen may have deleterious effects, however, including the formation of free radicals.[1] It is prudent for the practitioner to target a range of oxygen saturation values (e.g., 90% to 95%) and minimize the FIO_2 accordingly, though greater concentrations may be appropriate in anticipation of surgical maneuvers that are likely to increase intrapulmonary shunt and decrease oxygen saturation. Isoflurane may be preferred because it attenuates hypoxic pulmonary vasoconstriction to a lesser extent than other inhalational agents, although this has not been studied in children[2]; nitrous oxide is avoided. IV opioids have a sparing effect on the concentration of inhalational anesthetics required, and therefore may limit the attenuation of hypoxic pulmonary vasoconstriction. Alternatively, total IV anesthesia may be used (see Chapter 8).

A variety of approaches have been described to prevent and treat pain after videoscopic procedures. Infiltration of the incision sites with bupivacaine before skin incision decreases postoperative pain.[3,4] Infiltration with bupivacaine was found to be superior to IV fentanyl or tenoxicam for reducing postoperative pain.[5] The combination of general anesthesia with regional anesthesia that also contributes to postoperative analgesia is particularly desirable for thoracotomy, but may also be beneficial for thoracoscopic procedures. This is especially true when thoracostomy tube drainage, a source of significant postoperative pain, is used after surgery. In addition, regional blockade for postoperative analgesia facilitates deep breathing and coughing, which may limit atelectasis and pneumonia. A variety of regional anesthetic techniques have been described for intraoperative anesthesia and postoperative analgesia, including intercostal and paravertebral blocks, intrapleural infusions, and epidural anesthesia (see Chapters 42, 43, and 44).

VENTILATION AND PERFUSION DURING THORACIC SURGERY

Ventilation is normally distributed preferentially to the dependent regions of the lung, so that there is a gradient of increasing ventilation from the least to the most dependent lung segments. Because of gravitational effects, perfusion normally follows a similar distribution, with increased blood flow to dependent lung segments; therefore ventilation and perfusion are normally well matched. In infants, however, ventilation is normally distributed to the nondependent areas of the lung and perfusion is more evenly distributed because of their smaller anteroposterior distance that mitigates the effect of gravity. These two effects result in increased ventilation/perfusion ($\dot{V}/\dot{Q}$) mismatch. During thoracic surgery, several factors act to further increase $\dot{V}/\dot{Q}$ mismatch. General anesthesia, neuromuscular blockade, and mechanical ventilation may decrease functional residual capacity of both lungs. Compressing the dependent lung in the lateral decubitus position may cause atelectasis. Surgical retraction and/or SLV collapse the operative lung. Hypoxic pulmonary vasoconstriction, which diverts blood flow away from underventilated lung, minimizes $\dot{V}/\dot{Q}$ mismatch, which may be diminished by inhalational anesthetic agents and other vasodilating drugs. These factors apply equally to infants, children, and adults. The overall effect of the lateral decubitus position on $\dot{V}/\dot{Q}$ mismatch in infants, however, differs from that with older children and adults.

In adults with unilateral lung disease, oxygenation is optimal when the patient is placed in the lateral decubitus position with the healthy lung in the dependent ("down") position and the diseased lung in the nondependent ("up") position.[6] Presumably, this is related to an increase in blood flow to the dependent, healthy lung and a decrease in blood flow to the nondependent, diseased lung because of the hydrostatic pressure (or gravitational) gradient between the two lungs. This phenomenon promotes $\dot{V}/\dot{Q}$ matching in the adult patient undergoing thoracic surgery in the lateral decubitus position.

In infants with unilateral lung disease, however, oxygenation is improved with the healthy lung "up."[7] Several factors account

for this discrepancy between adults and infants. Infants have a soft, easily compressible rib cage that cannot fully support the underlying lung. Therefore functional residual capacity is closer to residual volume, making airway closure more likely in the dependent lung even during tidal breathing.[8] When the adult is placed in the lateral decubitus position, the dependent diaphragm has a mechanical advantage because it is "loaded" by the abdominal hydrostatic pressure gradient. This pressure gradient is reduced in infants, thereby reducing the functional advantage of the dependent diaphragm. The infant's small size also reduces the hydrostatic pressure gradient between the nondependent and dependent lungs. Consequently, the favorable increase in perfusion to the dependent, ventilated lung is attenuated in infants.

Finally, the infant's increased oxygen requirement, coupled with a small functional residual capacity, predisposes to hypoxemia. Infants normally consume 6 to 8 mL of O_2/kg per minute compared with adult rates of 2 to 3 mL of O_2/kg per minute.[9] For these reasons, infants are at an increased risk of significant hemoglobin desaturation during surgery in the lateral decubitus position.

A modest increase in $PaCO_2$ may be beneficial in children during thoracoscopic procedures. In a study of 12 children undergoing video-assisted thoracoscopic surgery for patent ductus arteriosus closure, hypercapnea targeting $PaCO_2$ values between 50 and 70 mm Hg increased cardiac output, central venous, and arterial oxygen tension.[10] Ventilating patients during SLV to a greater PCO_2 target also results in less volutrauma and barotrauma—that is, lung injury related to use of large tidal volumes and increased inflating pressures (see below).

THORACOSCOPY

With the miniaturization of instruments, progress in video technology, and growing experience among pediatric surgeons, video endoscopic surgery of the chest, or thoracoscopy, is being performed for an increasing number of pediatric surgical indications (Table 15.1). Advantages of thoracoscopy include smaller chest incisions, reduced postoperative pain, and more rapid postoperative recovery compared with thoracotomy (Table 15.2, Fig. 15.1).[11,12] Endoscopes can be passed through a needle and trocar system and digital video signals can be electronically modified to yield sharp, detailed, color images with a minimum light intensity. Digital cameras are designed to maintain an image in an upright orientation regardless

of how the telescope is rotated. They are also equipped with an optical or digital zoom to magnify the image or give the illusion of moving the telescope closer to the object of interest. The smallest of telescopes use fiberoptics and are less than 2 mm in diameter (Fig. 15.2). Two-millimeter disposable ports, mounted on a Veress needle, are used for introduction of these small instruments. Larger instruments and ports are used in larger children and for more complex cases.

A second area of major advance in video endoscopic surgery is the development of the endoscopic suite, in which all necessary cables and wiring are located within equipment booms, ceilings, and walls. The manipulation of digital images is controlled by voice or touchscreen command either from the operative field or at a conveniently located station nearby. High-quality digital images are displayed on flat-panel monitors that can be positioned within a comfortable viewing range. Remote-controlled cameras can direct any view in the room to any of the monitors or to a remote site. Digital radiographs can be routed from the radiology department to the OR, and consultants in remote locations can be viewed on monitors in the OR so that the surgeon can see to whom he or she is speaking. An additional feature of newer endoscopy suites is voice-controlled bed positioning. Robotic tools can be vocally directed to position telescopes in the surgical field

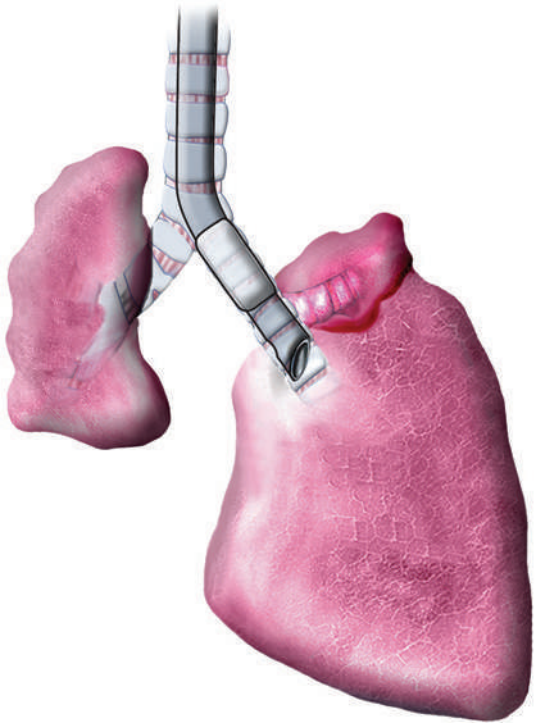

FIGURE 15.3 Placement of a single-lumen endotracheal tube (ETT) for left-sided single-lung ventilation results in obstruction of the upper lobe orifice if the distance from the proximal cuff to the tip of the ETT is longer than the main-stem bronchus.

for optimal viewing; these surgical "telemanipulators" facilitate microsurgery in confined spaces, even for small infants. Other endoscopic robots are being developed for a wide range of surgical applications.

Thoracoscopy can be performed while both lungs are being ventilated using CO_2 insufflation and placement of a retractor to displace lung tissue in the operative field. However, SLV is extremely desirable during thoracoscopy because lung deflation improves visualization of thoracic contents and may reduce lung injury caused by the use of retractors.

TECHNIQUES FOR SINGLE-LUNG VENTILATION IN INFANTS AND CHILDREN

Use of a Single-Lumen Endotracheal Tube

The simplest means of providing SLV is to intentionally intubate the ipsilateral main-stem bronchus with a conventional single-lumen endotracheal tube (ETT).[13] When the left bronchus is to be intubated, the bevel of the ETT is rotated 180 degrees and the child's head is turned to the right.[14] The ETT is advanced into the bronchus until breath sounds on the operative side disappear. A fiberoptic bronchoscope (FOB) may be passed through or alongside the ETT to confirm or guide placement. Alternatively, fluoroscopy may be used to guide and position the ETT.[15] When a cuffed ETT is used, the length of the cuff must be less than the length of the main-stem bronchus, and the proximal cuff must be placed just beyond the carina so that the right upper lobe orifice is not occluded (Fig. 15.3).[16] This technique is simple and requires no special equipment other than an FOB. This may be the preferred technique of SLV in emergency situations, such as airway hemorrhage or contralateral tension pneumothorax.

Problems can occur when using a single-lumen ETT for SLV. If a smaller, uncuffed ETT is used, it may be difficult to provide an adequate seal of the intended bronchus. This may prevent the operative lung from adequately collapsing or fail to protect the healthy, ventilated lung from contamination by purulent material or blood from the contralateral lung. Also, one is unable to suction the operative lung using this technique. Hypoxemia may occur as a result of obstruction of the upper lobe bronchus, especially when the short right main-stem bronchus is intubated.

Variations of this technique have been described, including intubation of both bronchi independently with small ETTs.[17–20] One main-stem bronchus is initially intubated with an ETT, after which another ETT is advanced over an FOB into the opposite bronchus. The disadvantages of these techniques include technical difficulties and trauma to the tracheal and bronchial mucosa. Even after successful bilateral bronchial intubation, the inner diameters of the tubes will be small, limiting gas flow and impeding suctioning of the airways.

Use of Balloon-Tipped Bronchial Blockers

A Fogarty embolectomy catheter or an end-hole, balloon wedge catheter (e.g., 5F Arndt Endobronchial Blocker (AEB; Cook Medical, Bloomington, IN) may be used for bronchial blockade to provide SLV (Fig. 15.4).[21–24] Placement of a Fogarty catheter is facilitated by bending the tip of its stylet toward the bronchus on the operative side. An FOB may be used to reposition the catheter and confirm appropriate placement. Various techniques for placing an end-hole catheter outside the ETT have been described. Using one such method, the bronchus on the operative side is initially intubated with an ETT[21]; a guidewire is then advanced into that bronchus through the ETT, the ETT is removed, and the blocker advanced over the guidewire into the bronchus. An ETT is then reinserted into the trachea alongside the blocker catheter. The catheter balloon is positioned in the proximal main-stem bronchus under fiberoptic guidance. The guidewire may be removed to allow oxygen insufflation via the catheter lumen.

A variety of other techniques for placing the blocker outside the ETT have been described.[25] Alternatively, if an FOB small enough to pass through the indwelling ETT is not available, fluoroscopy may be used to visualize the blocker balloon and facilitate placement just distal to the carina (Fig. 15.5). With an inflated blocker balloon the airway is completely sealed, providing more predictable lung collapse and better operating conditions than with an ETT in the bronchus.

One potential problem with this technique is dislodgment of the blocker balloon into the trachea, blocking ventilation to both lungs and/or preventing collapse of the operative lung. The balloons of most catheters currently used for bronchial blockade have low compliance properties (i.e., low volume, high pressure). They require 1 to 3 mL of air or saline to fully inflate. Overdistention of the balloon can damage or even rupture the airway.[26] One study, however, reported that bronchial blocker cuffs produced lower "cuff-to-tracheal" pressures than double-lumen tubes.[27] The operative lung cannot be suctioned and continuous positive airway pressure (CPAP) cannot be provided to the operative lung if needed when closed-tip bronchial blockers are used.

When a bronchial blocker is placed outside the ETT, care must be taken to avoid injury caused by compression and resultant ischemia of the tracheal mucosa. The sum of the catheter diameter and the outer diameter of the ETT should not significantly exceed the tracheal diameter. Outer diameters for pediatric-size ETTs are shown in Table 15.3. These numbers provide an estimate of the predicted tracheal diameter, which should approximate the size of the uncuffed ETT predicted to produce a seal in the trachea.

Adapters have been developed that facilitate ventilation during placement of a bronchial blocker through an indwelling ETT.[28,29]

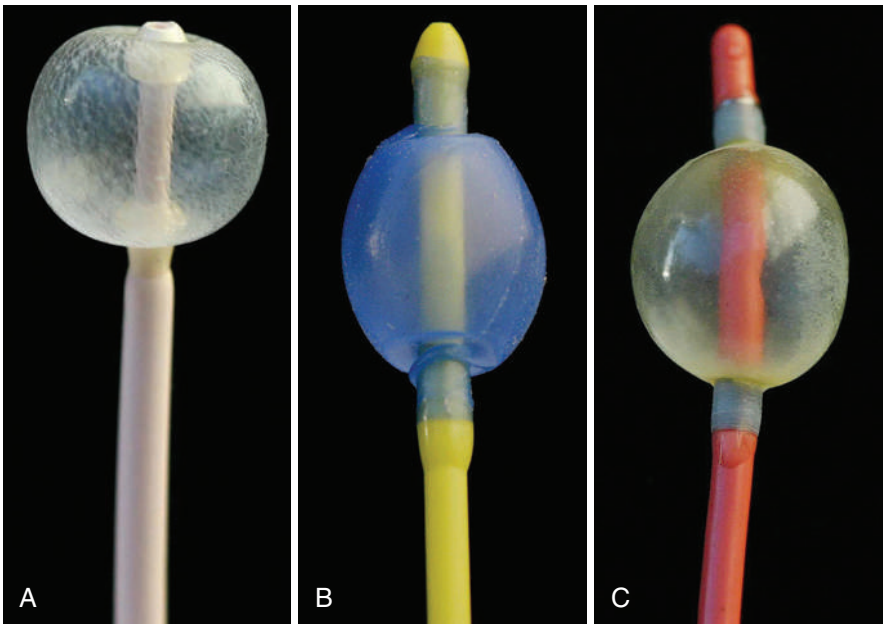

FIGURE 15.4 A variety of balloon-tipped catheters have been used for single-lung ventilation, including an Arrow balloon wedge catheter **(A)** (Arrow International, Inc., Reading, PA), a Cook pediatric bronchial blocker **(B)** (Arndt blocker, Cook Medical, Inc., Bloomington, IN), and a Fogarty embolectomy catheter (Edwards Lifesciences Corp, Irvince, CA) **(C)**. ID, internal diameter; *OD,* outer diameter.

A 5F endobronchial blocker with a multiport adapter has been designed for use with an FOB in children (Cook Medical).[30] The balloon is elliptical so that it conforms to the bronchial lumen when inflated. The blocker catheter has a maximum outer diameter of 2.5 mm (including the deflated balloon), a central lumen with a diameter of 0.7 mm, and a distal balloon with a capacity of 3 mL. The balloon has a length of 1.0 cm, corresponding to the length of the right main-stem bronchus in children approximately 2 years of age.[31] The blocker is placed coaxially through a dedicated port in the adapter, which also has a port for passage of an FOB and ports for connection to the anesthesia breathing circuit and ETT (Fig. 15.6). The FOB port has a plastic sealing cap, whereas the blocker port has a Tuohy-Borst connector (B. Braun, Bethlehem, PA) that locks the catheter in place and maintains an airtight seal. Because oxygen can be administered during passage of the blocker and FOB, the risk of hypoxemia during blocker placement is diminished. Insufflation of oxygen via the blocker lumen decreases intrapulmonary shunt, improves oxygenation, and therefore allows delivery of a lower FiO_2 to the ventilated lung to minimize oxygen toxicity. The blocker may be repositioned with FOB guidance during surgery.

When an FOB is used to place a bronchial blocker, both the blocker catheter and FOB must pass through the indwelling ETT. The smallest ETT through which the catheter and FOB can be passed must be larger than the sum of the outer diameters of the two. The 5F Cook bronchial blocker and an FOB with a 2.2-mm diameter, for example, may be inserted through an ETT with an internal diameter as small as 5.0 mm; for children with an indwelling ETT smaller than this, a blocker catheter can be positioned under fluoroscopy (see Fig. 15.5).[32]

Use of a Univent Tube

The Univent tube (Fuji Systems Corporation, Tokyo) is a conventional ETT with a second lumen containing a small blocker catheter that can be advanced into a bronchus (Fig. 15.7).[33,34] A balloon located at the distal end of this small tube serves as a blocker. Univent tubes require an FOB for successful placement. Univent tubes are now available in sizes with internal diameters as small as 3.5 and 4.5 mm for use in children older than 6 years of age.[35] Because the blocker tube is firmly attached to the main ETT, the Univent blocker balloon is less likely to be displaced than when other blocker techniques are used. The blocker tube has a small lumen that allows egress of gas and can be used to insufflate oxygen or suction the operated lung.

One disadvantage of the Univent tube is the large cross-sectional area occupied by the blocker channel, especially in the smaller size tubes. Therefore, Univent tubes have a large outer diameter with respect to their inner (luminal) diameters (Table 15.4). Smaller Univent tubes have a disproportionately high resistance to gas flow.[36] The Univent tube's blocker balloon has low-volume, high-pressure characteristics, predisposing to mucosal injury during normal inflation.[37,38]

Use of Double-Lumen Tubes

All double-lumen tubes (DLTs) are essentially two tubes of unequal length molded together. The shorter tube ends in the trachea, and the longer tube ends in the bronchus (Fig. 15.8). DLTs for older children and adults have cuffs located on the tracheal and bronchial lumens. The tracheal cuff, when inflated, allows positive-pressure ventilation. The inflated bronchial cuff allows ventilation

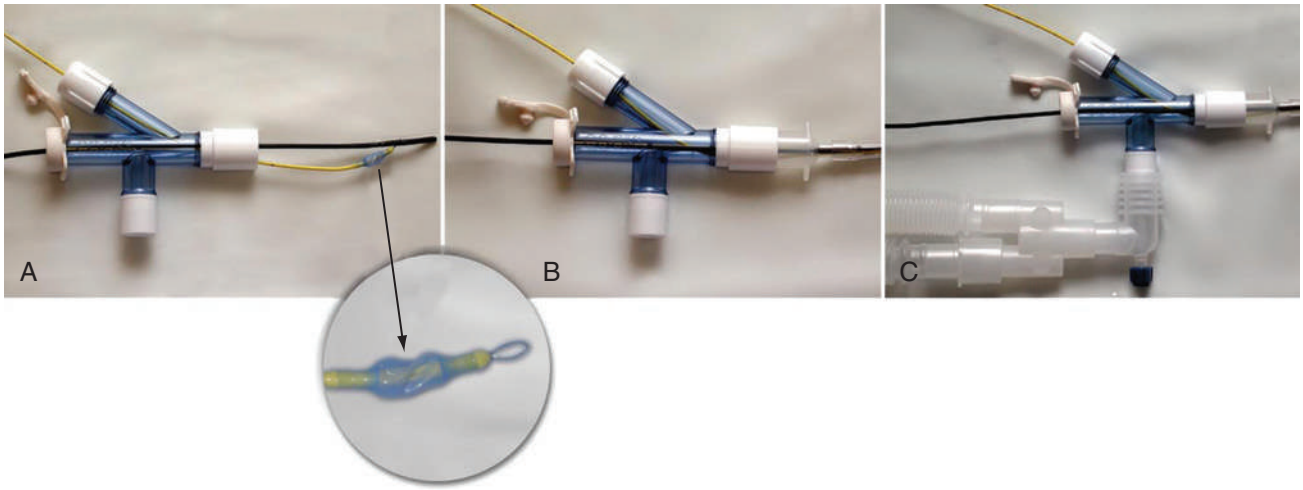

FIGURE 15.6 The Cook 5F endobronchial catheter is shown inserted in the multiport adapter. **A,** The adapter has four ports for connection to the breathing circuit, fiberoptic bronchoscope (FOB), endobronchial catheter, and endotracheal tube. After the FOB and endobronchial catheter have been inserted through the multiport adaptor, the FOB is placed through the monofilament loop at the distal end of the catheter (*arrow*). The multiport adaptor is then attached to the indwelling endotracheal tube **(B)** and the breathing circuit **(C)**. The FOB is directed into the main-stem bronchus on the operative side. The catheter is then advanced until the monofilament loop slides off the end of the FOB into the bronchus. (Photographs by Elliot Krane, MD.)

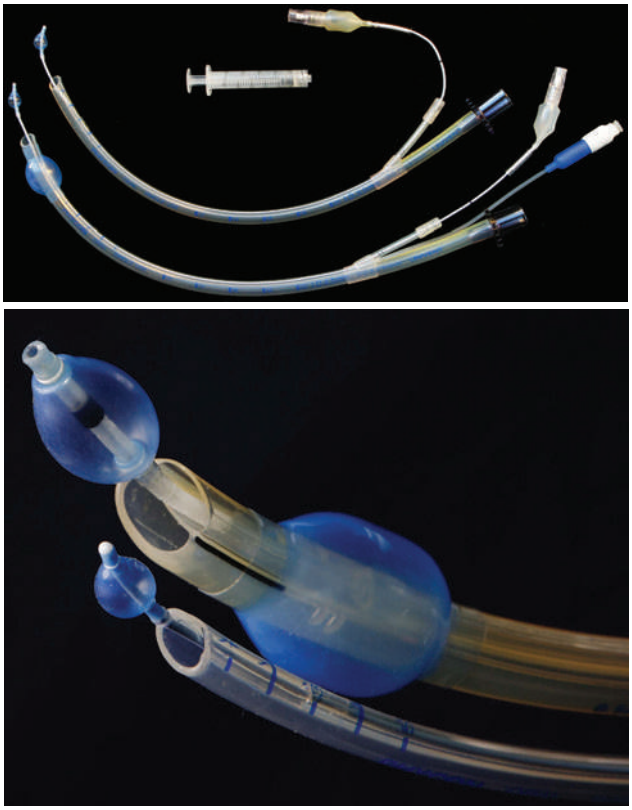

FIGURE 15.7 The Univent tube is available in a variety of adult sizes, as well as 3.5-mm internal-diameter and 4.5-mm internal diameter sizes for use in children (*top*). The adult tubes have a tracheal cuff and an end-hole bronchial blocker, allowing administration of oxygen and suction (*bottom*). The pediatric tubes are uncuffed and have a closed-tip blocker. (Photographs by Michael Chen, MD.)

to be diverted to either or both lungs and protects each lung from contamination from secretions, purulent material, or blood originating from the contralateral side.

Marraro described a bilumen tube for infants.[39] This tube consists of two separate uncuffed tracheal tubes of different lengths attached longitudinally. This tube is not available in the United States. The smallest cuffed DLT commercially available in the United States is a 26F size (Teleflex Medical, Research Triangle Park, NC). This DLT may be used in children as young as 8 years old. DLTs are also available in sizes 28F and 32 F (Nellcor brand [Covidien, Mansfield, MA]); these are suitable for children 10 years of age and older. Numerous manufacturers produce clear, disposable, polyvinyl chloride Robertshaw-design (P[3] Medical, Briston, England) DLTs, which are available in sizes 35F to 41F (Table 15.5). Essentially, they consist of similar features with small modifications in cuff shape and location. A colored bronchial cuff, commonly blue, permits

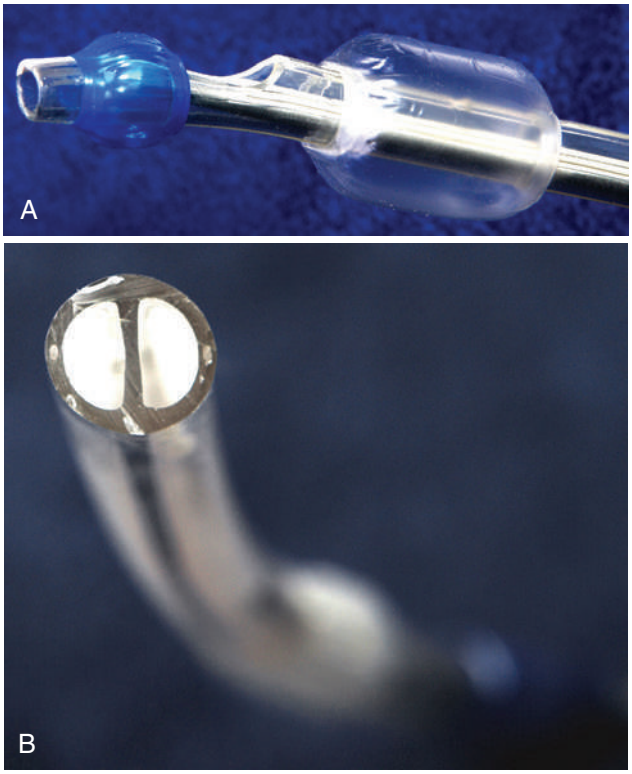

FIGURE 15.8 Although the bronchial lumen of a double-lumen tube appears to be round **(A),** both the bronchial and tracheal lumens are D-shaped, as evident in a cross-sectional view **(B)**. Their actual lumens have restricted limiting diameters. (Photographs by Michael Chen, MD.)

TABLE 15.5 Double-Lumen Tube Dimensions

Size (Fr)	Main Body OD (mm)	Limiting Diameter Tracheal Lumen (mm)	Limiting Diameter Bronchial Lumen (mm)
26[a]	8.7	N/A	N/A
28[b]	9.4	3.1	3.2
32[b]	10.6	3.5	3.4
35[b]	11.7	4.5	4.3
37[b]	12.4	4.7	4.5
39[b]	13.1	4.9	4.9
41[b]	13.7	5.4	5.4

Note: The limiting diameters correspond to the largest suction catheter or fiberoptic bronchoscope that can be placed via the lumen under ideal circumstances (e.g., adequate lubrication).
French (F) gauge is $\pi \times$ OD (~3 $\times$ OD) (mm). Comparing data in this table to those in Table 15.3, the OD of the DLTs corresponds to the following tracheal tubes: 26F DLT is equivalent to that of a 6.0- to 6.5-mm ID tracheal tube; a 28F is equivalent to a 6.5- to 7.0-mm ID; and a 32F is equivalent to an 8.0-mm ID. Cuff thickness is 0.049 mm; therefore a cuff adds 0.10 mm to overall OD of tube.

DLT, double-lumen tube; *ID,* internal diameter; *OD,* outer diameter.

easy identification by fiberoptic bronchoscopy. In general, the cuffs used in DLTs are high-compliance cuffs that are designed to exert less pressure on the tracheal and bronchial mucosa compared with low-compliance cuffs. For right-sided DLTs, the endobronchial cuff is donut shaped and allows the right upper lobe ventilation opening to be positioned at the right upper lobe orifice. Despite this design, right upper lobe occlusion may occur because of the shorter length of the right main-stem bronchus.[2,40] Therefore right-sided DLTs are used infrequently.

A novel mechanism for determining whether the child's airway is large enough to accommodate a DLT and, if so, what size DLT is optimal, is printed three-dimensional (3D) airway modeling.[41,42] It is now possible to create a full-scale, anatomically accurate, transparent model of the tracheobronchial tree on a 3D printer using data from computed tomography (CT) scanning. A variety of approaches to SLV can be tested on the model, including placement of a bronchial blocker inside or outside of an ETT as well as a DLT. For the former approach, the appropriate size ETT and bronchial blocker may be selected. If a recent CT scan has been obtained, as is common among patients for whom thoracic surgery is planned, there may be no additional imaging cost or radiation exposure required to create a 3D printed model. As 3D printers become more widely available and the cost of creating 3D printed models of an individual patient's tracheobronchial tree decreases, this technique may be more widely used for planning SLV as well as for training anesthesiologists how to perform these procedures more effectively.

DLTs are inserted in children using the same technique as in adults, and left DLTs are almost exclusively used.[43] The tip of the tube is inserted just past the vocal cords, and the stylet is withdrawn. The DLT is rotated 90 degrees to the appropriate side and then advanced into the bronchus. After intubation, the tracheal cuff is inflated first and equal breath sounds should be confirmed. To prevent mucosal damage from excessive pressure applied by the bronchial cuff, the cuff is inflated with incremental volumes to seal air leaks around the bronchial cuff into the trachea. Inflation of the bronchial cuff seldom requires more than 2 mL of air. After inflation of the bronchial cuff, bilateral breath sounds should be rechecked to confirm that the bronchial cuff is not herniating across the carina to impede contralateral lung ventilation. Fiberoptic bronchoscopy can be used to directly visualize the proximal edge of the bronchial cuff in the left bronchus, just distal to the carina. One simple way to verify that the tip of the bronchial lumen is located in the designated bronchus is to clamp the tracheal lumen at the level of the connector and then observe and auscultate left and right lungs. Usually, inspection will reveal unilateral movement of the ventilated hemithorax. With the tracheal lumen clamped, auscultation of the chest will demonstrate air entry in the left lung and no ventilation in the right lung. After auscultation and release of the tracheal clamp, the bronchial lumen is clamped and the tracheal lumen is ventilated to confirm movement and breath sounds of the right lung. Whenever a right-sided DLT is used, ventilation of the right upper lobe must be verified. This can be accomplished by careful auscultation over the right upper lung field or, more accurately, by fiberoptic bronchoscopy. When a left-sided DLT is used, the risk of occluding the left upper lobe bronchus by advancement of the bronchial tip into the distal left main bronchus should be considered.

DLTs may be malpositioned in up to 48% of cases despite careful inspection and auscultation.[44] The simplest way to evaluate proper positioning of a left-sided DLT is to perform fiberoptic bronchoscopy through the tracheal lumen. The carina is then visualized, and only the proximal edge of the bronchial cuff should be identified just distal to the carina. Herniation of the bronchial cuff over the carina to partially occlude the contralateral main-stem bronchus should be excluded. Fiberoptic bronchoscopy should then be performed via the bronchial lumen to identify the patent

left upper lobe orifice. When a right-sided DLT is used, the right upper lobe bronchial orifice must be identified while the bronchoscope is passed through the right upper lobe ventilating slot.

The use of an FOB to facilitate positioning of DLTs in children depends on the availability of small instruments. FOBs with an external diameter of 3.6 mm are commonly available and will pass through a 35F DLT. Smaller FOBs are needed when 26F, 28F, and 32F DLTs are used (see Table 15.5 for "limiting diameters").

In the adult population, the depth of insertion of the DLT is directly related to the height of the patient.[45] No equivalent measurements are available as yet in children. Fortunately, there are very few reports in children of airway damage from DLTs.

The high-volume, low-pressure cuffs should not damage the airway, provided that the cuffs are not overinflated with air or distended with nitrous oxide. Alternatively, saline may be used to inflate the cuffs.

A disadvantage of DLTs is the need to change the DLT to a single-lumen ETT if mechanical ventilation is required after surgery. This is a particular problem for children in whom tracheal intubation was difficult initially because of anatomic or functional limitations. Even when an airway was not classified as difficult preoperatively, it may become difficult secondary to facial and supraglottic edema, the presence of secretions and/or blood in the airway, and laryngeal trauma from the initial intubation. The use of an ETT exchange catheter may facilitate the exchange of a DLT for a single lumen ETT.[46] These devices are commercially available in a variety of sizes (Cook Medical) and allow oxygen insufflation and jet ventilation (see E-Fig. 14.3A-H).

Several important caveats should be considered before using an ETT exchange catheter. First, it must be small enough to pass through the tracheal lumen of the DLT. This should be tested in vitro before the procedure is performed in vivo. Second, it should never be advanced against resistance, and the clinician must always be cognizant of the depth of insertion; perforations of the tracheobronchial tree have been reported.[47] Third, a jet ventilator should be immediately available in case the new ETT does not follow the exchange catheter into the trachea and oxygenation via the exchange catheter is needed. The jet ventilator should be preset to a peak inspiratory pressure of 25 psi (172 kPa) by an inline regulator. When passing an ETT over an ETT exchange catheter, a laryngoscope should be used to facilitate passage of the ETT into the trachea. It should be noted that the tip of the ETT may hang up on the laryngeal inlet and may require a 90-degree rotation clockwise or counterclockwise to successfully pass, should this occur.

General Considerations in the Management of Single-Lung Ventilation

Once the ETT, bronchial blocker, or DLT is in place, airway pressures should be confirmed during SLV. If peak airway pressure is 20 cm H_2O during two-lung ventilation with a given tidal volume, inflating pressure should not exceed 40 cm H_2O in SLV when the same tidal volume is delivered during SLV. In general, smaller tidal volumes with increased respiratory rates are used to deliver somewhat reduced minute ventilation with SLV as with two-lung ventilation. Some degree of permissive hypercapnia is targeted to minimize lung trauma.

After the child has been placed in the lateral decubitus position, proper ETT, bronchial blocker, or DLT position should be reconfirmed, because displacement may occur when turning the patient. Two-lung ventilation should be maintained for as long as possible before switching to SLV. When SLV is required, the minimum FIO_2 needed to maintain an acceptable oxygen saturation should be used. Assuming an intact hypoxic pulmonary vasoconstriction response, PaO_2 during SLV and an FIO_2 of 1.0 should be between 150 and 210 mm Hg.[48] The lungs should be initially ventilated with a tidal volume of 6 to 8 mL/kg at a ventilatory rate that maintains the $PaCO_2$ between 45 and 60 mm Hg, unless this degree of hypercapnia cannot be tolerated because of other physiologic factors (e.g., concomitant metabolic acidosis). Inadequate tidal volumes may lead to atelectasis in the ventilated lung (reduced functional residual capacity), and increased intrapulmonary shunting, resulting in hypoxemia. Large tidal volumes may force blood to the nondependent lung (similar to the application of positive end-expiratory pressure), thereby increasing the intrapulmonary shunt.[49,50]

After the institution of SLV, PaO_2 may continue to decrease for up to 45 minutes. Should hypoxemia develop, proper positioning of the indwelling blocker or tube should be reconfirmed by fiberoptic bronchoscopy, if possible. Several techniques can be used to improve oxygenation. The most effective maneuver for improving PaO_2 is the application of CPAP to the nondependent lung.[51] Insufflation of oxygen to achieve a CPAP of 10 cm H_2O, for example, produces alveolar inflation and decreases intrapulmonary shunt fraction. Usually this can be accomplished without significant expansion of the lung or interference with surgical conditions. If the PaO_2 continues to decrease despite the application of CPAP to the deflated lung, a malpositioned bronchial blocker or tube should be considered. This may be signaled by a sudden increase in the inflation pressure, a decrease in tidal volume, and/or a change in the capnogram. When a DLT is in place, the surgeon may aid repositioning. The surgeon can palpate the bronchi and manually occlude the main bronchial lumens, thereby guiding the tip of the DLT into the correct position. When the cause of the hypoxemia and/or hypercarbia cannot be readily identified, the balloon or cuff should be deflated and both lungs ventilated after informing the surgeon of the problem.

SLV may be associated with substantial lung injury, and measures should be undertaken to minimize adverse effects of SLV on the lung. Collapse and subsequent reexpansion of lung tissue during SLV has been associated with an increase in proinflammatory markers and alveolar damage.[52,53] In a study of 28 children undergoing SLV for thoracic surgery, a preoperative dose of methylprednisolone 2 mg/kg IV decreased both interleukin 6 levels and respiratory resistance, and increased the serum concentrations of tryptase and the antiinflammatory cytokine, interleukin 10. Three of 15 children in the placebo group and none of the 13 in the treatment group experienced clinically significant intraoperative and postoperative respiratory complications.[54]

A potentially therapeutic intervention to mitigate lung injury associated with SLV is the administration of surfactant. Surfactant instilled into the subsequently deflated lung reduced the concentration of inflammatory cytokines in a piglet model of SLV.[55] A more clinically practical method of reducing lung injury during SLV is to minimize the FIO_2 and use a lung protective strategy during the procedure. The use of 50% O_2 caused less lung injury in animals subjected to SLV for 3 hours than 100% O_2.[56] Young pigs that were mechanically ventilated with a lung protective strategy using a tidal volume of 5 mL/kg and a positive end-expiratory pressure (PEEP) of 5 cm H_2O demonstrated less lung injury than those ventilated with a tidal volume of 10 mL/kg and no PEEP.[57] Anesthesiologists should consider the use of the minimum FIO_2 needed to maintain an acceptable oxygen saturation, as well as small tidal volumes and adequate levels of PEEP, in the ventilated lung

TABLE 15.6 Tube Selection for Single-Lung Ventilation in Children

during SLV to minimized lung injury. Preoperative administration of corticosteroids should also be considered.

Guidelines for selecting appropriate tubes (or catheters) for SLV in children are shown in Table 15.6. There is considerable variability in overall size and airway dimensions in children, particularly in adolescents. The recommendations shown in Table 15.6 are based on average values for airway dimensions. Larger DLTs may be safely used in large adolescents.

SURGICAL LESIONS OF THE CHEST

Neonates and Infants

A variety of congenital intrathoracic lesions for which surgery is required may occur in the neonatal or infancy period. These include lesions of the trachea and bronchi, lung parenchyma, and diaphragm, as well as vascular abnormalities.

Tracheal stenosis may be acquired or congenital. Tracheal stenosis occurs most commonly because of prolonged tracheal intubation, often in preterm infants with respiratory distress syndrome. Ischemic injury of the tracheal mucosa may occur as a result of a tight-fitting ETT at the level of the cricoid cartilage, which becomes scarred and constricted after a period of time. *Subglottic stenosis* may develop, resulting in stridor and respiratory distress after a trial extubation. Nasal CPAP with high-flow oxygen may be used to maintain the oxygen saturation early after extubation. If oxygen desaturation and hypercarbia persist despite the CPAP, tracheal reintubation may be required.

Tracheal and/or esophageal compression may occur as a result of a variety of lesions in the chest, including vascular rings and slings (see also Chapters 14 and 33).

An FOB is used to evaluate the severity of the stenosis and exclude other causes of stridor (e.g., vocal cord paralysis or laryngomalacia). When general anesthesia is required, inhalational anesthesia may be administered via a face mask, with the FOB inserted through an adapter in the mask and into the nasopharynx. This is usually performed while the infant breathes spontaneously.[58] Noninvasive imaging studies are being increasingly used for the diagnosis of a variety of congenital airway lesions, including vascular rings.[58] Bronchography and "virtual" CT scanning may also be useful.[59,60]

A cricoid split procedure may be performed for infants with acquired subglottic stenosis. After diagnostic bronchoscopy, the trachea is either intubated with an ETT or a rigid bronchoscope is left in place during the operation. Anesthesia may be maintained with inhalational agents or an IV anesthetic technique, such as with propofol and remifentanil.[61] Typically, an ETT ID 0.5 mm larger than the original ETT is placed after the repair.

For infants with severe *congenital tracheal stenosis,* a laryngotracheoplasty may be performed. This procedure involves the placement of a costal, auricular, or laryngeal cartilage graft into the anterior and/or posterior trachea.[62] In some cases, a stent may be positioned within the trachea. These infants may require a tracheal tube and mechanical ventilation for a variable period of time postoperatively. In these cases, sedation, analgesia, and at times neuromuscular blockade are maintained after surgery.

Pulmonary sequestrations result from disordered embryogenesis, producing a nonfunctional mass of lung tissue supplied by anomalous systemic arteries. Children may present with cough, pneumonia, and failure to thrive; these signs often occur during the neonatal period, and usually before 2 years of age. Diagnostic studies include CT of the chest and abdomen, and arteriography. Magnetic resonance imaging may provide high-resolution images, including definition of the vascular supply, which may obviate the need for angiography. Surgical resection is performed once the diagnosis is confirmed. Nitrous oxide should be avoided in these cases. Positive-pressure ventilation does not usually expand pulmonary sequestrations.

Congenital cystic lesions in the thorax may be classified into three categories.[63] *Bronchogenic cysts* result from abnormal budding or branching of the tracheobronchial tree. They may cause respiratory distress, recurrent pneumonia, and/or atelectasis because of lung compression. *Dermoid cysts* are clinically similar to bronchogenic cysts but differ histologically because they are lined with keratinized, squamous epithelium rather than respiratory (ciliated columnar) epithelium. They usually manifest later in childhood or adulthood. *Cystic adenomatoid malformations* are structurally similar to bronchioles but lack associated alveoli, bronchial glands, and cartilage.[64] Because these lesions communicate with the airways, they may become overdistended as a result of gas trapping, leading to respiratory distress in the first few days of life. When they are multiple and air filled, cystic adenomatoid malformations may resemble congenital diaphragmatic hernias radiographically. Treatment is surgical resection of the affected lobe. As with congenital diaphragmatic hernias, prognosis depends on the amount of remaining lung tissue, which may be hypoplastic because of compression in utero.[65]

Congenital lobar emphysema often manifests with respiratory distress shortly after birth.[66] This lesion may be caused by "ball-valve" bronchial obstruction in utero, causing progressive distal overdistention with fetal lung fluid. The resultant emphysematous lobe may compress lung tissue bilaterally, resulting in a variable degree of hypoplasia. Congenital cardiac deformities are present in about 15% of children with congenital lobar emphysema.[67] Radiographic signs of hyperinflation may be misinterpreted as tension pneumothorax or atelectasis on the contralateral side (Fig. 15.9). Positive-pressure ventilation may exacerbate lung hyperinflation. Nitrous oxide is contraindicated, and isolation of the lungs during anesthesia is desirable (see also Chapter 37, Fig. 37.10).

Congenital diaphragmatic hernia is a life-threatening condition that occurs in approximately 1 in 2000 live births. Failure of a

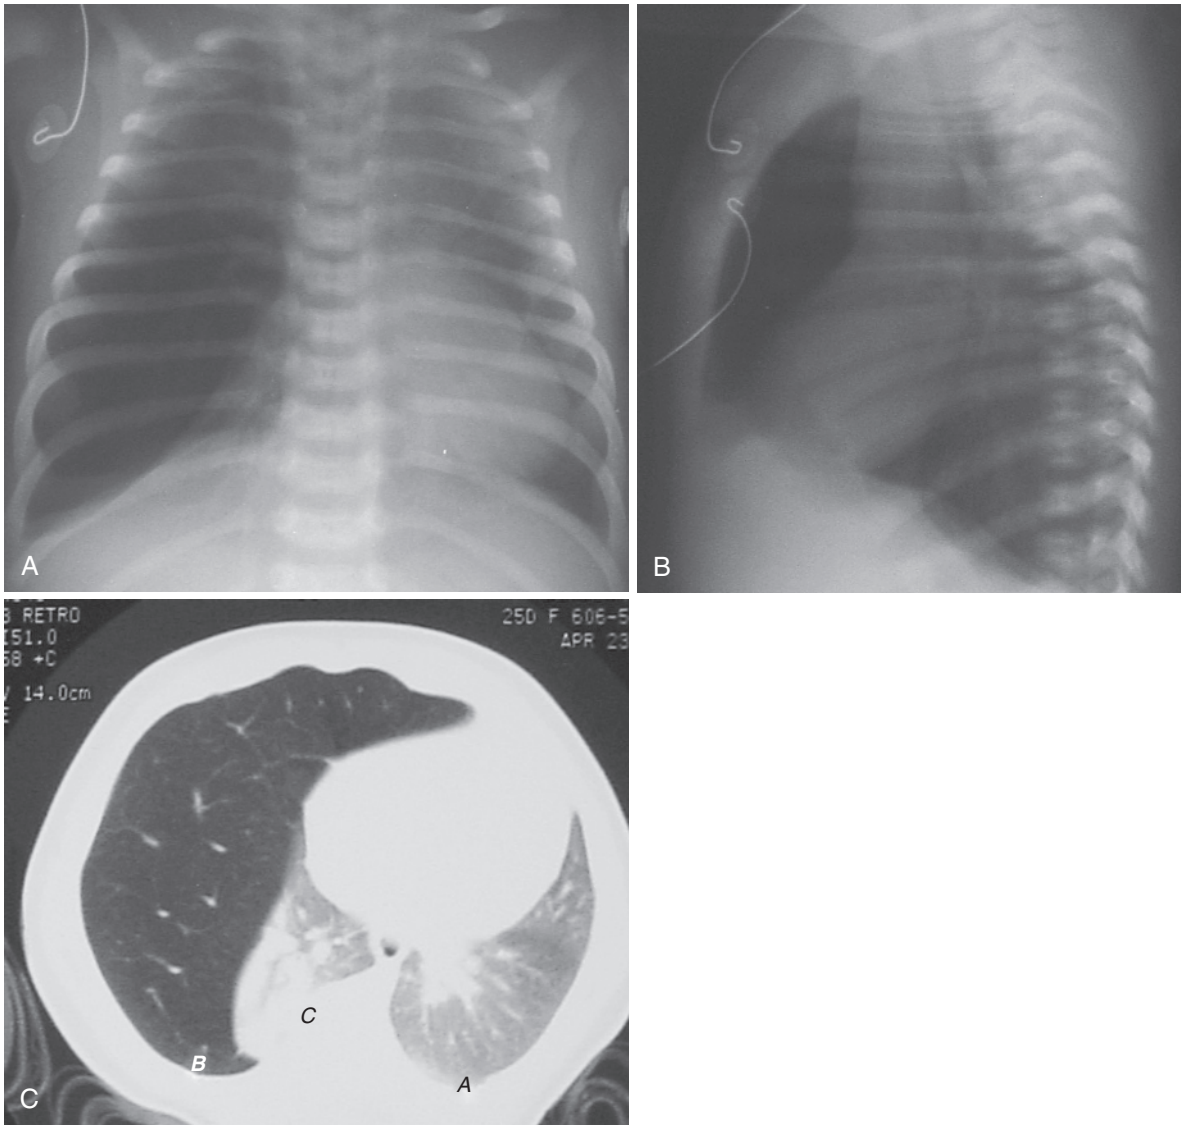

FIGURE 15.9 Congenital lobar emphysema of the right lower lobe. Plain radiography illustrates hyperlucency of the right lung on the anteroposterior image **(A)** and posterior displacement of the heart and mediastinum on the lateral image **(B)**. The computed tomography scan **(C)** demonstrates compression of the left lung *(A)* and right upper lobe *(C)* as well as hyperinflation of the right lower lobe *(B)*.

portion of the fetal diaphragm to develop allows abdominal contents to enter the thorax, interfering with normal lung growth. In 80% to 90% of diaphragmatic defects, a portion of the posterior diaphragm fails to close, (80%–85% of cases on the left side), forming a triangular defect known as the *foramen of Bochdalek.* Hernias through the foramen of Bochdalek that occur early in fetal life usually cause respiratory failure immediately after birth owing to pulmonary hypoplasia. The diagnosis is often made prenatally, and fetal surgical repair has been described.[68] Neonates present with tachypnea, a scaphoid abdomen, and absent breath sounds over the affected side. Chest radiography typically shows bowel in the left hemithorax, with deviation of the heart and mediastinum to the right and compression of the right lung (Fig. 15.10). Right-sided hernias (see Fig. 15.10C) may occur late and manifest with milder signs. In the presence of significant respiratory distress, bag-and-mask ventilation should be avoided and immediate tracheal intubation should be performed (see also Chapter 37). Distention of the thoracic gut postnatally with aggressive bag-and-mask positive pressure further compresses the inflated lungs, rendering ventilation and oxygenation more difficult.

Because pulmonary hypertension with right-to-left shunting contributes to severe hypoxemia in neonates with congenital diaphragmatic hernia, a variety of pulmonary vasodilators have been used to increase oxygenation. These include tolazoline, prostacyclin, dipyridamole, and nitric oxide.[69–73] High-frequency oscillatory ventilation has been used in conjunction with vasodilator therapy to improve oxygenation before surgery.[74] Occasionally, prostaglandin E_1 is used to maintain a patent ductus arteriosus and reduce right ventricular afterload. In cases of severe lung hypoplasia and pulmonary hypertension refractory to these therapies (e.g., PaO_2 <50 mm Hg with FIO_2 of 1.0), extracorporeal membrane oxygenation (ECMO) should be initiated early to

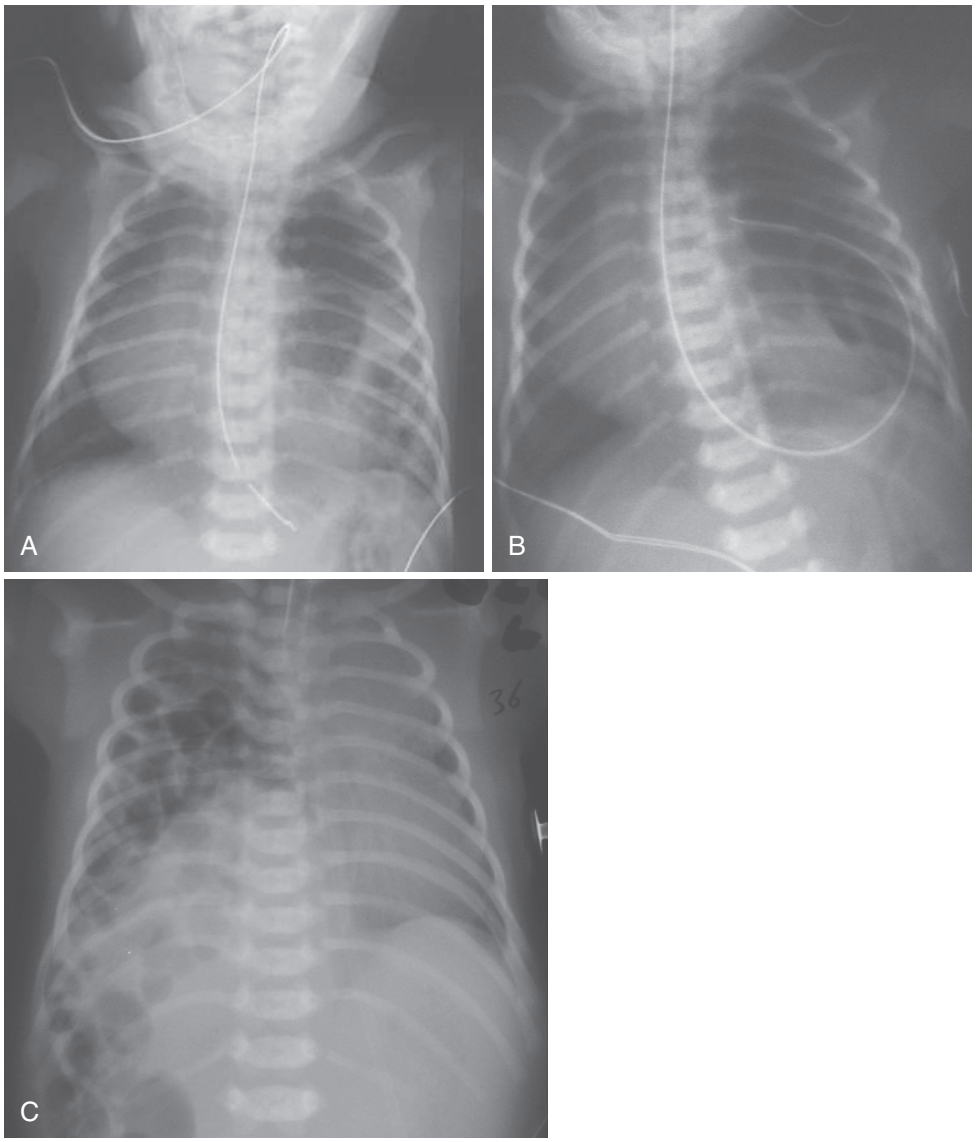

FIGURE 15.10 The majority of congenital diaphragmatic hernias are left sided. **A,** Chest radiography demonstrates the presence of bowel in the left hemithorax. **B,** A nasogastric tube has been advanced into the stomach. **C,** Congenital diaphragmatic hernias may also occur on the right side.

avoid progressive lung injury. Improved outcomes have been associated with early use of ECMO followed by delayed surgical repair.[75]

A particularly poor prognosis is predicted if congenital diaphragmatic hernia is associated with cardiac deformities, preoperative alveolar-to-arterial oxygen gradient greater than 500 mm Hg, or severe hypercarbia despite aggressive ventilation strategies.[76,77] Prognosis has also been correlated with pulmonary compliance and radiographic findings.[78,79]

Surgical correction via a subcostal incision with ipsilateral chest tube placement may be performed before, during, or immediately after ECMO.[80,81] In neonates undergoing surgical repair without ECMO, pulmonary hypertension is the major cause of morbidity and mortality. Hyperventilation to induce a respiratory alkalosis and 100% oxygen may be administered to decrease pulmonary vascular resistance. The anesthetic should be designed to minimize sympathetic discharge, which may exacerbate pulmonary hypertension (e.g., a high-dose opioid technique). The lungs of these infants should be ventilated with small tidal volumes and low inflating pressures to avoid a pneumothorax on the contralateral (usually right) side. Both nitric oxide and high-frequency oscillatory ventilation have been used during surgical repair.[82,83] A high index of suspicion of right-sided pneumothorax should be maintained, and a thoracostomy tube should be placed in the event of acute deterioration of respiratory or circulatory function. It is also imperative that normal body temperature, intravascular volume, and acid-base status be maintained. Mechanical ventilation is continued postoperatively in nearly all infants because lung compliance is markedly reduced after surgery (a consequence of returning the thoracic gut to the abdomen and the increased abdominal pressure on the diaphragm).

Failure of the central and lateral portions of the diaphragm to fuse, comprising *10%–15% of cases of diaphragmatic hernias,* results in a retrosternal defect known as the *foramen of Morgagni.* This

usually manifests as signs of bowel obstruction rather than respiratory distress. Repair is usually performed via an abdominal incision (see also Chapter 37).

Tracheoesophageal fistula and/or *esophageal atresia* occur in approximately 1 in 4000 live births. In 80% to 85% of afflicted infants, this lesion includes esophageal atresia with a distal esophageal pouch and a proximal tracheoesophageal fistula.[84,85] The fistula is usually located one to two tracheal rings above the carina. Affected neonates present with spillover of pooled oral secretions from the pouch and may develop progressive gastric distention and tracheal aspiration of acidic gastric contents via the fistula. A common association is the **VACTERL** complex, consisting of **v**ertebral, **a**norectal, **c**ardiac, **t**racheal, **e**sophageal, **r**enal, and/or **l**imb defects.[86] Esophageal atresia is confirmed when an orogastric tube passed through the mouth cannot be advanced more than about 7 cm (Fig. 15.11). The proximal pouch tube should be secured and continuous suction applied, after which a chest radiograph is diagnostic (see also Chapter 37).

Mask ventilation and tracheal intubation are avoided before surgery if possible, because they may exacerbate gastric distention and further compromise respirations. Once the trachea is intubated, it is occasionally necessary to occlude the tracheal orifice of the fistula with the tracheal tube. The tip of the tracheal tube is positioned just above the carina by auscultation of diminished breath sounds over the left axilla as the tube is advanced into the right main-stem bronchus, after which the tube is retracted until breath sounds are increased over the left chest (Fig. 15.12A). A small FOB may be passed through the tracheal tube to confirm appropriate placement. Rarely, an emergency gastrostomy is performed because of massive gastric distention. Placement of a balloon-tipped catheter in the fistula via the gastrostomy may be performed under guidance with an FOB, to prevent further gastric distention and/or enable effective positive-pressure ventilation in cases of significant lung disease or very large fistulas (see Fig. 15.12B).[87] "Antegrade" occlusion of a tracheoesophageal fistula has also been reported with a balloon-tipped catheter advanced through the trachea into the fistula (see Fig. 15.12C).[88] Preoperative evaluation should be performed to diagnose associated anomalies, particularly cardiac, musculoskeletal, and gastrointestinal defects, which occur in 30% to 50% of affected infants.[89] A poor prognosis for infants with tracheoesophageal fistula and esophageal atresia has been associated with prematurity and underlying lung disease, as well as the coexistence of other congenital anomalies.[90]

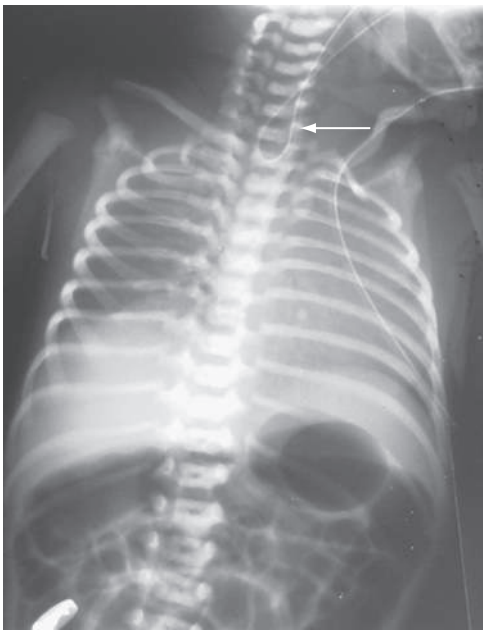

FIGURE 15.11 Tracheoesophageal fistula with esophageal atresia. Note the feeding tube coiled in the esophageal pouch (*arrow*) and the presence of a large volume of gas in the abdomen.

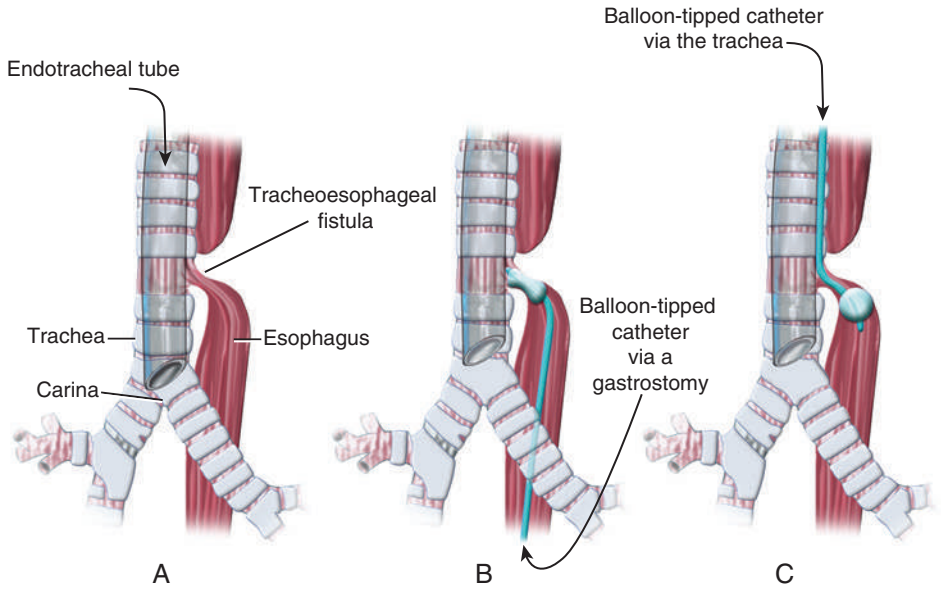

FIGURE 15.12 Methods for minimizing gastric insufflation in infants with a tracheoesophageal fistula. The tip of the ETT may be placed distal to the fistula in cases in which the fistula is well proximal to the carina **(A)**. Alternatively, a balloon-tipped catheter may be placed in the fistula via a gastrostomy **(B)** or via the trachea **(C)**.

Surgical repair has generally involved a right thoracotomy and extrapleural dissection of the posterior mediastinum, although a thoracoscopic approach has become more common recently. In most cases, the fistula is ligated and primary esophageal anastomosis is performed ("short gap atresia"). In cases in which the esophageal "gap" is long, the proximal segment is preserved for subsequent staged anastomosis, with or without intestinal interposition.[85] The trachea may be intubated with the infant breathing spontaneously, or during gentle positive-pressure ventilation with small tidal volumes to avoid gastric distention. If a gastrostomy tube is in place, occlusion of the fistula may be confirmed by cessation of bubbling via underwater tubing connected to the gastrostomy or the appearance of CO_2 in the end-tidal gas.[65] Alternatively, the tracheal tube may be positioned in the main-stem bronchus, opposite the side of the thoracotomy incision, until the fistula is ligated.

Esophageal atresia without connection to the trachea occurs much less commonly. These lesions are generally diagnosed by radiography after inability to pass an orogastric tube, at which time an absence of gas in the abdomen may be noted (see Fig. 37.9). So-called H-type tracheoesophageal fistula without esophageal atresia is relatively rare. Infants with H-type lesions may present later in childhood or adulthood with recurrent pneumonias or gastric distention during positive-pressure ventilation (see E-Fig. 37.2).[91,92]

Persistent symptoms associated with aspiration and respiratory distress after fistula ligation warrant investigation. Radiographic investigations including a barium swallow and/or rigid bronchoscopy with a 30-degree scope may be needed to identify a persistent fistula or a second fistula.[93]

Childhood

Some of the lesions described earlier may not be diagnosed until childhood. These include pulmonary sequestration, cystic lesions, and lobar emphysema. Other disorders for which thoracic surgery is performed in children, either for definitive treatment or diagnostic purposes, include neoplasms, infectious diseases, and musculoskeletal deformities.

Anterior mediastinal masses include neoplasms of the lung, mediastinum, and pleura. These tumors may be primary or metastatic. Perhaps the most common primary tumors are *lymphoblastic lymphoma,* a form of non-Hodgkin lymphoma, and *Hodgkin disease.* Less commonly, teratomas (germ cell tumors), thymomas, as well as thyroid, parathyroid, and mesenchymal tumors may manifest as anterior mediastinal masses.[94] Signs and symptoms that result from vascular and/or airway compression may include dyspnea, orthopnea, pain, coughing, pleural effusion, and/or superior vena cava syndrome (swelling of the upper arms, face, and neck).[95,96]

Preoperative evaluation should include CT, echocardiography, and flow-volume studies whenever feasible (see Fig. 13.7). Tracheal, bronchial, and/or vascular (superior vena cava or pulmonary outflow tract) compression, as detected by CT, is associated with a high incidence of serious complications during induction of anesthesia.[96] However, CT scans are static pictures that may not identify dynamic compression of an airway or vascular outflow tract. These tumors may occur as extrathoracic or intrathoracic, variable obstruction or fixed obstruction. Echocardiography identifies compression of the superior vena cava or pulmonary outflow tract. Flow-volume loops may be effective in detecting dynamic compression of the airways, although their utility in adult patients has been questioned[97] (see Chapter 13 and Figs. 13.6 and 13.7).

Establishing the correct diagnosis often requires a tissue biopsy. More often than not, there is an urgency to secure the tissue for diagnosis, because T-cell–type non-Hodgkin lymphoblastic lymphomas, which constitute 30% to 40% of non-Hodgkin lymphoma, have a 12-hour doubling time.[98] A rapid diagnosis and chemotherapy prescription may prevent widespread dissemination of the tumor. Indeed, today, the 5-year survival of Hodgkin and non-Hodgkin lymphoblastic lymphoma exceeds 80%. Every effort should be made to secure a tissue diagnosis by lymph node or bone marrow biopsy using local anesthesia or sedation, thereby precluding the need for general anesthesia and facilitating early treatment.[99] If peripheral tissue diagnosis cannot be obtained and signs of severe airway and/or circulatory compromise are present, careful consideration should be given to administering a 12- to 24-hour burst of corticosteroids, initiating chemotherapy, and/or treating with limited radiation to decrease the size of the tumor and reduce the risk of life-threatening compression of the airway or major vessels under anesthesia. The risk is that any or all of these interventions may cause involution of the tumor and compromise the tissue diagnosis; thus some oncologists prefer to avoid such interventions prebiopsy.[100,101] Corticosteroids effect a reduction in tissue mass (i.e., tumor lysis) of lymphomas by inducing apoptosis in the tumor via a number of mechanisms.[102] One study found that four features were predictive of perianesthesia complications in these children: orthopnea, upper body edema, great vessel compression, and main-stem bronchial compression (odds ratio of 5.1 to 8).[103] A second study found that the extent of vascular and airway compression, according to radiologic investigations, was predictive of perianesthesia complications.[99] It must be emphasized that adolescents and adults have different risk factors than children younger than 8 years of age. In adults, for example, intraoperative complications have been associated with pericardial effusions diagnosed by CT scans, whereas postoperative respiratory complications have been associated with greater than 50% tracheal compression on preoperative CT.[104] Great care must be taken to properly prepare these children and the families for general anesthesia, together with the attendant risks.

Induction of anesthesia in children with anterior mediastinal masses may be associated with severe airway obstruction and circulatory collapse.[99] This may occur even in children without signs or symptoms of respiratory or cardiovascular compromise.[105,106] Therefore a preoperative assessment of what position provides the most reliable and consistently good gas exchange should be sought from the child or the parents (nocturnal sleep position). Recommended anesthetic techniques for children with anterior mediastinal masses include inhalation induction or a slow IV induction (with ketamine or propofol), with maintenance of spontaneous respirations. The latter offsets the effect of gravity, which pulls the tumor onto the pulmonary artery, superior vena cava, and/or tracheobronchial tree, causing life-threatening cardiopulmonary consequences.[98,101,107] The use of CPAP while maintaining spontaneous respirations maintains functional residual capacity that is otherwise reduced under anesthesia.[108] In adolescents and adults, neuromuscular blockade is commonly used to facilitate tracheal intubation and prevent coughing associated with DLT placement. The morbidity associated with neuromuscular blockade appears to be minimal as long as appropriate precautions are taken. The actual risks in young children, however, have not been studied.[104] Keeping the head of the bed elevated may decrease the deleterious effects of supine positioning, including cephalad displacement of the diaphragm and secondary reduction of thoracic volume.[109] Placing the child in a partial or even full left lateral decubitus position may help to maintain airway patency and reduce cardiovascular and/or tracheal compression.[98] Performing tracheal

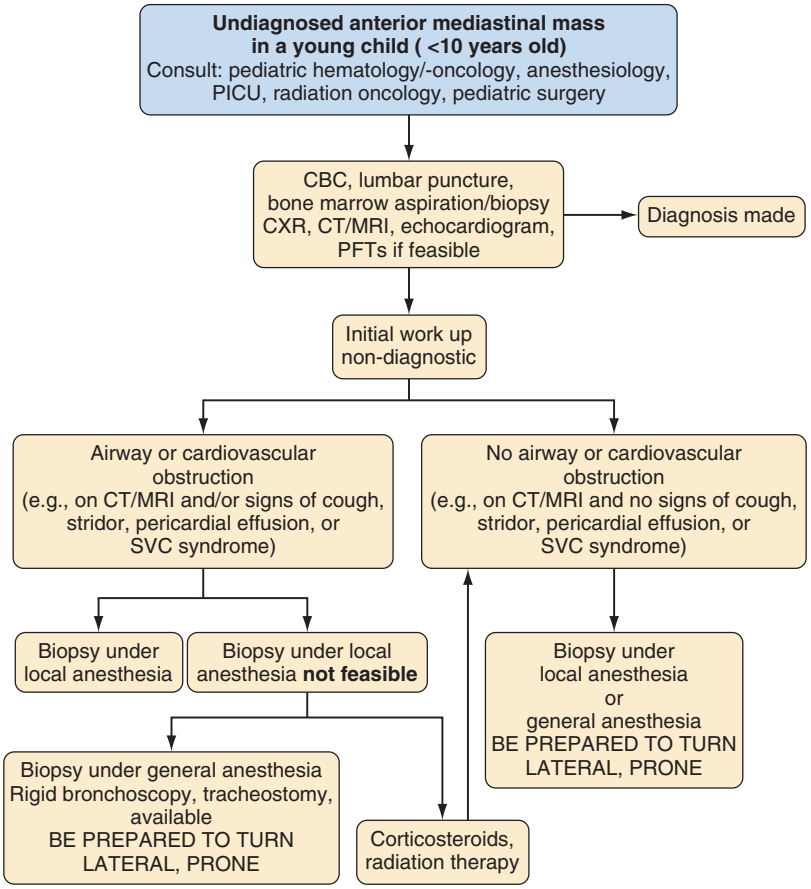

FIGURE 15.13 Algorithm for management of a child with a mediastinal mass. *CBC,* complete blood cell count; *CPB,* cardiopulmonary bypass; *CT,* computed tomography; *CXR,* chest radiograph; *LP,* lumbar puncture; *MRI,* magnetic resonance imaging; *PFTs,* pulmonary function tests; *PICU,* pediatric intensive care unit; *SVC,* superior vena cava.

intubation while the patient is deeply anesthetized, without the use of muscle relaxants and positive-pressure ventilation, preserves the normal transpulmonary pressure gradient and improves flow through conducting airways.[110–112] The loss of negative intrathoracic pressure associated with neuromuscular blockade increases the risk of severe airway compression and reduction in pulmonary blood flow (i.e., cardiac output).[113] As an alternative to tracheal intubation, use of a laryngeal mask airway has been described.[114] However, this could be a hazardous airway should the child need to be turned prone to restore cardiac output. The use of a helium-oxygen (70%/30%) mixture has been recommended to decrease the resistance to breathing and to increase hemoglobin saturation when an anterior mediastinal tumor compresses the trachea and/or bronchi (where turbulent gas flow exists).[114] It should be remembered that at least 70% helium is needed to substantively increase the flow in the airway; this concentration limits the inspired concentration of oxygen. In the event of tracheal or bronchial collapse or the sudden disappearance of the capnogram (signaling a loss of pulmonary outflow) under anesthesia, lateral or prone positioning and/or rigid bronchoscopy may be lifesaving.[98] Alternatively, towel clips or similar devices may be placed in the xiphoid cartilage and sternal notch to lift the sternum and restore patency of the collapsed structure while a longer-term solution is planned. Performing a median sternotomy and cardiopulmonary bypass in this situation has been recommended but is impractical unless access for partial bypass has been established before induction of anesthesia.[101] Institutions should have an algorithm in place for the evaluation of children with anterior mediastinal masses that includes a multidisciplinary approach (Fig. 15.13).

Summary

The anesthesiologist caring for infants and children undergoing thoracic surgery faces many challenges. An understanding of the primary underlying lesion as well as associated anomalies that may affect perioperative management is paramount. Preoperative and intraoperative communication with the surgeon is also essential. A working knowledge of respiratory physiology and anatomy in infants and children is required for the planning and execution of appropriate intraoperative care. Familiarity with a variety of techniques for single-lung ventilation suited to the child's size will provide optimal surgical exposure while minimizing trauma to the lungs and airways.

Congenital Heart Disease

INCIDENCE

Congenital heart disease (CHD) is the most common congenital anomaly, affecting approximately 1% of live births.[1] Although CHD represents the leading cause of neonatal mortality, advances in medical and surgical management over the past several decades, including significant contributions related to anesthesia care, now allow for survival of most affected infants.[2,3]

A bicuspid aortic valve is the most common cardiac defect, occurring in up to 1% of the population (Video 16.1).[4,5] Intracardiac communications, including ventricular septal defects (VSDs; Video 16.2) and atrial septal defects (ASDs; Video 16.3) represent the next most common congenital pathologies.[6,7] Among cyanotic lesions, tetralogy of Fallot (TOF) predominates, affecting almost 6% of children with CHD (Fig. 16.1).[8] In the first week of life, D-transposition of the great arteries is the most frequently encountered cause of cardiac cyanosis (Fig. 16.2); TOF may not be detected until later in life because in some infants cyanosis is absent or only mild arterial desaturation is present.

SEGMENTAL APPROACH TO DIAGNOSIS

The segmental, sequential approach is the essence of diagnostic assessment in CHD.[9–11] It assumes a stepwise, systematic examination of all cardiac structures or segments and their relationships (i.e., connections or alignments between segments) by navigating through the heart in the direction of blood flow. The principle of this scheme is that specific cardiac chambers and vascular structures have characteristic morphologic properties that determine their identities, rather than their positions within the body.[12]

The approach starts by determining the cardiac position within the thorax, the direction of the cardiac apex, and the arrangement or situs of the thoracic and abdominal organs. The cardiac position can be described as the spatial location of the majority of the cardiac mass within the thorax, using the sternum as the midline reference (Fig. 16.3). The cardiac orientation refers to the alignment from the base (great arteries) to the apex (ventricular apex). In most cases, the cardiac position and base-to-apex orientation are in agreement, meaning that both are aligned in the same direction. Thus, for simplicity the following terms are frequently used in clinical practice: *levocardia* if the heart is in the left hemithorax and the ventricular apex is directed toward the left (as is case of the normal heart); *dextrocardia* if the heart is located in the right hemithorax and the apex is toward the right; and *mesocardia* if the heart and apex are in midline position. An abnormal location of the heart within the thorax (i.e., cardiac malposition) can result from displacement by adjacent structures or underlying noncardiac malformations (e.g., diaphragmatic hernia, lung hypoplasia, scoliosis).

The visceral situs, or sidedness, of the abdominal organs (i.e., liver and stomach) and atrial situs are considered independently (Fig. 16.4). Visceral situs is classified as *solitus* (i.e., normal arrangement of viscera, with the liver on the right, stomach on the left, and a single spleen on the left), *inversus* (i.e., inversion of viscera, with the liver on the left and stomach on the right), or *ambiguous* (i.e., indeterminate visceral position). Abnormal arrangements or sidedness of the abdominal viscera, heart, and lungs, as seen in heterotaxy syndromes, are associated with a high likelihood of complex cardiovascular disease. The atrial situs, atrioventricular (AV) connections, ventricular looping (i.e., position of the ventricles as a result of the direction of bending of the straight heart tube

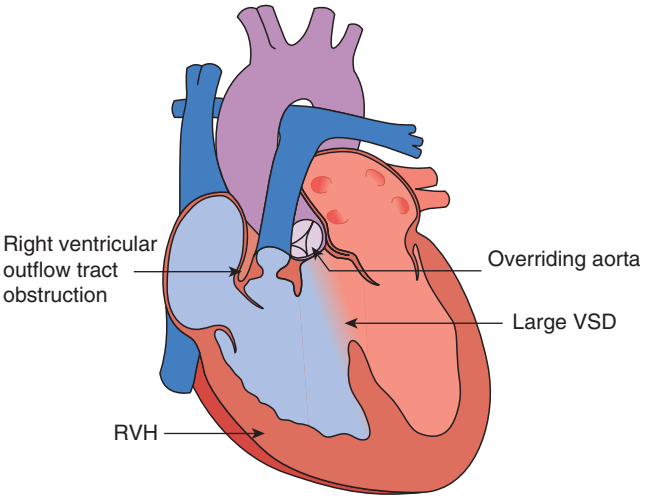

FIGURE 16.1 The anatomic features of tetralogy of Fallot are depicted, consisting of right ventricular outflow tract obstruction (may occur at any or a combination of valvar, subvalvar, and supravalvar levels), a large ventricular septal defect (*VSD*), aortic override, and right ventricular hypertrophy (*RVH*). The purple color in the aorta represents arterial desaturation from intracardiac right to left shunting. Note the infundibular narrowing and the hypoplastic pulmonary arteries.

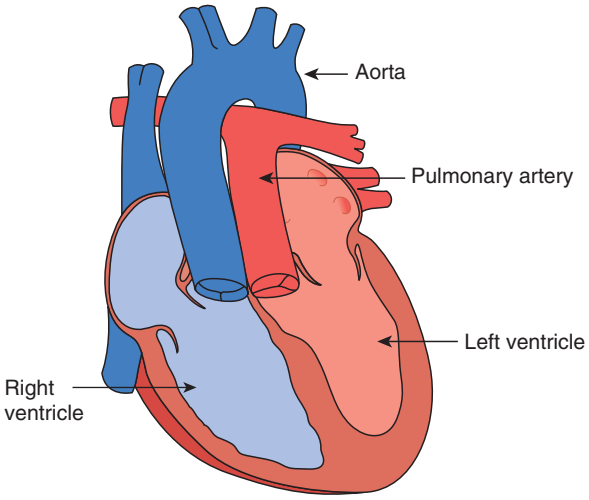

FIGURE 16.2 Diagrammatic representation of D-transposition of the great arteries displaying the discordant ventriculoarterial connections. In this lesion the right ventricle ejects blood into the aorta and the left ventricle ejects blood into the pulmonary artery. Intercirculatory mixing is essential for survival in this anomaly.

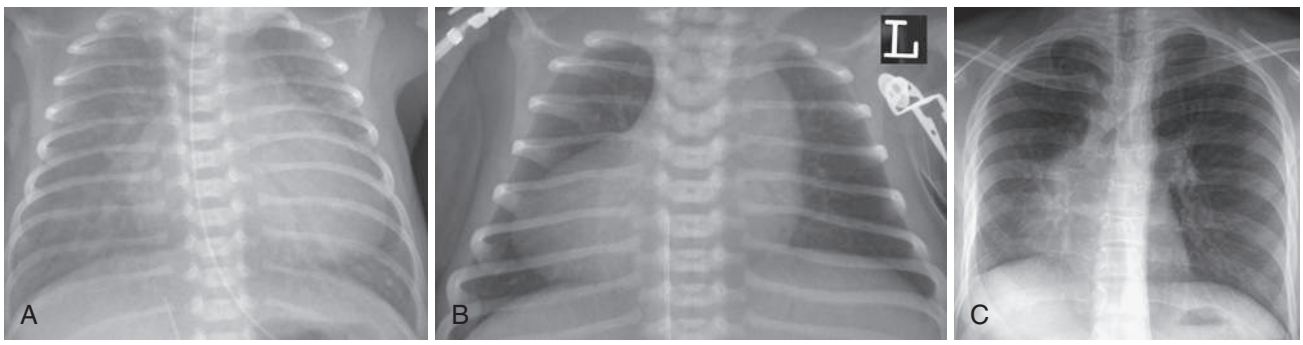

FIGURE 16.3 Chest radiographs demonstrate various cardiac positions within the thorax. **A,** Levocardia (left-sided position). **B,** Dextrocardia (right-sided position). **C,** Mesocardia (centrally located cardiac mass).

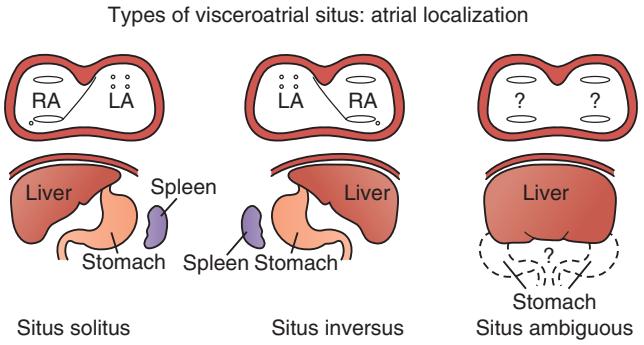

FIGURE 16.4 Three types of visceroatrial situs are shown. *Situs solitus* indicates a normal arrangement of the viscera and atria, with the right atrium (*RA*) on the right side and the left atrium (*LA*) on the left side. The stomach and spleen are on the left, and the liver is on the right. *Situs inversus* indicates inverted arrangement of viscera and atria, with the RA on the left side and the LA on the right side, as in a mirror image of *situs solitus*. In visceral *situs inversus*, the stomach and spleen are on the right, and the liver is on the left. *Situs ambiguous* denotes that the visceroatrial situs is anatomically uncertain or indeterminate because the anatomic findings are ambiguous. (From Park. Chamber localization and cardiac malposition. In: *Park's Pediatric Cardiology for Practitioners,* Sixth Edition. Philadelphia: Elsevier; 2014:314–318.)

during early development), ventriculoarterial connections, and the relationship between the great vessels are then delineated. Additional goals of the complete morphologic evaluation in CHD include, among other aspects, interrogation of structures such as the branch pulmonary arteries, aortic arch, and coronary arteries.

Associated malformations are described, including number, size, and location of septal defects, valvar pathology, and great vessel abnormalities. Whereas many types of congenital defects fall neatly into well-known classification schemes, others, such as those associated with heterotaxy syndromes where there is malposition of the heart and abdominal organs, are often more difficult to precisely define.

PHYSIOLOGIC CLASSIFICATION OF DEFECTS

The wide spectrum of cardiovascular malformations in the pediatric age group presents a challenge to the clinician who does not specialize in the care of these children. Even for those with a focus or interest in cardiovascular disease, the range of structural defects and the varied associated hemodynamic perturbations can be overwhelming (see Chapter 23).

Several classification schemes have been proposed to characterize and categorize the various congenital cardiac defects, including some that categorize structural defects into simple or complex lesions, consider the presence or absence of cyanosis, or recognize whether pulmonary blood flow is increased or decreased.[13–15] A physiologic classification system can facilitate understanding of the basic hemodynamic abnormalities common to a group of congenital or acquired lesions and assist in patient management (Table 16.1).[16,17] The following approach sorts pediatric heart disease into six broad categories according to the underlying physiology or common features of the pathologies.

Volume Overload Lesions

Volume overload lesions typically are caused by left-to-right shunting at the level of the atria, ventricles, or great arteries. If the location of the shunt is proximal to the mitral valve (e.g., ASD, partial anomalous pulmonary venous return, unobstructed total anomalous pulmonary venous return), right heart dilation occurs. Lesions distal to the mitral valve (e.g., VSD, patent ductus arteriosus [PDA], truncus arteriosus) lead to left heart dilation. Children with AV septal defects, also known as AV canal or endocardial cushion defects, also fit into this category. The magnitude of the shunt and resultant pulmonary-to-systemic blood flow ratio ($\dot{Q}_{pulm}/\dot{Q}_{sys}$) dictate the presence and severity of the symptoms and guide medical and surgical therapies. Diuretic therapy and afterload reduction are beneficial in controlling pulmonary overcirculation and ensuring adequate systemic cardiac output. Surgical interventions or transcatheter approaches may be required to address the primary pathology associated with ventricular volume overload (see Chapter 22).

TABLE 16.1 Physiologic Classification of Congenital Heart Disease (Representative Lesions)

Volume Overload Lesions
Atrial septal defect
Ventricular septal defect
Atrioventricular septal defect
Patent ductus arteriosus
Truncus arteriosus
Obstruction to Systemic Blood Flow
Aortic stenosis
Coarctation of the aorta
Interrupted aortic arch
Hypoplastic left heart syndrome
Obstruction to Pulmonary Blood Flow
Pulmonary stenosis
Tetralogy of Fallot
Pulmonary atresia
Parallel Circulation
D-Transposition of the great arteries
Single-Ventricle Lesions
Tricuspid atresia
Double-inlet left ventricle
Unbalanced atrioventricular septal defect
Intrinsic Myocardial Disorders
Cardiomyopathy
Myocarditis

Obstruction to Systemic Blood Flow

Several lesions are associated with systemic outflow tract obstruction. Conditions characterized by ductal-dependent systemic blood flow in the neonate include critical aortic stenosis, severe aortic coarctation, aortic arch interruption, and hypoplastic left heart syndrome. Prostaglandin E_1 therapy maintains ductal patency and ensures adequate systemic blood flow until surgical or transcatheter intervention is performed in the first few days of life to relieve the systemic outflow obstruction. Inotropic and/or mechanical ventilatory support are often necessary in the affected neonate/small infant. These children frequently also have significantly increased pulmonary blood flow with a large $\dot{Q}_{pulm}/\dot{Q}_{sys}$ ratio, requiring diuretic therapy and manipulation of the systemic and pulmonary vascular resistances to control blood flows.

Obstruction to Pulmonary Blood Flow

Defects with pulmonary outflow tract obstruction include those with ductal-dependent pulmonary blood flow. Critical pulmonary valve stenosis and pulmonary atresia with intact ventricular septum, for example, are anomalies that rely on patency of the ductus arteriosus for pulmonary blood flow. Affected infants frequently require prostaglandin E_1 infusions for management of their cyanosis until the pulmonary outflow obstruction is relieved or bypassed.

Parallel Circulation

In the neonate with D-transposition of the great arteries, the pulmonary and systemic circulations operate in parallel rather than in the normal configuration in series. In this condition, the right ventricle ejects deoxygenated blood into the aorta, and the left ventricle ejects oxygenated blood into the pulmonary arteries. Mixing of blood in this setting can occur at the atrial, ventricular, or ductal levels (see Fig. 16.2). Although prostaglandin E_1 therapy maintains ductal patency and enhances intercirculatory mixing, balloon atrial septostomy to create or enlarge an existing restrictive interatrial communication, allowing for or augmenting mixing, is necessary in some infants. Mixing at the atrial level is considered much more effective than at the ventricular or ductal levels.

Single-Ventricle Lesions

This category is the most heterogeneous group, consisting of defects associated with AV valve atresia (i.e., tricuspid atresia), heterotaxy syndromes, and many others.[18] In some cases, both atria empty into a dominant ventricular chamber (i.e., double-inlet left ventricle), and although a second rudimentary ventricle can be present, the physiology is that of a single-ventricle or univentricular heart. Other cardiac malformations with two distinct ventricles (i.e., unbalanced AV septal defect) can also be considered in the functional single-ventricle category because of associated defects that may preclude a biventricular repair. A common feature of these lesions is complete mixing of the systemic and pulmonary venous blood at the atrial or ventricular level. Another frequent finding is aortic or pulmonary outflow tract obstruction.

An important goal in single-ventricle management involves optimization of the balance between the pulmonary and systemic circulations early in life. This is a critical issue because low pulmonary vascular resistance and limitation of the ventricular volume load are prerequisites for later palliative strategies and optimal outcomes in these children. These considerations are also relevant for anesthesia management during noncardiac surgery (see Chapter 23).[19–23] The child with single-ventricle physiology represents a high-risk group for adverse events during noncardiac surgery.[24]

Intrinsic Myocardial Disorders

Children with primary cardiomyopathies or myocarditis have intrinsic diseases of cardiac muscle. They frequently have impaired systolic and/or diastolic ventricular function and benefit from therapies tailored to their particular disease process.

Acquired Heart Disease

CARDIOMYOPATHIES

The term *cardiomyopathy* refers to diseases of the myocardium associated with cardiac dysfunction.[25,26] They have been classified as primary and secondary forms.[27] Primary forms are those predominantly involving the heart owing to genetic mutation, including ion channelopathies, acquired disease, or mixed. The most common types in children are hypertrophic, dilated or congestive, and restrictive cardiomyopathies. Other forms include left ventricular noncompaction[28–30] and arrhythmogenic right ventricular dysplasia.[31–33] Secondary forms of cardiomyopathies are those with systemic involvement in other organ systems as seen in association with neuromuscular disorders such as Duchenne muscular dystrophy, glycogen storage diseases (i.e., Pompe disease), hemochromatosis or iron overload, and mitochondrial disorders. Chemotherapeutic agents such as anthracyclines can result in dilated cardiomyopathy.[34] It is important to understand the hemodynamic processes behind the myocardial disease and implications for acute and chronic management.

Hypertrophic cardiomyopathy (HCM) is characterized by ventricular hypertrophy without an identifiable hemodynamic cause that results in increased myocardial wall thickness.[35] This accounts for almost 40% of cardiomyopathies in children.[36–38] The condition represents a heterogeneous group of disorders, and most of the identified genetic defects exhibit autosomal dominant inheritance patterns.[39,40] This is the most common cause of sudden cardiac death (SCD) in athletes.[41,42] Some children with HCM have systemic outflow tract obstruction (i.e., obstructive cardiomyopathy). It is unclear whether the few with hypertrophic obstructive cardiomyopathy, previously known as idiopathic hypertrophic subaortic stenosis, are at increased risk for SCD compared with children without obstruction.

Most children with HCM present for evaluation of a heart murmur, syncope, palpitations, or chest pain. Occasionally, an abnormal electrocardiogram (ECG) leads to referral. An accurate family history is essential. An apical impulse is often prominent. Auscultation may reveal a systolic ejection outflow murmur that becomes louder with maneuvers that decrease preload or afterload (e.g., standing, Valsalva maneuver) or increased contractility. The murmur decreases in intensity with squatting and isometric hand grip. A mitral regurgitant murmur can also be present. The ECG meets criteria for left ventricular hypertrophy in most children (Fig. 16.5). In some, the electrocardiographic findings can be striking (Fig. 16.6). A hypertrophied, nondilated left ventricle is a diagnostic feature as determined by two-dimensional echocardiography (Video 16.4 A and B). In many children, the hypertrophy can be asymmetric (Video 16.5A and B). Echocardiography is the preferred imaging tool for long-term assessment of ventricular wall thickness, chamber dimensions, presence and severity of obstruction, systolic and diastolic function, valve competence, and response to therapy. Other diagnostic approaches such as cardiac catheterization and magnetic resonance imaging (MRI) can add helpful information in some cases.

The care of children with HCM includes maintenance of adequate ventricular preload, particularly in those with dynamic obstruction. Diuretics are not indicated and can be detrimental to the hemodynamic state by reducing left ventricular volume and increasing the outflow tract obstruction. Drugs that augment myocardial contractility (e.g., inotropic agents, calcium infusions) are not well tolerated. Patients usually undergo continuous electrocardiographic monitoring (i.e., Holter recording) and exercise testing for risk stratification.[43] β-Blockers and calcium channel blockers are the primary drugs for outpatient therapy.[44] Therapies range widely and include longitudinal observation with medical management of heart failure and arrhythmias, implantation of cardioverter-defibrillators, surgical myotomy or myectomy, transcatheter alcohol septal ablation, and cardiac transplantation.

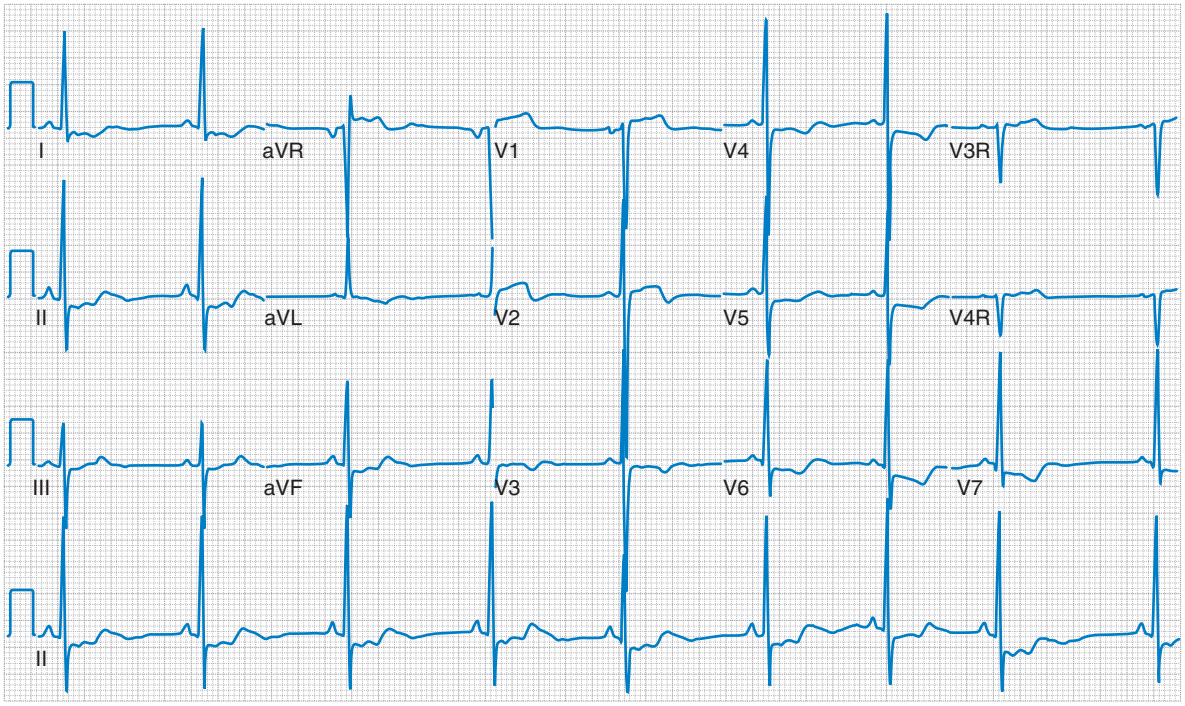

FIGURE 16.5 The electrocardiogram from an adolescent with hypertrophic cardiomyopathy demonstrates left ventricular hypertrophy (i.e., deep S wave in V_1 and tall R waves over the left precordial leads). The ST-segment depression and T-wave inversion over the left precordial leads are related to repolarization changes associated with left ventricular hypertrophy, also known as a *strain pattern*. Reciprocal ST-segment elevation can be seen over the right precordial leads. This recording is consistent with sinus bradycardia (heart rate average of 50 beats/minute).

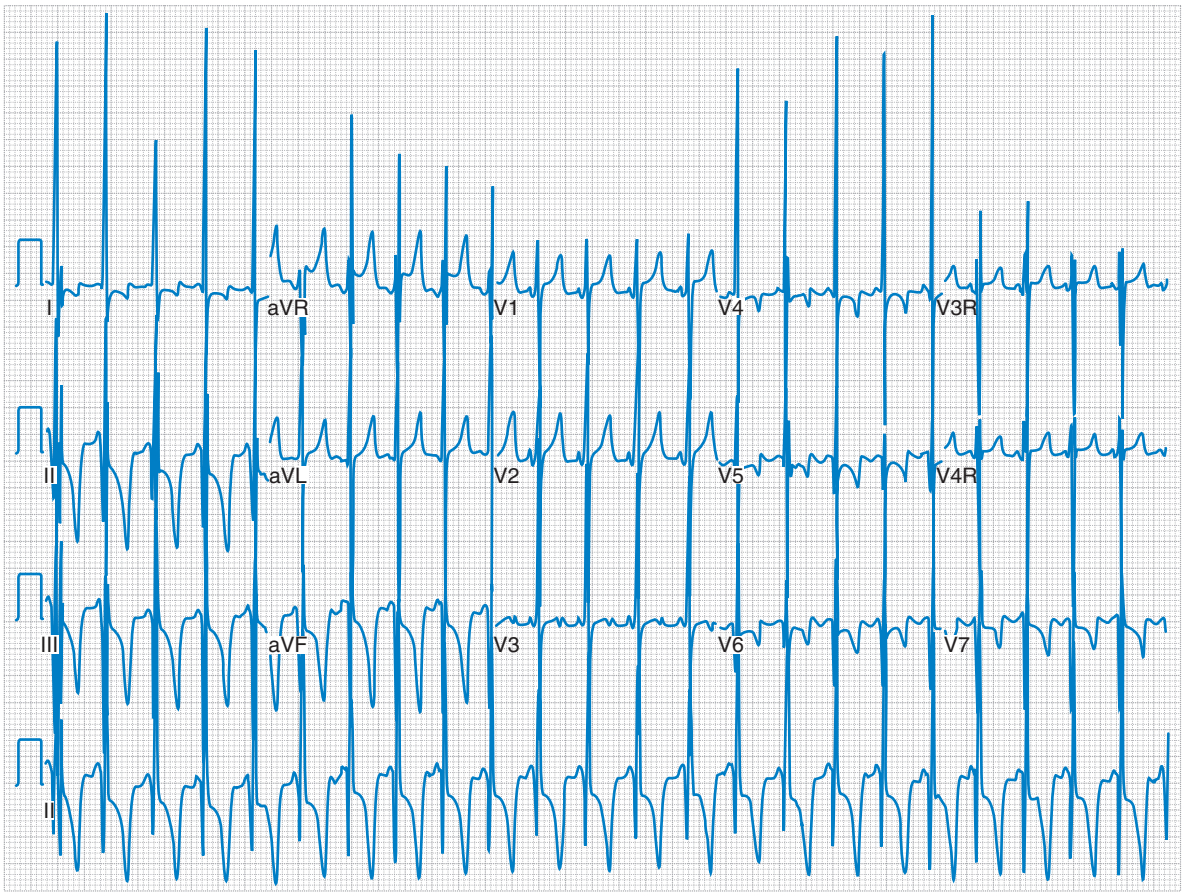

FIGURE 16.6 Pompe disease is an inherited disorder characterized by the accumulation of glycogen in cells. The electrocardiographic tracing for an infant with this glycogen storage disease and a severe form of hypertrophic cardiomyopathy displays dramatic right and left ventricular voltages, in addition to ST-segment and T-wave abnormalities. The recording is displayed at full standard (10 mm/mV), meaning that the electrocardiogram was not reduced in size to fit on the paper.

Dilated cardiomyopathy (DCM), also known as congestive cardiomyopathy, is characterized by thinning of the left ventricular myocardium, dilation of the ventricular cavity, and systolic functional impairment.[45–47] The broad number of etiologies range from genetic or familial forms to those caused by infections, metabolic derangements, toxic exposures, and degenerative disorders.[48,49] Chronic tachyarrhythmias can also lead to DCM that may or may not improve after control of the rhythm disturbance.[50,51]

Most children with DCM present with signs and symptoms of congestive heart failure (e.g., tachypnea, tachycardia, gallop rhythm, diminished pulses, hepatosplenomegaly). The chest radiograph typically demonstrates cardiomegaly, pulmonary vascular congestion, and in some cases, atelectasis (Fig. 16.7). The ECG can identify the likely cause of the cardiac dysfunction in those with cardiomyopathy caused by rhythm disorders or anomalous origin of the left coronary artery from the pulmonary artery (ALCAPA). The ECG can confirm the diagnosis by demonstrating a dilated left ventricle with decreased systolic function (Video 16.6A and B). Therapy in the acute setting is supportive and aimed at stabilization. Management includes afterload reduction, inotropic support, and mechanical ventilation. Unlike children with HCM, those with DCM have a volume-loaded, poorly contractile ventricle. Gentle diuresis is beneficial. The infusion of large fluid boluses is poorly tolerated and can result in hemodynamic decompensation and cardiovascular collapse. The outcomes of children with dilated cardiomyopathy vary. For most, either the extent of cardiac dysfunction remains unchanged or recovery of left ventricular systolic function occurs, but others eventually require cardiac transplantation.[52,53] A subset of children with severe disease may require mechanical circulatory support as a bridge to recovery or cardiac transplantation (Fig. 16.8A and B) (see Chapter 21).[54–56]

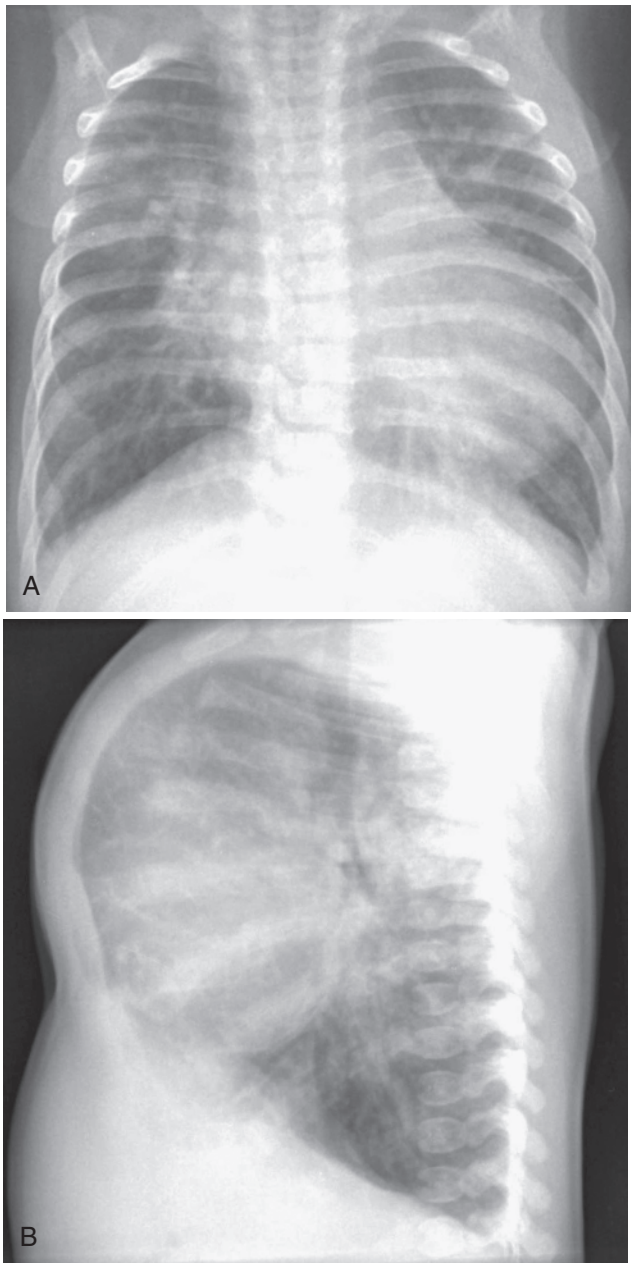

FIGURE 16.7 Chest radiographs of a young child with dilated cardiomyopathy in the posteroanterior **(A)** and lateral **(B)** projections demonstrate moderate to severe cardiomegaly and pulmonary vascular congestion.

Restrictive cardiomyopathy (RCM) is the least common of the major types of cardiomyopathies (5%) and portends a poor prognosis when it manifests during childhood.[57–59] The disorder is characterized by diastolic dysfunction related to a marked increase in myocardial stiffness resulting in impaired ventricular filling; most cases are thought to be idiopathic. Presenting symptoms are nonspecific and primarily respiratory. Occasionally, the diagnosis is made after a syncopal or sudden near-death event. The physical examination can demonstrate hepatosplenomegaly, peripheral edema, and ascites.

The echocardiographic hallmark of RCM is that of severe atrial dilation and normal or small-sized ventricles (Video 16.7). The marked diastolic dysfunction leads to increased end-diastolic pressures, left atrial hypertension, and secondary pulmonary hypertension. Children with RCM are prone to thromboembolic complications and anticoagulation therapy is frequently recommended. This is an important consideration during perioperative care because adjustments in the anticoagulation regimen may be necessary. Atrial and ventricular tachyarrhythmias can also occur. Optimal medical treatment is controversial because no specific agents or strategies have been shown to significantly alter outcomes.[60] Similar to children with HCM, diuretics often cause a decrease in the needed preload with detrimental effects on hemodynamics. Inotropic agents are not indicated because systolic function is preserved and the arrhythmogenic properties of inotropic drugs can induce a terminal event. In many centers, cardiac transplantation has been effectively used.[61]

MYOCARDITIS

Myocarditis is defined as inflammation of the myocardium, often associated with necrosis and myocyte degeneration.[62–64] In the United States, it is most often caused by a viral infection. Over the past 20 years, the spectrum of viral pathogens causing myocarditis has changed, such that adenovirus, enteroviruses (e.g., coxsackievirus B), and parvovirus have become the most frequent causes of fulminant disease.

The overall true incidence of myocarditis is unknown because it is frequently underdiagnosed and unrecognized as a nonspecific viral syndrome. A large, 10-year, population-based study on cardiomyopathy found an annual incidence of 1.24 cases per 100,000 children younger than 10 years of age; only a fraction of cases represented those with myocarditis.[65] The diagnosis is made using clinical history, physical examination, and imaging modalities. Myocarditis is highly suspected when a child presents

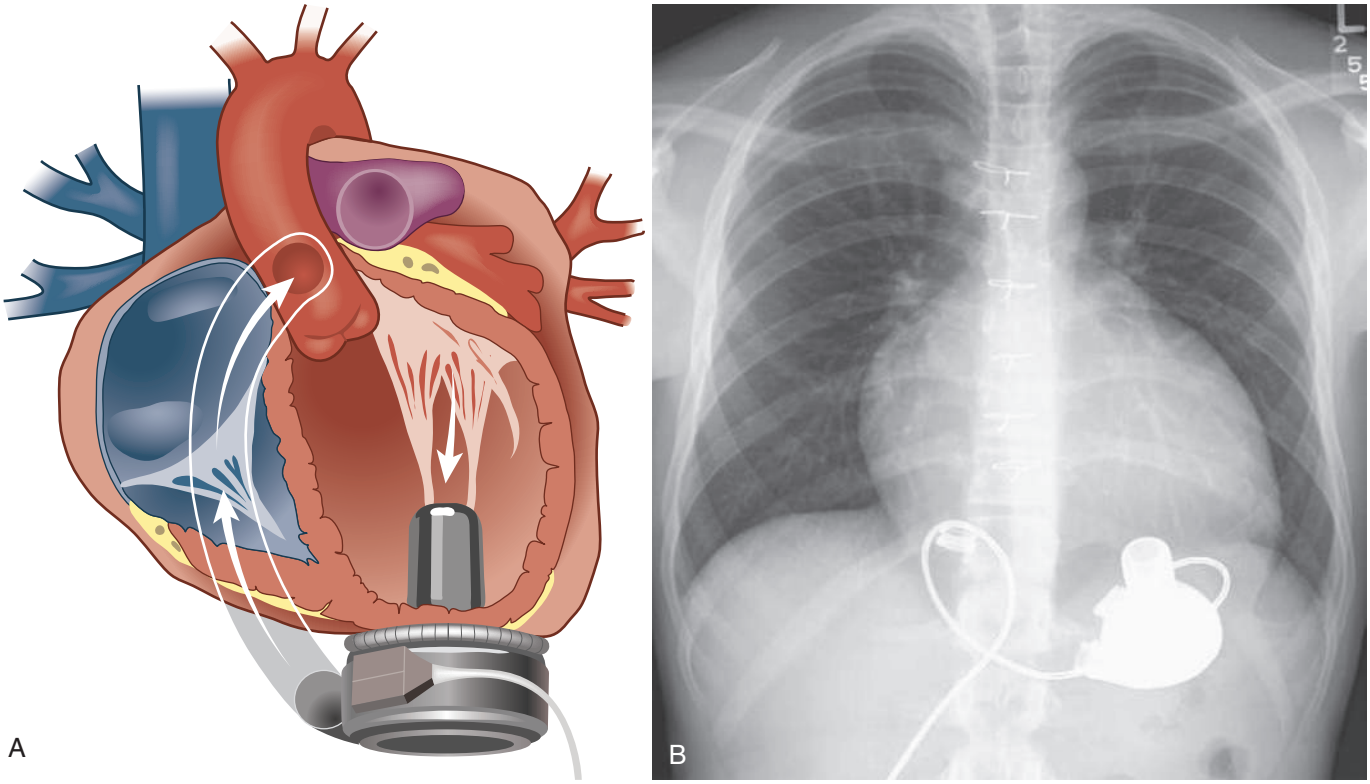

FIGURE 16.8 Mechanical circulatory support may be required in children with dilated cardiomyopathy (DCM) and severe cardiac dysfunction. **A,** HeartWare ventricular assist system (HeartWare LVAD, Framingham, MA). This miniaturized implantable device consists of a small continuous-flow pump with integrated inlet cannula placed in the left ventricle, an outflow graft placed in the aorta (not radiopaque), and a driveline that connects to an external controller with a power source. **B,** Chest radiograph of a child with end-stage DCM after placement of HeartWare ventricular assist device for circulatory support as a bridge to cardiac transplantation. (Illustration **A** printed with permission from Texas Children's Hospital.)

FIGURE 16.9 The chest radiograph of a child with acute myocarditis shows severe cardiomegaly and mildly increased pulmonary vascularity.

with new-onset congestive heart failure or ventricular arrhythmias without evidence of structural heart disease. The ECG typically demonstrates low-voltage QRS complexes with tachycardia, which sometimes is ventricular in origin. Chest radiography often shows cardiomegaly with pulmonary vascular congestion (Fig. 16.9). Echocardiography displays ventricular dilation with decreased systolic function, similar to DCM, and it is useful in the exclusion of alternative diagnoses, such as pericardial effusion or coronary artery anomalies. Myocarditis is a clinical diagnosis because definitive confirmation requires the analysis of tissue obtained through myocardial biopsy in the catheterization laboratory or the operating room (rarely performed).

Many children with myocarditis have subclinical or mild clinical disease, whereas others progress to overt heart failure or arrhythmias, or both. Among children with heart failure, approximately one-third will regain full ventricular function, one-third will recover but continue to demonstrate impaired systolic function, and one-third will require cardiac transplantation.[66,67] A subset of children, not all of whom initially manifest severe symptoms in the acute period, will progress to develop DCM.

Although no specific therapies have been identified to directly treat the myocardial injury, a variety of strategies have been used.[68,69] The current paradigm includes diuresis and afterload reduction to improve myocardial performance without placing a large burden on an already failing heart. Rhythm disturbances are treated

appropriately. Therapy with immune modulation or suppression with intravenous (IV) immunoglobulin is the standard of care at many centers.[70,71] Mechanical circulatory support may be required in fulminant disease (see Chapter 21).[72,73]

RHEUMATIC FEVER AND RHEUMATIC HEART DISEASE

Acute rheumatic fever and rheumatic heart disease are leading causes of death related to acquired cardiac disease in developing countries and still occur, albeit infrequently, in developed countries.[74,75] The availability of antibiotic therapy for streptococcal tonsillopharyngitis (strep throat) has markedly reduced the incidence of this disease in the United States, but sporadic cases still occur.[76] The peak incidence in children occurs between 5 and 14 years of age.

Rheumatic fever results from infection by particular strains of group A β-hemolytic *Streptococcus* or *Streptococcus pyogenes* leading to a multisystemic inflammatory disorder. The incubation period for most strains of group A β-hemolytic *Streptococcus* is typically 3 to 5 days, although some children present with a more remote history of pharyngitis.

The clinical diagnosis of rheumatic fever is based on the Jones criteria. The combination of manifestations (major and minor) necessary to meet these criteria has been modified several times over the years. The most recent revision of the Jones criteria considered the contributions of echocardiography in the diagnosis of cardiac involvement.[77] The most common manifestations of acute rheumatic fever are carditis and arthritis; thus these are considered major criteria for diagnosis. Cardiac involvement or carditis occurs in 50% of children with their first attack of rheumatic fever. Rheumatic heart disease represents a sequela of the acute process, and it most frequently affects the mitral and aortic valves. The polyarticular arthritis has a migratory pattern, typically affecting large joints.

Primary prevention of rheumatic fever and rheumatic heart disease begins with prompt recognition and appropriate treatment of the initial streptococcal infection.[78] Penicillin is considered the treatment of choice for most patients. Secondary prevention with antibiotic prophylaxis is aimed at avoiding recurrences in individuals with a known history of rheumatic fever as they are considered at high risk. The duration of prophylaxis depends on several factors. Intramuscular injections of penicillin every 3 to 4 weeks is recommended. Current AHA guidelines no longer propose infective endocarditis (IE) prophylaxis for patients with rheumatic heart disease, except for those few instances where a prosthetic valve has been inserted or prosthetic material used in valve repair (refer to the following section).[79] In these cases, an alternate to penicillin is used because of the potential development of drug resistance.

Elective or emergent surgery may be required in a subset of children with severe cardiac involvement.[80] Mitral valve regurgitation is often the cause of congestive symptoms; medical management therefore has limited efficacy. Valve repair is always preferred to replacement.

INFECTIVE ENDOCARDITIS

Causes and Treatment

CHD has become the primary risk factor for IE in children in developed countries.[81,82] The risk is largely based on the nature of the cardiac condition. The infection results from deposition of bacteria or other pathogens on tissues in areas of abnormal or turbulent blood flow. The diagnosis of IE is made clinically by applying the modified Duke criteria.[83,84] Major criteria include demonstration of microorganisms (two positive blood culture results) and evidence of pathologic lesions by echocardiography. The presentation of the disease can be acute or subacute. New or changing heart murmurs can indicate the development of regurgitation or obstruction on an affected valve. Physical findings of systemic embolization (i.e., minor criteria) include splinter hemorrhages (i.e., linear streaks under the nail beds), Janeway lesions (i.e., painless macules on the hands or feet), Osler nodes (i.e., small, painful nodules on the fingers), and Roth spots (i.e., retinal hemorrhages with clear centers). Inflammatory markers, such as erythrocyte sedimentation rate and C-reactive protein, are typically increased, albeit nonspecific. Microscopic hematuria, as a manifestation of renal involvement, is frequently seen.

Acute bacterial endocarditis is most commonly caused by *Staphylococcus aureus*.[85] The clinical presentation includes high fevers, chills, myalgias, fatigue, and lethargy. Some children present in a critically ill state or in shock. Both left- and right-sided IE can occur in children with CHD.[86] Children with indwelling venous catheters have an expanded spectrum of pathogens known to cause acute IE, including coagulase-negative staphylococcal species or other nonbacterial organisms.

Subacute bacterial endocarditis (SBE) often has a more indolent course and presentation. Children present with low-grade fever, malaise, anemia, and somatic complaints such as fatigue or weakness. Most frequently, one of the *Viridians streptococcus* group and *Enterococcus* species is the underlying pathogen.

Initial evaluation for bacterial endocarditis includes serial blood cultures obtained from separate sites before initiation of antimicrobial therapy. The temporal frequency of cultures depends on the clinical scenario and stability of the child. In up to 20% of children with evidence of IE, a pathogen cannot be isolated (i.e., negative-culture endocarditis), requiring empirical treatment throughout. Transthoracic echocardiography is routinely performed to evaluate for evidence of vegetations or other abnormalities.[87] Although visualization of a vegetation establishes the diagnosis, a negative study does not exclude the diagnosis. Depending on how strongly the diagnosis is suspected, further imaging, including transesophageal echocardiography, may be necessary (Video 16.8A and B).[88] These imaging modalities are also valuable during follow-up.

Parenteral antibiotics are initiated after blood cultures are collected. Broad-spectrum agents are used initially, and after a pathogen has been identified, the antibiotic regimen is narrowed. Daily blood cultures are obtained until they remain sterile, confirming the adequacy of treatment. A prolonged course of antibiotics (i.e., 4–6 weeks) is required in all children. This can be facilitated by placement of a peripherally inserted central catheter (PICC). Home therapy for IE is feasible in some patients, but it depends on many factors, including clinical status, initial response to antibiotics, sensitivity of the organism to antimicrobial therapy, and the ability of infrastructure to support outpatient treatment of a serious infection (e.g., parental or family member's ability, home health care provider).

In some cases, children with IE require surgical intervention. Failure of medical therapy (i.e., inability to clear the bacteremia), abscess formation, refractory heart failure, large vegetation, and serious embolic phenomenon are indications for surgical intervention. Typically, the procedures involve resection of a vegetation, tissue debridement, or repair of consequent cardiac abnormalities. These children should subsequently receive endocarditis prophylaxis for at-risk procedures for the rest of their lives.

A high level of suspicion for IE must be maintained when evaluating a child with known heart disease and persistent bacteremia (or fungemia) or a fever of unknown origin. The same holds true for any child with foreign material in the heart or vascular tissue, such as indwelling central venous catheters, transvenous pacemakers or defibrillators, and closure devices.

Endocarditis Prophylaxis

The risk for developing IE from transient bacteremia is extremely small in children with normal intracardiac anatomy; however, as previously discussed, certain cardiac conditions are predisposed to acquiring endocarditis. The American Heart Association guidelines do not recommend antibiotic prophylaxis based exclusively on an increased lifetime risk of endocarditis. They propose that it should be restricted to those at greatest risk for an adverse outcome resulting from IE. Children in this category include those with specific congenital heart defects or after certain interventions, prosthetic cardiac valves, a history of IE in the past, and cardiac transplant recipients with valvular disease (Table 16.2).[79] Since the implementation of these guidelines in 2007, a review of 1157 cases of IE from 37 pediatric institutions reported no change in the incidence of this condition between 2003 and 2010, supporting the current prophylaxis guidelines.[89]

Transient bacteremia can occur during dental procedures that involve the gingival tissues or the periapical region of teeth or perforation of the oral mucosa.[90] Although several respiratory tract procedures are associated with transient bacteremia, no definitive data demonstrate a cause-and-effect relationship between these procedures and IE. Caution may be warranted for children at high risk undergoing invasive procedures of the respiratory tract that involve incision or biopsy of the mucosa. In contrast to previous guidelines, routine prophylactic administration of antibiotics solely to prevent IE is not recommended for those undergoing genitourinary or gastrointestinal tract procedures. However, for specific clinical scenarios, antibiotic prophylaxis may be considered.[91] Routine endoscopy or transesophageal echocardiography does not merit routine antibiotic administration. Prophylaxis is not considered necessary for cardiac catheterization; and although many practitioners routinely administer antibiotics during transcatheter placement of devices, there is insufficient evidence to support this practice.

TABLE 16.2 Indications for Endocarditis Prophylaxis by the American Heart Association

- Congenital heart disease
  - Unrepaired cyanotic congenital heart defect, including palliative shunts and conduits
  - Completely repaired congenital heart defect with prosthetic material or device (whether placed at surgery or by transcatheter intervention, during the first 6 months after the procedure)
  - Repaired congenital heart defect with residual defect(s) at the site or adjacent to the site of a prosthetic patch or device
- Prosthetic cardiac valve
- Prior history of infective endocarditis
- Cardiac transplant recipient with valvular disease

From American Heart Association, Inc.

The guidelines recommend the administration of antibiotic prophylaxis 30 to 60 minutes before the procedure to achieve adequate tissue concentrations of antibiotics before bacteremia occurs (Table 16.3). The standard prophylactic regimen for children is for oral amoxicillin. For the child who is allergic to penicillin or ampicillin, oral alternatives include cephalexin, clindamycin, azithromycin, or clarithromycin. In children who are unable to ingest oral medications, alternative antibiotics include ampicillin, cefazolin, and ceftriaxone by an IV or intramuscular route. Since IV access is obtained in the majority of children who present for elective surgery or medical procedures after induction of anesthesia, it is prudent to administer the antibiotics as soon as IV access has been established to achieve adequate tissue levels of antibiotic before skin incision or other sources of bacteremia. If the child is allergic to penicillin or ampicillin and unable to swallow oral medications, cefazolin, ceftriaxone, or clindamycin can be used.

Although there was initial hesitation to alter the practice regarding endocarditis prophylaxis for patients with CHD undergoing gastrointestinal or genitourinary procedures following the most recent guidelines, many health care providers have now adopted the updated recommendations.[92,93]

KAWASAKI DISEASE

Kawasaki disease (i.e., mucocutaneous lymph node syndrome) is a fairly common and potentially fatal form of systemic vasculitis of unknown origin.[94] It is a condition seen predominantly in

TABLE 16.3 American Heart Association Guidelines for Prevention of Infective Endocarditis: Antibiotic Regimens

Situation	Antibiotic	DOSE[a] Children	DOSE[a] Adults
Able to take oral medication	Amoxicillin	50 mg/kg	2 g
Unable to take oral medication	Ampicillin	50 mg/kg IM or IV	2 g IM or IV
	or		
	Cefazolin or ceftriaxone	50 mg/kg IM or IV	1 g IM or IV
Allergic to penicillins or ampicillin and able to take oral medication	Cephalexin[b,c]	50 mg/kg	2 g
	or		
	Clindamycin	20 mg/kg	600 mg
	or		
	Azithromycin or clarithromycin	15 mg/kg	500 mg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone[c]	50 mg/kg IM or IV	1 g IM or IV
	or		
	Clindamycin	20 mg/kg IM or IV	600 mg IM or IV

IM, intramuscular; *IV*, intravenous.
[a]Single dose to be administered 30 to 60 minutes before the procedure. **The total pediatric dose should not exceed the adult dose.**
[b]Alternatively, another first- or second-generation oral cephalosporin is administered in an equivalent pediatric or adult dosage.
[c]Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria to penicillins or ampicillin.
From American Heart Association, Inc.

infants and young children. The disease can affect the coronary arteries resulting in dilation and aneurysmal formation.[95,96]

The diagnosis relies on clinical features. To meet criteria, a child must have persistent fevers and at least four of the following findings [97]:

- Polymorphous exanthem
- Peripheral extremity changes (e.g., erythema, desquamation, edema of the hands or feet)
- Bilateral, nonexudative conjunctivitis
- Cervical lymphadenopathy (often unilateral)
- Oral changes (i.e., strawberry tongue; red, dry, or cracked lips)

Nonspecific findings can include irritability, hydrops of the gallbladder, sterile pyuria, arthritis, and aseptic meningitis. Acute-phase reactants and thrombocytosis are usually present.

Intravenous gamma globulin (IVIG) and high-dose aspirin are recommended during the acute phase of the disease. In some cases, additional antiinflammatory therapy is needed. The incidence of coronary artery aneurysms is significantly reduced if high-dose IVIG is administered within the first 10 days of the illness. The presence of coronary artery aneurysms is considered diagnostic for Kawasaki disease (Fig. 16.10). In children with coronary artery aneurysms, low-dose aspirin therapy is administered, in some cases in combination with anticoagulants or antiplatelet drugs.[98] Myocardial ischemia and infarction, although uncommon, are important potential complications.[99] Anesthetic care in these children requires careful consideration regarding myocardial oxygen demand and supply; on rare occasions, coronary revascularization may be necessary.

CARDIAC TUMORS

Cardiac tumors are rare in children. The natural history and optimal treatment strategies are often determined from limited case series and small studies.[100–102] Atrial myxomas represent more than 90% of cardiac tumors in adults, but in children, they tend to be rhabdomyomas or fibromas.[103,104] Less common types include hemangiomas, myxomas (Video 16.9), Purkinje cell tumors, and teratomas. In adults, most tumors are found in the left atrium, but cardiac tumors in children can occur in any cardiac chamber. Malignant primary tumors are rare, and data on their outcomes are limited. Other nonprimary cardiac tumors, such as neuroblastoma, can invade vascular structures and extend into the heart.

Rhabdomyomas are the most common primary cardiac tumors in children.[105] They often involve the ventricular septum and left ventricle, and in most cases there are multiple tumors. Although they are considered benign, children can present with cardiomegaly, congestive heart failure, arrhythmias, or sudden death. The significance of a rhabdomyoma is determined largely by its size and any obstruction it may cause. Tumors of this type tend to regress over time or completely resolve; surgery is not indicated unless symptoms are present. Many children with cardiac rhabdomyomas have associated tuberous sclerosis.

Cardiac fibromas are the second most common type of pediatric primary cardiac tumors.[106] They are typically single and involve the ventricular free wall. In a subset of fibromas, the tumor can invade the conduction system. Surgery or cardiac transplantation may be required. The tumors can be very large, and complete surgical resection can alter cardiac function.

The primary concerns in the perioperative care of children with cardiac tumors are the impact of the mass on hemodynamics and the associated abnormalities of cardiac rhythm.[107]

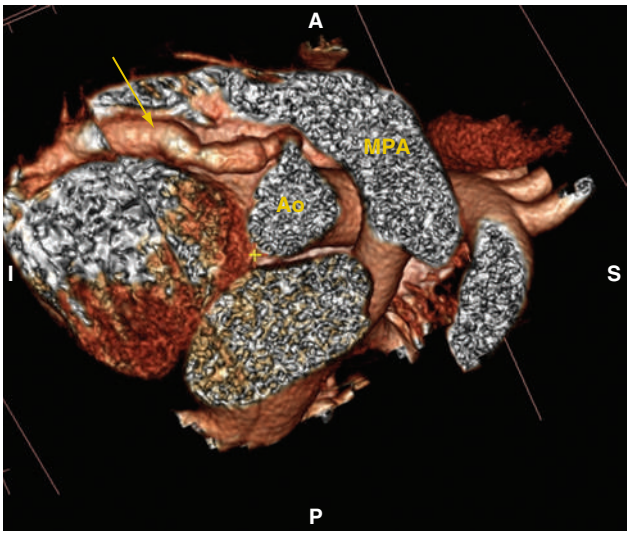

FIGURE 16.10 Magnetic resonance reconstruction at the level of the great vessels in a child with Kawasaki disease demonstrates a large, fusiform coronary artery aneurysm (*arrow*). *A*, anterior; *Ao*, aorta; *I*, inferior; *MPA*, main pulmonary artery; *P*, posterior; *S*, septal.

Heart Failure in Children

DEFINITION AND PATHOPHYSIOLOGY

Heart failure is a major field of interest and investigation in pediatric cardiology and the subject of various publications, scientific meetings, and several textbooks.[108–111] The cellular basis of heart failure, compensatory mechanisms, and therapeutic strategies in children have received the most attention. The following discussion highlights key concepts as they relate to anesthetic practice.

Heart failure is considered to be a pump and circulatory failure involving neurohumoral aspects of the circulation. Several conditions may ultimately compromise the ability to generate an adequate cardiac output to meet the systemic circulatory demands. This disease state does not necessarily imply impairment of ventricular systolic function. Diastolic heart failure is an increasingly recognized clinical entity.

ETIOLOGY AND CLINICAL FEATURES

Pediatric heart failure results from markedly different etiologies from those reported in adults.[112] The causes of heart failure in children vary with age. In the perinatal period, cardiac dysfunction can be related to birth asphyxia or sepsis or constitute an early presentation of CHD. The neonate with heart failure frequently presents with clinical signs of a low cardiac output state. Causes include left-sided outflow obstruction (e.g., aortic stenosis, aortic coarctation, hypoplastic left heart syndrome), severe valve regurgitation (e.g., Ebstein anomaly), or absent pulmonary valve syndrome.

During the first year of life, heart failure is predominantly caused by structural heart disease. Other causes include cardiomyopathies owing to inborn errors of metabolism or acute events such as myocarditis. In infants with heart failure, tachypnea, dyspnea, tachycardia, feeding difficulties, and failure to thrive are prominent features. The physical examination can display grunting respirations, rales, intercostal retractions, a gallop rhythm, and hepatosplenomegaly. Frequently, a mitral regurgitant murmur is present.

Beyond the first year of life, heart failure is a consequence of previous surgical interventions, unpalliated or unrepaired cardiovascular disease, cardiomyopathies, myocarditis, or anthracycline therapy for a malignancy. Occasionally, a child may present with severe ventricular systolic impairment related to ongoing myocardial ischemia as a result of a coronary artery anomaly or rarely because of acquired pathologies such as Kawasaki disease. Older children with heart failure exhibit exercise intolerance, fatigue, and growth failure, whereas adolescents have symptoms similar to those of adults (Table 16.4).

TREATMENT STRATEGIES

Therapy is tailored to the cause of the cardiac dysfunction and may include supportive care, mechanical ventilation, inotropic support, afterload reduction, prostaglandin E_1 therapy to maintain pulmonary or systemic blood flow, maneuvers to balance the systemic and pulmonary circulations, catheter-based interventions, and/or surgery.[113–116] The main goal of therapy for acute heart failure is to maintain organ perfusion. Pharmacologic agents include inotropes (used on a very-short-term basis, if necessary) and inodilators. Favored agents for use in children are diuretics, including aldosterone antagonists, angiotensin-converting enzyme inhibitors, and β-blockers.[117,118] Other drugs that have received attention in the management of pediatric heart failure include nesiritide (a recombinant form of human B-type natriuretic peptide) and carvedilol (a third-generation β-blocker).[119–121] An overview of diagnostic strategies and available therapies for pediatric heart failure can be found in Fig. 16.11.

ANESTHETIC CONSIDERATIONS

Anesthesia for children with heart failure can be quite challenging. The severity of the condition and degree of baseline decompensation can influence the likelihood of an untoward event and the potential for hemodynamic instability and a poor outcome. Several publications have addressed the risks associated with anesthesia in this setting.[122–124] It is important to first reexamine the risk/benefit ratio in these patients before going forward with the planned procedure. In most surgical settings, tracheal intubation and mechanical ventilation are indicated. The need for invasive monitoring should be based on the clinical situation, anticipated nature of the procedure, and impact on hemodynamic state.

TABLE 16.4 Symptoms Characteristic of Heart Failure in Children

	Commonly Encountered	Less Commonly Encountered
Infants and young children	• Tachypnea • Feeding difficulty (reflux, vomiting, feeding refusal) • Diaphoresis • Pallor	• Cyanosis • Palpitations • Syncope • Facial edema • Dependent edema • Ascites
Older children and adolescents	• Fatigue • Effort intolerance • Dyspnea • Orthopnea • Abdominal pain • Nausea • Vomiting	• Palpitations • Chest pain • Dependent edema • Ascites

Syndromes, Associations, and Systemic Disorders: Cardiovascular Disease and Anesthetic Implications

Many disorders, including those resulting from chromosomal abnormalities, single-gene defects, gene deletion syndromes, known associations (i.e., nonrandom occurrence of defects), and teratogenic exposure, can manifest as cardiovascular disease. The coexistence of frequently associated multiple organ system comorbidities with cardiovascular disease presents several challenges to the anesthesia care provider.

CHROMOSOMAL SYNDROMES

Trisomy 21

Trisomy 21 (Down syndrome) is the most common chromosomal anomaly, occurring with a frequency of 1 per 800 live births. The incidence increases sharply with advanced maternal age. Down syndrome results from Trisomy 21 in most children, but it may occur from a balanced or unbalanced chromosomal translocation or mosaicism. The phenotypes are indistinguishable. Affected children are typically smaller than normal for age. Craniofacial features include microbrachycephaly, short neck, oblique palpebral fissures, epicanthal folds, Brushfield spots, small and low-set ears, macroglossia, and microdontia with fused teeth. Mandibular hypoplasia and flattened facial features are common. A narrow nasopharynx with hypertrophic lymphatic tissue (e.g., tonsils, adenoids) in combination with generalized hypotonia frequently leads to obstructive sleep apnea. Other conditions include developmental delay, cervical spine disorders with vertebral and ligamentous instability (i.e., subluxation risk), thyroid disease, leukemia, obesity, subglottic stenosis, and gastrointestinal problems, particularly duodenal atresia.[125]

The preoperative assessment of children with Down syndrome should include a comprehensive evaluation and management plan to minimize risks.[126] The intellectual disability of these children may require the use of premedication or sedatives. Specific issues of concern include the potential for upper airway obstruction caused by a large tongue, postextubation stridor, and cervical spine injury.[127–130] Vascular access can be challenging. Subjectively, children have small and abnormal radial vessels, vascular hyperreactivity, fragile tissue consistency, and an increased risk for complications after arterial cannulation.[131]

Cardiovascular defects occur in 40% to 50% of children with Down syndrome, and it has been recommended that they all should undergo screening for CHD in early infancy.[132] The most common lesions include AV septal defects (Video 16.10), VSDs, TOF, and PDA. Bradycardia under anesthesia occurs commonly, although the mechanism is poorly understood.[133,134] Pulmonary hypertension can result from the cardiac pathology or from chronic hypoxemia caused by upper airway obstruction (i.e., obstructive sleep apnea) and should be considered in their management. Reduced nitric oxide bioavailability has been reported in patients with Down syndrome, leading to endothelial cell dysfunction and possibly explaining the observed increased pulmonary vascular reactivity.[135]

Trisomy 18

Trisomy 18 (Edwards syndrome) is recognized as the second most common chromosomal trisomy (1 per 3500 live births). Most children exhibit microcephaly, delayed psychomotor development, and developmental delay.[136] Characteristic craniofacial features include micrognathia or retrognathia and microstomia, which can affect airway management, as well as malformed ears, and microphthalmia.[137–139] Skeletal anomalies include clenched fingers and severe growth retardation. Neurologic problems include hypotonia and central nervous system malformations. Their high mortality rate is related to cardiac and renal problems, feeding difficulties, sepsis, and apnea caused by neurologic abnormalities.

Cardiovascular disease, consisting primarily of VSDs and polyvalvular disease, is present in most children with trisomy 18.[140,141] Implications for anesthesia care include the increased risk of congestive heart failure and aspiration pneumonia.[137] These children can require interventions to address associated gastrointestinal or genitourinary anomalies.

Trisomy 13

Trisomy 13 (Patau syndrome) is an uncommon autosomal trisomy with an incidence that ranges from 1 per 5000 to 12,000 live births. Major features include cleft lip and palate, holoprosencephaly, polydactyly, rocker-bottom feet, microphthalmia, microcephaly, and severe developmental delay.[142,143] Almost all children have associated cardiovascular defects, including PDA, septal defects, valve abnormalities, and dextrocardia.[140] The overall prognosis for these children is extremely poor.

Turner Syndrome

Turner syndrome is a genetic disorder characterized by partial or complete X chromosome monosomy.[144] The estimated incidence is 1 per 5000 live-born female infants. Spontaneous miscarriages occur commonly in affected fetuses. Features of this syndrome include webbed neck, low-set ears, multiple pigmented nevi and micrognathia, lymphedema, short stature, and ovarian failure.[145] Systemic manifestations include cardiac defects (notably aortic coarctation and bicuspid aortic valve), hypertension, hypercholesterolemia, renal anomalies, liver disease, and inflammatory bowel disease. Obesity is common in older children, together with an increased incidence of endocrine abnormalities such as hypothyroidism and diabetes.[144,146]

GENE DELETION SYNDROMES

Williams Syndrome

Williams syndrome (also known as Williams-Beuren Syndrome) is a congenital disorder with an incidence of 1 per 10,000–20,000 live births. In most cases, it results from a deletion in the long arm of chromosome 7, altering the elastin gene.[147] Features of Williams syndrome are elfin facies, hypersocial personality, endocrine abnormalities (including hypercalcemia and hypothyroidism), developmental delay, growth deficiency, and altered neurodevelopment. Structural cardiovascular abnormalities, which occur in 80% of these children, most commonly include valvar and supravalvular aortic stenosis (Fig. 16.12) and aortic coarctation.[148,149] The arteriopathy, manifested as stenosis, can also involve the pulmonary arteries, origins of the coronary arteries, or other vessels (e.g., aortopathy). Diffuse narrowing of the abdominal aorta can be associated with renal artery stenosis.

Several reports have described acute hemodynamic deterioration, cardiovascular collapse, and death during anesthesia.[150–152] Two conditions can increase morbidity and the potential for anesthesia and sedation-related cardiac arrest: coronary artery abnormalities, leading to myocardial ischemia, and severe biventricular outflow

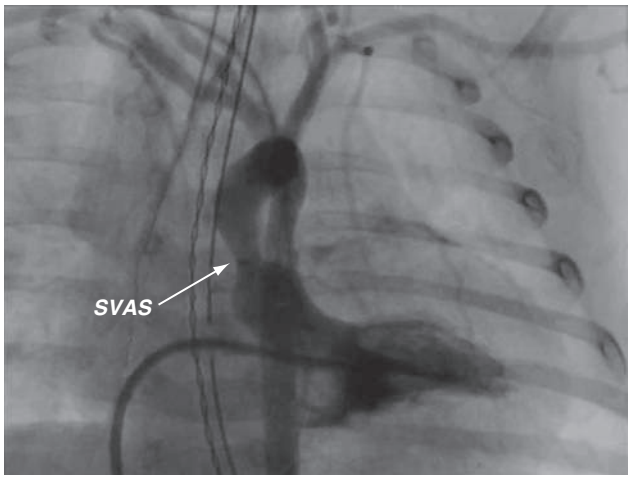

FIGURE 16.12 The angiogram displays the classic angiographic appearance of supravalvar aortic stenosis (*SVAS, arrow*) in a child with Williams syndrome.

tract obstruction. A comprehensive cardiac evaluation of all children is advisable because the spectrum of disease and the potential for devastating implications in affected individuals vary.[153] Children undergoing sedation or anesthetic care occasionally require further studies and even management changes before proceeding with a planned procedure. Even asymptomatic children and those without evidence of clinical cardiovascular disease might be at risk for major morbidity and death during situations associated with hemodynamic stress. Extreme vigilance and particular attention to signs of myocardial ischemia is warranted, as is a plan of action in the event of acute decompensation. This syndrome is one of the leading causes of cardiac arrest in the Pediatric Perioperative Cardiac Arrest (POCA) registry and requires the consideration of specific management issues.[154]

In view of these concerns and the fact that resuscitative efforts are frequently unsuccessful and refractory to aggressive efforts in children with elastin arteriopathy, the following measures have been proposed: (1) careful risk/benefit assessment of the planned procedure should be undertaken, (2) children should be cared for by personnel with expertise in this patient population and potential challenges that may be encountered, and (3) the care should be delivered at institutions with the resources to support the need for an acute intervention and an aggressive resuscitation.[152]

Children with Williams syndrome can exhibit some degree of muscular weakness, and the cautious use of neuromuscular blocking drugs has been recommended.[155] Associated neurodevelopmental delay, attention-deficit disorder, and autistic behavior often require a premedication. Subclinical hypothyroidism is common in these children.[156] Renal manifestations include renovascular hypertension, reduced function, and hypercalcemia-induced nephrocalcinosis.

Chromosome 22q11.2 Deletion Syndrome: DiGeorge and Velocardiofacial Syndrome

The 22q11.2 deletion syndrome, with an estimated incidence of approximately 1 per 3000 live births, encompasses DiGeorge, conotruncal face, and velocardiofacial syndromes. The syndrome is also known as CATCH 22, a mnemonic for **c**ardiac defects, **a**bnormal facies, **t**hymic hypoplasia, **c**left palate, and **h**ypocalcemia, all of which are commonly present. Cardiac malformations, speech delay, and immunodeficiency are the most common features of the chromosome 22q deletion syndromes.[157] Because no single feature is overwhelmingly associated with the deletion, the diagnosis should be considered for any child with a conotruncal anomaly, neonatal hypocalcemia, or any of the less common features when seen in association with dysmorphic facial features.

Cardiac malformations are often described as conotruncal anomalies; however, outflow tract problems are also common.[158] The remainder of the cardiac defects encompass an enormous spectrum of pathologies, leaving only a minority with a normal cardiovascular system. As a consequence of thymic hypoplasia, children can have diminished T-cell numbers and function. Their immunodeficiency requires the use of irradiated blood products and strict aseptic precautions during vascular access. Neurodevelopmental features include primarily speech delay and attention-deficit disorders. Psychiatric disorders are well described in these individuals.[159]

SINGLE-GENE DEFECTS

Noonan Syndrome

Noonan syndrome, an autosomal dominant disorder of variable expression, occurs with a frequency of 1 per 1000 to 2500 live births. The syndrome is one of a group of related conditions, collectively known as RASopathies or developmental syndromes of Ras/mitogen-activated protein kinase (MAPK) pathway dysregulation. Dysmorphic features in Noonan syndrome include neck webbing, low-set ears, chest deformities, hypertelorism, and short stature. The diagnosis is suspected from key clinical features.[160] In neonates, the facial features may be less apparent; however, generalized edema and excess nuchal folds can be present as in Turner syndrome. The facial features are more difficult to detect in later adolescence and adulthood.

The disorder is associated with a high incidence of cardiovascular involvement (about 80%-90%) and pulmonary valve dysplasia or stenosis is the most common feature.[161] HCM can develop during the first few years of life in some children.[162] Clinical problems can also include developmental delay and bleeding diathesis.[163]

Marfan Syndrome

Marfan syndrome is a multisystem disorder with variable expression resulting from a mutation in the fibrillin gene, a connective tissue protein, located on chromosome 15. Clinical manifestations typically involve the cardiovascular, skeletal, and ocular systems.[164,165] Cardiovascular pathology includes mitral valve prolapse and regurgitation, ascending aortic dilation (Fig. 16.13), and main pulmonary artery dilation. The risk of aortic dissection increases considerably as the aortic size increases, but it can occur at any point in the course of the disease.[166] Cardiac arrhythmias can be related to valvular heart disease, cardiomyopathy, or congestive heart failure.

Medical therapy with either β-blocker or angiotensin receptor blocker is standard therapy and blood pressure control in children with aortic root dilation should be continued perioperatively.[167] Aortic root replacement in Marfan syndrome has been associated with a greater risk of repeat dissection and recurrent aneurysm compared with other children who have undergone similar interventions.[168] It is wise to maintain hemodynamics near baseline values in the perioperative period. After aortic root surgery, some individuals can require chronic anticoagulation therapy. Preoperative hospitalization may be necessary to adjust the anticoagulation regimen in anticipation of surgery in these children. In emergency

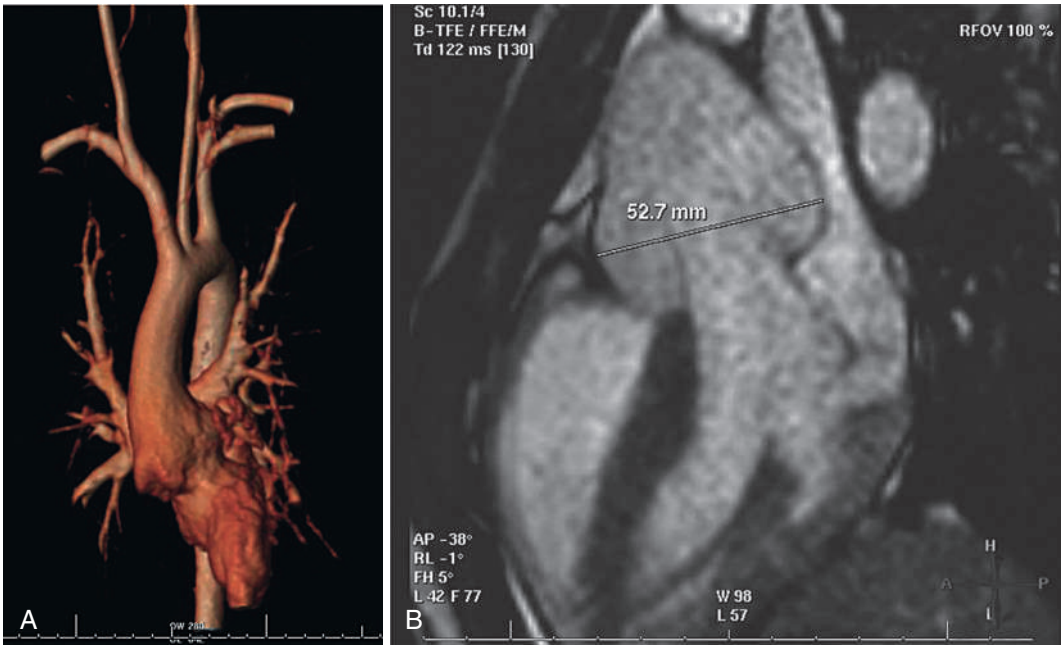

FIGURE 16.13 A severely dilated aortic root as displayed by magnetic resonance imaging in a patient with Marfan syndrome. The three-dimensional reconstruction **(A)** and sagittal view **(B)** demonstrate the aneurysmal appearance of the aortic root.

cases, administration of coagulation factors and other blood products may be required. In addition to vascular pathology, children with Marfan syndrome have a predisposition for ventricular dilation and abnormal systolic function.[169,170]

Several factors can result in pulmonary disease in these children.[171] Chest wall deformities and progressive scoliosis can contribute to restrictive lung disease. The fibrillin defect can affect lung development and homeostasis, impairing pulmonary function. Development of a spontaneous pneumothorax is relatively common.

CHARGE Syndrome

CHARGE syndrome is a genetic disorder characterized by congenital anomalies that include **c**oloboma, **h**eart defects, choanal **a**tresia, **r**etardation of growth and development, **g**enitourinary problems, and **e**ar abnormalities.[172] Most affected patients have mutations on the *CHD7* gene (chromodomain helicase DNA-binding protein), located on chromosome 8q12. The syndrome is estimated to occur at a rate of 1 per 8000 to 10,000 live births. Cardiac defects occur in as many as 50% to 70% of children and commonly include conotruncal and aortic arch anomalies.[173] Delayed growth and development usually results from cardiac disease, nutritional problems, and/or growth hormone deficiency. Most children have some degree of cognitive impairment. The anesthetic implications, in addition to those related to the cardiac defects, focus on the airway. In a retrospective review, upper airway abnormalities other than choanal atresia and cleft lip and palate were reported in 56% of children.[174] A high risk of postoperative airway events has also been reported in affected patients.[175]

ASSOCIATIONS

VACTERL (or VATER) Association

VACTERL association is an acronym given to describe a series of nonrandom anomalies that include **v**ertebral, **a**nal, **c**ardiovascular, **t**racheo**e**sophageal, **r**enal, and **l**imb defects.[176] Up to 75% of children with VACTERL association have CHD. The most common lesions include VSDs, ASDs, and TOF. Complex pathology such as truncus arteriosus and transposition of the great arteries occur less frequently.

Vertebral and tracheal anomalies can complicate airway management and regional anesthesia. Approximately 70% of children with VACTERL have vertebral anomalies, usually consisting of hypoplastic vertebrae or hemivertebra, that predispose to scoliosis. Anal atresia or imperforate anus is reported in about 55% of cases. These anomalies often require surgery in the first days of life. Esophageal atresia with tracheoesophageal fistula occurs in a large number of affected infants. Low birth weight (<1500 g) and associated cardiac pathology are independent predictors of mortality in infants undergoing surgery for esophageal atresia or tracheoesophageal fistula (see Chapter 37). The presence of a ductal-dependent cardiac lesion further increases perioperative morbidity and mortality.[177] Limb defects occur in most children, potentially affecting vascular access and monitor placement. Renal defects occur in about 50% of children.

OTHER DISORDERS

Tuberous sclerosis is a rare genetic disease with an autosomal dominant inheritance pattern and an incidence of approximately 1 per 25,000 to 30,000 births.[178] It can be attributed to spontaneous mutations in most children. This systemic disease primarily manifests as cutaneous and neurologic symptoms, but cardiac and renal lesions are frequent findings.

The presence of upper airway nodular tumors, fibromas, or papillomas in affected children can interfere with airway management. Developmental delay, autism, attention-deficit disorder, and aggressive behavior are common. Brain and renal tumors (60% to 80%) can produce significant comorbidities. Cardiac pathology includes cardiac rhabdomyoma in 60% of children and coexisting CHD in 33% of cases.[179,180] Cardiac abnormalities with obstruction to blood flow, heart failure, arrhythmias, conduction

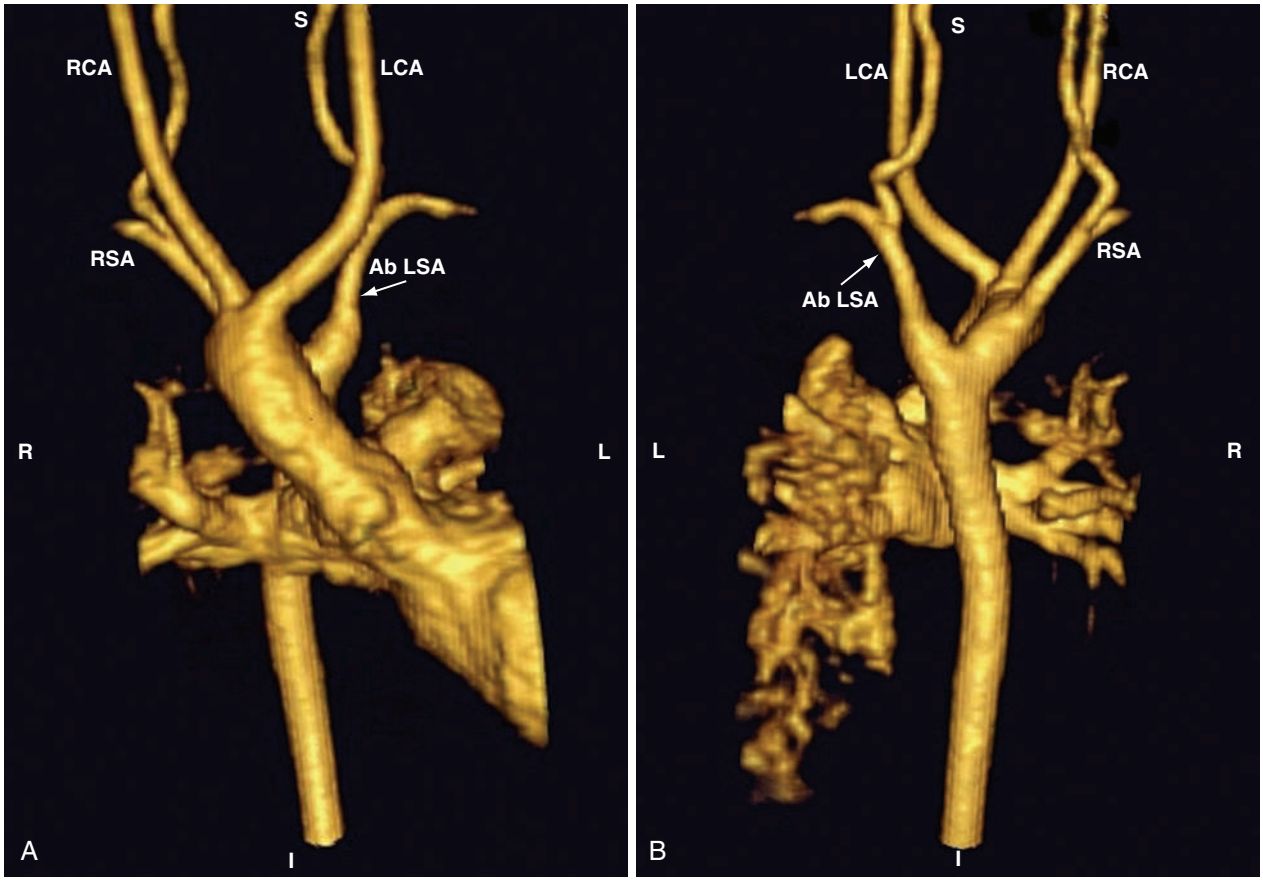

FIGURE 16.14 Three-dimensional reconstruction of a vascular ring obtained by magnetic resonance imaging. The images display an anterior **(A)** and posterior **(B)** orientation of a right aortic arch with an aberrant left subclavian artery (*Ab LSA*). The first arch vessel is the left carotid artery (*LCA*), followed by the right carotid artery (*RCA*), and right subclavian artery (*RSA*). The Ab LSA is the most distal branch originating from the descending aorta and coursing posterior to the esophagus toward the left arm. This vessel can be compressed by a transesophageal echocardiographic probe. *I*, inferior; *L*, left; *R*, right; *S*, superior.

defects, or preexcitation can affect the selection of anesthetic agents. Preoperative evaluation in most cases should include an ECG to evaluate for arrhythmia, conduction defects, or preexcitation.[181,182] Blood pressure and renal function should also be assessed. Anticonvulsants should be optimized and continued until the morning of surgery. Baseline medical treatment should be resumed as soon as possible because seizures are the most common postoperative complication.

Selected Vascular Anomalies and Their Implications for Anesthesia

ABERRANT SUBCLAVIAN ARTERY

An aberrant or anomalous subclavian artery in the classic setting arises from the descending aorta as a separate vessel distal to the usual last subclavian artery, in a posterior location. In a left aortic arch, this arrangement is as follows: the first branch is the right carotid artery, the second is the left carotid artery, and the third is the left subclavian artery. The aberrant right subclavian artery, rather than arising proximally from the innominate artery as the first arch vessel, originates distal to the left subclavian artery as the fourth branch and courses behind the esophagus toward the right arm. This branching variant is one of the most common aortic arch anomalies, occurring in 0.4% to 2% of the general population. It may or may not be associated with CHD.[183] This anomaly has a high incidence among children with Down syndrome and is associated with VSDs, TOF, and other cardiac lesions. In a right aortic arch, the anomalous left subclavian artery originates distal to the origin of the right subclavian artery (Fig. 16.14). This anomaly can be seen in the context of conotruncal malformations. The diagnosis of an aberrant subclavian artery is made by most currently available imaging modalities.

This variant has several implications:

- It can influence the location of placement of a systemic-to-pulmonary artery shunt.
- It should be considered in the selection of a site for arterial line placement if transesophageal echocardiography is planned during surgery. The aberrant vessel can be compressed along its retroesophageal course by the imaging probe, resulting in inaccurate recordings.[184] Regardless of the site of arterial line placement, it may be wise to monitor the arm supplied by the anomalous vessel by pulse oximetry or other methods during esophageal instrumentation.

- It is sometimes a component of a vascular ring.
- Rarely, older children with an aberrant subclavian artery and without the findings of a complete vascular ring can complain of mild dysphagia (i.e., dysphagia lusoria).

PERSISTENT LEFT SUPERIOR VENA CAVA TO THE CORONARY SINUS

A persistent left superior vena cava (LSVC) is a form of anomalous systemic venous drainage identified in 4.4% of children with CHD, most frequently those with septal defects.[185] It represents a venous remnant that typically involutes during development. If it persists, it remains patent and drains through an enlarged coronary sinus into the right atrium. Bilateral superior vena cavae can be present (Fig. 16.15), or the right superior vena cava can be absent. Bilateral superior vena cavae can communicate through an innominate or bridging vein. This anomaly has several implications:

- In the absence of an innominate vein, a catheter placed in the left arm or left internal jugular vein and advanced into the central circulation can rest within the coronary sinus, a potentially undesirable location in a small infant. On chest radiography, an unusual course is identified as the catheter courses along the left aspect of the mediastinum and can be mistaken for intracarotid, intrapleural, or mediastinal locations.
- An LSVC can be of relevance during venous cannulation for cardiopulmonary bypass to ensure adequate venous drainage and optimal operating conditions.
- The presence of an LSVC is important in patients with single-ventricle physiology undergoing palliation involving a cavopulmonary (Glenn) connection.
- The anomaly can be associated with a dilated coronary sinus. On echocardiography, it can be confused with other defects, including an ostium primum ASD (i.e., one that lies in the inferior aspect of the atrial septum) or anomalous pulmonary venous return to the coronary sinus.
- On occasion, an LSVC can drain to an unroofed coronary sinus or directly into the left atrium, in which case a right-to-left shunt is present. It can be identified by injection of agitated saline into a left arm or left neck vein while performing an echocardiogram, and it can be associated with systemic arterial desaturation. This constitutes a risk for paradoxical systemic embolization.
- During cardiac surgery, an enlarged coronary sinus can interfere with the administration of retrograde cardioplegia.
- It can confound transvenous placement of a pulmonary artery catheter in some cases.

Evaluation of the Child With a Cardiac Murmur

The finding of an incidental murmur during the perioperative period can result in significant distress to the child or family; trigger additional diagnostic studies, including a cardiology consultation; and has the potential to delay the scheduled procedure when identified preoperatively. Although cardiac auscultation is a challenging skill that takes many years of practice to master,[186] it is important for the anesthesiologist who routinely cares for children to recognize the main physical findings that may distinguish an innocent cardiac murmur from a pathologic one. Knowledge of several core concepts and red flags can help avoid overlooking potentially important diagnoses.

About 90% of normal children have a murmur at some point in their lives. It is most commonly identified during the neonatal

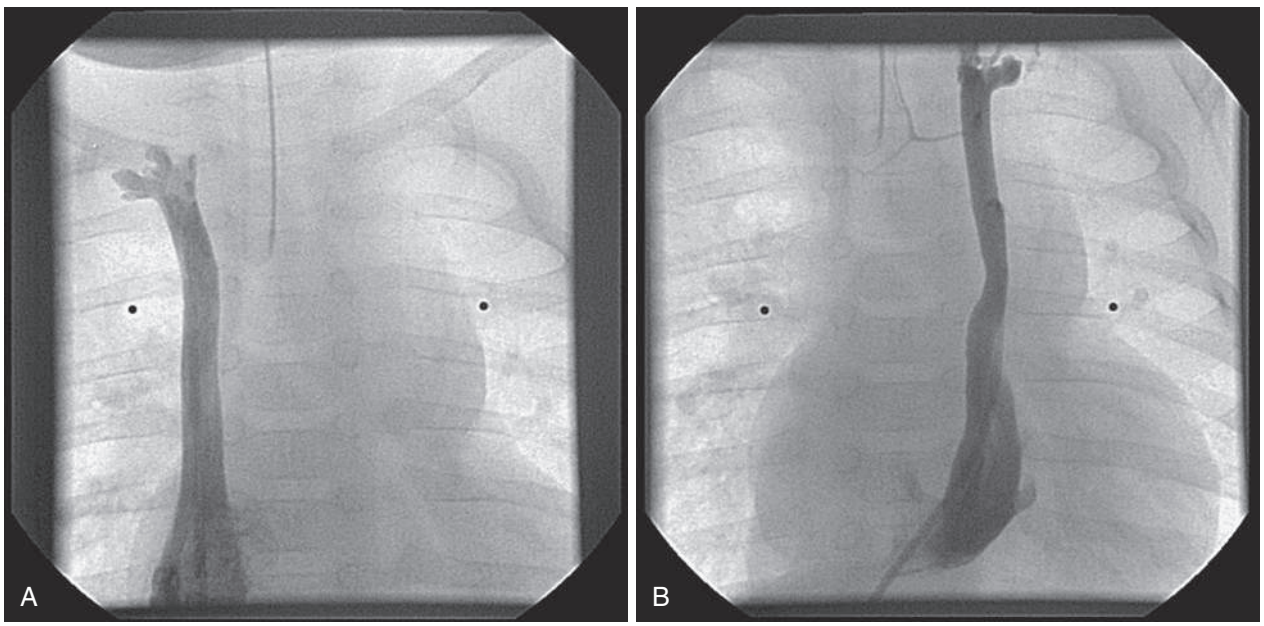

FIGURE 16.15 Bilateral superior vena cavae can exist separately or communicate through an innominate or bridging vein. **A,** The angiogram depicts the superior vena cava, normally a right-sided structure, as it drains into the right atrium. **B,** In the same patient, an angiogram shows drainage of a large left superior vena cava into the coronary sinus. The catheter courses from the inferior vena cava into the right atrium, coronary sinus, and left superior vena cava. Contrast injection into the left superior vena cava demonstrates no innominate vein between the two cavae. The coronary sinus is dilated as it receives the systemic venous blood from the left superior vena cava.

period and early school years. Most murmurs are functional, considered innocent in nature, and require no special treatment. This diagnosis is based on physical findings consistent with the benign nature of the specific murmur.

Although a complete discussion of cardiac murmur evaluation is beyond the scope of this chapter, it is important to review those findings that help to distinguish innocent from pathologic murmurs.[187,188] The basic systematic approach to assessing a heart murmur is the same as when evaluating any child's cardiovascular system.[189,190] The chest should be auscultated with both the diaphragm and bell of the stethoscope in the positions of the four primary cardiac valves in a quiet environment. Innocent murmurs in infancy and childhood include pulmonary flow murmur, a Still murmur, physiologic pulmonary branch stenosis, venous hum, and carotid bruit. Innocent murmurs are usually of low intensity (grades I and II of VI) and associated with a normal cardiovascular examination (e.g., normal precordial activity, first and second heart sounds, peripheral pulses, capillary refill). Innocent murmurs, such as those associated with peripheral pulmonary branch stenosis, right ventricular outflow murmurs, and Still murmurs, are usually soft, systolic ejection type, and not holosystolic in duration. Physiologic murmurs often resolve by changing the child's hemodynamic state with maneuvers such as lying down or sitting up or with temporal changes such as resolution of fever and improvement in anemia. Diastolic or continuous murmurs are typically pathologic, with the exception of a venous hum. This murmur is thought to be related to turbulent flow of systemic venous return in the jugular veins and superior vena cava and is best heard at the base of the neck. *Murmurs accompanied by a palpable thrill are always pathologic.*

When there is doubt regarding the benign or pathologic nature of a murmur, consultation with a pediatric cardiologist is indicated. A chest radiograph and ECG, although thought by some to add minimal value in the initial diagnostic assessment of a cardiac murmur and to not be cost-effective, can be helpful when considering if further consultation is indicated.[191]

Basic Interpretation of the Electrocardiogram in Children

Despite the increasing applications of imaging modalities in the structural and functional assessment of pediatric heart disease, electrocardiography continues to play a significant role in the diagnosis and management of these children. An ECG is considered an integral part of the evaluation of most children with congenital or acquired cardiovascular pathology.

Although the characteristic features of a normal ECG in infants and children were described many decades ago, it is surprising that it continues to be one of the most often misinterpreted screening tests in pediatric medicine.[192] This is largely because of the developmental changes that occur in the normal individual as he or she progresses from the neonatal period through childhood, adolescence, and adulthood.[193] Normal values for children of different ages have been established.[194] Knowledge of normal configurations and values for various ages of children is essential for accurate interpretation.[195] Immediately after birth, there is a predominance of right ventricular forces represented by tall R waves in the right precordial leads (V_1 and V_2) (Fig. 16.16).[196] Over the first several years, the ECG changes to a more familiar left heart–dominant configuration with larger S waves in the right precordial leads and a gradual RS progression with tall R waves in the left precordial leads (V_5 and V_6) (Fig. 16.17). The predominance of right heart forces and the need to evaluate for dextrocardia are the primary reasons that pediatric ECGs should include the V_3R and V_4R leads, which are not routinely obtained in adult studies. These electrodes are placed in the corresponding V_3 and V_4 locations over the right hemithorax.

Clinical information of relevance in the interpretation of an ECG includes the child's age, gender, suspected or documented diagnosis, and indications for the examination. Several requirements are essential for accurate interpretation, including appropriate skin preparation, electrode placement, and an artifact-free recording. The approach to the pediatric ECG should be systematic and organized. Determination of the rate and rhythm, with evaluation of the P-wave vector and the relationship between each P wave and QRS complex, is the first step. It is important to consider the influences of age, autonomic nervous system, level of physical activity, medications, pain, and temperature on the child's heart rate. The P wave should be upright or positive in leads I and aVF, indicating that the sinus node is the pacemaker of the heart (i.e., sinus rhythm) (see Fig. 16.17). Normally, the P wave should precede the QRS complex. Next, the QRS electrical axis should be determined. The QRS frontal plane axis is determined by identifying the most isoelectric lead, which is perpendicular to the direction of ventricular depolarization. Alternatively, the direction of depolarization in leads I and aVF can be examined to roughly estimate the axis. As with all other components of the evaluation, the physiologic changes that occur with growth are responsible for the change in normal values for the QRS axis based on age. Regardless of age, QRS axes that lie in the northwest quadrant (between 180 and 270 degrees with an S-wave–dominant pattern in leads I and aVF) are always abnormal and merit further investigation. This is a classic finding in children with AV septal defects. Evaluating the T wave, or repolarization axis, is also important, because a difference of greater than 90 degrees between the QRS and T-wave axes can represent strain on the ventricle, a potential finding in ventricular hypertrophy (see Fig. 16.5).

After the evaluation of rhythm and axes is complete, each component of the cardiac cycle as reflected by the ECG should be examined.[197] The P wave represents atrial systole, and its morphology, with particular interest in leads II and V_1, can demonstrate right atrial (P-wave amplitude >2.5 mm or 3.0 mm based on age) or left atrial (P-wave duration >100-120 msec based on age) enlargement (Fig. 16.18). The PR interval represents the time required for passage of an impulse from the sinoatrial node until ventricular depolarization and is largely composed of the AV nodal delay. A prolonged PR interval, which is age specific, indicates first-degree AV block. A short PR interval should prompt evaluation of the QRS duration for signs of preexcitation (i.e., Wolff-Parkinson-White syndrome), although a short PR interval can also reflect a low right atrial pacemaker (Fig. 16.19).

The QRS complex represents ventricular depolarization. The QRS duration should be examined in a lead with a Q wave present (often lead V_5 or V_6) for signs of conduction delay. Age-dependent normal values are important, because the upper limit of normal QRS duration is only 80 msec in neonates. The presence of a wide QRS complex with an RSR′ pattern in V_1 indicates a right bundle branch block, whereas a QS pattern in V_1 and a tall notched R wave in V_6 is consistent with a left bundle branch block. Other conditions associated with prolongation of the QRS duration include ventricular preexcitation and ventricular pacing.

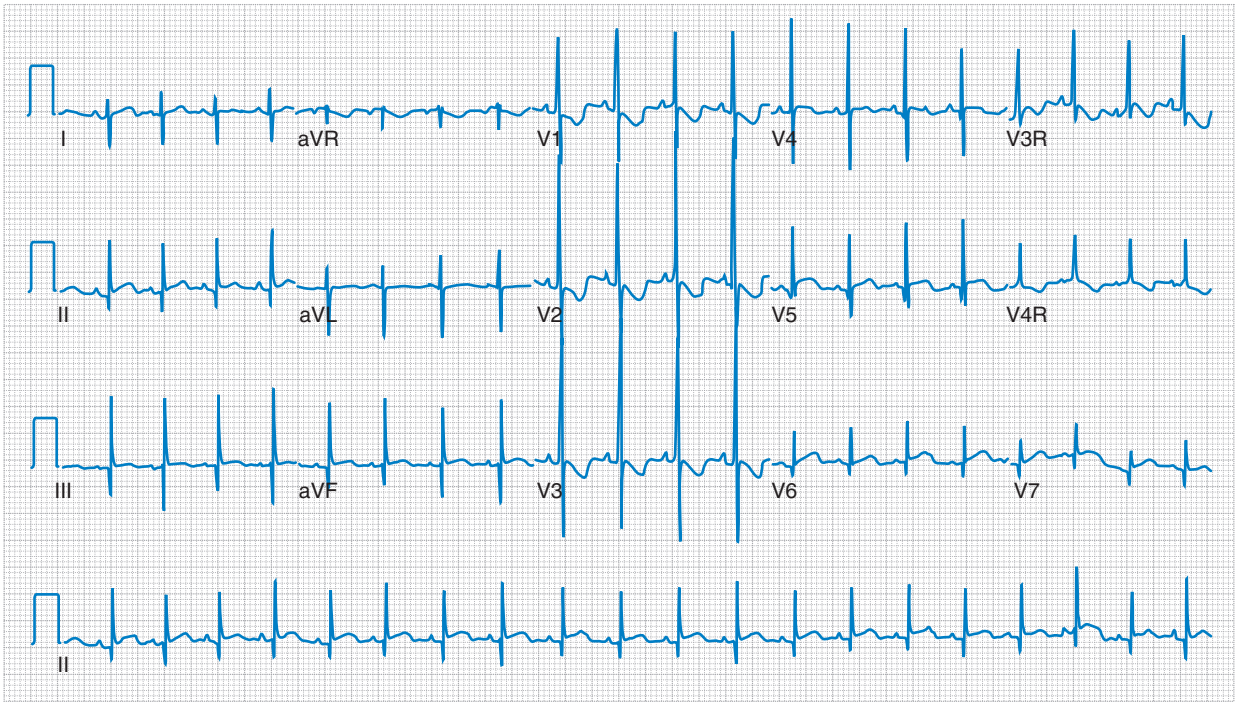

FIGURE 16.16 Normal electrocardiogram for a 2-day-old neonate shows the expected predominance of right ventricular forces during this period (i.e., tall R waves in the right precordial leads, V_1 and V_2). The inverted T waves in $V_{1\text{-}3}$ are normal for this age.

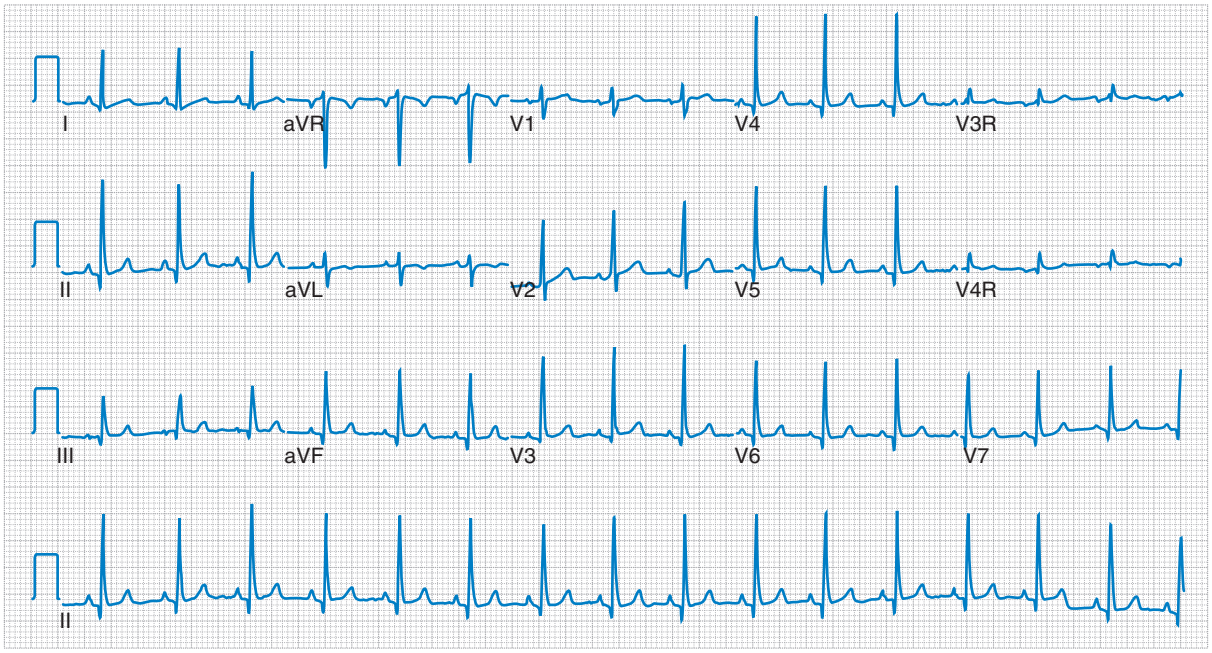

FIGURE 16.17 The normal electrocardiographic tracing was recorded for a 10-year-old child. The typical left heart–dominant configuration of children this age is characterized by gradual RS progression with tall R waves in the left precordial leads (V_5 and V_6). This contrasts with the right ventricular–dominant pattern seen during infancy and early childhood. The tracing demonstrates normal sinus rhythm as indicated by positive P waves in leads I and aVF.

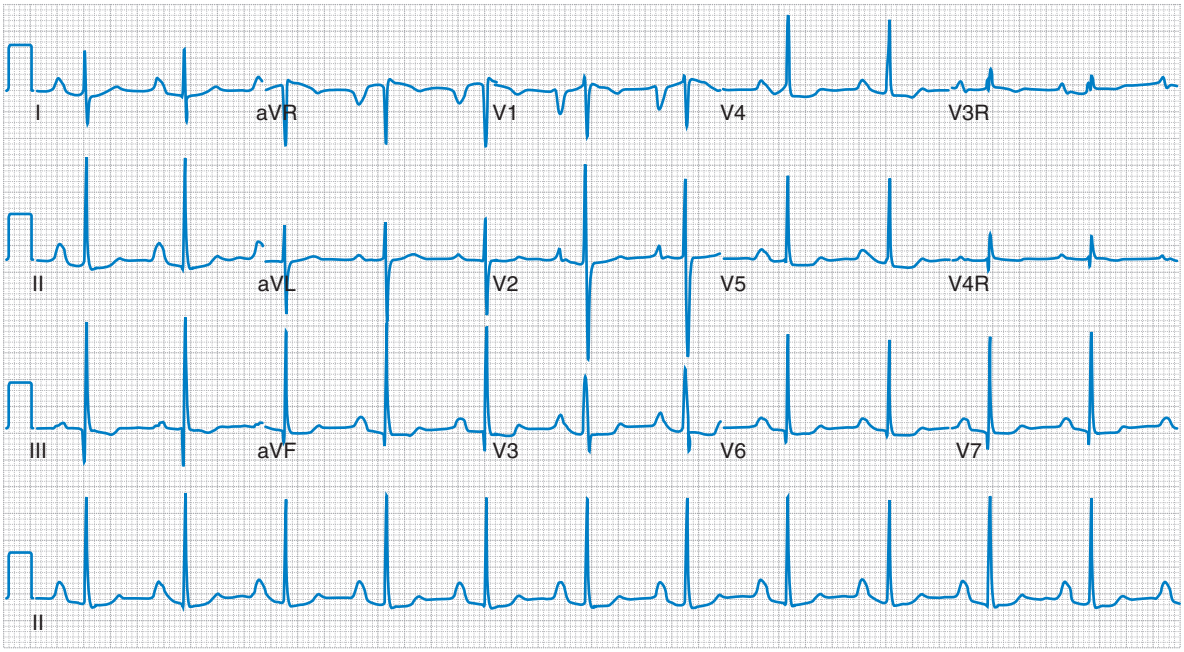

FIGURE 16.18 The tracing was obtained in the emergency room for a patient subsequently found to have restrictive cardiomyopathy. Biatrial enlargement is reflected by the tall and wide P waves in leads II and V_1, respectively.

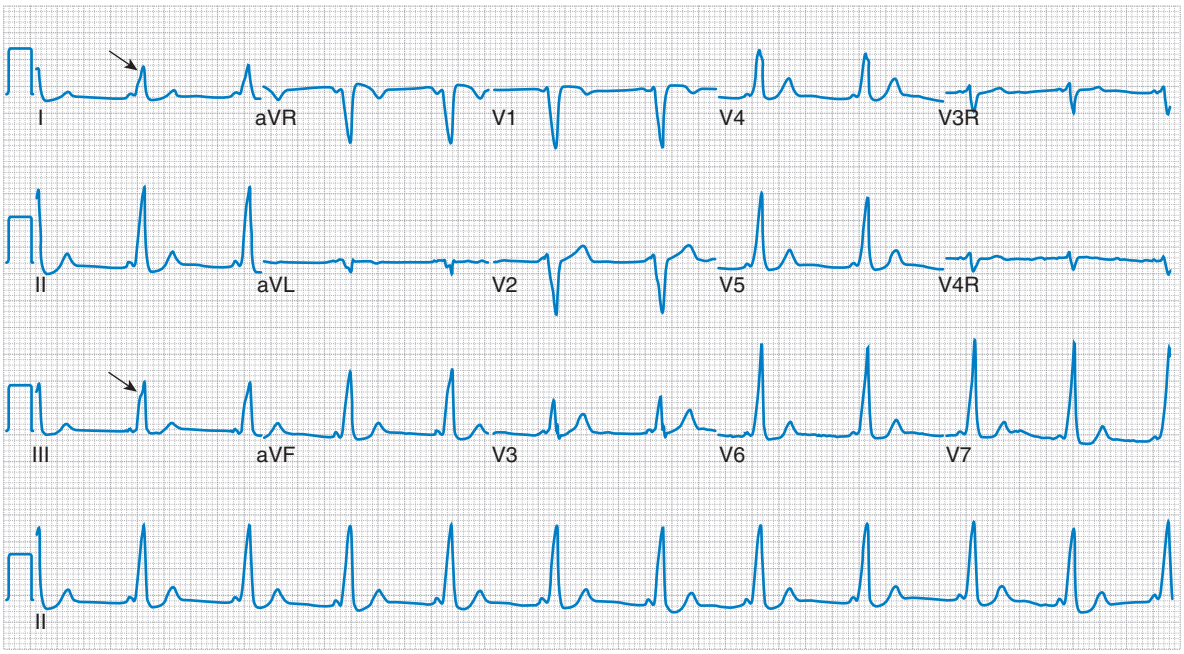

FIGURE 16.19 The tracing demonstrates the typical electrocardiographic features of Wolff-Parkinson-White syndrome: short PR interval, delta wave (*arrows*), and prolongation of the QRS interval.

In addition to the QRS duration, the components of the QRS complex should be examined. Q waves are often present in the lateral and inferior leads and in lead aVR, but they should be narrow (<40 msec) and shallow (age-dependent but usually <5-mm deep). Deep or wide Q waves suggest myocardial ischemia and require further evaluation. An uncommon but crucial finding occurs in infants with ALCAPA. Classically, the ECG in this lesion demonstrates deep, wide Q waves in leads I and aVL with ST-segment and T-wave changes in the anterior distribution (V_2 to V_4) consistent with compromised myocardial blood flow (Fig. 16.20). The QRS amplitudes are also important in assessing left and right ventricular hypertrophy. Conditions associated with increased QRS voltages that likely require echocardiographic assessment include HCM, left ventricular noncompaction, and Pompe disease (see Figs. 16.5 and 16.6).

ST segments should be flat and should not be depressed more than 0.5 mm or elevated more than 1 mm in any lead. The major exception to this rule is when there is gradual upsloping of the

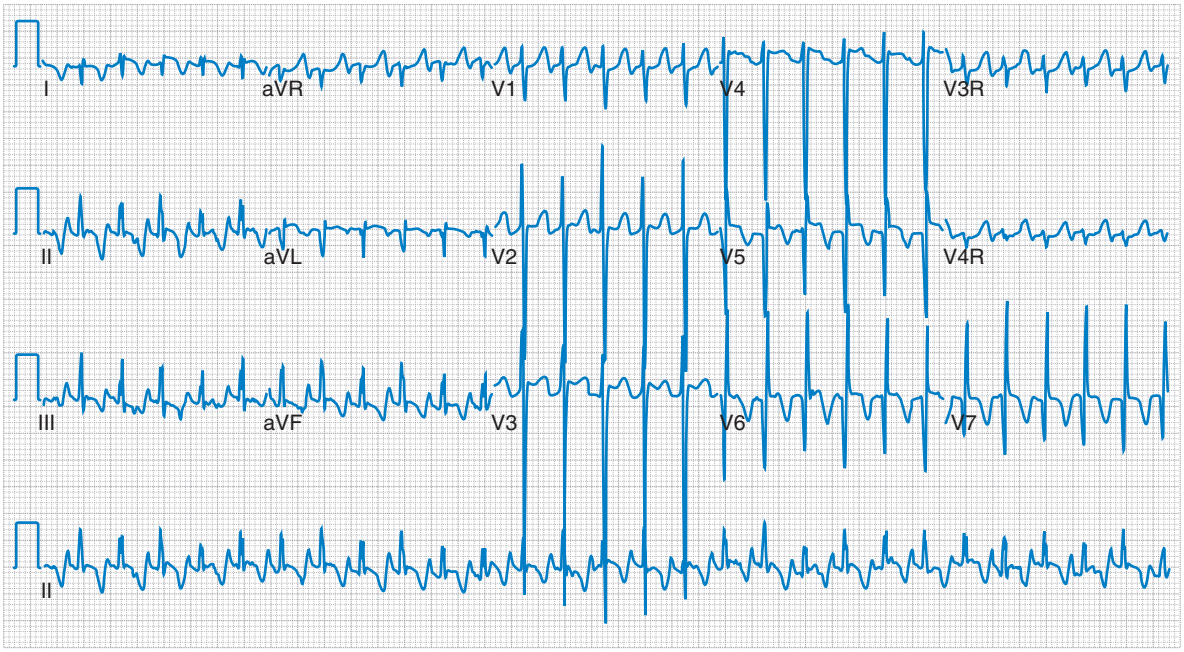

FIGURE 16.20 Electrocardiographic tracing for an infant with poor ventricular function who was found to have anomalous origin of the left main coronary artery from the pulmonary root. The presence of Q waves in aVL and the diffuse ST-T wave changes suggest ischemia and are classic for this anomaly.

ST segment in the mid-precordial leads, as seen in early repolarization. T waves represent ventricular repolarization and should all be upright in the precordial leads at birth. Within 1 to 3 days they become inverted, initially in V_1 and eventually in V_2, V_3, and sometimes in V_4. Starting at several years of age, the T waves return to the upright position in the reverse order. In normal adolescents and adults, the T wave in lead V_1 can be upright or inverted. The only limb lead that typically displays an inverted T wave is aVR.

An aspect of the cardiac cycle that must be examined on any ECG is the QT interval, the time from the onset of ventricular depolarization (marked by the onset of the QRS complex), until the completion of repolarization (marked by the end of the T wave). It represents the duration of electrical activation and recovery of the ventricular myocardium, and it is measured as follows:

$$\text{Corrected QT (QTc)} = \frac{\text{Measured QT interval}}{\text{Square root of preceding R-Rinterval}}$$

A QTc that exceeds 470 msec is considered abnormal, regardless of age. All QTc values that exceed normal values for age merit further investigation. Medications that prolong the QT interval should be avoided until the child has been evaluated by a cardiologist.

Although a detailed organized approach to interpretation of a pediatric ECG is necessary, there are occasions when particular conditions or circumstances cause global electrocardiographic changes that must be quickly recognized. One such case that can occur in the operating room is related to the electrocardiographic changes associated with hyperkalemia. As the potassium level increases, the T-wave amplitude increases. This is followed by widening of the QRS duration (see Figs. 9.7 and 16.21) owing to an intraventricular conduction delay and by AV block and arrhythmias, including ventricular tachycardia and fibrillation. Other electrolyte disturbances can result in characteristic changes on the ECG:

- Hypokalemia: decreased T-wave amplitude, ST-segment depression, and the presence of U waves
- Hypercalcemia: shortening of the QT interval, sinus rate slowing, and sinoatrial block
- Hypocalcemia: lengthening of the QT interval
- Hypomagnesemia: enhanced effects of hypocalcemia

Essentials of Cardiac Rhythm Interpretation and Acute Arrhythmia Management in Children

Rhythm abnormalities can be seen during the preoperative assessment, in the operating room, or in the postoperative period. Considerations usually include identification of the rhythm disorder, establishing the need for acute therapy, deciding whether to consult a pediatric cardiologist, and conveying pertinent information to the consultant to assist in the characterization of the rhythm disturbance and to establish a management plan.[198] The following principles should be considered in addressing these issues:

1. Operating room, bedside, or transport monitors and strip recordings facilitate the recognition of rhythm disorders, but in most cases, they are inadequate for definitive diagnosis. A 15-lead surface ECG and rhythm strip should be obtained for all children when feasible.
2. Clinicians caring for children should have a basic knowledge of cardiac rhythm interpretation. Although a comprehensive discussion of arrhythmia interpretation is beyond the scope of this chapter, a brief overview of the characteristic features of normal and abnormal cardiac rhythms in the pediatric age group is presented in the following section.
3. The need for acute therapy for a rhythm disturbance should be based primarily on the nature of the disorder, urgency of

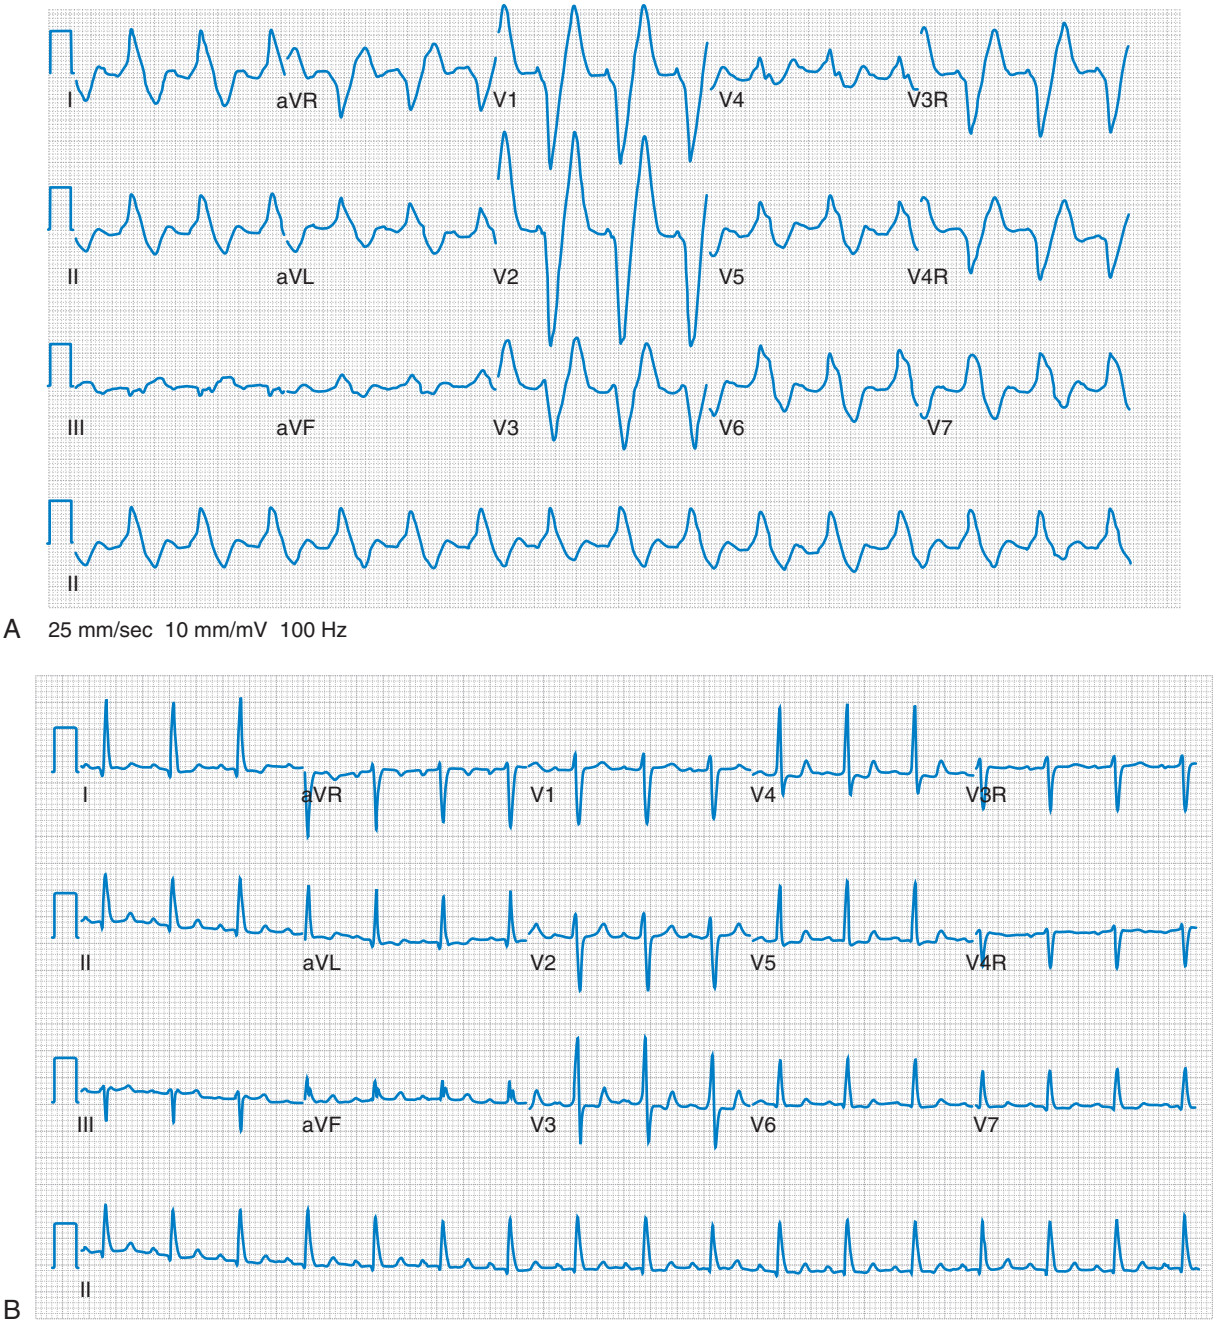

FIGURE 16.21 These electrocardiographic changes can result from hyperkalemia. **A,** Marked widening of the QRS complexes is associated with peaked T waves. If untreated, this condition may progress to ventricular fibrillation and asystole. **B,** A tracing obtained several hours after treatment of the electrolyte disturbance in the same patient demonstrates resolution of the electrocardiographic changes.

the situation, and the likelihood that this abnormality would or would not be tolerated beyond the immediate short-term period. The guidelines established by the American Heart Association for Pediatric Advanced Life Support should be followed in all patients.[199] In otherwise healthy children and in contrast to ventricular arrhythmias, supraventricular tachyarrhythmias are rarely life-threatening.

4. The degree of comfort in the characterization and management of pediatric cardiac arrhythmias is likely to be quite variable among anesthesia care providers. For arrhythmias caused by respiratory compromise, electrolyte imbalance, or metabolic derangements, consultation with a pediatric cardiologist is probably not required. This is also the case for variants or benign rhythm disturbances such as sinus arrhythmia, low atrial rhythms, or occasional premature atrial beats. Consultation is appropriate for most children with known structural or acquired cardiovascular pathology, in those with a history of a cardiac rhythm disorder under the care of a cardiologist, and in most of those with acute arrhythmias, particularly when initiation of antiarrhythmic drug therapy is contemplated.

5. Information that may be helpful to a consultant includes pertinent details regarding the child's history, clinical diagnosis, nature of the procedure/intervention, relevant laboratory values, description or characterization of the rhythm abnormality, associated hemodynamic parameters, circumstances surrounding the event (including the presence or absence of an intracardiac catheter), review of the pharmacologic agents administered (including anesthetic agents), and other therapies if applicable. The specialist should assist in the characterization of the rhythm disorder, advise about whether further evaluation is indicated, make recommendations for treatment, and facilitate diagnostic/therapeutic interventions as necessary.

BASIC RHYTHMS

Sinus Rhythm

Sinus rhythm is characterized by a P wave that precedes every QRS, a QRS that follows every P wave, and an upright P wave in leads I and aVF (see Fig. 16.17).

Sinus Arrhythmia

Sinus arrhythmia represents cyclic changes in the heart rate during breathing. This is a normal finding in healthy children (Fig. 16.22).

Sinus Bradycardia

Sinus bradycardia is characterized by sinus rhythm with heart rates below normal for age (see Fig. 16.5). Slow heart rates can be observed during sleep or at times of high vagal tone. When there is significant sinus bradycardia, a slow junctional escape rhythm or a slow atrial rhythm originating from an ectopic focus can be present. Certain forms of CHD may be prone to slow heart rhythms (i.e., heterotaxy syndromes).

In the intraoperative setting, particularly during induction of anesthesia, sinus bradycardia can occur with laryngoscopy, tracheal intubation, and tracheal suctioning. Sinus bradycardia can also result from drug administration (i.e., opioids) or increased parasympathetic tone. This type of sinus bradycardia rarely poses significant hemodynamic compromise and, if necessary, can be easily treated with removal of the stimulus, administration of a vagolytic agent (e.g., glycopyrrolate and atropine), or with chronotropic drugs such as epinephrine. Sinus bradycardia can also result from hypoxemia, hypothermia, acidosis, electrolyte imbalance, or increased intracranial pressure. Bradycardia related to hypoxemia should be treated promptly with the administration of supplemental oxygen and appropriate airway management (see Chapter 40). The approach to other secondary forms of sinus bradycardia should focus on addressing the underlying cause. For worrisome slow heart rates, particularly in small infants, or for clinical evidence of compromised hemodynamics, pharmacologic therapy (i.e., epinephrine, atropine, or isoproterenol infusion) or temporary pacing should be considered.

Sinus Tachycardia

During sinus tachycardia the heart rate is above normal for age (Fig. 16.23). In the perioperative setting this is often the result of surgical stimulation, stress, pain, hypovolemia, anemia, fever, medications (i.e., inotropic agents), or a high catecholamine state. Treatment is directed at the underlying cause. Sustained sinus tachycardia can be detrimental as it may impair diastolic filling time, reduce ventricular preload, and compromise cardiac output. Children at risk for hemodynamic decompensation include those with significant degrees of ventricular hypertrophy or diastolic dysfunction, aortic stenosis, and HCM.

Junctional Rhythm

A junctional rhythm is characterized by QRS complexes of morphology identical to that of sinus rhythm without preceding P waves. This rhythm is slower than the expected sinus rate. When this rhythm completely takes over the pacemaker activity of the

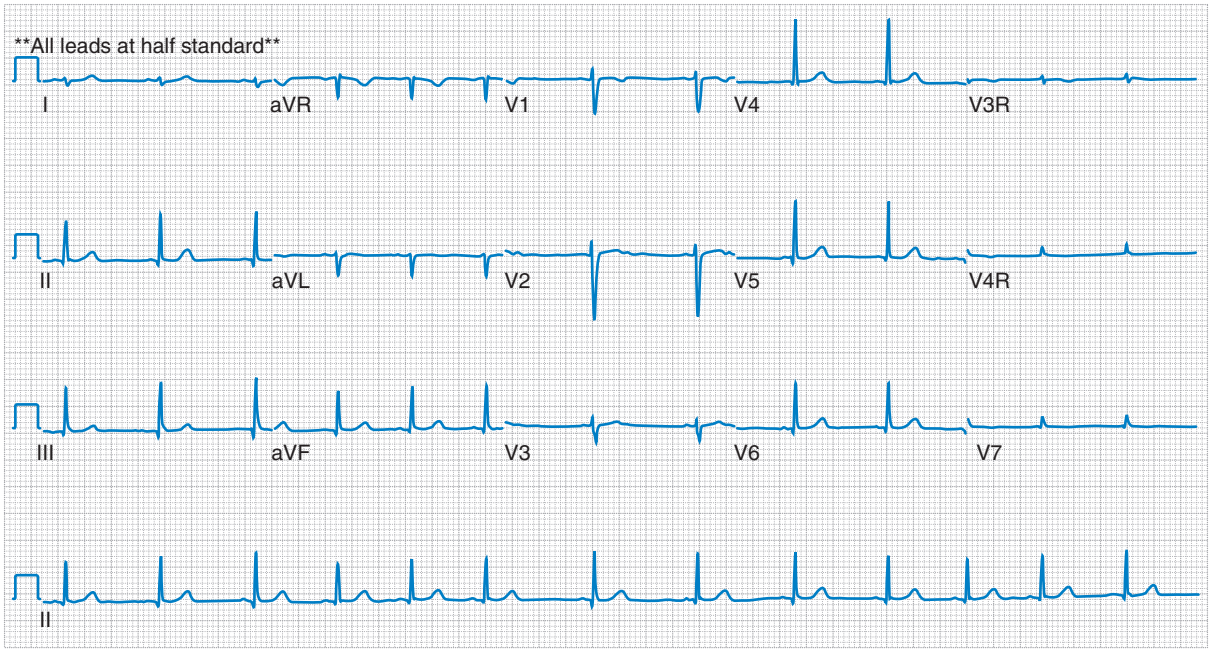

FIGURE 16.22 The rhythm tracing displays the normal heart rate variability with respiration. There is a normal increase in heart rate during inspiration. This sinus arrhythmia is a natural response and is more commonly seen in children than adults.

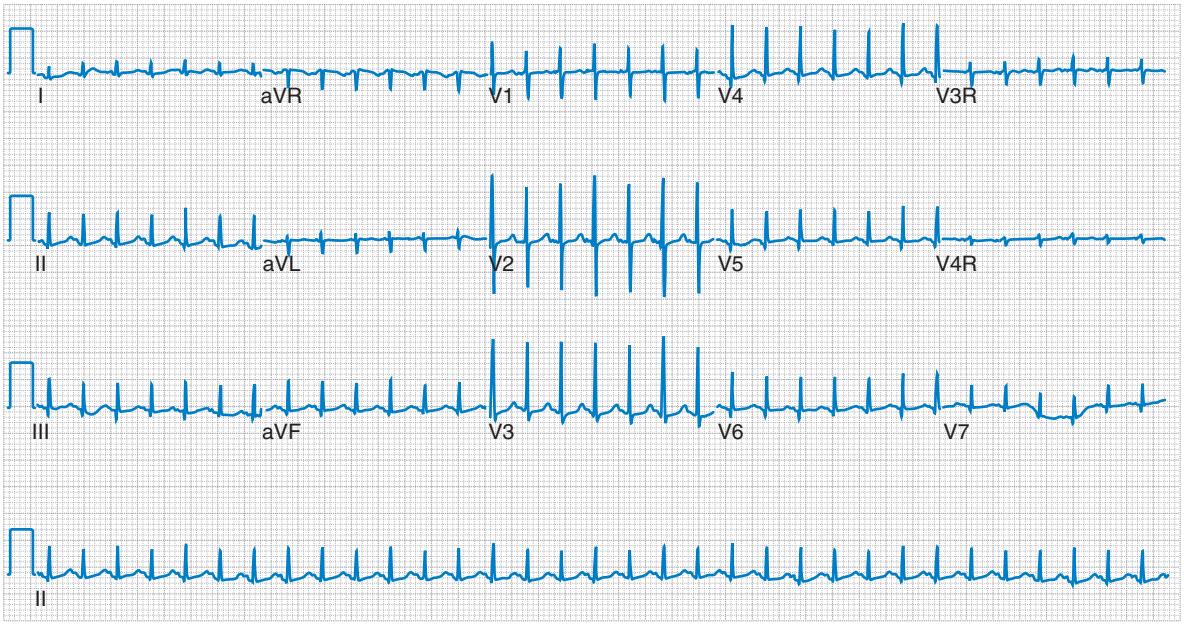

FIGURE 16.23 Electrocardiogram for a febrile infant with sinus tachycardia, characterized by a heart rate above normal for age and QRS complexes of normal appearance preceded by P waves, which are upright in leads I and aVF.

heart, retrograde P waves and AV dissociation can be seen. Junctional rhythm during cardiac surgery is frequently the result of manipulation or dissection near the right atrium. The central venous pressure contour typically demonstrates prominent cannon *a* waves (i.e., right atrial pressure wave at the end of systole) owing to the loss of AV synchrony (Fig. 16.24). The lack of atrial contribution to ventricular filling can result in decreases in the systemic arterial blood pressure.

CONDUCTION DISORDERS

Bundle Branch Block

Incomplete right bundle branch block pattern (rSR′ in the right precordial leads with near-normal QRS duration) occurs in children with right ventricular volume overload (e.g., those with ASDs). Complete right bundle branch block (QRS complex >100 msec for infants, 120 msec for older children) is frequently seen in children after surgical procedures that involve the right ventricular outflow tract. This is characterized by an rSR′ wave pattern in V_1, an inverted T wave, and a wide and deep S (slurred) wave in V_6. Left bundle branch block is an uncommon finding in the pediatric age group that can result from cardiac interventions along the left ventricular outflow tract. Criteria for this conduction disorder include a prominent QS or rS complex in lead V_1 and tall, wide, and often notched R wave in leads I, aVL, and V_6.

Atrioventricular Block

First-Degree Atrioventricular Block

In first-degree AV block, there is prolongation of the PR interval beyond the normal range for age. Each P wave is followed by a conducted QRS. This may be found in healthy individuals but can also be seen in various disease states. First-degree AV block is a benign condition requiring no specific treatment.

Second-Degree Atrioventricular Block

There are several forms of second-degree AV block. Mobitz type I (Wenckebach) and Mobitz type II are the two predominant types. They are characterized by a periodic failure to conduct atrial impulses to the ventricle (i.e., P wave without following QRS complex). In a type I, second-degree AV block, there is a gradual lengthening of the PR interval with eventual failure of conduction of the next atrial impulse to the ventricle. The RR intervals concomitantly shorten. The degree of AV block is expressed as the ratio of P waves to QRS complexes (i.e., 2 : 1, 3 : 2). This can occur during periods of high vagal tone or in the postoperative setting. It is usually a benign phenomenon that requires no therapy. In the less frequent type II second-degree AV block, there is a relatively constant PR interval before an atrial impulse that fails to conduct. This is considered a more serious conduction disturbance and merits further investigation.

Third-Degree Atrioventricular Block

Third-degree (complete) AV block is characterized by total failure of conduction of atrial impulses to the ventricle. It can be congenital or acquired. There is complete AV dissociation, with more atrial than ventricular contractions, and the ventricular rate is usually slow and regular (Fig. 16.25). Temporary pacing may be indicated in the acute setting.

CARDIAC ARRHYTHMIAS

Supraventricular Arrhythmias

Premature Atrial Contractions or Beats

Isolated premature atrial contractions (PACs) are relatively common in infants and small children. On the ECG, the early P waves exhibit a morphology and axis that are different from those in normal sinus rhythm. Premature atrial contractions can be conducted to the ventricles normally, blocked at the AV node, or conduct aberrantly (i.e., abnormal QRS morphology). They are usually benign and require no therapy. If a central venous catheter is present, the tip position should be evaluated.

Supraventricular Tachycardia

Supraventricular tachycardia (SVT) is the most common significant arrhythmia in infants and children.[200,201] It is characterized by a regular tachyarrhythmia (tachycardia heart rate is age dependent

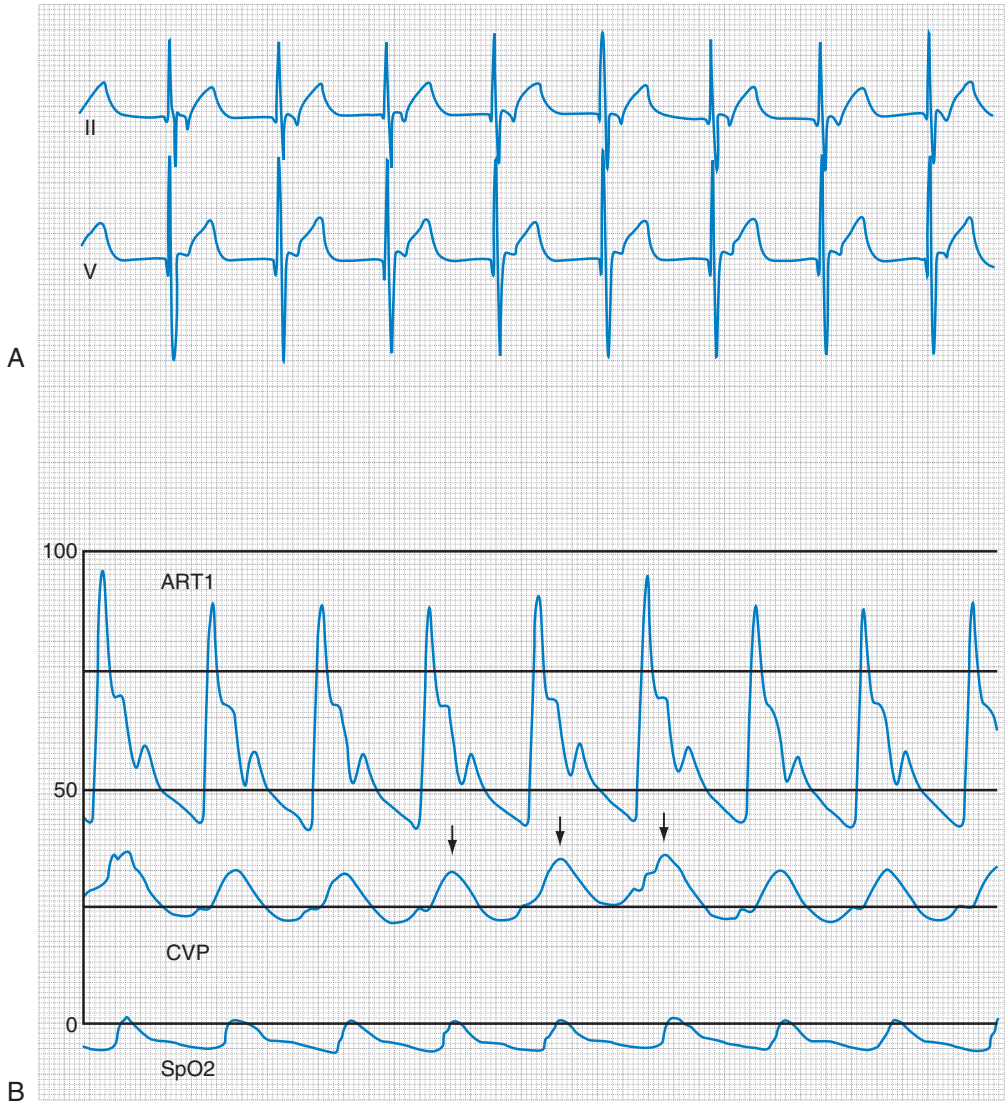

FIGURE 16.24 **A,** The tracing obtained during cardiac surgery at the time of right atrial dissection demonstrates the features of a junctional rhythm. Retrograde P waves are identified after the QRS complexes. **B,** The central venous pressure (*CVP*) tracing demonstrates prominent cannon *a* waves (*arrows*) related to the loss of atrioventricular synchrony (scale of 0–30 mm Hg for CVP).

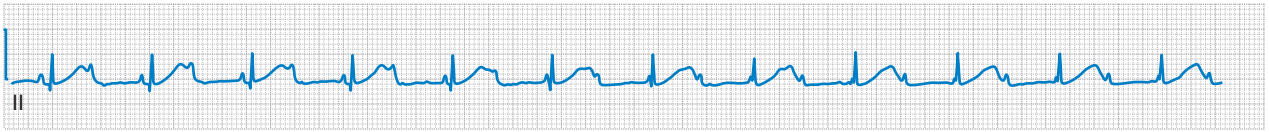

FIGURE 16.25 Rhythm strip demonstrates independent atrial and ventricular activity (i.e., atrioventricular dissociation) and failure of any atrial impulses to conduct to the ventricles. These features characterize a complete atrioventricular block.

but typically exceeding 230 beats/minute in children) with a narrow or usual complex QRS morphology. Supraventricular tachycardia can occur in structurally normal hearts and in various forms of CHD. *Usual complex* implies that the QRS morphology in tachycardia is similar to that in normal sinus rhythm (Fig. 16.26). Occasionally, widening of the QRS in SVT can result from bundle branch block or related to the tachycardia mechanism (i.e., SVT with aberrancy). A wide QRS complex can make the distinction between supraventricular and ventricular tachycardia difficult.

The two types of SVT are automatic and reentrant. They can be differentiated by assessing characteristics of the tachycardia, usually assisted by the input from a specialist. The evaluation of a tachyarrhythmia should include a surface 15-lead ECG and continuous rhythm strip to document onset and termination. If

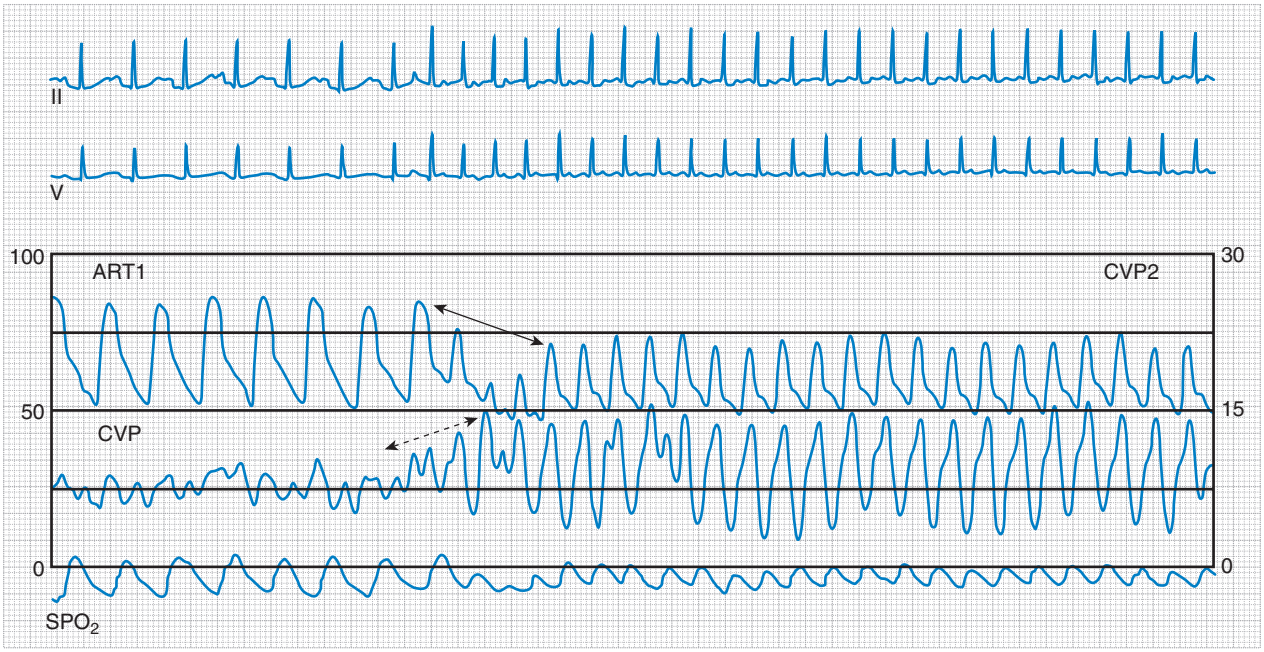

FIGURE 16.26 The initial portion of the intraoperative recording demonstrates normal sinus rhythm. A premature atrial beat initiates a narrow complex tachycardia (i.e., QRS morphology is the same as in sinus rhythm). The supraventricular tachycardia is associated with hemodynamic changes such as a decrease in the systemic arterial pressure (ART 1, scale of 0-100 mm Hg) (*solid arrow*) and increase in the central venous pressure (CVP, scale of 0-30 mm Hg) (*broken arrow*). Spo_2, oxygen saturation.

a medication such as adenosine has been administered, a recording of the response to the drug or pacing maneuvers should be obtained. The management of SVT depends on the clinical status of the child, type of tachycardia, and precise electrophysiologic mechanism. General management principles include the following:

- Hemodynamic stability should be determined. Synchronized direct current cardioversion (0.5-1.0 J/kg) should be performed for hemodynamic instability.
- Antiarrhythmic therapy is based primarily on the clinical condition and suspected tachycardia mechanism. Vagal maneuvers can be considered but should not delay treatment. Adenosine is the drug of choice in the acute setting for diagnosis and termination of most supraventricular tachycardias.[202] β-Blockers are most often used for chronic therapy.
- Others measures include treatment of fever (if present), sedation, correction of electrolyte disturbance, and decreasing or withdrawing medications associated with sympathetic stimulation (i.e., inotropic agents) or with vagolytic properties.
- In addition to pharmacologic therapy, atrial pacing or cardioversion may be required.

Ventricular Arrhythmias

Premature Ventricular Contractions or Beats

Premature ventricular contractions (PVCs) are characterized by prematurity of the QRS complex, a QRS morphology different from that in sinus rhythm, usually a prolongation of the QRS duration for age, abnormalities of the ST segment and T wave, and premature ventricular activity not preceded by a premature atrial beat. PVCs of a single QRS morphology (i.e., uniform), without associated symptoms, and in children with structurally normal hearts are considered benign. An ECG during sinus rhythm should allow careful measurement of the QT interval. Further investigation and consultation are warranted in the presence of PVCs of multiple morphologies (i.e., multiform), if they occur with moderate frequency or in succession (i.e., couplets or runs) and are associated with symptoms or a structurally abnormal heart.

Ventricular ectopy in the perioperative period can be the result of profound hypoxemia, electrolyte disturbances, or metabolic derangements. Other causes include the use of recreational drugs, myocardial injury, poor hemodynamics, and prior cardiac surgical intervention.

Ventricular Tachycardia

Ventricular tachycardia (VT) is relatively uncommon in children. It is defined as three or more consecutive ventricular beats occurring at a rate greater than 120 beats/minute (Fig. 16.27). The QRS morphology in VT is different from that in sinus rhythm, and the QRS duration is typically prolonged for age. ECG features that support this diagnosis include AV dissociation, intermittent fusion (i.e., QRS complex of intermediate morphology between two other distinct QRS morphologies), QRS morphology of VT similar to that of single PVCs, and tachycardia rate in children usually below 250 beats/minute.

Acute onset of VT in pediatric patients can be caused by hypoxia, acidosis, electrolyte imbalance, or metabolic problems. Ventricular tachycardia can also occur in the context of depressed ventricular function, halothane anesthesia with or without hypercarbia, poor hemodynamics, prior surgical interventions, cardiomyopathies, myocardial tumors, acute injury (e.g., inflammation, trauma), and prolonged QT syndromes.[203]

Long QT Syndrome

Long QT syndrome (LQTS) (Fig. 16.28) is an electrical cardiac disturbance that can predispose children to arrhythmias that include

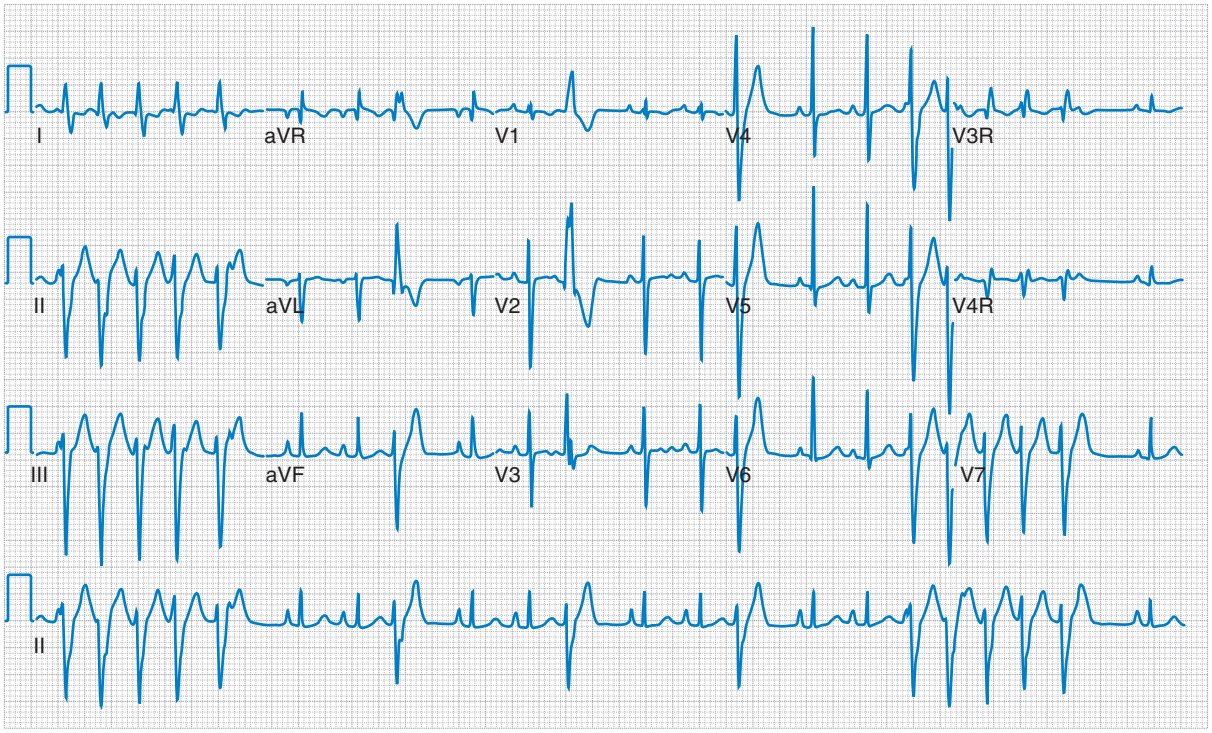

FIGURE 16.27 The tracing demonstrates frequent, uniform premature ventricular beats and episodes of nonsustained, monomorphic ventricular tachycardia.

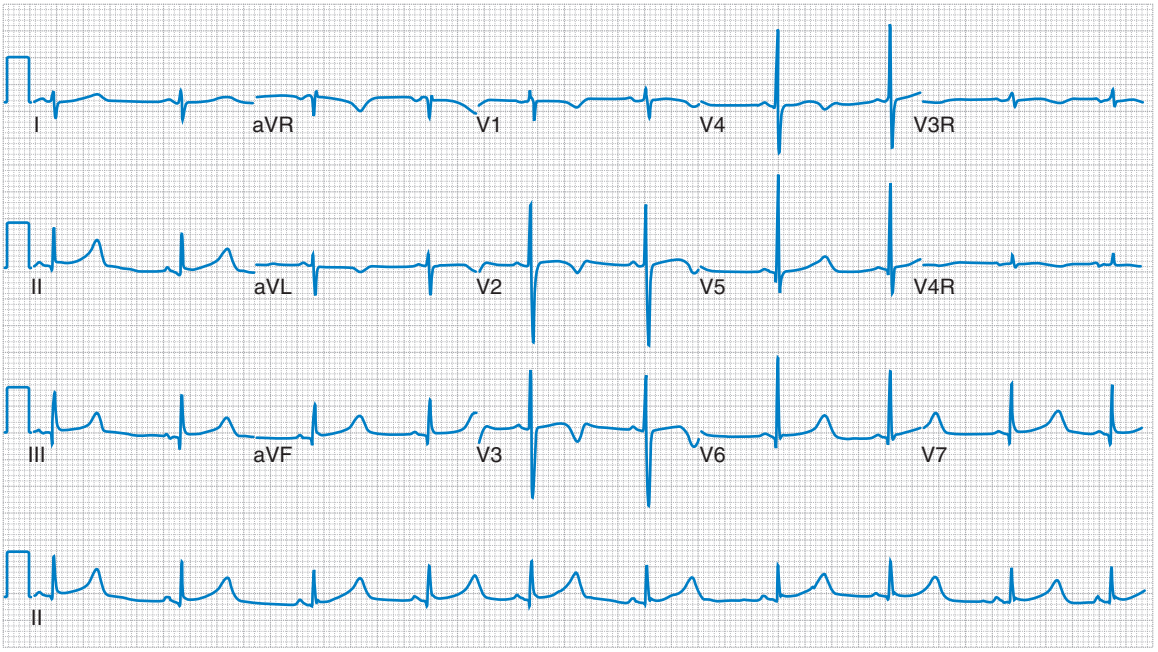

FIGURE 16.28 For a patient with long QT syndrome, the electrocardiogram demonstrates prolongation of the QT interval.

torsades de pointes ventricular tachycardia (Fig. 16.29), ventricular fibrillation, and bradyarrhythmias; any of these can result in syncope, cardiac arrest, or sudden death.[204] It occurs with an incidence of 1 per 2500 births; congenital and acquired forms have been described. The congenital varieties are likely the result of genetic defects in the ion channel proteins responsible for maintaining electrical homeostasis.[205] The Romano-Ward form of LQTS accounts for 90% of pediatric cases; it has an incidence of 1 per 10,000 births and an autosomal dominant pattern of inheritance. The Jervell Lange-Nielsen syndrome has an incidence

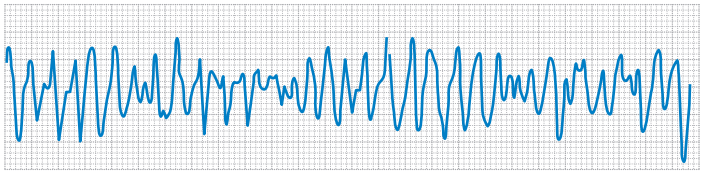

FIGURE 16.29 The rhythm strip displays positive and negative oscillation of QRS complexes, which is characteristic of torsades de pointes ventricular tachycardia.

of 1 per 1,000,000 births, an autosomal recessive pattern of inheritance, and an association with deafness. Diagnostic criteria for LQTS include electrocardiographic findings, clinical history (e.g., deafness, syncope), and family history. Prolongation of the QTc on the resting ECG is the hallmark of this syndrome but may not always be present.

An important consideration in the care of children with LQTS is ensuring adequate β-adrenergic blockade preoperatively and minimizing adrenergic stimulation.[206] The risk for developing torsades de pointes from the many drugs known to trigger it is almost unpredictable; these drugs have been divided into several groups that are listed and updated online at https://crediblemeds.org.[207]

In a retrospective study of children with LQTS, three adverse events were reported during emergence from anesthesia immediately after administration of ondansetron and anticholinesterase medications; one was described as torsades de pointes.[208] These arrhythmias resolved quickly with IV β-blockers, lidocaine, or the administration of both agents. The report suggests that children with LQTS are at risk for arrhythmias during periods of enhanced sympathetic activity (i.e., during emergence), particularly in the presence of drugs that prolong the QT interval. Conditions (e.g., hypothermia) and drugs that are known to prolong the QT interval should not be combined if possible. Despite the fact that most IV medications and inhalational agents routinely administered during anesthesia prolong the QT interval, adverse events are rare. This may be attributed in part to the need for a second abnormality beyond a prolonged QT interval to be present to trigger arrhythmias (e.g., increased dispersion of repolarization). Fortunately, most anesthetics do not increase the dispersion of repolarization.

Torsades de pointes is a rare but potentially life-threatening arrhythmia. To trigger torsades, a second phenomenon must occur (e.g., increased dispersion of repolarization). Dispersion of repolarization refers to the variance in the rate of repolarization; in this case, it is a circumscribed region in the heart muscle (i.e., transmurally from the epicardium to the endocardium). There is much debate over how to quantify an increased dispersion of repolarization from surface ECGs. Some suggest the dispersion is the QTc-max to QTc-min, whereas others recommend measuring the duration of the T wave from its peak to the end; in both instances the upper limit of normal is 65 msec and abnormal values exceed 100 msec.

Prolongation of the QT interval and genesis of torsades de pointes occur more commonly in the presence of several conditions and drugs: electrolyte derangements (e.g., hypokalemia, hypocalcemia, hypomagnesemia), combination drug therapies (e.g., antibiotics, antiarrhythmic agents, class III antiarrhythmics such as amiodarone and procainamide), antipsychotic drugs, neurologic or endocrine abnormalities (e.g., hypothyroidism), 5-HT_3 receptor–blocking drugs (except palonosetron), neostigmine, stress (including induction of and emergence from anesthesia and laryngoscopy), female gender, bradycardia, and coronary artery disease. Although many anesthetics prolong the QT interval, few affect the dispersion of repolarization (as in the case of sevoflurane), and the risk of torsades de pointes during general anesthesia in children is rare.[209]

Management of ventricular tachycardia requires the following considerations:

1. Although some atypical forms of supraventricular tachyarrhythmias may mimic VT, a wide QRS tachycardia should always be considered to be of ventricular origin.
2. The initial approach in the setting of an acute ventricular rhythm disturbance consists of prompt evaluation of clinical status and hemodynamic stability. Sustained ventricular arrhythmias are poorly tolerated and require immediate attention. In the unstable child, cardiopulmonary resuscitation should be instituted while preparing for cardioversion. Expert consultation is advisable when advanced drug therapy is contemplated. Potential pharmacologic interventions include lidocaine, amiodarone, and procainamide. The latter two should not routinely be administered during torsades de pointes owing to QT prolongation.
3. Magnesium sulfate is considered the first-line treatment of torsades de pointes. Procainamide and amiodarone are contraindicated owing to prolongation of the QT interval. Isoproterenol and overdrive pacing can be effective for bradycardia. Electrical cardioversion (1-2 J/kg) should be performed only if the arrhythmia is refractory to pharmacologic treatment.
4. LQTS should be treated with β-blockade (not overdrive pacing); some forms of the LQTS may require the implantation of a cardioverter-defibrillator.

Ventricular Fibrillation

Ventricular fibrillation (VF) is an uncommon arrhythmia in children. It is characterized by chaotic, asynchronous ventricular activity that fails to generate an adequate cardiac output. The ECG during VF demonstrates low-amplitude, irregular deflections without identifiable QRS complexes. A loose ECG electrode can mimic these surface electrocardiographic features, therefore immediate clinical assessment should be performed and adequate pad contact ensured when VF is suspected.

Management of VF includes the following considerations:

1. This is a lethal arrhythmia if untreated.
2. Immediate defibrillation (initial dose of 2 J/kg) is the definitive therapy. Cardiopulmonary resuscitation, beginning with chest compressions, should be immediately instituted and continued for 2 minutes. If defibrillation is unsuccessful, the energy dose should be doubled (4 J/kg) and repeated. Pediatric paddles (2.2 cm in diameter) are recommended for children weighing less than 10 kg. Adult paddles (8 to 9 mm in diameter) are suggested for children weighing more than 10 kg to reduce impedance and maximize current flow.
3. Adequate airway control and chest compressions should be rapidly instituted while preparing for defibrillation or between

shocks if several defibrillation attempts are needed. Resuscitative drugs and amiodarone should be considered without delaying defibrillation.

Pacemaker and Defibrillator Therapy in the Pediatric Age Group

PACEMAKER NOMENCLATURE

Pacemaker nomenclature follows the guidelines of the North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group (Table 16.5)[210]:

- First letter: chamber(s) paced (A = atrium, V = ventricle, D = dual or both, O = none)
- Second letter: chamber(s) sensed (A = atrium, V = ventricle, D = dual or both, O = none)
- Third letter: pacemaker response to sensing (I = inhibited, T = triggered, D = dual response, O = none)
- Fourth letter: rate modulation (R = rate modulation, O = none)
- Fifth letter: multisite pacing (A = atrium, V = ventricle, D = dual or both, O = none)

The most common pacing modes are listed in Table 16.6.

TABLE 16.6 Most Common Pacing Modes

Single-Chamber Pacing
AAI: atrial demand pacing (atrial pacing and sensing, inhibited on sensed beat)
AAIR: atrial demand pacing (atrial pacing and sensing, inhibited on sensed beat), rate responsiveness
VVI: ventricular demand pacing (ventricular pacing and sensing, inhibited on sensed beat)
VVIR: ventricular demand pacing (ventricular pacing and sensing, inhibited on sensed beat), rate responsiveness
Asynchronous Pacing (No Sensing)
AOO: fixed-rate atrial pacing
VOO: fixed-rate ventricular pacing
DOO: fixed-rate AV pacing
Dual-Chamber Pacing
DDD: paces and senses both chambers
DDDR: paces and senses both chambers, sensor-driven rate responsiveness

PERMANENT CARDIAC PACING

Indications

The updated guidelines for device-based therapy of cardiac rhythm abnormalities were published in 2013.[211] In general terms, indications for permanent cardiac pacing in children include symptomatic sinus bradycardia, bradycardia-tachycardia syndromes, congenital third-degree AV block, and advanced second- or third-degree AV block.[211,212]

Perioperative Considerations

It is essential for anesthesia providers involved in the care of patients with a cardiac implantable electronic device (CIED) to understand basic aspects such as indications for placement, functionality, and potential issues that may be encountered perioperatively.[213] Device interrogation is an essential part of the preoperative evaluation in all patients with an implanted pacemaker.[214,215] Results of a recent 15-lead ECG should be reviewed if available. Familiarity with unit type, settings, date of and indications for implantation, device location, and underlying cardiac rhythm is highly recommended. If records are not available and there is no identification card providing details about the unit implanted, a radiopaque marker on a chest radiograph can assist in the identification of the device. Major pacemaker manufacturers can also be contacted by telephone at any time because they maintain computerized records of all implanted devices.

Reprogramming may be required before the planned procedure to avoid potential problems with pacemaker malfunction related to electrocautery. This represents one of the most common potential sources of electromagnetic interference in children with implanted cardiac devices. Recommendations for the perioperative management of the patient with a cardiac pacemaker include the use of bipolar cautery rather than a unipolar configuration if possible, avoiding cauterization near the site of the generator, and positioning the indifferent plate (dispersive pad) for electrocautery as far away as possible from the pacemaker so that the device is not between the electrocautery electrodes.[216] Devices such as the harmonic scalpel and battery-operated, hot wire, handheld cautery units do not interfere with implanted cardiac devices. Rate-responsive features of pacemakers should be deactivated in most cases.

Chronotropic drugs and alternate pacing modalities should be readily available in the event of pacemaker malfunction and compromising underlying rate. Although inserting a transvenous pacemaker has been recommended for children with complete AV block who were undergoing pacemaker implantation, a 10-year review indicated no benefit to routine preoperative temporary

pacing.[217] Capture thresholds can be affected by pharmacologic agents, and this should be considered if pacing is required in the child receiving antiarrhythmic drug therapy.

Perioperative conditions can also influence pacing thresholds. A magnet should be accessible to allow asynchronous pacing if required. Most generators respond to magnet application by pacing at a fixed rate asynchronously (i.e., AOO, VOO, or DOO). A potential problem is that the specific magnet rate, as determined by the manufacturer for the particular device, can be different from the desirable or optimal pacing rate. The use of a magnet should not be considered a substitute for preoperative pacemaker interrogation/programming. In addition to perioperative electrocardiographic monitoring, additional modalities that confirm pulse generation during pacing (e.g., esophageal stethoscope for assessment of heart sounds, pulse oximetry, invasive arterial blood pressure monitoring) are strongly encouraged. The device should be tested and reprogrammed after the procedure is completed.

Transcutaneous Pacing

Several devices that combine defibrillation and cardioversion capabilities with external pacing features are available. Emergency transthoracic pacing can be considered as a temporizing measure for children with symptomatic bradycardia,[218] but this has not been effective in the treatment of asystole in children.[219] Pacing electrode size should be selected according to patient size (e.g., smaller adhesive pads for weight <15 kg). Device settings typically include pacing rate and power output. Sedation may be necessary to tolerate soft tissue discomfort. Prolonged periods of transcutaneous pacing can result in local cutaneous injury. In addition to monitoring for pacemaker capture by ECG, ongoing clinical assessment of the adequacy of cardiac output should be undertaken.

Implantable Cardioverter-Defibrillators

The primary goal of an implantable cardioverter-defibrillator (ICD) is the prevention of sudden death. Children with long QT syndrome, HCM, history of near-death events, arrhythmogenic right ventricular dysplasia, and operated CHD with a history of malignant arrhythmias represent potential candidates for device implantation.[211,212] The capabilities of these units include pacing and defibrillation. It may be feasible to terminate tachyarrhythmias by pacing.

As more children have received implantable devices in the past few years, an increasing number of them may require anesthetic care. The main considerations associated with intraoperative care of patients with these devices relate to monitoring, managing issues with potential for electromagnetic interference, and performing emergent defibrillation, cardioversion, or heart rate support.[213–215] Perioperative consultation with a cardiologist or electrophysiologist is essential in most, if not all, cases. These devices should be interrogated and likely require programming before and at the conclusion of the planned procedure.

Diagnostic Modalities in Pediatric Cardiology

CHEST RADIOGRAPHY

The standard posteroanterior and lateral chest radiographs provide clues to a child's underlying cardiovascular anatomy; however, plain radiographs are an insensitive screening tool for cardiac disease.[220] Children with numerous types of significant CHD can have initially normal-appearing radiographs; alternatively, an infant with a poor inspiratory effort and the presence of a large thymus can give the appearance of cardiomegaly and have normal intracardiac anatomy (Fig. 16.30).

FIGURE 16.30 For a neonate with apneic episodes undergoing evaluation for potential cardiac disease, the radiograph demonstrates a poor inspiratory effort resulting in a large cardiothymic silhouette, making interpretation of cardiac size difficult. No evidence of cardiac disease was identified in this child.

Interpretation of a chest radiograph begins with identification of the patient's name and ensuring that the right-left orientation of the radiograph is correct. All catheters and tubes should be followed to verify their location, course, and likely site of termination. The bones and soft tissues should be inspected for evidence of sternal wires, fractures, vertebral anomalies, or wide intercostal spaces, suggesting a prior thoracotomy. Sidedness, including the location of the gastric bubble, liver, and position and orientation of the cardiac mass, should be observed. The lung parenchyma should be examined for evidence of focal consolidation, such as pneumonia or atelectasis, and for pulmonary vascular markings.

The cardiac silhouette and great vessels should be assessed. In young children, the thymus can obscure the superior portions of the cardiac shadow. Careful inspection of the cardiac silhouette includes an assessment of overall size and evidence of individual chamber or vessel dilation. The size of the main pulmonary artery segment can provide further evidence of the degree of pulmonary overcirculation in children with left-to-right shunt lesions. The tracheal indentation can usually be seen and is useful in determining aortic arch sidedness, although in a young child with a prominent thymus, this can be difficult to assess.

More useful than an individual radiograph as a diagnostic tool are serial chest films obtained to monitor a child's cardiovascular status over time. In a young child with a volume overload lesion, the physical examination and growth parameters coupled with the degree of cardiomegaly and pulmonary overcirculation are more helpful than more advanced imaging techniques. A plain chest radiograph can also guide initiation and titration of pharmacologic therapy and the timing of a surgical intervention.

BARIUM ESOPHAGRAM

The current applications and uses of barium esophagram (swallow) studies in the diagnosis of CHD are limited. This modality has been largely replaced by MRI and chest tomography. In some

FIGURE 16.31 Barium swallow in a child with respiratory symptoms demonstrates an indentation posteriorly in the mid-esophagus, which is consistent with a vascular ring (in this particular case was caused by an aberrant subclavian artery with a retroesophageal course).

cases, a barium esophagram is used as an initial screening tool when there is concern about the presence of a vascular ring, usually because of airway symptoms or, less likely, feeding or swallowing difficulties.[221,222] Most common types of vascular rings in children are (1) a double aortic arch and (2) a right aortic arch with an aberrant left subclavian artery and left-sided ligamentum arteriosus. The indentation pattern in the barium column is suggestive of the specific vascular anomaly (Fig. 16.31).

ECHOCARDIOGRAPHY

Echocardiography is the gold standard for the initial evaluation and serial assessment in most types of pediatric heart disease.[223] Ultrasound transducers are used to acquire real-time images of cardiovascular structures. Various echocardiographic modalities are available, including transthoracic, transesophageal, fetal, epicardial, intracardiac, and intravascular ultrasound.[224–229] Each plays an important role in the evaluation and management of children with suspected or known cardiovascular disease.

Advantages of echocardiography include its noninvasive nature, provision of excellent temporal and spatial resolution, generation of portable real-time images, cost-effectiveness, and ease of use. As with any type of ultrasound, these waves are transmitted well through homogeneous tissues and fluid but poorly through air and bone. Another limitation of echocardiography is related to limited acoustic windows in certain patient groups, such as those who have undergone multiple prior cardiothoracic procedures, older individuals, or children with a significant amount of soft tissue or body fat. For this reason cardiovascular MRI is being increasingly used for noninvasive imaging. Additional challenges of echocardiography include the need to obtain serial two-dimensional tomographic images by sweeping the transducer scan in multiple planes to reconstruct these into three-dimensional structures in one's mind and to achieve expert interpretation. Despite these limitations, echocardiography remains the main diagnostic imaging modality for most children. Many medical and surgical management strategies are primarily based on the findings allowed by this approach.

A standard transthoracic study consists of a two-dimensional examination, M-mode imaging, and Doppler evaluation (i.e., color flow, pulsed-wave, or continuous-wave modalities). Two-dimensional imaging provides structural assessment of the heart and vasculature. Cross-sectional images are obtained from several windows that allow excellent anatomic detail in multiple planes (Video 16.11). In most cases, this is adequate for a detailed segmental evaluation of the cardiac anatomy as described earlier. M-mode echocardiography allows one-dimensional imaging of the heart with excellent temporal resolution (Fig. 16.32). It is known as an *ice pick view* of the heart in real time and is primarily used in the assessment of ventricular dimensions and function.

Color flow Doppler techniques allow evaluation of directionality and velocity of blood flow. In addition to detecting flow across cardiac valves and vessels, color flow imaging allows demonstration of subtle lesions such as small septal defects that can be difficult to identify by standard two-dimensional imaging alone. Traditionally, flow toward the transducer is displayed in red, and flow away is represented as blue. Turbulent blood flow is associated with increased Doppler velocities and can be readily identified as a mosaic of colors; it typically has a greenish tint (Video 16.12).

Pulsed- and continuous-wave Doppler represent spectral modalities that complement the color flow data and provide quantitative information. Pulsed-wave interrogation localizes specific sites of stenosis or turbulence but is limited in the magnitude of velocities it can detect. Continuous-wave Doppler allows quantification of much higher velocities (see Video 16.12). Velocities obtained with spectral Doppler provide estimates of pressures within various cardiac chambers by applying the simplified Bernoulli equation. It states that the difference in pressure between two locations is approximately four times the square of the velocity of the jet of flow between them:

$$\text{Pressure gradient (in mm Hg)} = 4 \times V^2$$

The applications of three-dimensional echocardiography continue to evolve, including in patients with CHD.[230–232] This approach can provide clear and useful volumetric assessments when the images are adequate. A significant advantage of this modality is that it is able to display cardiovascular structures and their interrelationships in detail, in many cases facilitating the understanding of pathologic conditions over two-dimensional imaging. The technology is particularly helpful in cases of complex anatomy. Three-dimensional echocardiography can also be useful when interventions are planned.

Interpretation of an Echocardiographic Report

Measurements of Cardiac Chambers and Vessel Dimensions

Several measurements are routinely obtained during an echocardiographic examination. They include left ventricular end-diastolic (LVED) and left ventricular end-systolic (LVES) dimensions, thickness of the interventricular septum and left ventricular posterior wall, measurements of valve annular sizes and great artery dimensions, and left atrial volume. To determine whether these are appropriate for the child being examined, the measurements are referenced to values obtained in normal children matched for body surface area. This is accomplished by reporting the measured value and a *z* score, representing standard deviations of measured values from the mean in a comparative population.

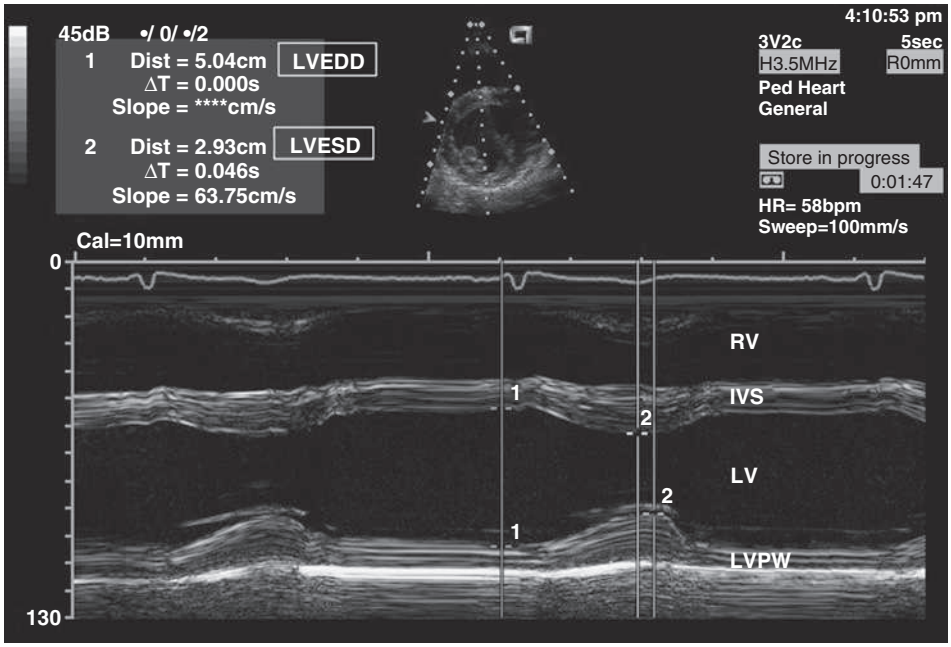

FIGURE 16.32 An M-mode echocardiogram enables determination of left ventricular dimensions and calculation of left ventricular shortening fraction. *IVS*, interventricular septum; *LV*, left ventricle; *LVEDD*, left ventricular end-diastolic dimension; *LVESD*, left ventricular end-systolic dimension; *LVPW*, left ventricular posterior wall; *RV*, right ventricle.

Assessment of Ventricular Function

Several echocardiographic techniques are able to provide information regarding ventricular performance. Two of the most commonly reported indexes of ventricular systolic function are shortening fraction and ejection fraction. Shortening fraction (SF) represents the percent of change in left ventricular diameter during the cardiac cycle. This is calculated using the following equation:

$$\text{SF}(\%) = (\text{LVED dimension} - \text{LVES dimension}/\text{LVED dimension}) \times 100$$

Values range from 28% to 44%, with a normal mean value of 36%. This index, however, depends on ventricular preload and afterload.

Ejection fraction (EF) is the fraction of blood ejected by the ventricle (stroke volume) relative to its end-diastolic volume. This represents the percentage of blood ejected from the left ventricle with each heartbeat. EF is derived by volumetric analysis of the left ventricle by means of the following equation:

$$\text{EF}(\%) = (\text{LVEDV} - \text{LVESV}/\text{LVEDV}) \times 100$$

In the equation, LVEDV is the left ventricular end-diastolic volume, and LVESV is the left ventricular end-systolic volume. Normal values range between 56% and 78%. A low EF is associated with impaired systolic function; however, cardiac dysfunction can also occur in the presence of a normal EF, as in the case of diastolic heart failure.

Although these functional indexes are routinely and easily obtained, they have significant limitations. Estimation of EF is based on geometric assumptions for the elliptical left ventricle, and this may not be applicable to a systemic right ventricle or other types of ventricular geometries (e.g., single ventricle). This accounts for an ongoing interest in alternative approaches that may provide more sensitive and comprehensive information regarding ventricular performance, even in the absence of clinical disease. These techniques include the myocardial performance index, also known as the Tei index, which combines systolic and diastolic intervals to assess global ventricular function,[233,234] Doppler tissue imaging (DTI), which is used to evaluate intramural myocardial velocities,[235] and strain and strain rate imaging to quantitate the rate of segmental myocardial deformation.[236] Although values in normal children have been established for these imaging modalities and alterations in the presence of pathologic conditions have been described, additional studies documenting their clinical applications in specific types of cardiovascular pathology are needed.

Estimation of Pressures

The peak velocity of a tricuspid regurgitant jet can be used to estimate right ventricular systolic pressure, which should equal pulmonary artery systolic pressure in the absence of pulmonary stenosis or outflow tract obstruction (Video 16.13). For example, if a peak regurgitant velocity of 3 m/second is recorded across the tricuspid valve using the simplified Bernoulli equation, the pressure gradient or difference between the right atrial and right ventricular systolic pressures can be estimated to be $4 \times 3^2 = 36$ mm Hg. If a normal right atrial pressure is assumed (4–6 mm Hg), it would predict a right ventricular systolic pressure of approximately 40 mm Hg. Similarly, if the peak or maximal flow velocity across a VSD is measured at 4.5 m/second, it predicts a pressure gradient of $4 \times 4.5^2 = 81$ mm Hg between the ventricles, implying that the defect is pressure restrictive and the right ventricular and pulmonary artery systolic pressures are relatively low.

Evaluation of Gradients

Estimation of a peak instantaneous gradient is the most clinically useful method for quantifying the severity of obstructions across semilunar valves and outflow tracts. It is derived by application of the simplified Bernoulli equation. When these gradients are measured across the pulmonary valve, they tend to correlate more

closely with catheterization peak-to-peak gradients than with those measured across the aortic valve, for which mean gradients (obtained by automated integration of the velocities under a spectral Doppler tracing) have been shown to correlate more closely.[237] The mean rather than peak gradient determined by Doppler echocardiography is considered a better metric of the severity of the obstruction across AV valves and other low-flow venous pathways.

Evaluation of Regurgitant Lesions

Evaluation of the severity of regurgitant lesions in most pediatric cardiac centers remains largely a qualitative assessment. It is usually characterized as mild, moderate, severe, or a combination thereof when there is overlap among these categories. Serial echocardiographic assessments and comparative data are clinically more meaningful than an isolated report.

MAGNETIC RESONANCE IMAGING

Cardiovascular MRI-angiography has emerged as a complementary technology to the other imaging modalities (Videos 16.14 and 16.15). Benefits have been reported in the assessment of complex pathology, delineation of systemic and pulmonary vascular anomalies, evaluation of global and regional ventricular function, assessment of myocardial viability, and characterization of pulmonary blood supply in children with structural alterations of the pulmonary vascular tree.[238–244] Additional applications that may further expand the utility of cardiovascular MRI include the quantification of left-to-right shunts and measurement of blood oxygen saturation.[245–247] MRI is also beneficial for guiding interventions in pediatric heart disease.[248,249]

Although the temporal resolution of MRI is inferior to echocardiography, new sequences and techniques allow real-time acquisition similar to that of fluoroscopy. An important aspect in the acquisition of MRI data with high spatial resolution is the use of cardiac and respiratory gating to allow sampling during only specific portions of the cardiac and respiratory cycles. Slow heart rates and low respiratory rates facilitate this process. In contrast to computed tomography (CT), MRI does not expose the child to radiation; this makes it preferable for serial examinations that many young children with cardiovascular pathology require. However, this may be associated with the need for multiple encounters that require deep sedation/anesthesia and their inherent risks.

Because of the nature of the magnetic fields generated in MRI, the presence of several types of metal, including pacemakers, ICDs, cerebrovascular clips/coils, and recently implanted intracardiac or intravascular coils and devices, are considered contraindications. Titanium hardware can minimize the artifact produced by the foreign material; stainless steel generates significant artifacts within the MRI study.

An additional limitation of MRI is the need for the child to remain immobile during long examinations to optimize the image quality. For small children, this usually necessitates the use of deep sedation or general anesthesia.[250–252] For infants with complex and often cyanotic CHD, specialists are often asked to provide care during these radiologic procedures. The severity of the cardiovascular disease and the need for breath-holding can add to the challenges presented to the anesthesia care provider in a remote location.[253] The lengthy nature of the studies and the significant time requirements to perform postprocessing of the images cause MRI to be much more time intensive for the interpreting physician than other noninvasive imaging modalities.

As MRI technology improves with faster scans, increasing availability, and decreasing cost, it will continue to play an increasing role in the diagnosis and longitudinal follow-up of congenital and acquired pediatric heart disease.

COMPUTED TOMOGRAPHY

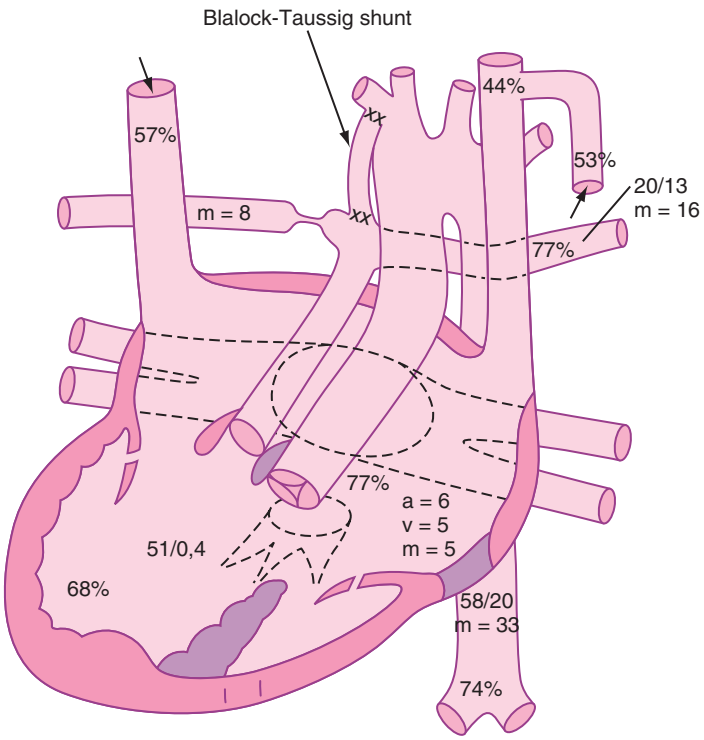
CT, with or without electrocardiographic gating, represents an option among the various cardiovascular imaging modalities (Fig. 16.33).[254,255] The major advantage of CT over MRI is the very rapid scan times, and for most children, sedation is minimal or not required. A significant drawback of CT is the large radiation burden, although it typically is estimated to be similar to or slightly greater than a diagnostic cardiac catheterization, and the likely need for iodinated contrast agents with their concomitant risks. It should be noted that radiation dose varies among institutions. Optimizing the dose of radiation while maintaining an adequate diagnostic image quality continues to be an ongoing area of investigation.[256]

Cardiac CT is not as accurate as MRI to delineate intracardiac anatomy, but it provides excellent spatial resolution and

FIGURE 16.33 Computed tomography images show the detailed anatomy in an infant with severe aortic arch obstruction (*arrows*).

information on extracardiac structures. CT has been beneficial in the evaluation of aortic arch anomalies and vascular rings and for defining systemic and pulmonary venous returns. Additional applications of this technology include assessing abnormalities of the coronary arteries (congenital and acquired) and evaluating cardiovascular disorders associated with airway pathology where dynamic recordings and three-dimensional reconstructions provide detailed information.

CARDIAC CATHETERIZATION AND ANGIOGRAPHY



Cardiac catheterization invasively measures intracardiac and vascular pressures and blood oxygen saturation coupled with angiography to assess cardiac anatomy and hemodynamics (Figs. 16.34 and 16.35). Before the era of two-dimensional echocardiography, cardiac catheterization was frequently used for diagnostic purposes. With the advances in noninvasive imaging, diagnostic procedures represent a relatively small proportion of these studies. Current indications for cardiac catheterization at most centers include the assessment of physiologic variables such as pressure and resistance data, measurements of shunt ratios, anatomic definition when other diagnostic modalities are inadequate, need for electrophysiologic testing or treatment, and when catheter-based interventions are anticipated.

Most catheterizations are performed for interventions including endomyocardial biopsies; angioplasties and stenting of stenotic vessels, dilation of valves, and conduits; and occlusion techniques for native defects (Video 16.16), fistulous connections, and surgically created communications no longer considered necessary (Fig. 16.36) (see also Chapter 22). In some cases, such as critically ill neonates with complex heart disease, catheter-based interventions such as balloon atrial septostomy and other procedures can be lifesaving.

Access to the central circulation is usually accomplished percutaneously through a femoral approach. Most examinations involve hemodynamic evaluation with recording of pressure data through catheters positioned at various sites of interest. Oxygen saturation data are obtained by reflectance oximetry or blood gas measurement from various cardiac chambers and vessels. In contrast to the oxygen saturation calculations derived from a blood gas analysis, reflectance oximetry provides measured values. This allows determination of oxygen content (i.e., total amount of hemoglobin in the blood) and, when combined with values of oxygen consumption, assessment of blood flows and other calculations (e.g., shunts).[257] Additional data that can be obtained include pressure gradients, cardiac output, and parameters for deriving vascular resistances and valve areas. Although basal measurements would ideally be performed under conditions that mimic an awake state, this is not feasible in children and in most cases requires the use of deep sedation or general anesthesia. Baseline hemodynamic assessment and oximetric data calculations are optimally obtained under conditions of normocarbia while the inspired oxygen concentration is kept low and relatively constant.

Fluoroscopy and cineangiography are essential components of most cardiac catheterization studies. Of the two, cineangiography accounts for most of the radiation exposure as images are recorded during the injection of contrast material, typically at 15 or 30 frames per second. Consequently, there is concern about radiation dose and risk during cardiac catheterization.[258] Most angiograms are obtained during biplane imaging by positioning the equipment to obtain optimal views allowing for delineation of the pathology in question (i.e., axial angiography) (Video 16.17, A and B).[259]

Although cardiac catheterization has evolved over the years, providing an improved margin of safety, it remains an invasive procedure involving risks.[260–263] They include excessive blood loss, vascular complications, infection, arrhythmias, vascular or cardiac perforation, systemic air embolization, myocardial ischemia, and those associated with the administration of contrast agents. These complications are more likely to occur in neonates and infants rather than the older child.[264] Interventional catheterizations, by the nature of the procedures, are associated with a greater rate of complications and potential for morbidity and mortality. However, as transcatheter interventions become safer and more effective, an increasing number of infants and children may obviate the need for surgery, often undergoing procedures on an outpatient basis.[265] Evolving approaches in this field include percutaneous implantation of valves, strategies that combine cardiac catheterization and surgical

intervention (hybrid procedures), and catheter-based interventions during fetal life.[266–270]

Interpretation of a Cardiac Catheterization Report

Pressure Data

Atrial pressure tracings are characterized by several waves (*a*, *c*, and *v* waves) and descents (*x* and *y*). Reported values correspond to the *a* and *v* waves and the mean pressures. The right atrial pressure is typically *a* wave dominant. The mean right atrial pressure is normally less than 5 mm Hg. The left atrial pressure tracing is typically *v* wave dominant. The mean left atrial pressure rarely exceeds 8 mm Hg. Abnormal pressure waveforms are often associated with AV valve stenosis, regurgitation, rhythm disturbances, and pericardial disease.

Ventricular pressures are recorded and reported during systole, at end systole, and at end diastole. For the right ventricle, systolic pressure is normally 25 to 30 mm Hg, with end-diastolic pressures of 5 to 7 mm Hg. The systolic pressure in the left ventricle increases with age and should equal the systolic arterial pressure. The end-diastolic pressure is typically less than 10 mm Hg.

The pulmonary artery pressure is reported in terms of systolic, diastolic, and mean pressures. The systolic pulmonary artery pressure in a normal child should be equal to the right ventricular systolic pressure, and the mean pulmonary artery pressure should not exceed 20 mm Hg. The pulmonary artery wedge pressure is obtained by advancing a catheter into a distal vessel until it is occluded, reflecting the left atrial pressure.

The aortic pressure and contour of the tracing depend on the site of interrogation. Typically, there is an increase in the systolic pressure as the catheter navigates toward the peripheral circulation. This phenomenon is known as *pulse wave amplification*.

Pressure gradients, or the pressure differences between two distinct sites, can be measured in several ways (i.e., mean gradient and peak gradient). It is important to consider that several factors may affect their determination. This is significantly influenced by the severity of the obstruction and the ventricular function. Smaller gradients can be seen in patients under sedation or anesthesia.

Shunt Calculations

Shunts are characterized in terms of their direction (e.g., left-to-right, right-to-left, bidirectional) and magnitude. Left-to-right shunts can be quantified based on the pulmonary ($\dot{Q}_{pulm}$) to systemic ($\dot{Q}_{sys}$) blood flow ratio. In the equation, $S_{sys}aO_2$ is the systemic arterial O_2 saturation, $S\bar{v}o_2$ is the mixed venous O_2 saturation, $S_{pulm}vO_2$ is the pulmonary venous O_2 saturation, and $S_{pulm}aO_2$ is the pulmonary arterial O_2 saturation.

$$\frac{\dot{Q}_{pulm}}{\dot{Q}_{sys}} = \frac{(S_{sys}aO_2 - S\bar{v}O_2)}{(S_{pulm}vO_2 - S_{pulm}aO_2)}$$

A $\dot{Q}_{pulm}/\dot{Q}_{sys}$ shunt ratio that exceeds 3 : 1 is considered significant, although smaller ratios can be associated with considerable symptoms.

Cardiac Output Determinations

The volume of blood ejected by the heart into the systemic circulation, or cardiac output, can be derived in several ways. Thermodilution measurements use saline as an indicator to measure pulmonary blood flow. In the absence of intracardiac shunts, this is equivalent to cardiac output (expressed as liters per minute). In the Fick method, oxygen is used as an indicator, and cardiac output is obtained by the application of the following formula:

$$\dot{Q}_{sys} = (\text{L/minute}) = \frac{VO_2(\text{L/minute})}{C_{sys}O_2 - C\bar{v}O_2}$$

In the equation, $\dot{V}O_2$ is the oxygen consumption (assumed or measured), $C_{sys}O_2$ is the systemic arterial O_2 content, and $C\bar{v}O_2$ is the mixed venous O_2 content. The O_2 content = O_2 saturation × (1.36 × 10 × hemoglobin concentration).

Vascular Resistances

Resistance represents the change in pressure in the systemic or pulmonary circulation with respect to flow. It is expressed in Wood units (in mm Hg/L per minute) and is usually normalized for body surface area. The systemic vascular resistance (SVR) and pulmonary vascular resistance (PVR) are derived as follows:

$$SVR = (\text{aortic mean pressure} - \text{right atrial mean pressure})/\dot{Q}_{sys}$$

$$PVR = (\text{pulmonary artery mean pressure} - \text{pulmonary capillary wedge pressure or left atrial pressure})/\dot{Q}_{sys}$$

Perioperative Considerations for Children With Cardiovascular Disease

GENERAL ISSUES

Anesthesia for children with heart disease can be both challenging and daunting because of the following[271]:

- The remarkable spectrum of disease
- The wide range of congenital lesions and their underlying physiologic consequences
- The numerous interventional and surgical options in CHD (Table 16.7), in addition to their hemodynamic implications
- The fact that many parents are unaware of the full extent or details of the child's lesion or abnormalities

To optimally care for these children, the following objectives should be met:

- Familiarity with the cardiovascular defects
- Understanding of the physiologic abnormalities and available therapies
- Recognition of signs of limited reserve, compensatory mechanisms, and perioperative risks[272]
- Ability to identify the potential impact of the proposed intervention/surgical procedure on the child's underlying condition, anticipate if/how it will be tolerated, and be prepared to manage any problems that may arise

This combination of formidable challenges and difficult objectives can be intimidating even for the most experienced clinician. When caring for children with complex cardiovascular disease, an interdisciplinary approach is recommended, allowing for the formulation and execution of optimal individualized management plans. If available, consultation with the child's cardiologist or primary care physician should include inquiries about the details of the child's disease, overall clinical status, past and current medical treatment, prior catheterization or surgical interventions, and presence of residual pathology. The interaction between members of the perioperative team should allow an exchange of information, discussion of concerns, and recommendations that can facilitate patient care and the development of comprehensive care plans.[273] This is particularly important in the management of children with complex pathology.

A complete medical history and focused examination is essential during the preoperative assessment. In addition to evaluating the child's disease processes, overall clinical status, and functional

TABLE 16.7 Surgical Procedures for Congenital Heart Disease

Procedure	Description	Goal or Result
Arterial switch (Jatene) operation	Arterial trunks transected above the level of the semilunar valves, relocated to their appropriate respective ventricles, coronary arteries reimplanted into the neoaortic root	Establishes the normal ventriculo-arterial connection (right ventricle to pulmonary artery and left ventricle to aorta) in D-transposition of the great arteries
Atrioventricular septal defect (atrioventricular canal/endocardial cushion defect) repair	Patch closure of atrial and ventricular communications, reconstruction of atrioventricular valves, closure of cleft in left-sided atrioventricular valve	Eliminates the intracardiac shunts
Blalock-Taussig shunt	Communication between innominate or subclavian artery and pulmonary artery; "modified" implies placement of a graft	Allows for or augments pulmonary blood flow
Central shunt, Waterston shunt, Potts shunt, Mee shunt	Communication between the systemic and pulmonary circulations	Allows or increases pulmonary blood flow
Closure of septal defect	Patch or primary closure of communication at the atrial or ventricular level	Eliminates an intracardiac shunt
Coarctation repair	Relief of aortic arch obstruction (various approaches)	Establishes patency across the aortic arch
Damus-Kaye-Stansel procedure	End-to-side anastomosis of main pulmonary artery onto the aorta; necessitates reestablishing pulmonary blood flow through an alternative route (graft from a systemic artery into the pulmonary artery or a right ventricular to pulmonary artery conduit)	Allows unobstructed systemic outflow in the context of single ventricle associated with obstruction to aortic flow or other settings
Division or ligation of patent ductus arteriosus	Obliteration of the communication at the level of the ductus arteriosus	Eliminates shunting at the level of the great arteries
Fontan procedure	Connection that directs inferior vena cava blood into the pulmonary circulation	Separates the pulmonary and systemic circulations in patients with single ventricle physiology; usually the final step in the single-ventricle palliation pathway
Glenn anastomosis (cavopulmonary connection)	Anastomosis between superior vena cava and pulmonary artery (bidirectional implies flow from superior vena cava into both pulmonary arteries)	Provides pulmonary blood flow while unloading the single ventricle; may be the first or intermediate step in the single-ventricle palliation pathway
Konno-Rastan procedure (aortoventriculoplasty)	Enlargement of the left ventricular outflow tract and aortic annulus; defect created in the ventricular septum to enlarge the outflow tract repaired with a large patch	Alleviates subvalvar and valvar aortic obstruction; when the aortic root is replaced by an autologous pulmonary root, it is referred to as a Ross-Konno procedure. Alternatively, cryopreserved homograft tissue can be used in the form of an extended aortic root replacement.
Nikaidoh procedure	Involves reconstruction of left ventricular outflow tract with translocation of aortic root after division of outlet septum and excision of the pulmonary valve, patch closure of ventricular communication, and completion of right ventricular to pulmonary artery anastomosis with pericardial patch	For management of transposition of the great arteries with pulmonary stenosis and a ventricular septal defect.
Norwood procedure (stage I palliation)	Involves aortic reconstruction, an atrial septectomy, and placement of a systemic-to-pulmonary artery shunt (modified Blalock-Taussig shunt) or right ventricular to pulmonary artery conduit (Sano modification)	Addresses systemic outflow tract obstruction by allowing the right ventricle to eject into a reconstructed aorta. Atrial septectomy provides unobstructed drainage of the pulmonary venous return into the right atrium. The systemic-to-pulmonary artery connection supplies the pulmonary blood flow.
Pulmonary artery banding	Constrictive band placed around the main pulmonary artery	Limits excessive pulmonary blood flow
Rastelli operation	Creation of an intracardiac tunnel that allows left ventricular output into the aorta while closing a ventricular septal defect, and placement of a right ventricular conduit to pulmonary artery	Allows the left ventricle to eject solely into the aorta, abolishes intracardiac shunting at the ventricular level, and provides unobstructed pulmonary blood flow. The procedure results in separation of the pulmonary and systemic circulations.
Sano modification of the Norwood procedure	Placement of graft between the right ventricle and main pulmonary artery as an alternative to a modified Blalock-Taussig shunt in the Norwood operation	Provides pulmonary blood flow
Senning or Mustard procedure (atrial switch)	Intraatrial baffle procedure	Allows pulmonary venous blood to be rerouted through the tricuspid valve into the right ventricle (as the systemic chamber that ejects into the aorta). Systemic venous return is channeled across the mitral valve into the left ventricle, which pumps into the main pulmonary artery.

TABLE 16.7 Surgical Procedures for Congenital Heart Disease—cont'd

Procedure	Description	Goal or Result
Tetralogy of Fallot repair	Closure of ventricular septal defect and relief of right ventricular outflow tract obstruction	Eliminates intracardiac shunting at the ventricular level and addresses right ventricular outflow tract obstruction (often at several levels)
Truncus arteriosus repair	Closure of the ventricular septal defect and establishment of right ventricular to pulmonary artery continuity (usually with a homograft)	Abolishes intracardiac shunting and restores the normal connection between the ventricles and great arteries
Valvectomy	Valve excision	Relieves valvar obstruction
Valvotomy	Opening of stenotic valve	Relieves valvar obstruction
Valve replacement	Placement of bioprosthetic or mechanical valve	Addresses valvar pathology (obstruction and regurgitation)
Valvuloplasty	Valve repair	Relieves valvar regurgitation and stenosis
Yasui operation	Channels blood from the left ventricle across the ventricular septal defect into a reconstructed aorta (using the native pulmonary valve as the neoaortic valve). Establishes right ventricular to pulmonary artery continuity by means of a conduit.	Provides for a biventricular repair in infants with two adequately sized ventricles and obstruction to systemic outflow.

reserve, this allows appraisal of issues that may affect anesthesia management (e.g., limited vascular access, difficult airway, gastroesophageal reflux, manipulations of pulmonary and systemic blood flow and pressures). Available diagnostic studies (e.g., ECG, chest radiograph, echocardiogram, Holter monitor, cardiac catheterization, MRI, CT) should be reviewed. Depending on the nature of the procedure, complexity of the disease, and potential impact on perioperative outcome, additional evaluation and diagnostic studies may be warranted. In many cases, the anesthesiologist as a perioperative physician plays a major role in determining whether the available information is adequate.

A fundamental goal in the preoperative evaluation is the identification of children who are at increased risk because of cardiac and pulmonary limitations imposed by their cardiovascular disease. After the preoperative visit, the anesthesiologist caring for a child with CHD should understand the pathophysiology of the cardiac defect and implications of any previous interventions. Abnormal indexes that should raise potential concerns include hypoxemia (SpO_2 <75%), $\dot{Q}_{pulm}/\dot{Q}_{sys}$ exceeding 3 : 1, outflow tract gradients greater than 50 mm Hg, pulmonary hypertension (i.e., mean pulmonary artery pressure >25 mm Hg), increased pulmonary vascular resistance index (>2 Wood units/m^2), or polycythemia (i.e., hematocrit >60%). Several clinical states may place children at significant risk for severe cardiopulmonary decompensation during anesthesia and surgery: recent congestive heart failure, uncontrolled arrhythmias, severe ventricular dysfunction, unexplained syncope, substantial exercise intolerance, single-ventricle physiology, supravalvular aortic stenosis (Williams syndrome), or any condition associated with significantly impaired cardiac or pulmonary function. For some children, a planned admission to the intensive care unit following the procedure should be discussed with the parents, child, and care team preoperatively.

CLINICAL CONDITION AND STATUS OF PRIOR REPAIR

Children with CHD may require anesthesia care before or after palliation or following definitive procedures. Corrective procedures are those that result in a normal life expectancy and full cardiovascular reserve, and children undergoing these interventions usually require no further medical or surgical treatment. In the strict sense, only a few procedures fulfill these criteria: ligation, division, or occlusion of a PDA and closure of an isolated secundum ASD. Other interventions or surgical procedures can result in repair or correction but not necessarily in normal hemodynamics or life expectancy. The clinician should assume potential limitation in cardiovascular reserve, a need for follow-up, further medical management, and in some cases, additional catheter-based interventions or surgical therapies. In other cases, as in children with palliated CHD, the circulation may still be abnormal. These individuals have been reported to be at greater risk for adverse perioperative events.[24,274–277] Published data from the POCA registry examined anesthesia-related cardiac arrests in children with congenital and acquired heart disease.[154] Cardiac arrests occurred more frequently in children with heart disease than in those children without heart disease. Causes were primarily cardiovascular in nature. These events occurred more frequently in the general operating room, usually during the surgical maintenance phase. The most common anatomic substrate in this setting was that of a single ventricle, particularly those early in the palliation pathway. The overall mortality rate for children with heart disease was greater than those without heart disease, with the greatest mortality rate occurring in children with aortic stenosis (Williams syndrome) and cardiomyopathy.

The effects of previous procedures on the heart and other systems require careful consideration. Problems that can remain or develop after surgical intervention include residual shunts, valvar stenoses or outflow tract obstruction, valvar regurgitation, pulmonary hypertension, arrhythmias, and ventricular dysfunction. Children who require a detailed appraisal of perioperative risks are those with residual significant pathology, suspected or known pulmonary hypertension, single-ventricle physiology, and those after outflow conduit placement, valve replacement, or cardiac transplantation (see Chapters 17, 18, and 22).

Summary

Caring for children with heart disease is a major aspect of pediatric anesthesia practice. The spectrum of cardiovascular disease includes a wide range of structural defects and varied congenital or acquired diseases. The ability to provide optimal perioperative care heavily relies on a clear understanding of the basic pathophysiology of the lesions, familiarity with the commonly used diagnostic modalities and their clinical applications, and medical and surgical

treatment options available to affected individuals. In this chapter, we have presented basic concepts in cardiology that can enhance the overall knowledge of the practicing anesthesiologist in pediatric cardiovascular disease.

ACKNOWLEDGMENT

We wish to recognize Dr. Timothy C. Slesnick for his contributions to this chapter in a prior edition.

ANNOTATED REFERENCES

Bai W, Voepel-Lewis T, Malviya S. Hemodynamic changes in children with Down syndrome during and following inhalation induction of anesthesia with sevoflurane. *J Clin Anesth*. 2010;22:592-597.

The retrospective study evaluated whether children with Down syndrome are at increased risk for bradycardia and hypotension during and after sevoflurane induction. The investigation reported a significantly higher prevalence and degree of bradycardia in children with Down syndrome. Despite these findings, there were no differences between Down syndrome and control groups in the prevalence of hypotension or pharmacologic interventions.

Brown ML, DiNardo JA, Odegard KC. Patients with single ventricle physiology undergoing noncardiac surgery are at high risk for adverse events. *Paediatr Anaesth*. 2015;25(8):846-851.

The retrospective chart review examined outcomes of anesthetics in children with single ventricle physiology undergoing noncardiac surgery. There was no mortality in a high-risk subgroup of palliated children; however, adverse events associated with anesthetic care occurred in almost 12% of children.

Cordina RL, Celermajer DS. Chronic cyanosis and vascular function: implications for patients with cyanotic congenital heart disease. *Cardiol Young*. 2010;20:242-253.

This excellent article reviews the effects of chronic cyanosis and associated alterations in blood vessel structure and function, with an emphasis on the endothelium and important implications for patients with cyanotic congenital heart disease.

Matisoff AJ, Olivieri L, Schwartz JM, et al. Risk assessment and anesthetic management of patients with Williams syndrome: a comprehensive review. *Paediatr Anaesth*. 2015;25(12):1207-1215.

The article provides an overview of the clinical manifestations of Williams syndrome, proposes a method to estimate anesthetic risk, and outlines recommendations for periprocedural care of affected children.

Rossano JW, Shaddy RE. Heart failure in children: etiology and treatment. *J Pediatr*. 2014;165(2):228-233.

This comprehensive manuscript addresses important aspects of pediatric heart failure, including epidemiology, diagnosis, risk stratification, and current therapies.

Preoperative Evaluation

Congenital heart disease (CHD) accounts for nearly one-third of major congenital abnormalities, with an estimated worldwide birth prevalence of 9.1 cases per 1000 live births.[1] In the United States, this represents the birth of 40,000 babies with CHD each year.[2] Although CHD can occur in isolation, it is often associated with other cardiovascular and extracardiac malformations.[3] The incidence of CHD is increased in the presence of other congenital abnormalities, in children with chromosomal disorders such as trisomy 21, as well as in siblings of other children with CHD.[4] As diagnostic techniques have improved, many children with CHD are diagnosed antenatally or early postnatally.[5,6] In association with improvements in diagnostic ability, surgical techniques, and perioperative care, most centers have shifted their practices to definitively repair the defects earlier, with many undergoing corrective surgery as neonates.[7,8] Overall, about one-half of all children with CHD undergo cardiac surgery in the first year of life, and about 25% undergo surgery in the first month of life.[9,10]

The perioperative management of children with complex cardiac defects requires a dedicated team of surgeons, cardiologists, anesthesiologists, intensivists, perfusionists, and nurses. Professionals caring for these children are challenged by some of the greatest physiologic aberrations encountered in clinical medicine. The anesthesiologists responsible for the care of these children require a comprehensive understanding of cardiac anatomy, physiology, and pathophysiology and must be able to adapt to each nuance of rapidly changing pathophysiology as it is encountered.

In addition to treating children with CHD, the pediatric cardiac anesthesiologist may also be responsible for the care of adults with CHD, whose underlying cardiac problems differ substantially from those in children.[11] The success of pediatric cardiac surgery has resulted in an ever-increasing population with "grown-up CHD" (GUCHD), as most children with CHD are now expected to survive into adulthood.[12] The ideal approach for this group of patients is to care for them in specialist units.[13,14] Although these GUCHD centers are increasing in number and capacity, they are currently unable to provide universal coverage. In the meantime, the care of these patients falls to the most qualified physicians, including the pediatric cardiac anesthesiologist. Along with their underlying CHD, these patients often present with comorbidities of old age, thus presenting additional challenges.

When assessing children with complex cardiac defects, we rely to a large extent on echocardiography and magnetic resonance imaging (MRI) to acquire diagnostic data. Although fewer children are subjected to diagnostic angiography today, more interventional cardiac catheterization procedures are being performed. Many conditions such as patent ductus arteriosus (PDA), atrial septal defects (ASDs), and ventricular septal defects (VSDs) that would previously have been treated surgically are now treated in the angiography suite by interventional cardiologists. Other interventions include dilating arteries with balloon catheters with and without stents and coiling of aberrant or excessive collateral vessels. The pulmonary artery is commonly balloon dilated and stented, and coarctation of the aorta is treated similarly by balloon dilation. Stenotic valves are also commonly dilated. These procedures have led to the risk

of patients being transferred emergently from the angiography suite to the operating room.[15] For the individual child, there has been a dramatic decrease in morbidity as increasing numbers of conditions are treated in the angiography suite, but the risks of complications that occur in the angiography suite have increased as more complex procedures are performed (see Chapter 22).

THE PREOPERATIVE VISIT AND EVALUATION

The preoperative visit is an important part of the overall management of anesthesia for children with CHD.[16] The preoperative visit has several aims:

- Medical assessment
- Prescribing premedication
- Providing information
- Creating a relationship with the child and family
- Formulating an anesthetic plan

Medical Assessment

The anesthesiologist must have a clear and detailed understanding of the cardiac anatomy and pathophysiology, the surgery to be undertaken, as well as any associated congenital abnormalities or medical conditions. The medical assessment includes collation of information from the history, physical examination, and review of imaging and laboratory data. Most diagnostic information is obtained from the medical record. Particular attention should be paid to the echocardiographic, angiographic, MRI, and other imaging data; the chest radiograph; and the electrocardiogram. Many centers have joint cardiac conferences where decisions about treatment are discussed in a multidisciplinary forum. Reports from these meetings are valuable in the preoperative assessment.

In addition to gathering this specific diagnostic information, a directed history and physical examination should be performed to assess the overall condition of the child. Attention should focus upon assessing the presence and degree of cardiac failure, cyanosis, or risk of pulmonary hypertension. Information about previous surgical procedures should also be sought, as it may alter access to the central circulation and placement of invasive monitors. The general nutritional state of the child should be assessed; poor growth and development may be a sign of severe CHD. Other information should be sought that may have a bearing on the anesthetic plan. For example, repeat surgery and redo sternotomy may indicate the need to establish peripheral cardiopulmonary bypass (CPB) before surgically accessing the heart and great vessels for central CPB cannulation. This has a bearing on line placement because either jugulo-carotid or femoro-femoral bypass may be required; the appropriate area should be preserved for CPB cannulation and avoided for line placement. If the child received aprotinin within the preceding 12 months, another dose should not be given because the risk of anaphylaxis is increased within this period (Trasylol package insert: Bayer Pharmaceuticals Corporation, West Haven, CT. December 2006).[17]

The type of surgery to be performed is important. For example, if a Blalock-Taussig shunt is placed on the left, the arterial line should not be placed in the left arm because the trace will be lost or distorted during subclavian cross-clamping. If a superior cavopulmonary anastomosis (Glenn shunt) is planned, a short internal jugular catheter can be useful to monitor pulmonary artery pressure, but it should be removed early in the postoperative period so as not to risk the formation of thrombosis in the superior vena cava (SVC), with its potential disastrous consequences.

Good veins should be sought and marked for the application of local anesthetic cream. This is useful in sick children even if an inhalational induction is planned because it allows placement of a venous cannula during a very light plane of anesthesia and avoids myocardial depression from large concentrations of inhalation anesthetics.

Prescribing Premedication

The use of sedative premedication can be useful, but this practice varies widely. Numerous medications and routes of administration may be used, and ample recommendations exist, but the use of premedication is often dictated by local preferences and not always evidence-based. There is heightened awareness and increasing concerns about the possibility of postoperative behavioral problems resulting from inadequate preparation and handling the uncooperative child preoperatively.[18] It is important for of the pediatric anesthesiologist to reduce perioperative anxiety in children by both nonpharmacologic and pharmacologic methods.[19] While prescribing premedication is best assessed on an individual basis, some general considerations apply to most children who present for pediatric heart surgery. Premedication for infants younger than 6 months of age is usually unnecessary. Premedication for older, healthy children who show little anxiety and with whom good preoperative rapport can be established is also often unnecessary. However, older children, particularly those who have undergone previous surgery, have fears about anesthesia and surgery. Although it is important to address their fears, sedative premedication may play a pivotal role in achieving adequate anxiolysis for parental separation and a smooth induction. Premedication in children with severe congestive heart failure is probably best used judiciously, if at all, as the effects of the usually prescribed doses may be unpredictable. On the contrary, children with dynamic obstruction to the left or right ventricular outflow tracts often benefit from sedative premedication because crying and struggling during induction may worsen obstruction. Cyanotic children (e.g., those with tetralogy of Fallot [TOF]), may develop increasing cyanosis if agitated during induction. However, it is important to monitor cyanotic children after premedication and provide supplemental oxygen as needed because they exhibit a blunted ventilatory response to hypoxia.[20,21] In the United States, supplemental premedication is sometimes administered under the direct supervision of the anesthesiologist in the preoperative facility, providing for a calm child and gentle separation from the parents. In the United Kingdom, where induction of anesthesia takes place in a dedicated anesthesia room, parents are present until after the induction, often making additional premedication unnecessary.

The most common premedication is oral midazolam (0.5-1.0 mg/kg).[22] However, the effect of midazolam may be unpredictable as it may cause paradoxical reactions, with agitation and dysphoria instead of anxiolysis and sedation. Numerous other medications including ketamine, clonidine, temazepam, chloral hydrate, and dexmedetomidine have been effective premedications in children with CHD.[23]

Giving Information

Providing information to the parents and to the child in a manner that is nonthreatening and appropriate to the child's age and developmental stage is a key element of the preoperative visit. This information includes the use of sedative premedication, fasting times, the type of induction, the type and likely position of invasive lines, the need for a stay in an intensive care unit (ICU) postoperatively, and the expected length of that stay. The use of other monitors such as transesophageal echocardiography (TEE) should be outlined and any contraindications identified, along with the

probability that a blood transfusion may be necessary. Questions about the risk of anesthesia and surgery should be addressed to the satisfaction of the parents (see Chapter 4).

Creating Rapport With the Child and Family

By creating a good relationship with the family, the anesthesiologist can reduce the anxiety of the child and the parents. The family develops a sense of trust, which can improve their hospital experience. A good rapport with the child may also facilitate a smoother anesthetic induction, and the use of specific nonpharmacologic techniques of reducing perioperative anxiety can be tailored to the child's individual preferences and possible previous experiences.

Formulating an Anesthetic Plan

After assessing the child, it is possible to formulate a detailed anesthetic plan. The anesthesiologist should have acquired a complete understanding of the child's heart defect and its hemodynamic consequences, as well as any comorbidities. The detailed anesthetic plan consists of a choice of anesthetic agents, techniques, ventilatory management and inotropic/vasoactive support to attain a set of appropriate hemodynamic goals for the individual patient.

UPPER RESPIRATORY TRACT INFECTION AND CARDIAC SURGERY

Otherwise healthy children undergoing elective noncardiac surgery in the presence of an upper respiratory tract infection (URI) are more likely to suffer respiratory complications (Table 17.1). These complications typically are minor, are easily managed, and usually result in minimal morbidity[24–26]; the decision to proceed with noncardiac surgery in a child with a URI is made on an individual basis (see Chapter 4).[27–29]

The decision to proceed with cardiac surgery in children with a URI may be difficult. Although children with cardiac failure are prone to multiple URIs, they may also have signs that can mimic URIs. Surgery may be relatively urgent, and postponing surgery could increase the risk to the child. Cardiac surgery in children with URIs is likely to increase the duration of stay in the ICU and prolong the duration of mechanical ventilation, although overall hospital stay may not be prolonged. Proceeding with surgery increases the incidence of atelectasis and postoperative bacterial infections. However, neither the mortality rates (4.2% with URIs vs. 1.6% without URIs) nor long-term sequelae in children with URIs who undergo cardiac surgery are significantly increased.[30] The children with URIs were significantly younger and smaller, which may account in part for the greater but statistically insignificant increased mortality rate; this should be taken into consideration when contemplating whether to proceed with surgery. Children who are scheduled for a Glenn shunt or completion of the Fontan circulation may be at particular risk because an increase in pulmonary vascular resistance (PVR) can adversely affect surgical outcome. It is prudent to postpone surgery in a child with a URI who is scheduled for elective cardiac surgery. If the surgery is urgent, discussion with the surgical team is required to correctly assess the risks and benefits to the child.

TABLE 17.1 Diagnosis of Upper Respiratory Tract Infection

At least two of the following signs plus confirmation by a parent:
- Rhinorrhea
- Sore or scratchy throat
- Sneezing
- Nasal congestion
- Malaise
- Cough
- Fever >100.4°F (38°C)

Data from Schreiner MS, O'Hara I, Markakis DA, Politis GD. Do children who experience laryngospasm have an increased risk of upper respiratory tract infection? *Anesthesiology* 1996;85:475–480.

Perioperative Challenges in Pediatric Cardiac Anesthesia

CYANOSIS

Cyanotic children compensate for chronic hypoxia with increased erythropoiesis, increased circulating blood volume, vasodilation, and metabolic adjustments of factors such as the circulating concentration of 2,3-diphosphoglycerate (2,3-DPG). These changes facilitate greater delivery of oxygen to tissues. The increase in blood viscosity with polycythemia increases vascular resistance and sludging, which may result in renal, pulmonary, and cerebral thromboses, especially in dehydrated children.[31–33] Long periods without oral intake preoperatively and postoperatively should be avoided in children with polycythemia, unless adequate intravenous (IV) hydration is provided.

PVR increases more than systemic vascular resistance (SVR) when the hematocrit increases, further decreasing pulmonary blood flow in children who already have a compromised pulmonary circulation. Coagulopathies are common in children with cyanotic CHD and may adversely affect surgical hemostasis.[34,35] Furthermore, chronic hypoxemia can cause important changes in vascular function and structure, some of which are maladaptive and probably contribute to impaired cardiovascular performance.[36] When the hematocrit exceeds 65%, excessive viscosity impairs microvascular perfusion and outweighs the advantages of increased oxygen-carrying capacity. Reduction of red blood cell volume can correct the coagulopathy and improve hemodynamics when increases in hematocrit are extreme.[37] However, treatment of hyperviscosity in patients with cyanotic heart disease is controversial[38,39]; guidelines for managing adults with CHD suggest the judicious use of phlebotomy and address the issue of potential complications.[40]

INTRACARDIAC SHUNTING

In CHD, much of the pathophysiology involves communications between chambers or vessels that are normally separate, resulting in shunting of blood between ventricles, atria, the great arteries, or a combination of these, depending on the nature of the lesion. Management of shunting during anesthesia is a major concern that requires an understanding of the factors that control shunting.

Restrictive and Unrestrictive Shunts

When communications are small, the size of the defect limits shunting and considerations of relative PVR and SVR become correspondingly less important in determining the degree of shunting. When there is a large pressure differential at the same level of the circulation on either side of a communication, the communication is restrictive. Flow is limited across the defect, and other factors that determine shunt flow become less important. This is usually the situation in children with mild heart disease that is asymptomatic or minimally symptomatic, such as small ASDs and VSDs or a small PDA.

Dependent Shunting During Anesthesia

In children with dependent shunts, the direction and degree of intracardiac shunting are determined by the circulatory dynamics. Control of circulatory dynamics to minimize the shunt is a major goal of anesthesia management. Because shunting depends on the relationship between SVR and PVR, anesthesia management often revolves around control of relative vascular resistances.

In children with dependent right-to-left shunts, the shunt increases when SVR decreases or PVR increases. In children with dependent left-to-right shunts, the shunt increases when SVR increases and PVR decreases. In children with bidirectional or balanced shunting, changes in vascular resistance increase the net shunt away from the side with increased vascular resistance.

For practical purposes, acute increases in left-to-right shunts during anesthesia are of clinical importance in several situations. A substantial steal of systemic blood flow by the pulmonary circulation can occur in conditions with unrestrictive, significant, left-to-right shunting such as atrioventricular (AV) canal, truncus arteriosus, and hypoplastic left heart syndrome. Left-to-right shunting is well tolerated, except when pulmonary steal leads to systemic hypotension, increasing acidosis from poor systemic end-organ perfusion or insufficient coronary perfusion. Shunting from right to left, because it is accompanied by at least some degree of arterial oxygen desaturation, is more frequently a problem during anesthesia.

IMPAIRED HEMOSTASIS

Hemostasis is impaired after bypass in infants and children to a greater extent compared with adults. The initiation of CPB triggers contact activation of the hemostatic systems, with ongoing coagulation and fibrinolysis, as well as the initiation of a systemic inflammatory response, both contributing to the coagulopathy. In infants and children, these effects are further compounded by a larger size of the CPB circuit relative to patient size. In this patient population, impaired hemostasis after bypass results from a combination of immature coagulation factor synthesis, hemodilution after bypass, and a complex interaction involving consumption of clotting factors and platelets. At birth, the levels of vitamin K–dependent coagulation factors in healthy, full-term neonates are only 40% to 66% of adult values. During the first month of life, these levels increase to 53% to 90% of adult values (see also Chapter 2).[41,42] However, in children with CHD, especially those with cyanosis or systemic hypoperfusion, coagulation factors often continue to be depressed owing to impaired hepatic protein synthesis. Although antithrombin III levels are also low, true heparin resistance is rare in infants because of parallel decreases in coagulation factors.

At the onset of CPB, the introduction of the prime volume, which is two to three times greater than the child's blood volume, dilutes the clotting factors, particularly fibrinogen to 50% and platelets to 30% of their prebypass values. This degree of dilution occurs even when the pump circuit is primed with whole blood. Greater dilution may occur when packed red blood cells (PRBCs) are used in the priming volume. At the conclusion of neonatal bypass, the activity of clotting factors is often extremely low, the fibrinogen concentration is frequently less than 100 mg/dL, and the platelet count is only 50,000 to 80,000/mm^3.[43–45] In addition to these quantitative changes, functional changes in the platelets occur during bypass. Extracorporeal circulation causes a loss of platelet adhesion receptors, activation of platelets, and formation of leukocyte-platelet conjugates. Platelet adhesion receptors in cyanotic children are depressed to a greater extent than in those with acyanotic cardiac defects. Heparin also impairs platelet function independent of CPB.[46,47]

Cardiac surgery is associated with significant activation of the fibrinolytic system.[48,49] Inadequate heparin concentrations during CPB may also contribute to postoperative bleeding because inadequate anticoagulation may allow continued activation of the hemostatic pathways. Ongoing activation of the coagulation cascade causes the consumption of platelets and clotting factors. The standard measurement of anticoagulation for bypass, the activated clotting time (ACT), shows a poor correlation with heparin concentrations (usually measured using the surrogate, anti-Xa) in children undergoing CPB.[50] In one study, the use of individualized heparin monitoring and heparin titration was associated with larger doses of heparin but smaller doses of protamine for antagonism.[51] Activation of the clotting cascade using that heparin-protamine regimen is also reduced, thus potentially decreasing bleeding in the postoperative period.[51–53] As a result of this multifactorial coagulopathy, blood loss is a greater problem in children than in adults and is a particular problem in neonates and small infants (see Chapter 19).[54]

Strategies to Reduce Bleeding After Bypass

In an effort to normalize factors and platelets to effective concentrations, some medical centers use fresh whole blood in the cardiopulmonary circuit prime. In adult patients and in an in vitro aggregation study, transfusion of fresh whole blood provided equal or greater hemostatic and functional benefit when compared with transfusion of platelet concentrates. In children, transfusion with fresh whole blood less than 48 hours from harvest reduced the blood loss compared with transfusion of reconstituted whole blood (e.g., packed erythrocytes, fresh frozen plasma [FFP], and platelets).[55] Other studies have shown that the use of fresh whole blood in the prime in neonatal and pediatric cardiac surgery reduced transfusion requirements[56,57] and improved outcomes.[58] However, the benefits of using fresh whole blood to prime the CPB circuit have been questioned in at least one study, which showed no advantage from its use and an increased length of stay in the ICU, as well as increased perioperative fluid overload in the group treated with fresh whole blood.[59] It is possible that different pediatric patient populations (e.g., age, cyanotic vs. noncyanotic CHD) derive different benefits from the use of fresh whole blood. Until this matter is clarified, it is difficult to make clear recommendations about its use in pediatric cardiac surgery. Moreover, fresh whole blood is often difficult to obtain. The units must be refrigerated for 24 to 48 hours while donor screening is performed, and storage causes significant platelet injury. Insistence on fresh whole blood places tremendous pressures on the transfusion service and donor center to coordinate the matching of donor types with recipient needs. Furthermore, in the presence of suitable, simpler alternatives to this blood component management strategy, it is likely that a considerable number of centers will continue to use individual blood component administration to treat bleeding and coagulopathy in children undergoing heart surgery.

Therefore individual component therapy remains the standard of practice in most institutions. In neonates and small infants with dilutional coagulopathy, platelets should be given in combination with cryoprecipitate to correct the defect in clotting. An initial dose of platelets (10 mL/kg) may need to be repeated. Platelets are usually administered if bleeding persists and the platelet count is less than 100,000/mm^3.[60] Cryoprecipitate contains high concentrations of fibrinogen, factor VIII, von Willebrand factor, and factor XIII. Fibrinogen and von Willebrand factor are required for platelet

adhesion and aggregation to occur. Platelet adhesion and aggregation are the fundamental first steps in primary hemostasis (see Chapters 10 and 12). The subsequent step of platelet degranulation switches on the entire coagulation cascade and cannot take place without adhesion and aggregation.[61] Administration of FFP, which is not evidence-based for this type of coagulopathy, may excessively dilute the red cell mass and platelets.[62]

Transfusion guidelines have been described for adults and have been shown to reduce postoperative bleeding and transfusion requirements.[63,64] Although similar guidelines have not been as forthcoming for children in whom the practice frequently seems to be more empirical, there is a growing body of evidence that point-of-care (POC) monitoring of hemostasis is useful to guide specific blood component therapy in children undergoing heart surgery.[65] In a surgical context, the time it takes to return routine coagulation tests is often too long for clinical decision making. Consequently, POC platelet count and viscoelastic monitoring of coagulation such as thromboelastography and thromboelastometry are being increasingly used to make timely informed decisions about blood product administration.[66] The use of transfusion algorithms in pediatric cardiac surgery has reduced blood product requirements and bleeding[67,68]; however, further work is needed to produce well-validated guidelines for monitoring and treating bleeding in children undergoing heart surgery.

Antifibrinolytics

The antifibrinolytics used in pediatric cardiac surgery include aprotinin, ε-aminocaproic acid (EACA) and tranexamic acid (TXA). EACA and TXA are lysine analogs that reduce bleeding after cardiac surgery in adults and children,[69,70] with apparent similar efficacy and safety.[71–73] Doses of EACA and TXA for pediatric cardiac surgery have yet to be clearly established. Furthermore, in view of the disproportion between circulating blood volume and CPB prime volume, a drug target concentration that differs between neonates and children, as well as other differences in pharmacokinetics, suggest that different dosing schemes should be used in neonates and smaller children compared with older children.[74–76]

Aprotinin is a serine protease inhibitor no longer available in many countries, and with only very limited availability in others, after its marketing license was withdrawn because of safety concerns. In fact, despite having been studied thoroughly in adults, its use remains a cause for great concern. Early evidence demonstrated that aprotinin reduces bleeding, reduces the time taken to extubation, shortens ICU stay, and reduces overall mortality rates.[77] However, subsequent studies have contradicted these earlier findings.[78] The same volume of evidence has not been published for children, although several studies suggest that it is effective in reducing bleeding and that it reduces the duration of postoperative mechanical ventilation.[34,79–81] An increased risk of renal failure or stroke in adults undergoing revascularization surgery has been reported.[82] The same investigators reported an increase in the 5-year mortality rate for adults after the use of aprotinin in revascularization surgery, mostly resulting from stroke and myocardial infarction.[83] Aprotinin has increased the 30-day mortality rate by as much as one-third compared with TXA or EACA.[78] However, it appears that the early data regarding increased death rates have not been supported by a subsequent study and that the benefits may outweigh risks in specific populations.[84] While aprotinin use in adults is still surrounded by significant controversy, taking into account the differences in pathophysiology and underlying risk factors, it seems plausible that data about increased mortality from stroke and myocardial infarction have only limited relevance for the pediatric population. Similarly, it appears unlikely that the risk of renal failure associated with the use of aprotinin in children is the same as it is in adults, despite some concerns about its propensity to cause acute kidney injury (AKI) in children,[85] which another study failed to demonstrate.[86] An important additional safety consideration pertains to the risk of severe hypersensitivity reactions. The reported incidence of side effects in children varies. Even though anaphylaxis seems to be infrequent in pediatric patients after primary exposure, the risk of such a severe reaction is increased after reexposure, particularly if it occurs within 12 months after the most recent prior aprotinin exposure.[17,87] This has led the manufacturer to issue a black box warning for aprotinin reexposure within 1 year of a prior exposure. The Food and Drug Administration (FDA) has also recommended that aprotinin should be administered only in the operative setting when CPB can be started quickly, in the event of a severe reaction. Uncertainty about the relative safety profiles of aprotinin and the lysine analogs is met with similar considerations about the effectiveness of these different drugs. Whereas there is some evidence that EACA or TXA are at least as effective as aprotinin,[88,89] research has also suggested that aprotinin use may decrease the output of the chest drain,[90] effect superior blood-sparing effect,[91] as well as confer differences in other outcomes such as cytokine activation or early indexes of postoperative recovery.[92] In fact, it appears that aprotinin may have unique antiinflammatory properties, which may benefit pediatric patients.[93] Further research is needed to clarify issues concerning safety and relative effectiveness of the two classes of drugs, as well as proving benefits and improve effective dosing schemes in specific patient populations (see Chapter 20).

Topical Agents

The use of topical agents to promote clot formation and reduce bleeding after cardiac surgery is common. The most frequently used topical agents are fibrin sealants. Fibrin sealants mimic the stages of the blood coagulation process. Unlike the synthetic adhesives, they are biocompatible.[94] Fibrin sealants are usually sourced from plasma components, and most contain virally inactivated human fibrinogen and thrombin with different quantities of factor XIII, antifibrinolytic agents, and calcium.[95] When the fibrinogen and thrombin are mixed during the application process, the fibrinogen is converted to fibrin monomers. This results in the formation of a semirigid fibrin clot. By mimicking the later stages of the coagulation process, these sealants stop bleeding and assist in wound healing.[94] They have significantly reduced bleeding in children undergoing heart surgery.[96]

Ultrafiltration

Ultrafiltration is a process that results in the production of an ultrafiltrate by means of convection forces and a hydrostatic pressure gradient across a semipermeable membrane. Thus free water and low–molecular-weight substances are removed from a child during and after CPB. It provides many benefits, including increasing the hematocrit, concentrating the clotting factors and platelets, increasing blood pressure, reducing PVR, and removing inflammatory mediators in the ultrafiltrate. It has significantly reduced bleeding after cardiac surgery in children.[97-99]

Desmopressin

Desmopressin acts by increasing plasma concentrations of factor VIII and von Willebrand factor (see also Chapters 10 and 12). It

has been effective in reducing bleeding after CPB in adult cardiac surgery[100] and its use is indicated in specific subgroups of patients.[101–103] Unfortunately, studies in children failed to demonstrate a similar effectiveness in reducing bleeding or transfusion requirements.[104]

Anesthesia Management for Surgery Requiring Cardiopulmonary Bypass

MONITORING

Noninvasive monitoring during pediatric cardiac surgery includes pulse oximetry, five-lead electrocardiography, an automated blood pressure cuff, a precordial or esophageal stethoscope, continuous airway manometry, inspired and expired capnography, anesthetic gas and oxygen analysis, multiple-site temperature measurement, and volumetric urine collection. The pulse oximeter is especially important when managing children with congenital cardiac disease. At least two probes should be placed on different limbs in the event that one fails during the procedure. In children with cyanotic heart disease, conventional pulse oximetry overestimates arterial oxygen saturation as saturation decreases[105–108]; this error tends to be exacerbated in the presence of severe hypoxemia.[109] When monitoring children with a shunt across the ductus arteriosus, a probe should be placed on the right upper limb to measure preductal oxygenation, and a second probe should be placed on a toe to measure postductal oxygenation (children with a right-sided aortic arch may require the probe to be placed on a left upper limb). Children undergoing repair of coarctation of the aorta should be monitored with a pulse oximeter on the right upper limb, because it may be the only reliable monitor during the repair, and blood pressure cuffs should be placed before and after the coarctation. These two cuffs may be cycled and the differential documented before and after surgical correction.

Monitoring end-tidal carbon dioxide tension (P_{ETCO_2}) is of value in most children. However, in children with cyanotic-shunting cardiac lesions, the P_{ETCO_2} measurement may be less reflective of P_{aCO_2} because of ventilation-perfusion mismatching.[110–112] Arterial blood gases are the most accurate measure of the adequacy of ventilation and oxygenation. To provide rapid decision making, it is helpful to have the blood gas analysis machine located in or near the cardiac operating room.[113,114]

Monitoring ionized calcium concentrations is essential during surgical procedures in which significant quantities of citrated blood are infused rapidly or when entire blood volumes are replaced. Neonates are particularly prone to disturbances in their ionized calcium concentration when citrated whole blood, FFP, or platelets are infused. Those with limited cardiac reserve tolerate ionized hypocalcemia poorly because of their greater sensitivity to the myocardial effects of citrate infusion (see Chapter 12).[115] In isolation, the total serum calcium concentration is misleading.

Temperature monitoring during CPB is a critical guide to adequate brain cooling and to appropriate rewarming before separation from bypass. Because it is not practical to measure brain temperature directly, surrogate measuring sites including the tympanic membrane, nasopharyngeal, and rectum have been used. The nasopharyngeal site most closely matches true brain temperature and is the site at which temperature is most often monitored. The tympanic and rectal sites tend to overestimate the brain temperature.[116] Measurement of skin temperature gives an indication about peripheral perfusion and provides information about adequate peripheral rewarming.

After induction of anesthesia, an arterial catheter should be placed in children who will undergo CPB. The radial artery may be percutaneously cannulated with relative ease, even in infants. In neonates, the femoral arteries are frequently used for arterial access, and the axillary arteries may also be used. The radial, femoral, and axillary arteries all seem to constitute suitable sites for arterial cannulation and invasive blood pressure monitoring, with complication rates similar to those in adults.[117,118] The brachial artery is generally avoided because it is an end artery, lacking collateral circulation, although one retrospective series of 200 children reported complication rates similar to other arterial sites.[119] Catheters placed in the dorsalis pedis or posterior tibial artery often provide inaccurate hemodynamic data, especially after separation from bypass, and it may become difficult to sample blood for laboratory testing. In the rare circumstance that peripheral arterial cannulation cannot be accomplished percutaneously, consideration should be given to obtaining arterial access by the cutdown method; alternatively, the surgeon may place a catheter in the internal mammary artery after sternotomy, and a sterile monitoring line may be passed over the drapes.

Central venous catheters are very useful for both central venous pressure monitoring and as a safe, reliable route for the administration of inotropes or vasopressors as well as potentially venoirritant solutions. For cardiac surgical procedures, there are two commonly used methods of obtaining central access. The decision of which to use may be determined in part by institutional bias. In the first method, the cardiac surgeons expose the heart quickly and have it available for inspection and estimation of filling pressures. Central lines can be readily established from the surgical field and handed off to the anesthesia team. These transthoracic central lines are useful but carry a small amount of risk.[120,121] The second method is percutaneous insertion of central venous lines via the subclavian or internal jugular vein.[122–124] This route is particularly useful for long, complex procedures, especially when access to the infant is limited or the heart is not exposed. It is important to appreciate that the internal jugular or subclavian route may fail or be associated with pneumothorax, hemorrhage, and hematoma formation after puncture of major arteries.[125,126] Cannulation of the external jugular vein may avoid some of these serious complications when the catheter can be successfully threaded into the central circulation.[127] Increasingly, ultrasound-guided techniques are being used to establish central venous access (see also Chapter 49). In the United Kingdom, the use of ultrasound for the placement of these lines is recommended by the National Institute of Clinical Excellence (NICE); ultrasound is used routinely for the placement of central lines.

In children with unrestrictive VSDs or ASDs, including hearts with a single ventricle or single atrium, central venous pressure is identical to left ventricular filling pressure. Cannulation of vessels that drain into the SVC should be approached with caution in children with univentricular anatomy who may undergo the Fontan procedure, because thrombosis of the SVC can be a devastating complication. In these children, the femoral veins may be the preferred sites for central venous access. Left-sided central venous lines in the SVC territory should also generally be avoided in cardiac patients. There is a greater risk of erosion and perforation from central venous catheters placed through the left internal jugular or left subclavian veins. Furthermore, in up to 10% of patients with CHD, these veins join a persistent left SVC that most often drains into the coronary sinus or left atrium, both undesirable locations for a central venous catheter tip.[128–130]

Percutaneously inserted pulmonary arterial catheters in children with intracardiac defects usually provide information that is not substantively different from that of a simple central line, are difficult to insert without fluoroscopy, and may not provide meaningful measurements of cardiac output. As a result, they are rarely used in pediatric cardiac patients. In circumstances that would be deemed useful, it is probably preferable to insert them surgically. In some complex CHDs and procedures in which postoperative left ventricular dysfunction is expected, it may be valuable to have continuous monitoring of pressures in the left heart. Such measurements are usually obtained via an LA pressure monitoring line inserted by the surgical team.[131–133]

Transesophageal Echocardiography

Use of perioperative echocardiography has become the standard of care in the United States for both adults[134–137] and children undergoing heart surgery.[138–140] In adult practice, anesthesiologists usually perform the transesophageal echocardiography (TEE), but in children, the TEE is more commonly performed by a pediatric cardiologist. This may reflect the increased complexity of congenital lesions and the difficulty in accurately assessing these lesions and their repairs. TEE is cost-effective[141] since its use can have a significant impact on surgical and medical management. In one study, a second bypass run was undertaken in 7.3% of cases based on the findings of the TEE, surgical alteration in the management in 12.7% and medical alteration in 18.5% of cases. Pediatric cardiac anesthesiologists usually can perform TEE before and after bypass if they have received adequate training.[142]

The introduction of small probes with multiplane capability has greatly increased the use of TEE, even in infants and neonates.[143,144] In 1999, a survey of centers in the United States indicated that 93% used intraoperative echocardiography and that all but one used TEE.[145] The American Society of Echocardiography and the Society of Cardiovascular Anesthesiologists have published guidelines for performing a comprehensive intraoperative TEE in adults[137] and children.[139]

Although the use of TEE in children is generally safe, complications do occur and may be more common in small infants.[146] Complications include damage to the mouth, tongue, oropharynx, esophagus, and stomach. Other complications include hemodynamic disturbance as a result of compression of the left atrium or other structures; erroneous invasive blood pressure monitoring may result if the compressed structure is an artery proximal to the arterial line insertion site. Interference with the airway also occurs in a small number of cases. This includes inadvertent extubation, right main-stem bronchus intubation, and compression of the tracheal tube. However, the overall incidence is small, approximately 2%.[147] Information gathered from the TEE examination takes place before and after bypass and may be divided broadly into two categories: hemodynamic assessment with monitoring and structural diagnostic information. Hemodynamic information includes information about ventricular function and filling.[148] Diagnostic information relates to confirmation of preoperative findings and assessment of the surgical repair.

Near-Infrared Spectroscopy

Near-infrared spectroscopy (NIRS) allows real-time monitoring of tissue oxygenation. This technology is based on the principle of optical spectrophotometry, making use of the fact that body tissues are relatively transparent to light in the near-infrared wavelength range. The majority of NIRS monitors use reflectance-mode NIRS, in which a region underlying the sensor is interrogated by a transmitter optode and a receiving sensor. The value obtained is a reflection of the underlying heterogeneous tissue area, composed of arteries, veins, and capillaries, as well as other nonvascular tissues. Even though there are several reports of the applicability of this technology to monitor other tissue beds[149,150] such as the renal and splanchnic circulations, cerebral NIRS has received the most attention in the context of pediatric cardiac surgery. This noninvasive monitoring is becoming widely used during CPB in children to assess the adequacy of oxygen delivery to the brain.[151–153] This may lead to improved neurologic outcomes after cardiac surgery, although there is no clear evidence for target based NIRS values in humans. One algorithm suggested that a 20% drop from baseline bilaterally was significant and should trigger efforts to increase the cerebral saturation, such as optimizing the neck position, increasing mean arterial pressure, increasing arterial CO_2, or increasing the hematocrit. If the change was unilateral, it may be related to incorrect aortic cannula positioning.[154] To be most accurate, baseline readings should be undertaken prior to the induction of anesthesia as anesthesia itself may result in changes (see Chapter 52).

INDUCTION OF ANESTHESIA

In the United Kingdom, most children are anesthetized in an anesthesia induction room, which is a small room immediately adjacent to the operating room, and in most cases, the parents are present at the induction. Anesthesia is commonly induced while the child is sitting with or being held by a parent. It is possible to engage some older children to hold the mask themselves during the first stages of induction; alternatively, some parents can hold the mask for the child as he or she is anesthetized. After the child is asleep, he or she is transferred to the anesthetic trolley, where venous and arterial access is secured and the trachea is intubated. This contrasts with the practice in most centers in North America, where induction of anesthesia usually occurs in the operating room.

The method of induction, either intravenously or by inhalation, should be tailored to the child and the cardiac defect. When an IV induction is selected (e.g., mask induction is refused) but IV access appears to be difficult, ketamine may be given intramuscularly or orally to sedate the child during the attempts. Application of a local anesthetic cream such as EMLA (eutectic mixture of local anesthetics; AstraZeneca, Wilmington, DE) or Ametop Gel (Smith-Nephew, Mississauga, ON, Canada) also reduces the pain of injection. However, this requires close communication in that suitable veins should be identified during the preoperative visit and clear instructions are given to the parents or nursing staff regarding where and when the cream should be applied (1 hour for EMLA and 30 minutes for Ametop). When IV access is already present, an IV induction is preferred. In severely ill children, it is generally advisable to secure IV access before induction of anesthesia.

Sevoflurane is the most commonly used inhalational induction agent in children. Sevoflurane is very rapid acting and should be used with care in the child with CHD because high concentrations can produce bradycardia, hypotension, and apnea if not titrated carefully. Concentrations should be rapidly reduced after an adequate depth of anesthesia is achieved (remembering that the minimum alveolar concentration [MAC] in children is 2.5%) to limit myocardial depression. To facilitate establishing IV access when the concentration of sevoflurane must be restricted,

application of local anesthetic cream is helpful because it allows cannulation at a much lighter plane of anesthesia. In children who are cyanotic with a right-to-left shunt and reduced pulmonary blood flow, inhalational inductions are slow. Moreover, in neonates and young infants with large right-to-left shunts, the desired depth of anesthesia may not be achieved; the end-tidal concentration does not accurately reflect the blood and brain partial pressures. Many include nitrous oxide during inhalational inductions for two reasons. First, it is odorless; therefore it can be started before the introduction of the sevoflurane to sedate the child before the stronger-smelling anesthetic is introduced. Second, it allows a smoother and more rapid induction compared with sevoflurane alone. Concentrations up to 70% nitrous oxide can be used to smooth induction of anesthesia even in cyanotic children, but the nitrous oxide should be replaced with air and oxygen or 100% oxygen as soon as IV access is obtained and a muscle relaxant is given. Some children do not want an inhalational induction out of fear of the mask. To address this problem, we put the mask aside and begin the induction by cupping our hands with the elbow of the breathing circuit between two fingers and slowly bringing our hands toward the face from under the chin (this gas mixture is heavier than air). It is important to warn the child about each event before it occurs (such as a mask applied to the face) and, when possible, to demonstrate the action on yourself, a parent, or a toy animal to avoid startling or scaring the child. Some children prefer to hold the mask themselves, or if the child is accompanied by a parent and unable to hold the mask, the parent may hold it. Good premedication often aids this process (see also Chapter 4).

For sick children in whom an IV induction is preferable, several options are available. In neonates, for example, those with coarctation of the aorta or with hypoplastic left heart syndrome who are not ventilated before coming to the operating room, one approach is to administer fentanyl in a dose of 2 to 3 μg/kg, followed by pancuronium and then by a very low dose (i.e., sedative dose) of sevoflurane or isoflurane. Fentanyl obtunds the hypertensive response to intubation, and the pancuronium maintains cardiac output by maintaining the heart rate. The very-low-dose inhalational agent provides the sedation or anesthesia. In older children, etomidate is an excellent choice as an induction agent, providing stable hemodynamics, although it does cause pain on injection. Ketamine is also widely used for IV induction in neonates and older children. Ketamine maintains or increases blood pressure, heart rate, and cardiac output. The exact mechanism of these effects of ketamine is unknown; ketamine may stimulate the release of endogenous stores of catecholamines, although it is a negative inotrope in the denervated heart.[155] This negative inotropic effect may make ketamine a poor choice in children in whom catecholamine stimulation may already be maximal, such as in severe cardiomyopathy.[156] It may also be a poor choice if tachycardia is undesirable, such as in the case of aortic stenosis.

Monitors should ideally be applied before induction begins, although applying monitors can upset the child, which can be detrimental (e.g., the child with TOF who begins to cry and precipitates a tet spell). A pulse oximeter probe may be the only monitor applied before induction of anesthesia. Sevoflurane and other halogenated agents may provide another advantage by offering a degree of ischemic preconditioning to the heart and to other organs, particularly the brain and kidney. In fact, sevoflurane use has decreased biochemical markers for myocardial and renal injury in coronary artery bypass grafting in adults.[157] Current evidence suggests a role of inhalational anesthetic agents in improving outcomes after cardiac surgery, in particular for some subsets of patients.[158–160] Further research is needed to clarify their protective role in different organs and systems, in noncoronary and noncardiac surgery, as well as recommended doses and timing of administration.[161] It is thought that the same effect is observed in children. Sevoflurane, but also midazolam and propofol, protect against myocardial injury in pediatric cardiac surgery when using cardiac troponin T as a marker of such damage.[162] One study has demonstrated definite cardioprotective effects from inhalational agents in children,[163] although these effects do not seem to be universally applicable to all children undergoing heart surgery, suggesting the need for further investigations.[164]

MAINTENANCE OF ANESTHESIA

Maintenance of anesthesia in children with CHD depends on the preoperative status and the response to induction of anesthesia. Whether inhalational agents, additional opioids, or other IV agents are used for maintenance depends on the tolerance of the child and postoperative plans for ventilation. If a primary opioid-based anesthetic is chosen, additional opioid should be administered on initiation of CPB to offset dilution from the pump prime and to maintain adequate opioid plasma concentrations. Awareness during adult cardiac surgery has been reported when amnestic agents were not used. Although small children may be unable to describe such events, the potential for awareness during pediatric cardiac surgery should not be underestimated. In effect, while it is unclear whether the incidence of awareness in children is more or less than in adults,[165,166] anesthesiologists should be cognizant of the possibility of intraoperative awareness in pediatric anesthesia, and mindful of the potential short- and long-term psychological effects of such a complication.[167–169] Recently, a national audit project in the United Kingdom (NAP5) suggested strategies to minimize the risk of awareness in pediatric cardiac surgery[170] that in part may depend on the several factors, including the child's age, hemodynamic stability, predicted duration of surgery and CPB, and plans for postoperative ventilation. The choice of a specific strategy is often dictated by institutional or personal preferences. Different agents, singly or in combination, may prevent awareness: an inhalational agent may be administered through the membrane oxygenator with an anesthetic vaporizer; IV midazolam (0.2 mg/kg) may be administered at the institution of CPB; propofol may be given by infusion during the bypass period. More recently, the use of a dexmedetomidine infusion has been proposed to attenuate awareness as it attenuates the hemodynamic and neuroendocrine responses to surgical stress and CPB in pediatric cardiac surgery.[171] Other benefits include decreased intraoperative anesthetic requirements and postoperative opioid consumption,[172] which suggest it may have a role in reducing the possibility of awareness. However, dexmedetomidine is *not* a general anesthetic (conferring 0.5 MAC equivalence) and its effectiveness in preventing awareness has not been established.[173] In one study, dexmedetomidine conferred a protective effect in the heart, brain, kidney, and lungs; the administration of dexmedetomidine may contribute to improved outcomes, a decrease in postoperative mortality, and a reduced incidence of complications and delirium in adults undergoing cardiac surgery.[174] Dexmedetomidine also slows sinus and AV node conduction[175]; this may prove useful in those with junctional ectopic tachycardia (JET).

INSTITUTION AND SEPARATION FROM BYPASS

Before initiation of CPB, the surgeon requests heparin to be given; after administration (preferably flushed through a central

venous catheter) but *before the initiation of bypass*, the ACT should be determined. By convention, the ACT measurement should be at least three times greater than the baseline value or greater than 480 seconds. Despite significant interindividual variations in heparin dose requirements and multiple problems associated with its use, heparin remains the anticoagulant of choice for CPB.[176,177] In fact, achieving an adequate balance between the appropriate amount of heparin to minimize the risk of thrombosis and platelet activation while reducing the risk of bleeding from overanticoagulation may be particularly challenging in children.[50] Similarly, the use of the ACT as the sole metric of anticoagulation may hold a number of inaccuracies, based on the inconsistent relationships between plasma heparin concentrations, thrombin inhibition, and coagulation tests.[178] Individualized management of anticoagulation and its reversal seem to result in less activation of the coagulation cascade, less fibrinolysis, and reduced blood loss and transfusion requirements. However, until further research defines the clinical impact of these findings, it is likely that the use of heparin and ACT measurement for anticoagulation management will remain the standard of care in most centers (see also Chapter 19).[51] When bypass is started, additional anesthetic drugs should be administered to counteract the effects of dilution and adsorption by the CPB circuit. Ventilation should cease. Both hypertension and hypotension may complicate bypass. Blood pressure may be controlled within an appropriate range to ensure end-organ perfusion by using α-adrenergic agonists or blockers such as phenylephrine and phentolamine. The child is usually cooled at this stage, guided by the nasopharyngeal temperature. If the heart is to be stopped, cardioplegia is given by the perfusionist after the aorta is cross-clamped to provide myocardial protection during the period of ischemia.[179,180] Cardioplegia is usually repeated every 20 to 30 minutes, although it is not required if the surgery is performed while the heart is beating. Myocardial damage is related to the duration of the aortic cross-clamping and the effectiveness of the myocardial protection.[181]

At an appropriate time during the surgery, the cross-clamp is removed, and perfusion to the heart is restored. The heart usually starts to beat in normal sinus rhythm, although this is not always the case. In the early phase of reperfusion, it is possible for various degrees of heart block to occur. However, these are usually short-lived and as the effects of cardioplegia wear off, normal sinus rhythm is usually restored. Persistent heart block may result from damage to the conducting system during surgery.

After release of the cross-clamp, any inotropes or vasodilators that are required are usually started. Rewarming may have begun before release of the cross-clamp, but more commonly, the child is rewarmed after release of the clamp.

When the child has adequately rewarmed, as reflected by (1) a normal core and minimal core-peripheral temperature gradient, (2) inotrope(s) infusion as needed, (3) restoration of satisfactory heart function, and (4) the adequate ventilation of the child's lungs, the child is ready to be weaned from CPB. If a TEE probe is in place, the heart should be scanned for the presence of air. If air is present, additional attempts to de-air the heart should be attempted before separating from bypass. In the initial stages after coming off bypass, additional volume can be administered through the aortic cannula by the perfusionist, usually under the direction of the surgeon or anesthesiologist. Many centers institute modified ultrafiltration at this point, which involves taking arterial blood from the aortic cannula and passing it through the ultrafine filter. This blood, which is oxygenated and warm, is then reinfused into the right atrium. As previously discussed, reported benefits from the use of modified ultrafiltration include increasing the hematocrit, concentrating the clotting factors and platelets, increasing blood pressure, reducing PVR, and removing inflammatory mediators from the patient. When this process is complete, a thorough TEE examination can be undertaken.

When the team is satisfied with the TEE result, the perfusionist and the surgical team should be informed that protamine will be administered soon. The surgeon should remove any pump suckers from the field, and the perfusionist should stop all pump suction. This is done to ensure that no protamine enters the bypass circuit in case it is necessary to reestablish bypass for any reason, especially if this needs to be done in an emergency situation. Once these preliminary activities are complete, the surgeon asks for protamine to be administered to antagonize the circulating heparin. At this point, a blood gas analysis is performed and the ACT repeated; the ACT should return to prebypass levels. Required blood products may be given during modified ultrafiltration or after the administration of protamine, usually while the surgeons are achieving hemostasis. As soon as reasonable stability is achieved and the chest is closed (or the decision to leave the chest open has been made), the child can then be transferred to the ICU.

Control of Systemic and Pulmonary Vascular Resistance During Anesthesia

In some children with hypoplastic left heart syndrome (HLHS) who present for a Norwood procedure, excessive blood flow to the lungs resulting from a relatively low PVR and a relatively high SVR steals blood from the systemic circulation, leading to hypotension, poor tissue oxygen delivery, myocardial ischemia, and progressive acidosis. However, when the reverse occurs and the PVR is greater than the SVR, the child develops progressive excessive desaturation.[182,183] Similar pathophysiology exists with other duct-dependent circulations and to some extent with other shunting lesions. It may prove difficult to manipulate the SVR and PVR predictably because control of PVR is poorly understood, vasoactive drugs usually are distributed on both sides of the circulation, and pharmacologic attempts to modify the degree and direction of shunting have produced unpredictable results.[184,185] Despite these problems, several techniques have proved useful in manipulating the relative PVR and SVR. Increasing inspired oxygen to 100% and by hyperventilation to a pH of 7.6 or greater decreases the PVR in children. Positive end-expiratory pressure, acidosis, hypothermia, and the use of 30% or less inspired oxygen can increase PVR. Potent inhalational anesthetics reduce SVR more than PVR. Etomidate does not change the pulmonary blood flow in children with TOF, whereas ketamine increases the flow in children with limited cyanosis (presumably by dilating the pulmonary artery) and decreases the flow in children with moderate cyanosis (by constricting the pulmonary artery).[186] Because vasoconstrictors such as phenylephrine increase SVR more than PVR, they are effective acutely in reducing right-to-left shunting and increasing left-to-right shunting in the operating room.

During cardiac surgical procedures, a direct method of selectively increasing PVR or SVR is to have the surgeon place partially obstructing tourniquets around pulmonary arteries or the aorta to increase resistance so that flow to the opposite side of the circulation increases. Although these are only temporary measures, they may reestablish a better relative balance of resistances and a more normal physiology in a deteriorating clinical situation.

Anesthetic Drugs Used in Pediatric Cardiac Anesthesia

INHALATIONAL AGENTS

Sevoflurane

Sevoflurane is the induction agent of choice for inhalational inductions in pediatric anesthesia.[187,188] It is associated with little myocardial depression or dysrhythmias,[189–191] and there is a reduced likelihood of precipitating airway hyperreactivity than that observed with other inhalational agents. It has specific advantages over halothane when used in children with CHD, particularly in children younger than 1 year of age and in cyanotic children.[192,193] In contrast to halothane, sevoflurane causes no reduction in heart rate at 1.0 and 1.5 MAC in healthy children compared with awake values.[194] However, at greater concentrations, it can slow the heart rate and depress respiration. Both features are important in children with CHD because a slow heart rate reduces cardiac output and hypoventilation leads to hypercarbia and hypoxia, which can increase PVR. In the absence of nitrous oxide, sevoflurane depresses myocardial contractility to a lesser extent than halothane during induction of anesthesia. However, it does decrease left ventricular systolic function to a limited extent as well as SVR, but in common with halothane and isoflurane, it does not alter the degree of left-to-right shunting through an ASD or VSD at concentrations of ~1 MAC in 100% oxygen.[195] Sevoflurane causes bradycardia in specific subsets of patients (e.g., trisomy 21)[196,197] and conduction abnormalities in susceptible children,[198] which may be clinically significant in children with marginal cardiovascular reserve. Sevoflurane should also be used with great caution in children with severe ventricular outflow tract obstruction.[199]

Isoflurane

Isoflurane is not recommended for induction of anesthesia because the frequency of laryngospasm is greater than 20%.[200] The inability to ventilate whether due to laryngospasm or other causes quickly leads to hypoxemia and hypercarbia, both of which increase PVR. This increase in PVR and the resulting pulmonary hypertension is poorly tolerated in small children with heart disease, especially in the presence of right-to-left shunting (see Chapter 7). Even though isoflurane depresses the hemodynamics in healthy neonates and infants to a similar extent as halothane at equipotent concentrations,[201,202] isoflurane may hold an advantage in children with CHD, as it depresses myocardial contractility to a lesser extent than halothane.[203,204]

Halothane

In the United States, Canada, and the United Kingdom, the use of halothane has all but ceased, but it is still widely used in other parts of the world. It is included here for completeness. Uptake of halothane in infants younger than 3 months of age is more rapid than it is in adults. This also is the case for the uptake of halothane by the myocardium.[205] Although the precise effects of halothane on the human neonatal myocardium are unknown, young rodents have a reduced cardiovascular tolerance for halothane but require greater amounts for anesthesia.[206] Studies in infants with normal cardiovascular systems have demonstrated a significant incidence of hypotension with bradycardia during induction with halothane.[207] During induction of anesthesia in normal infants, halothane decreases the cardiac index to 73% of awake values at 1.0 MAC and to 59% at 1.5 MAC.[202] The MAC for halothane in infants 1 to 6 months of age is the greatest of any age group.[208] This increased anesthetic requirement in infants, combined with the immaturity of their cardiovascular system, explains in part the relative cardiovascular intolerance of halothane by infants. In fact, hemodynamic depression associated with halothane has been shown to be inversely related to age in pediatric patients.[209] When compared with induction of anesthesia with sevoflurane, halothane decreased heart rate and systolic blood pressure in children of different age groups.[187] As such, atropine intramuscularly before induction and IV atropine during anesthesia partially offset the myocardial depression by halothane by attenuating the severity of the bradycardia and hypotension and increasing cardiac output. Despite the hypotension caused by halothane, it increases the arterial saturation in children with cyanotic CHD.[210]

A careful induction with sevoflurane is usually well tolerated in children with mild to moderate heart disease. However, large concentrations of potent inhalational agents may be an unwise choice for induction in young infants with severe cardiac disease. In children of any age with marginal cardiovascular reserve and in those with severe desaturation of systemic arterial blood due to right-to-left shunting, inhalational anesthetic-induced myocardial depression and systemic hypotension are poorly tolerated. A more appropriate use of these anesthetic agents in children with severe heart disease is the addition of low concentrations of the inhalational agent to provide amnesia and hypnosis, as well as to control possible hypertensive responses after an IV induction (see Chapter 7).

Nitrous Oxide

Nitrous oxide should be avoided for maintenance of anesthesia in children with CHD because of the risk of enlarging intravascular air emboli and the potential to increase the PVR. Nitrous oxide may expand microbubbles and macrobubbles, increasing obstruction to blood flow in arteries and capillaries. In all children with right-to-left shunts, there is a potential for these bubbles to be shunted directly into the systemic circulation and coronaries, a phenomenon designated by paradoxical embolization. The passage of air bubbles from the right to left sides is possible even in patients with predominantly left-to-right shunts, as the direction of shunting may transiently change under the influence of multiple factors during anesthesia and surgery. Consequently, care must be taken to ensure that no air bubbles are accidentally injected into the veins. Adverse outcomes after coronary air embolism are exacerbated by nitrous oxide.[211] The hemodynamic effects of venous air embolism are increased by nitrous oxide, even without paradoxical embolization.[212] In children with preexisting right-to-left shunts, paradoxical air embolism is clearly a potential problem; but even those with large left-to-right shunts can transiently reverse their shunts, as mentioned previously. This is particularly true during coughing or a Valsalva maneuver, when the normal transatrial pressure gradient is reversed. Right-to-left shunting of microbubbles of air after injection of saline into the right atrium has been demonstrated during these maneuvers.[213–215] Because coughing and Valsalva maneuvers may occur during anesthesia induction, even the most rigorous attention to removing air bubbles from IV lines may not prevent small amounts of air from reaching the systemic circulation. Microbubbles have also been observed after CPB.[216]

Nitrous oxide can increase PVR in adults.[217,218] However, in a 50% inspired concentration, it does not appear to affect PVR or pulmonary artery pressure in infants.[219] Nitrous oxide mildly decreases cardiac output at this concentration.[220] Avoidance of its use has been suggested in children with limited pulmonary

blood flow, pulmonary hypertension, or depressed myocardial function. In the well-compensated child who does not require 100% inspired oxygen, nitrous oxide (usually at concentrations of 50%) may be used during induction of anesthesia but discontinued before tracheal intubation. If a reduced inspired oxygen concentration is indicated to maintain an appropriate balance between PVR and SVR after tracheal intubation, air may be added to the inspired gas mixture.

INTRAVENOUS INDUCTION AGENTS

Ketamine

Ketamine is a dissociative anesthetic agent that is a good analgesic. It increases blood pressure, heart rate, and cardiac output. Although the mechanism responsible for these responses is incompletely understood, it is thought to result from its ability to stimulate the release of endogenous catecholamines.[221–223] Ketamine exerts a negative inotropic effect on isolated human myocardium in vitro,[224–226] which is dependent on the underlying adrenergic tone.[227,228] Consequently, the net effects of ketamine in vivo are likely to reflect the balance between its direct myocardial depressant effects and its ability to cause sympathetic stimulation. As such, it may be a poor choice for children in whom sympathetic stimulation may already be maximal, such as in those with severe cardiomyopathy. It is also a poor choice if tachycardia is undesirable, such as in a child with aortic stenosis. Ketamine is thought to have minimal effects on PVR in children with CHD as long as the airway and ventilation are well preserved.[229,230] These likely clinically insignificant effects on PVR seem to be applicable to children with normal[231,232] and increased[186,233,234] pulmonary artery pressures, although it has been shown to occasionally cause an increase in PVR, as well as a decrease in pulmonary blood flow in certain subsets of patients with CHD.[235] Ketamine is quite a versatile anesthetic that may be administered intramuscularly and orally when IV access is difficult or an inhalational induction is contraindicated. The usual IV dose of 1–2 mg/kg produces a very predictable response, and an intramuscular dose of 4 to 10 mg/kg (possibly combined with intramuscular midazolam) is less predictable. The oral dose of ketamine is 5 to 6 mg/kg. The use of ketamine varies greatly from one institution to another, with some units using it extensively and others using it rarely (see Chapter 7).

Etomidate

Etomidate is an imidazole derivative short-acting anesthetic without any analgesic properties. It is a very safe drug, with a median lethal dose (LD_{50})/median effective dose (ED_{50}) ratio of 26 in animal models,[236] which indicates that the lethal dose (LD) is 26 times greater than the effective dose (ED). Etomidate has little effect on systemic blood pressure, heart rate, and cardiac output after a single dose in healthy children[237]; it also appears to have minimal hemodynamic effects in children with CHD.[237,238] It has a favorable hemodynamic profile even when used in children in shock and appears to have a low risk of clinically important myoclonus or status epilepticus, pain on IV injection, and nausea and vomiting.[239,240] The major concern regarding etomidate is the increased mortality rates reported when it is administered as a continuous infusion. This grave adverse effect has been attributed to adrenal suppression.[241–243] The inhibition of steroid synthesis occurs after a prolonged infusion and after a single dose of etomidate, and this has created controversy regarding its use as an anesthetic agent, particularly in the ICUs in some jurisdictions.[244] The decrease in plasma cortisol and ACTH concentrations in children undergoing heart surgery after etomidate may persist for 24 hours or longer[245,246] and may be potentiated by the use of other anesthetic agents.[247] The notion that etomidate causes adrenal suppression is well established, but what remains unclear is whether patient outcomes differ after a single bolus dose for induction of anesthesia.[248] Newer analogs of etomidate have addressed these deficiencies and may lead to a surge in its use in the future (see also Chapter 7).

Propofol

Propofol is a rapidly acting IV hypnotic agent that may be administered as a single dose or by continuous infusion. It has no analgesic activity, but it possesses antiemetic properties, even in subhypnotic doses.[249–253] It is effective for prophylaxis against emergence agitation in young children.[254,255] Its short duration of action is the result of rapid redistribution and metabolism, which also allows the drug to be given by continuous infusion with limited accumulation. Induction doses decrease SVR, blood pressure, and cardiac output; the effect on heart rate varies. The ED_{50} for propofol in infants and small children is greater than it is in adults.[241–244,249,256–258] If propofol is given very slowly, smaller doses are required to achieve the anesthetic state, although the induction time increases. A slower infusion also results in more stable hemodynamics.[259] Pain on injection and involuntary movement after IV propofol have been concerns that have been overcome (see Chapter 7). However, there remain significant concerns about its potential to trigger a propofol-related infusion syndrome (PRIS). This rare but potentially lethal syndrome is characterized clinically by acute bradycardia progressing to asystole; it is frequently associated with progressive metabolic acidosis, hemodynamic instability, myocardial failure, and rhabdomyolysis, with or without the presence of hepatomegaly or lipemia after 4 mg/kg per hour infused for 48 hours.[260–263] The symptoms of PRIS may develop rapidly and often are refractory to aggressive pharmacologic treatment, requiring hemodialysis or hemoperfusion, with cardiorespiratory support as extracorporeal membrane oxygenation in some cases.[264–266] These concerns about propofol have led to recommendations to maintain close vigilance for developing signs indicative of PRIS, as well as limiting dose rates and duration when propofol is used as a continuous infusion.[267] Although propofol can be used safely in children with CHD, it is typically avoided as an induction agent in those with severe CHD, especially in those with a fixed cardiac output such as severe aortic or mitral stenosis; in these patients, it may cause severe hypotension due to its effects on SVR and blood pressure. It can be used by continuous infusion during CPB to reduce awareness and may be particularly useful if an early extubation is planned (see also Chapter 7).[268,269]

OPIOIDS

Fentanyl

As in adults with severe cardiac disease, an IV induction with fentanyl combined with pancuronium and 100% oxygen or air and oxygen provides hemodynamic stability even in very sick children with CHD, although it is not amnestic. Inclusion of IV midazolam or another amnestic agent is strongly urged to avoid awareness. In neonates and infants, the use of high-dose opioid anesthesia provides excellent hemodynamic stability, with suppression of the hormonal and metabolic stress responses.[270,271] When fentanyl or other opioids are combined with nitrous oxide, the negative inotropic effects of nitrous oxide may be evident, particularly in sicker children.[272] The high-dose fentanyl technique is effective in preterm neonates undergoing ligation of a PDA.[273] In high-risk, full-term neonates and in older infants with severe CHD, the high-dose fentanyl technique in doses of up to 75 µg/kg,

combined with pancuronium, maintains stable hemodynamics during induction, tracheal intubation, and surgical incision.[274] Oxygen saturation is well maintained and often improves during induction, even in cyanotic children.[275] The cardiac index, SVR, and PVR in infants given 25 μg/kg of fentanyl do not change substantively.[276] Combining pancuronium with fentanyl is desirable because the vagolytic effects of pancuronium offset the potential vagotonic effects of fentanyl. The hemodynamic stability reported in infants with the combination of high-dose fentanyl and pancuronium may not be replicated when other muscle relaxants are used (see Chapter 7).[277]

Sufentanil

Sufentanil (5 to 20 μg/kg), an alternative to fentanyl, is 5 to 10 times more potent than fentanyl but has a large margin of safety.[278,279] It is highly lipophilic and is rapidly distributed to all tissues. It is infrequently used in infants and children with CHD.

Remifentanil

Remifentanil is an ultra-short-acting opioid that is rapidly metabolized in the plasma and tissue by nonspecific esterases to an inactive metabolite. It has a very brief elimination half-life, with a context-sensitive half-life of only 3 minutes, independent of the duration of infusion (see Fig. 7.24). In pediatric cardiac surgery, it is an attractive alternative to fentanyl that provides intense analgesia during the most stimulating parts of surgery but facilitates rapid awakening and weaning from mechanical ventilation without residual opioid effect. Its pharmacodynamics are unaffected by CPB.[280] It provides stable hemodynamic conditions in children, although there is a tendency toward bradycardia and systemic hypotension.[281–283] It has no negative inotropic effect, even in the failing heart.[284]

A significant concern is the development of acute tolerance with increasing analgesic requirements after discontinuing remifentanil.[285–287] One study suggested that this is not clinically important.[288] Strategies to prevent tolerance to remifentanil have included nitrous oxide as well as IV magnesium infusions.[289,290] Remifentanil is also used for prolonged sedation of children in the ICU. Many units have moved toward early extubation and discharge from the ICU after cardiac surgery (i.e., fast tracking), and remifentanil is a useful drug in this setting (see also Chapter 7). Consideration must be given to transitioning to a longer-acting opioid before discontinuation of remifentanil.

NEUROMUSCULAR BLOCKING DRUGS

Pancuronium has been studied in depth in children with CHD.[291] When administered over a 60- to 90-second interval, pancuronium maintains heart rate and blood pressure.[292,293] An intubating bolus dose of pancuronium may produce tachycardia and increase cardiac output. This bolus dose effect is sometimes desirable to support cardiac output in infants in congestive heart failure because their stroke volume is fixed. Pancuronium may be the neuromuscular blocking drug (NMBD) of choice when high-dose opioid techniques are used to offset the vagotonic effects of opioids such as fentanyl. Other NMBDs are also widely used, particularly if patients are to be extubated in the operating room or early in the ICU.

LONG-TERM NEUROCOGNITIVE-DEVELOPMENTAL OUTCOMES ASSOCIATED WITH ANESTHESIA

Concerns have been raised about the possibility that many of the anesthetic agents such as inhalational anesthetics, propofol, ketamine, and midazolam may cause long-term neurocognitive-developmental problems in neonates and young infants.[294–297] This effect is thought to result from the neuronal apoptosis caused by these agents in newborn rodents and primates. Neither opioids nor dexmedetomidine have been implicated in these changes at the present date.[298,299] There is no evidence to directly link anesthetic exposure in infancy to long-term neurocognitive defects.[300] There is much ongoing research in this area (see Chapter 25), including an interest in elucidating the potential contributive role of different anesthetic techniques in determining neurodevelopmental outcomes in children undergoing heart surgery.[301–303] In fact, many full-term children with CHD have been shown to have widespread brain abnormalities with small brain volumes similar to those of preterm infants prior to any surgery or CPB.[304–306]

Regional Anesthesia

The use of regional anesthesia to provide pain relief during and after cardiac surgery in adults also reduces the stress response to surgery and may reduce morbidity and mortality. In adults undergoing cardiac surgery, the benefits of regional analgesia or anesthesia techniques, whether in isolation or combined with general anesthesia, include earlier extubation, fewer respiratory complications, a reduction in renal failure, fewer strokes, and less myocardial damage after CPB.[307–312] In animals, thoracic epidural anesthesia reduces myocardial damage after coronary occlusion.[313] Similar effects in improving blood flow, thus reducing coronary ischemia and myocardial damage, have been shown in humans by the use of thoracic epidural anesthesia in adults undergoing coronary bypass graft surgery.[314,315] The same benefits may be achieved by using intrathecal (spinal) analgesia.[316] For example, high spinal anesthesia using bupivacaine reduces the stress response to CPB and β-adrenergic dysfunction and improves cardiac performance after cardiac surgery in adults.[317]

Research into regional anesthesia and analgesia in pediatric cardiac surgery is limited. Caudal morphine has been used to provide postoperative analgesia and has produced good analgesia for about 6 hours while reducing analgesic requirements for up to 24 hours.[318] Two retrospective studies in children[319,320] included a variety of neuraxial regional anesthetic techniques. Most children were extubated in the operating room, although approximately 4% required reintubation within 24 hours. Adverse effects included emesis (39%), pruritus (10%), urinary retention (7%), postoperative transient paresthesia (3%), and respiratory depression (1.8%). The rate of adverse effects was less with a thoracic catheter epidural approach compared with various caudal, lumbar epidural, and spinal approaches.[320] Hospital duration of stay was unaffected by the presence of regional anesthesia complications. Although this study appears to indicate that regional analgesia is safe, the numbers in the study are too small to conclude that regional analgesia is safe for pediatric cardiac surgery.

The use of neuraxial regional anesthesia in children undergoing heart surgery remains controversial.[321,322] The main concern is the risk of bleeding and the potential for disastrous neurologic complications. The risks may be greater in children than in adults because of the presence of collateral vessels, increased venous pressure, coagulopathy related to cyanosis, and the use of aspirin. There remain many unanswered questions regarding neuraxial block in children, such as the true incidence of epidural hematoma, the time delay required between placement of the epidural catheter and full anticoagulation, and the correct management of a bloody tap, even though a considerable research effort has been made to address these issues.[319,323–325] The estimated risk of epidural

hematoma during cardiac surgery in adults is 1 case per 1000 patients and 1 case per 2400 patients for spinal and epidural block, respectively.[326] Whether the risks are similar or greater in children cannot be determined because the numbers of children reported thus far are too small. A large, randomized, prospective study to evaluate a true risk/benefit ratio without bias is needed; until such data are available, various commentators have advised great caution with the use of regional analgesia for cardiac surgery, and some have suggested that it may not be possible to perform the study required because of ethical considerations.[321]

More recently, there has been an increasing interest in bilateral thoracic paravertebral blocks (PVB) as a means of providing good-quality regional analgesia while possibly minimizing complications associated with neuraxial techniques. While their use in thoracic surgery has been shown to result in equally effective pain control and a better side-effect profile compared with thoracic epidurals in both adults[327,328] and children,[329,330] their use in cardiac surgery remains controversial. In fact, similar considerations about anticoagulation and neuraxial analgesia techniques in cardiac bypass procedures may apply to PVB, although the risk of serious neurologic complications resulting from bleeding and subsequent hematoma formation is, at least theoretically, reduced by the use of non-neuraxial analgesia. These concerns have been addressed in the literature in adult cardiac surgery,[331,332] and although PVB have been used for analgesia in children undergoing heart surgery and recommended by some authors; the evidence for their use in children is limited.[333–335] However, it is likely that hesitations in their routine use will persist until concerns about safety are completely clarified by a methodologically sound, large, randomized, prospective study.

Fast Tracking

Fast tracking refers to abbreviating the perioperative period of children undergoing cardiac surgery. Fast track programs, otherwise known as enhanced recovery programs, can be defined as protocols developed to reduce physiologic stress and postoperative organ dysfunction by optimizing all aspects of perioperative care. These protocols consist of a multimodal package of techniques designed to improve postoperative recovery, hence expediting return to health and functional status and reducing hospital length of stay. Fast track surgery programs improve the standardization of medical care and have been shown to result in improved outcomes and lower health care costs. Enhanced recovery programs for children undergoing heart surgery should include every phase of the child's journey from referral and preoperative evaluation to less invasive surgery, early weaning from respiratory support, extubation, and discharge from the ICU and hospital. In this context, the term "fast tracking" is generally used to designate extubation shortly after arrival to the intensive care unit, most commonly in the first 6 hours, whereas the term "ultra-fast" tracking usually refers to extubation of the trachea in the operating room immediately after surgery.

Early extubation of pediatric patients after cardiac surgery offers advantages in terms of cost and reduced morbidity associated with longer ICU stays.[336–340] The success of this approach depends on the close teamwork of a multidisciplinary team, with every member of the team working toward the same goal. Successful fast tracking usually requires the development of care pathways to ensure that the quality of patient care is not compromised.[341] Early extubation and discharge from the ICU requires preplanning and the adoption of a technique that facilitates this goal. The use of very large doses of fentanyl is not appropriate; alternative techniques have been used, including smaller doses of fentanyl in combination with inhalational agents[342,343] or the use of remifentanil in combination with inhalational agents or with propofol. Others have advocated regional anesthesia as a means of speeding extubation, but this approach remains controversial. It is important to choose a NMBD with a shorter duration of action than pancuronium to ensure that it is easy to reverse the neuromuscular block at the end of surgery. Other important considerations to ensure that early extubation is a success include adequate pain relief (e.g., IV paracetamol can be useful), patient-controlled or nurse-controlled analgesia, and antiemetics because nausea appears to be more of a problem in children who are extubated early.

Some clinicians advocate extubating the trachea in the operating room, whereas others advocate waiting until the child is in the ICU. Delaying the extubation until the child is in the ICU may save operating room time and may reduce the risks of cardiovascular instability, bleeding, and hypothermia.[344] Despite these concerns, the tracheas of many children are extubated in the operating room with good outcomes. While currently available evidence does not allow for a definitive evidence-based recommendation about early extubation in children undergoing heart surgery, data available at the present date attest its role in improving outcomes and reducing hospital length of stay. It is reasonable to conclude that fast track programs, possibly including tracheal extubation in the operating room, have now demonstrated their efficacy, safety, and feasibility in low- to medium-risk pediatric congenital cardiac surgery patients.[345–347]

Cardiopulmonary Bypass

CPB is discussed in Chapter 19.

Stress Response to Cardiac Surgery

Cardiac surgery and CPB are altered physiologic conditions associated with an amplified stress response characterized by the release of numerous hormonal and metabolic substances. This constitutes part of the systemic reaction to injury, which consists of a broad variety of hematologic, immunologic, and neuroendocrine effects. Substances released as part of the stress response include catecholamines, cortisol, growth hormone, glucagon, glucose, insulin, prostaglandins, complement, β-endorphins,[270,271,348,349] as well as oxidative stress mediators[350–352] and many others.[353–355] The cause of the elaboration of these substances is likely to be multifactorial: contact of blood with foreign surfaces, nonpulsatile flow, low perfusion pressure, anemia, hypothermia, myocardial ischemia, and possibly low levels of anesthesia. Other factors that contribute to the increase in stress hormones are delayed renal and hepatic clearance and exclusion of the pulmonary circulation during extracorporeal circulation.[356]

Neonates of all viable gestational ages, older infants, and children have nociceptive systems that are sufficiently developed and integrated with brainstem cardiovascular control centers to trigger humoral and circulatory responses to pain and stress.[357–360] Substantial humoral, metabolic, and cardiovascular responses to painful and stressful stimulation during surgery have been documented in neonates of all gestational ages and in older infants.[361,362] Hormonal stress responses in neonates subjected to cardiac and noncardiac operations are threefold to fivefold greater than those in adults after similar surgeries. Circulatory responses

to stressful stimuli in children include systemic and pulmonary hypertension.

Humoral stress responses are particularly extreme during and after cardiac surgery. These responses are characterized by increases in a number of circulating regulatory substances, including catecholamines, cortisol, insulin, glucagon, growth hormone, and β-endorphins; circulating concentrations of catecholamines may increase by as much as 400% over baseline preoperative concentrations. This is evidence of a massive activation of sympathetic outflow in response to surgical stimulation. Some of these responses may continue for several days postoperatively.[363]

It has been suggested that such extreme stress responses and neuroendocrine activation may be associated with greater morbidity and mortality. In adults, intraoperative adrenergic levels 50% above baseline are associated with significant postoperative alterations in β-adrenergic receptor function, including increased β-receptor density and decreased receptor affinity. Mortality among adults with severe congestive failure is associated with increased levels of hormones regulating cardiovascular function, including aldosterone, epinephrine, and norepinephrine.[364] In neonates undergoing cardiac surgery, increased concentrations of stress hormones may be associated with increased mortality rates.[363]

The metabolic response to stress in children includes increased oxygen consumption, glycogenolysis, gluconeogenesis, and lipolysis, which causes substantial intraoperative and postoperative catabolism. The metabolic response is usually related to changes in plasma cortisol, catecholamines, and other counterregulatory hormones such as glucagon and growth hormone. The most prominent clinical effects that result from activation of these processes are perioperative hypoglycemia and hyperglycemia, lactic acidemia, and negative nitrogen balance extending well into the postoperative period. Neonates and infants tolerate such metabolic derangements poorly. Their impaired tolerance is the result of a relative lack of endogenous reserves of carbohydrates, fat, and proteins; the large metabolic cost of rapid growth; a high obligate requirement for glucose by the relatively large brain; the immature hormonal control of intermediary metabolism; and the limited functional capabilities of immature enzyme systems in the metabolic organs. Severe stress responses superimposed on the normal neonatal and infant physiology may be poorly tolerated. However, it remains unclear whether these metabolic alterations may provide some beneficial effects for mobilizing the bodily resources to provide a metabolic milieu for healing tissues or they are purely maladaptive, resulting in detrimental effects on postoperative outcome.

Another factor is the potential effect of stress-induced hyperglycemia on the neurologic outcome. Neonates and young infants are capable of substantial rates of glucose production, mainly from glycogenolysis and gluconeogenesis during surgical stress that can result in hyperglycemia. Such hyperglycemic responses may be associated with poorer neurologic outcomes, particularly after a period of cerebral ischemia.[365] The use of high doses of fentanyl (>50 μg/kg) has reduced the hormonal stress response and resultant hyperglycemia and may lessen the risk of neurologic injury.[366]

In sufficient doses, opioids can blunt the stress responses in neonates, infants, and adults.[356,367,368] This blunting results in a more normal, homeostatic humoral and metabolic milieu in the circulation by reducing neuroendocrine activation and levels of regulatory hormones. In infants, the use of high-dose opioids for major surgical procedures and postoperative sedation substantially attenuates the neuroendocrine response to surgically induced pain and stress. Catecholamine release from intraoperative stress responses may predispose the vulnerable myocardium to dysrhythmias. In neonates with HLHS, sudden ventricular fibrillation occurred in 50% during surgical manipulation under halothane anesthesia. This incidence was dramatically reduced when high doses of fentanyl were introduced as the primary analgesic/sedative.[369] With the use of high-dose opioids, intraoperative ventricular fibrillation has virtually disappeared as a problem in this group of neonates.[370] Opioids increase the ventricular fibrillation threshold in isolated cardiac Purkinje fibers and alter action potential duration similar to that with class III antiarrhythmic agents.[371] Even electrophysiologic events in the neonatal heart, in addition to humoral and hemodynamic responses, may be altered by using high-dose fentanyl anesthesia to attenuate the effects of pain and stress.

REDUCING THE STRESS RESPONSE TO SURGERY AND BYPASS

Corticosteroids

Corticosteroids are used in many centers in an attempt to reduce the inflammatory response to surgery and bypass and improve outcomes after cardiac surgery.[372] However, there is huge variability in the formulation of the corticosteroids used, the doses administered, the timing of administration, and the indications for their use. Although several small studies in humans and animals suggest prophylactic corticosteroids in cardiac surgery may confer a benefit,[373,374] their routine use in children undergoing heart surgery is not supported by currently existing evidence.[375,376] Many investigators have called for a large multicenter study to determine the benefit of corticosteroids before bypass and the optimal dose and timing.[377]

Aprotinin

Aprotinin, which was originally used to reduce bleeding after CPB, is now also appreciated to confer significant antiinflammatory effects.[378–382] In adults, it has been shown to reduce mortality and length of ICU stay,[383] even though these effects were not replicated by later studies. In children, it improves pulmonary function in the postoperative period and reduces the time to extubation and ICU stay.[92] However, aprotinin is no longer available for routine use in the United States or continental Europe, because some grave concerns have been raised about its use increasing complications and mortality rates in adult cardiac surgery. In the United Kingdom, it is available for use on a named patient basis, but its use has been dramatically reduced as a result.

Allopurinol

Allopurinol is thought to provide protection against oxygen free radicals during reperfusion by inhibiting xanthine oxidase. It reduces oxygen free radical production and may reduce neurologic and cardiac damage after deep hypothermic circulatory arrest.[384] Analogously, it has been used in trials to prevent mortality and morbidity in neonates with hypoxic-ischemic encephalopathy.[385] This strategy does not appear to have developed widespread use, probably because of the lack of sufficient data to determine whether it has clinically important benefits and uncertainties about its effects on mortality and long-term neurodevelopmental outcomes.

Ischemic Preconditioning

The heart is capable of short-term rapid adaptation to brief ischemia such that during a subsequent, more severe ischemic insult, myocardial necrosis is delayed. Numerous animal studies have

been conducted to further characterize this property of the myocardium, which could have very important clinical applications. The infarct-delaying properties of ischemic preconditioning have been observed in all species studied. An ischemic period of 5 minutes is sufficient to initiate preconditioning, and the protective period lasts for 1 to 2 hours. Laboratory experiments have demonstrated that the stimulation of adenosine receptors initiates preconditioning and the intracellular signal transduction mechanisms involve protein kinase C and adenosine triphosphate (ATP)-dependent potassium channels, although there may be some differences between species. An analysis of studies of myocardial infarction in humans has demonstrated that some adults who report having had angina in the days before infarction have a better outcome after their infarction in part owing to the ischemic preconditioning. More direct evidence has come from an investigation of adults undergoing percutaneous transluminal angioplasty in whom the ST-segment changes induced by balloon inflation were more marked during the first inflation than the second. In adults undergoing coronary artery bypass grafting, the decline in ATP content during the first 10 minutes of ischemia was reduced in those subjected to a brief preconditioning protocol.[386–390]

It may be possible to protect organs other than the heart by ischemic preconditioning. It may even be possible to protect organs remotely by producing a period of ischemia in one area such as a limb, which then confers protection to remote organs.[391] One study demonstrated that the use of a blood pressure cuff to produce short periods of limb ischemia can produce beneficial effects on the heart, lungs, and generalized inflammatory response.[392] The effects of remote ischemic preconditioning (RIPC) on children undergoing heart surgery have been inconsistent, likely reflecting heterogeneity between different studies developed to evaluate its ischemia-delaying properties.[393]

A wide variety of anesthetic agents and anesthesia adjuvants have also been found to offer protection against ischemia to the heart and other organs, particularly the brain and kidney, by ischemic preconditioning mechanisms. Inhalational anesthetics, but also midazolam and propofol, among others, protect against myocardial injury in pediatric cardiac surgery. Other studies have shown definite cardioprotective effects from inhalational agents in children, although these do not seem to be universally applicable to all children undergoing heart surgery. Further research is needed to clarify their protective role for different patient populations, to different organs and systems, as well as recommended doses and timing of administration.

Glucose-Insulin and Potassium

The use of glucose-insulin and potassium has been advocated for more than 40 years in adult cardiac surgery. It is thought to protect the myocardium from the effects of ischemia caused by aortic cross-clamping.[394–397] Its effects have not been studied in children undergoing cardiac surgery.

Anesthesia Considerations for Specific Cardiac Defects

Discussion of anesthesia considerations for repair of every form of CHD is beyond the scope of this chapter. However, a brief discussion of the problems that may be encountered during repair of the more common congenital heart lesions is presented. It is useful to group lesions together because the management principles can be applied more generally within groups (Table 17.2).

TABLE 17.2 Classification of Congenital Heart Disease

Simple Left-to-Right Shunt: Increased Pulmonary Blood Flow
Atrial septal defect (ASD)
Ventricular septal defect (VSD)
Patent ductus arteriosus (PDA)
Endocardial cushion defect (e.g., atrioventricular septal defect [AVSD])
Aortopulmonary window (AP window)
Simple Right-to-Left Shunt: Decreased Pulmonary Blood Flow With Cyanosis
Tetralogy of Fallot (TOF)
Pulmonary atresia
Tricuspid atresia
Ebstein anomaly
Complex Shunts: Mixing of Pulmonary and Systemic Blood Flow With Cyanosis
Transposition of the great arteries (TGA)
Truncus arteriosus
Total anomalous pulmonary venous connection (TAPVC)
Double-outlet right ventricle (DORV)
Hypoplastic left heart syndrome (HLHS)
Obstructive Lesions
Aortic Stenosis
Mitral Stenosis
Pulmonary Stenosis
Coarctation of Aorta
Interrupted Aortic Arch

TABLE 17.3 Clinical Features of Cardiac Failure in Children

Failure to thrive	Cardiac murmur
Difficult feeding	Hepatomegaly
Breathlessness	Cardiomegaly
Recurrent chest infection	Pulmonary plethora
Tachycardia	Wheezing

SIMPLE LEFT-TO-RIGHT SHUNTS

Simple left-to-right shunts increase pulmonary blood flow. If the shunt is large, blood flow to the lungs can be as much as threefold to fourfold greater than normal, resulting in volume loading of the right heart. This can lead to right atrial and right ventricular enlargement that is potentially associated with tricuspid and pulmonary valve regurgitation. The combination of the aforementioned pathophysiologic consequences of large left-to-right shunts results in cardiac failure (Table 17.3).

Medical management of these children is primarily achieved with diuretics. If pulmonary blood flow is large and left untreated, pulmonary vascular disease begins to develop, resulting in pulmonary hypertension.[398–403] In the early stages, the changes are reversible, but in time, the changes may become irreversible. Eisenmenger syndrome refers to severe pulmonary hypertension that leads to suprasystemic pulmonary artery pressures that cause the shunt to reverse, leading to cyanosis. The previous left-to-right shunt reverses to become a right-to-left shunt. At this point, the child's condition becomes inoperable.

Increasingly, definitive surgery is being performed at a younger age to reduce the risk of developing pulmonary vascular disease. If early definitive surgery is not possible, a pulmonary artery band may be applied through a sternotomy incision but without CPB, to reduce pulmonary blood flow. This provides the infant the opportunity to grow, postponing the need for definitive surgery without increasing the risk of developing pulmonary hypertension. In the presence of substantively increased pulmonary blood flow, pulmonary vascular disease is often severe and irreversible by 1 year of age. Definitive surgery should be performed between 3 and 6 months of age to avoid this complication.

Atrial Septal Defect

ASD is a common heart defect in children, occurring in 1 of 1500 live births and accounting for approximately 10% of all CHD.[404,405] Several types of ASDs exist.

- Patent foramen ovale (PFO) is a normal fetal communication between the two atria that usually closes soon after birth. The PFO remains patent in up to 30% of people. PFO is usually left untreated in children.
- Primum ASD (Fig. 17.1A) is located in the inferior part of the atrial septum close to the AV valve and may be associated with a cleft mitral valve. This is a variant of AV septal defect (AVSD).

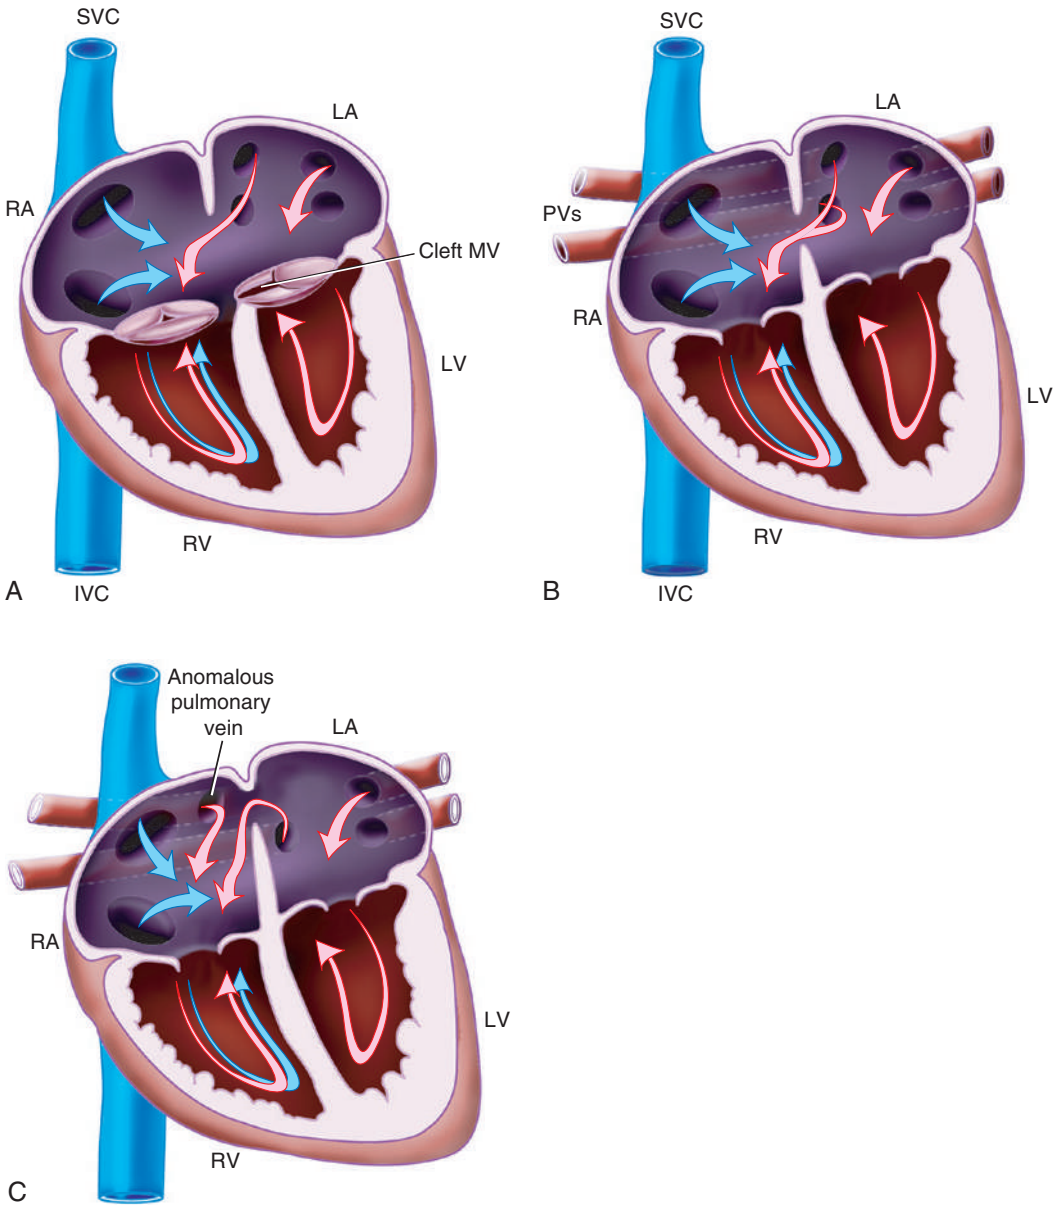

FIGURE 17.1 A, Diagram of a primum atrial septal defect (ASD) with the great vessels removed to show the left-to-right shunt through the defect and a cleft of the mitral valve (*MV*), also called a partial atrioventricular septal defect. **B,** Diagram of a secundum ASD with the great vessels removed to show the left-to-right shunt through the defect. **C,** Diagram of a sinus venosus ASD shows the left-to-right shunt through the defect close to the superior vena cava (*SVC*) and an anomalous pulmonary vein (*PV*) draining to the right atrium (*RA*). *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *MV,* mitral valve; *RV,* right ventricle. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals.* Milwaukee, WI: Maxishare; 2005.)

- Secundum ASD (see Fig. 17.1B) is found in the region of the fossa ovalis and results from a deficiency in the septum secundum.
- Sinus venosus ASD (see Fig. 17.1C) can be of the superior or inferior sinus venosus types, close to the opening of the SVC or inferior vena cava (IVC), respectively. It may be associated with anomalous pulmonary venous drainage.
- Coronary sinus ASD (i.e., unroofed coronary sinus) is a defect in the atrial wall that allows blood to flow from the left atrium to right atrium through the coronary sinus.
- Common atrium has a complete absence of the atrial septum. The AV valves may be abnormal or unaffected.

Many ASDs can be closed using a percutaneous, transcatheter device. PFO and secundum ASDs are most commonly closed using this technique.

Anesthesia Considerations

- These children can frequently be extubated on the operating table or early in the ICU, and smaller doses of opioids can be used. Alternatively, short-acting drugs (e.g., remifentanil) administered by infusion and possibly in combination with propofol are useful if early extubation is planned.
- The problems of postoperative pulmonary hypertension are seldom encountered.

Ventricular Septal Defect

VSD is the most common congenital defect in children, occurring in 1.5 to 3.5 of 1000 live births and accounting for more than 20% of CHD (Fig. 17.2A).[406,407] Four types are described: subarterial (5%), perimembranous (80%), inlet (5%), and muscular (10%). If the flow through the VSD is small, it is referred to as *restrictive*, but if the flow is large, it is called *unrestrictive*. A significant proportion of VSDs close spontaneously during the first few years of life. It is possible to close a small percent of VSDs in children using percutaneous, transcatheter devices.

Anesthesia Considerations

- Children who are asymptomatic preoperatively and undergo a predictably uncomplicated VSD surgical closure should be considered for fast tracking, and anesthetic management should aim to facilitate early extubation.
- Inotropic support may be required postoperatively for children in cardiac failure.
- Postoperative pulmonary hypertension may be a problem if the left-to-right shunt has been significant preoperatively or if the surgery is undertaken late.

Atrioventricular Septal Defect

AVSDs are also known as AV canal defects or endocardial cushion defects. They arise from a defect in the AV septum, with inadequate fusion of the superior and inferior endocardial cushions with the atrial septum and muscular ventricular septum, respectively. Their incidence is approximately 0.2 cases per 1000 live births, and they account for about 3% of CHD. They are commonly associated with trisomy 21, TOF, and DiGeorge syndrome (Table 17.4). It is worth noting that with a common AV valve annulus, the two separate valve orifices are referred to as the left and right AV valves, not the mitral and tricuspid valves. Three types of AVSD exist:

- Incomplete or partial AVSD usually consists of a primum ASD with a cleft in the anterior mitral valve leaflet; two separate AV valves are present and there is no VSD (see Fig. 17.1A).

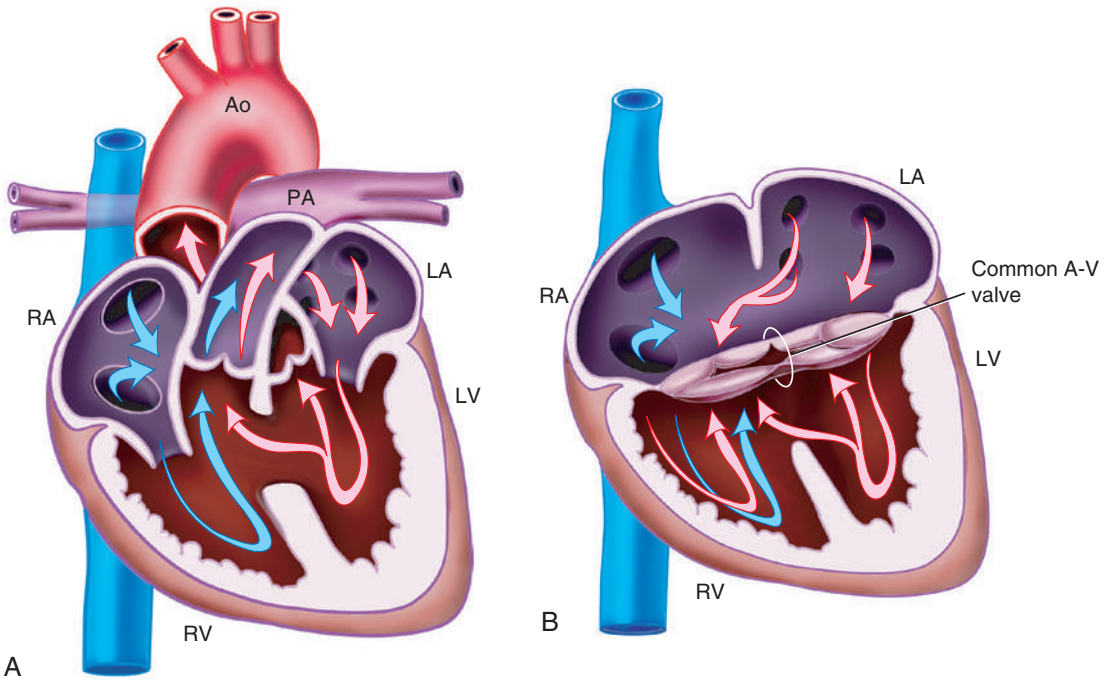

FIGURE 17.2 A, Diagram of a ventricular septal defect shows a left-to-right shunt. **B,** Diagram of a complete atrioventricular septal defect with the great vessels removed to show the left-to-right shunt through both atrial and ventricular components of the defect and a single common atrioventricular (*A-V*) valve. *Ao,* aorta; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals.* Milwaukee, WI: Maxishare; 2005.)

TABLE 17.4	Clinical Features and Concerns of DiGeorge Syndrome
Absent or small thymus	
T-cell abnormality with associated immunodeficiency	
Hypoparathyroidism with associated hypocalcemia	
Dysmorphic features, particularly a small mouth	
Increased surgical morbidity and mortality	
Irradiated blood products needed to prevent graft-versus-host disease	

- Complete AVSD consists of a large septal defect with atrial and ventricular components and a large common AV valve (see Fig. 17.2A).
- With transitional AVSD an ASD is present and the left and right AV valves may be only partially separated; the VSD may be small or moderate in size (see Fig. 17.2B).

Other descriptions of AVSD refer to balanced or unbalanced conditions, depending on the relative contributions of the two sides of the heart to the circulation. This in turn may depend on relative sizes of the two sides of the heart, but also on whether the AV valve is stenotic or atretic or if there is significant AV valve overriding (i.e., one AV valve emptying into two ventricles) or some of the valve chordae or papillary muscles are straddling (i.e., crossing to the other side of the ventricular septum). The hemodynamic effects associated with AVSD vary according to the type of defect and AV valve morphology and include shunting at the atrial or ventricular level and AV valve stenosis and/or regurgitation.

Anesthesia Considerations

- If the child has trisomy 21 or DiGeorge syndrome, the anesthesia implications of the associated comorbidities need to be managed.
- Inotropes are frequently required.
- Postoperative pulmonary hypertension may occur.
- There is often postoperative stenosis and/or regurgitation of one or both AV valves, with potential implications for hemodyamics and anesthesia management.
- TEE is particularly helpful in assessing the repair of the left AV valve.
- Heart block and dysrhythmias may occur postoperatively.

Aortopulmonary Window

Aortopulmonary window is a rare CHD defect in which there is a communication between the main pulmonary artery and the ascending aorta, and it accounts for 0.1% of CHD (Fig. 17.3). Four types are classified according to the size and exact position of the defect.[408] A left-to-right shunt is usually present. These children present with heart failure and are at risk for pulmonary vascular disease if not treated early. Aortopulmonary window is frequently associated with other cardiac and noncardiac anomalies:

- VACTERL: **V**ertebral anomalies, **A**nal atresia, **C**ardiac defect, **T**racheo**E**sophageal atresia, **R**enal anomalies, and **L**imb abnormalities
- CHARGE: **C**oloboma of the eye and central nervous system anomalies, **H**eart defects, **A**tresia of the choanae, **R**etardation of growth and development, **G**enital or urinary defects, and **E**ar anomalies
- CATCH-22 association (i.e., mnemonic for DiGeorge syndrome): **C**ardiac defect, **A**bnormal facies, **T**hymic hypoplasia, **C**left palate, **H**ypocalcemia (velocardiofacial syndrome), with 22q11 chromosome microdeletion (see Table 17.4)

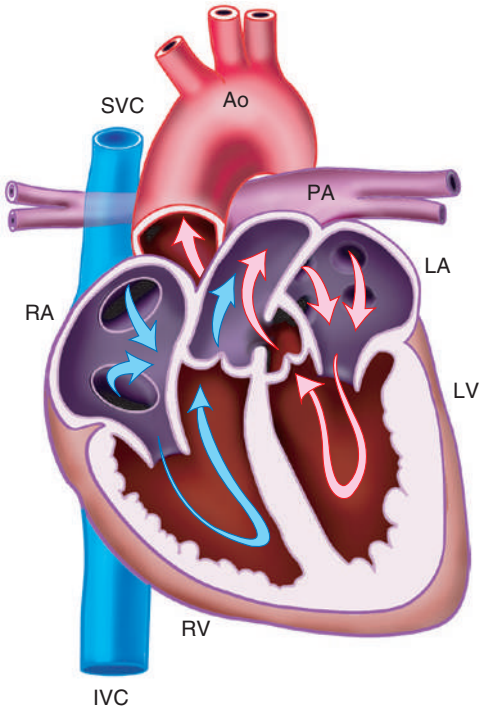

FIGURE 17.3 Diagram of an aortopulmonary window shows a left-to-right shunt through the defect. *Ao,* aorta; *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle; *SVC,* superior vena cava. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals.* Milwaukee, WI: Maxishare; 2005.)

Anesthesia Considerations

- Inotropes may be required.
- Postoperative pulmonary hypertension may be problematic.

Patent Ductus Arteriosus

The ductus arteriosus, a remnant from the fetal circulation, extends from the undersurface of the descending aorta, distal to the origin of the left subclavian artery, to the main pulmonary artery and usually closes soon after birth (see Fig. 18.1). However, it remains patent in approximately 1 of 2500 live births and accounts for about 10% of all CHD (Fig. 17.4). In the fetus, blood from the right ventricle is directed into the pulmonary artery, but because of the high PVR, it flows into the descending aorta through the ductus arteriosus. After birth, the PVR decreases, and blood flows from the aorta to the lungs. PDA is common in preterm infants, in whom it is associated with respiratory distress syndrome (RDS), intraventricular hemorrhage (IVH) and necrotizing enterocolitis (NEC); its presence may explain an ongoing requirement for mechanical ventilation. In these infants, should medical treatment fail to close the PDA, surgery is required to ligate or divide it, most often via a left thoracotomy approach, even though minimally invasive approaches are possible. The presence of a PDA may also only be detected in older children; but at this age, where size no longer constitutes a limitation for the use of endovascular devices, percutaneous closure by an interventional cardiologist is the preferred approach. The anesthesia implications are similar to those of other lesions described with left-to-right shunts preoperatively.

In many centers, the PDA is closed in preterm infants who weigh less than 1000 g and who are already mechanically ventilated in the neonatal intensive care unit (NICU). This avoids the need

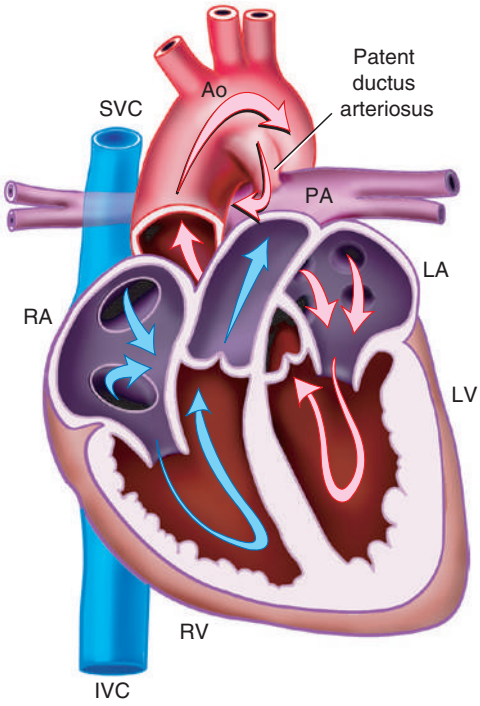

FIGURE 17.4 The diagram of a patent ductus arteriosus shows a left-to-right shunt. *Ao,* aorta, *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle; *SVC,* superior vena cava. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals*. Milwaukee, WI: Maxishare; 2005.)

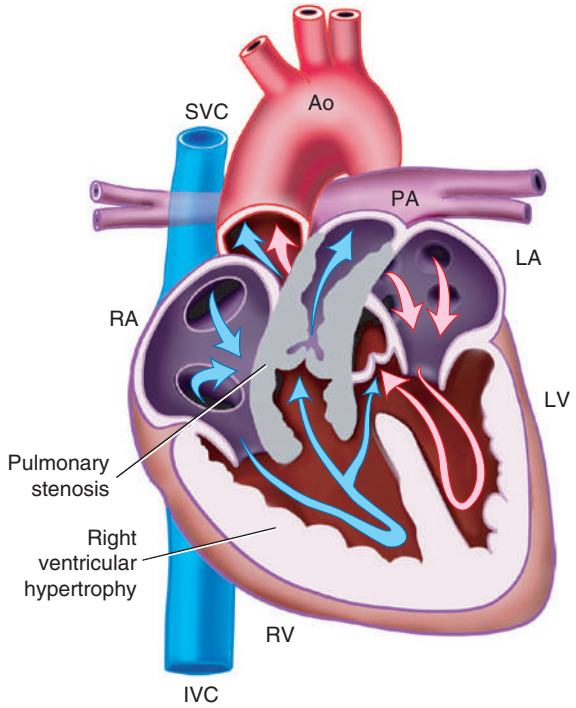

FIGURE 17.5 The diagram shows the features of the tetralogy of Fallot: ventricular septal defect, overriding aorta, right ventricular hypertrophy, and pulmonary stenosis. Pulmonary and subpulmonary obstructions are shown (*grey area*). The result is right-to-left shunting leading to cyanosis. *Ao,* aorta; *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle; *SVC,* superior vena cava. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals*. Milwaukee, WI: Maxishare; 2005.)

to transfer these very small infants to the operating room and the associated problems, particularly hypothermia.

Preoperative requirements include the following:

- Crossmatched blood
- Antibiotics (risk of endocarditis)
- Vitamin K

Particular perioperative risks include the following:

- Difficulty ventilating or hemoglobin desaturation because of lung retraction
- Inadvertent ligation of the aorta or pulmonary artery
- Tearing the PDA with massive hemorrhage
- Endocarditis
- Paradoxical air embolism

Monitoring

Monitoring includes the use of all standard monitors, including end-tidal carbon dioxide assessment, and two pulse oximeters, one on the right hand and one on a lower limb, thus monitoring preductal and postductal saturations. If the pulse is lost from the lower limb during a test clamping of the duct, it may indicate that the aorta has been clamped inadvertently. At the authors' institution, all the requirements are stipulated in a protocol and monitoring and other requirements are in place before the arrival of the operating room team.

Invasive blood pressure monitoring is helpful if already established but is not usually placed if not already in place. Monitors used in non–operating room sites may not be compatible with the electrocautery equipment, resulting in loss of monitoring whenever the cautery is used.

Anesthesia Considerations

- A dedicated IV line for fluids and drugs with a long (100 to 150 cm), low-caliber extension to allow access from a distance (space around the cots in NICU is limited)
- High-dose opioids
- Muscle relaxation
- The tracheal tube should have only a small air leak. A large leak may prevent adequate ventilation during lung retraction (recheck tube size and position before the start of the procedure, as well as security and correct position of the tip of the tube after repositioning in the decubitus position, before starting surgery).
- Intercostal nerve block can be placed by surgeon at the completion of surgery
- Glucose-containing fluids maintained at basal rates

SIMPLE RIGHT-TO-LEFT SHUNTS

Tetralogy of Fallot

TOF is the most common cyanotic CHD defect accounting for 6% to 11% of all CHD. Its hallmark is the anterocephalad deviation of the outlet septum, resulting in four features (Fig. 17.5):

- VSD
- Overriding aorta
- Right ventricular outflow tract obstruction (RVOTO)
- Right ventricular hypertrophy

The RVOTO ranges from mild to severe, and the level of the obstruction also varies. Commonly, a dynamic subpulmonary

infundibular obstruction is present. Dynamic narrowing of the infundibulum is frequently the cause of hypercyanotic episodes, also known as *tet spells*, in which there is an increase in the shunting of blood from right to left. However, the RVOTO may also be at the level of the pulmonary valve or main or branch pulmonary arteries (PAs). There are four main variants of TOF:

- TOF with pulmonary stenosis–the stenosis may be subvalvar, valvar, supravalvar, or any combination of the three; this represents the most common subtype of TOF.
- TOF with pulmonary atresia–severe variant, with no antegrade flow from the right ventricle into the pulmonary artery; it is commonly associated with hypoplastic pulmonary arteries with major aortopulmonary collateral arteries; if the pulmonary arteries are well developed, pulmonary blood flow is usually derived from a PDA.
- TOF with absent pulmonary valve–the pulmonary valve is dysplastic and incompetent, resulting in dilatation of the pulmonary arteries, causing bronchial compression and, if severe enough, breathing difficulties.
- TOF with AVSD–the rarest form of TOF, in which ASD and TOF coexist, making complete surgical repair particularly challenging.

The right-to-left shunt and cyanosis observed in children with TOF results from a combination of the RVOTO and VSD. The degree of hypoxemia depends on the relationship between the RVOTO and the SVR that determines the degree of right-to-left shunting across the ventricular septal defect. TOF may be associated with a large number of other cardiac and extracardiac anomalies. Extracardiac anomalies most commonly include DiGeorge syndrome (see Table 17.4) and trisomy 21.

Hypercyanotic Episodes

Hypercyanotic spells are episodes of cyanosis that occur in 20% to 70% of untreated children. They may be initiated by crying or feeding and may even occur during anesthesia. The cause of these spells is unclear, but metabolic acidosis, increased $PaCO_2$, circulating catecholamines, and surgical stimulation have all been implicated.

Management of a tet spell requires urgent intervention. Simple measures (e.g., morphine to reduce infundibular spasm, Valsalva maneuver or legs-to-knee chest position to increase SVR) may be effective. Early and aggressive use of a vasoconstrictor is essential (e.g., metaraminol or phenylephrine). Phenylephrine should be premixed and in a syringe for immediate use. Management may require any of the following:

- 100% oxygen and hyperventilation
- IV fluid bolus
- Sedation or analgesia (e.g., fentanyl, morphine) and paralysis
- Sodium bicarbonate
- Vasoconstriction
  - Phenylephrine is given as a 1-μg/kg bolus and doubled at 1-minute intervals until a satisfactory response is achieved (doses required in small preterm infants may be up to 30 μg/kg); this is followed by an infusion at 1 to 5 μg/kg per minute.
  - Norepinephrine is given at a rate of 0.01 to 0.2 μg/kg per minute, if central venous access is available.
  - β-Blockers are administered to relax infundibular spasm and reduce the heart rate.
  - Propranolol 15–20 μg/kg is given as a slow intravenous injection (max 100 μg/kg), and repeated depending on clinical effect.
  - Esmolol is given as a 500-μg/kg loading dose administered over 1 minute, followed by a continuous infusion at a rate of 50 to 250 μg/kg per minute.

Surgical Management

The optimal surgical management of children with TOF remains controversial. The choice is between initial palliation with a systemic-to-pulmonary shunt followed by a complete repair when the infant is older and complete repair during the neonatal or early infant period. The current trend is toward early complete repair.[409,410] Complete repair involves closure of the VSD and relief of the RVOTO. Relief of the RVOTO may require a transannular patch (i.e., a patch extending from the right ventricular outflow tract across the pulmonary valve annulus into the supravalvar area) that involves a right ventriculotomy. If this is the case, a significant degree of pulmonary regurgitation is inevitable. Right ventricular dysfunction is a particular problem after repair, and it usually manifests as RV restrictive physiology in the immediate postoperative period; compliance of the RV is greatly reduced, resulting in severe diastolic dysfunction. Long-term follow-up of patients with TOF repair has revealed the consequences of significant pulmonary regurgitation after a transannular patch technique to be more serious than previously anticipated. In fact, late RV dilatation and dysfunction with reduced tolerance to exercise, hemodynamic compromise, dysrhythmias, and an increased risk of sudden death have led surgeons to avoid a transannular patch whenever possible, often accepting a degree of pulmonary stenosis as a trade-off.[411–413] In the immediate postoperative period, JET is a particular risk after complete correction. JET is a self-limiting, narrow QT tachycardia, arising from increased automaticity from the AV node region, which does not predispose to more severe dysrhythmias. Its importance resides in the fact that it usually occurs postoperatively in the first 24 to 48 hours, when a degree of already existing cardiac dysfunction may be further aggravated by the rapid heart rate and loss of the contribution of atrial contraction to ventricular filling.

Anesthesia Considerations

SYSTEMIC-TO-PULMONARY SHUNT. The systemic-to-pulmonary shunt typically is a modified Blalock-Taussig shunt. This is a connection between the subclavian artery to a branch pulmonary artery via the interposition of a synthetic tube graft.

- The patient is usually a neonate or small infant.
- Sedative premedication is useful to prevent crying during induction, which may provoke a hypercyanotic spell.
- There is a risk of a hypercyanotic spell during induction and surgery.
- Inhalational or IV induction are both appropriate.
- Surgery is most often performed through a thoracotomy (left or right) but may occasionally be performed through a sternotomy.
- CPB is not usually required.
- Arterial and central venous access is required.
- Tracheal tube should be snug (or use a cuffed tracheal tube), with no or minimal air leak because lung retraction during surgery can make ventilation difficult.
- The arterial line should not be in the arm on the side that the shunt will be placed because the subclavian artery will be clamped, and the arterial pressure will be lost.
- Hemodynamic and respiratory disturbance can be problematic during surgery.
- The surgeon may request a small dose of heparin.
- Bleeding may occur after clamps are released; be prepared for a blood transfusion.

- Postoperatively, the pulmonary blood supply predominantly depends on the size of the shunt. If the shunt is too small, the infant may have a low saturation level; if the shunt is too large, the infant may develop heart failure or pulmonary edema and hypotension.
- Pulmonary blood flow also depends on systemic blood pressure; the greater the blood pressure, the more blood flows to the lungs and the higher the saturation.
- Milrinone is often combined with norepinephrine because norepinephrine increases the low diastolic pressure created by the shunt by systemic to pulmonary artery runoff in diastole, but does not produce the unwanted tachycardia seen with epinephrine.
- Postoperative ventilation may be required.

COMPLETE REPAIR. If the child is scheduled for early complete correction with no previous palliation by a systemic-to-pulmonary shunt, the child is likely to be a neonate or small infant. These children remain at risk for hypercyanotic spells. However, if the child has had a shunt placed previously, he or she is likely to be older and much less likely to have a hypercyanotic episode. Some children with less severe disease may not require a shunt and may be operated on when they are a bit older because they remain asymptomatic. Good sedative premedication is important in those at risk for hypercyanotic episodes.

- Both IV and inhalational induction agents are appropriate.
- CPB is required.
- Right ventricular dysfunction and pulmonary regurgitation may be postoperative problems.
- Intense inotropic support may worsen RVOTO postoperatively by dynamic narrowing of the RVOT; norepinephrine may be preferable to epinephrine in this setting, considering its predominant α-adrenergic effects.
- Milrinone may be particularly useful owing to its lusitropic properties, promoting diastolic relaxation of the stiff right ventricle.
- Surgeons frequently measure right ventricular pressure to assess the quality of the repair.
- Perioperative echocardiography is useful in assessing repair and right ventricular function.
- Excessive β-adrenergic stimulation and pyrexia may contribute to triggering JET postoperatively.

COMPLEX SHUNTS. In complex shunts (i.e., mixing shunts), there is mixing of pulmonary and systemic blood flow, with resulting cyanosis.

Transposition of the Great Arteries

Transposition of the great arteries (TGA) is common and accounts for about 6% of all CHD. It frequently occurs as an isolated lesion and is rarely associated with extracardiac anomalies. The operation most commonly performed in these infants is the arterial switch operation (ASO), the short- and long-term results of which have improved to such an extent that children with a good repair can expect a normal life.[414]

TGA refers to the situation in which the aorta arises from the morphologic right ventricle and the pulmonary artery arises from the morphologic left ventricle (Fig. 17.6). In this ventriculoarterial (VA) discordance, the atria are related to the ventricles in the normal way (i.e., AV concordance). This results in two circulations that run in parallel rather than in series, which is the normal anatomic arrangement. Without some mixing of the two circulations, the systemic circulation would remain completely deoxygenated. However, some mixing does occur through the PDA or through a VSD that is present in approximately 25% of cases. If there is no VSD and mixing is inadequate, ductal patency is maintained after birth with an IV prostaglandin E_1 infusion, and a balloon atrial septostomy is performed urgently in the neonatal period.

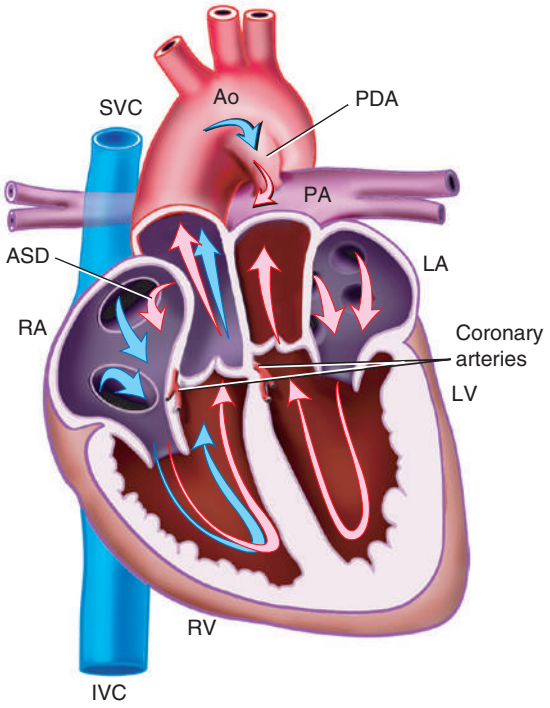

FIGURE 17.6 Diagram of transposition of the great arteries shows an intact ventricular septum. The aorta (*Ao*) arises from the right ventricle (*RV*), and the pulmonary artery (*PA*) arises from the left ventricle (*LV*). The coronary arteries arise from the aorta. These children are cyanotic. *ASD,* atrial septal defect; *IVC,* inferior vena cava; *LA,* left atrium; *PDA,* patent ductus arteriosus; *RA,* right atrium; *SVC,* superior vena cava. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals.* Milwaukee, WI: Maxishare; 2005.)

In TGA with an intact ventricular septum, the ASO should be performed early in the neonatal period, preferably in the first 2 to 3 weeks of life, because the left ventricle is exposed only to the pressure of the pulmonary circulation. The longer this situation is allowed to continue, the less the left ventricle will be able to adapt to the work required to pump blood at systemic pressure after corrective surgery. However, if there is an unrestrictive VSD, the left and right ventricle pressures equalize and both ventricles are exposed to systemic blood pressure, and the left ventricle is better conditioned to perform the work of the systemic ventricle after the ASO.

If untreated, most infants with TGA die in the first year of life of hypoxia and heart failure. Pulmonary vascular disease develops early and contributes to this high mortality rate.[415,416] The mechanism for the early development of pulmonary vascular disease is complex and not simply related to high pulmonary blood flow. However, the presence of a VSD further accelerates this process. These infants are at risk for pulmonary hypertensive crises in the postoperative period.[417]

Surgical Options

ARTERIAL SWITCH OPERATION. An ASO is the operation of choice if the intracardiac anatomy is appropriate. The ASO involves transecting the two main arterial trunks distal to their respective valves and switching them to produce VA concordance (Fig. 17.7).

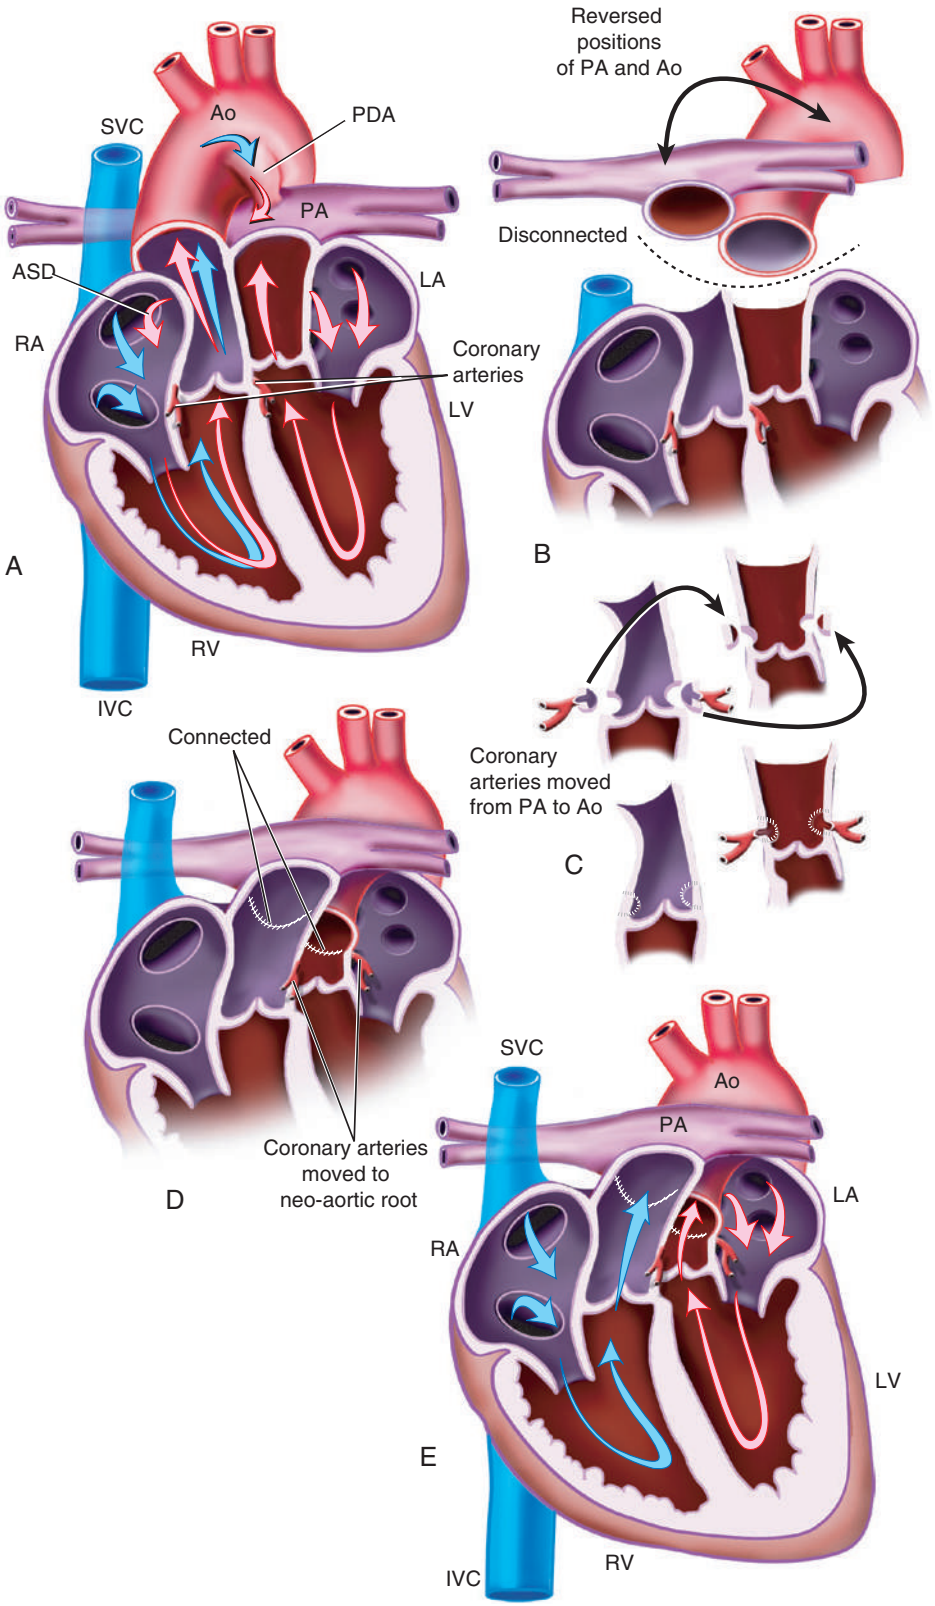

FIGURE 17.7 Diagram of an arterial switch operation. **A,** The original anatomy. The aorta (*Ao*), pulmonary arteries (*PA*), and coronary arteries are disconnected from their origins. **B,** The PA is moved anterior to the Ao. **C,** The Ao is connected to the left ventricle, and the PA is connected to the right ventricle. **D,** The coronary arteries are connected to the neoaortic root. **E,** Final configuration. *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *SVC,* superior vena cava. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals*. Milwaukee, WI: Maxishare; 2005.)

It also involves disconnecting the coronary arteries from the "old" aorta and reconnecting them to the neoaorta. This restores anatomic and physiologic normality. The coronary anatomy varies widely in TGA but must be well assessed preoperatively because moving the coronary arteries to the neoaorta is difficult but crucial to a successful outcome. In some cases, the coronary arteries run in the wall of the aorta (intramural), and this poses particular difficulties for the surgeon. Ventricular function after surgery depends largely on unrestricted flow in the coronary arteries.

MUSTARD AND SENNING PROCEDURES. The Mustard and Senning procedures are atrial switch operations. They involve the use of intraatrial baffles to redirect deoxygenated blood from the venae cavae to the left atrium, left ventricle, and pulmonary artery and oxygenated pulmonary venous blood to the right atrium, right ventricle, and aorta. They create AV discordance, restore physiologic but not anatomic normality, and leave the morphologic and physiologic right ventricle as the systemic ventricle. These procedures were performed as definitive procedures before the arterial switch became successful but are rarely used today as definitive repairs. They are still used as palliation in children with TGA, VSD, and pulmonary vascular disease.[418] In these cases, the VSD is left open. Atrial switch operations are also used as definitive repairs in congenitally corrected transposition of the great arteries (ccTGA or L-TGA), a rarer form of TGA with both AV and VA discordance. In these cases, an atrial switch is combined with an ASO, thus restoring AV and VA concordance, as components of what is denominated a double-switch procedure.[419–421]

RASTELLI PROCEDURE. The Rastelli procedure is used in children with TGA, VSD, and LVOTO. The procedure closes the VSD in a way that directs blood from the left ventricle to the aorta. The pulmonary artery is ligated just distal to the pulmonary valve, and a valved conduit is inserted from the right ventricle to the pulmonary artery. The result is continuity between the left ventricle and aorta and between the right ventricle and the pulmonary artery, and the LVOTO (i.e., subpulmonary area) is bypassed. In the past, the Rastelli procedure was performed at 2 to 3 years of age, following palliation in the neonatal period by a Blalock-Taussig shunt. However, as with other forms of CHD, there is currently a trend toward neonatal Rastelli repair, thus eliminating the need for previous palliation.

Anesthesia Considerations for the Arterial Switch Procedure

- The patient is a neonate in the first few weeks of life.
- Inhalational or IV induction is possible.
- Invasive arterial and central venous lines are required.
- Myocardial ischemia occurring after the cross-clamp is removed may be related to coronary air emboli or inadequate coronary anastomoses. A generous perfusion pressure after removal of cross-clamp encourages flushing air from coronary arteries. If ischemia results from an anatomic problem with the transferred coronary arteries, they may need to be redone with a second bypass run.
- TEE or epicardial echo is useful in assessing adequate de-airing, myocardial function, and adequacy of coronary anastomoses.
- Post-CPB myocardial dysfunction may result from one or more of the following:
  - Coronary air
  - Poor coronary transference
  - Poor myocardial protection
  - Inherently poor left ventricle
- The anesthesiologist should anticipate pulmonary hypertension.
- Inotropes are almost always required. Dopamine or epinephrine can be used, and milrinone is a particularly useful agent in these cases because it is an inodilator.
- After the repair, the pulmonary artery is anterior to the aorta. Any dilation of the pulmonary artery as a result of pulmonary hypertension can lead to coronary artery compression and myocardial ischemia.
- The left ventricle is frequently noncompliant, and volume should be increased with care and in small amounts. LA pressure can rise quickly if fluid is given injudiciously.
- Coagulopathy after bypass is common.
- Antifibrinolytics are often used.

Truncus Arteriosus

Truncus arteriosus is a rare congenital heart defect that occurs in about 0.7 of 1000 live births and accounts for about 1% of all CHD. The basic lesion is that of a common arterial outlet for the aorta and pulmonary artery associated with a single valve with variable morphology (called a truncal valve) and a VSD (Fig. 17.8). The different subtypes depend on how the pulmonary arteries arise from the aorta and on the size of the aorta. Blood mixes at the arterial level with a resultant high pulmonary blood flow. This leads to heart failure and early development of pulmonary hypertension. Surgery must be performed early in life to prevent pulmonary hypertension from becoming irreversible. Truncus arteriosus has a known association with DiGeorge syndrome (see Table 17.4). In the presence of this syndrome or uncertainty about an existing 22q11 deletion, irradiated blood products should be used and calcium concentrations carefully monitored.

Surgical repair involves separating the systemic and pulmonary circulations as well as closing the VSD. The pulmonary artery or arteries are disconnected from the aorta, and the truncal valve is repaired. The pulmonary arteries are then connected to the right ventricle, usually with a valved conduit. Circulatory arrest may be required. The early postoperative mortality rate ranges from 5% to 25%. Several factors are known to influence mortality, including the presence of other cardiac abnormalities, particularly truncal valve stenosis and coronary abnormalities, as well as chromosomal anomalies and low birth weight.[422,423]

Anesthesia Considerations

- The patient is a small neonate.
- Patients may already be intubated and ventilated and may be on inotropes.
- If the child is not ventilated, premedication is probably best avoided.
- Heart failure is possible.
- Repair is a high-risk procedure.
- Risks include a postoperative pulmonary hypertensive crisis.
- Invasive lines are required.
- Circulatory arrest may be required.
- Coagulopathy may occur after bypass.
- Antifibrinolytics are often used.

Anomalous Pulmonary Venous Drainage

Anomalous pulmonary venous drainage comprises about 2.5% of CHD and may be total (TAPVD) or partial (PAPVD). In TAPVD, all four pulmonary veins insert into an anomalous site, and in PAPVD, a subset of the veins insert into an anomalous site and the remaining veins insert into the left atrium. Survival is usually good but depends on the site of insertion, with survival poorer

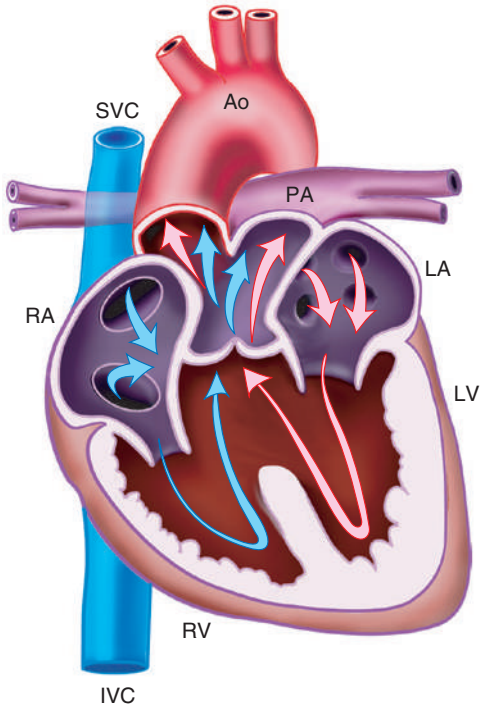

FIGURE 17.8 The diagram of a truncus arteriosus shows the common truncal valve and mixing of red and blue blood. *Ao,* aorta; *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle; *SVC,* superior vena cava. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals.* Milwaukee, WI: Maxishare; 2005.)

for the infracardiac than for the supracardiac and cardiac types; the size of the venous confluence at the insertion into the left atrium; and the presence or absence of obstruction. In some circumstances, even though the pulmonary veins may be appropriately connected to the left atrium, an ASD results in part of the pulmonary venous return being directed preferentially to the right atrium. Therefore it is probably more appropriate to refer to these forms of CHD as anomalous pulmonary venous drainage or return, even though the term anomalous pulmonary venous connection is also used. Four types of TAPVD exist:

- In supracardiac TAPVD, the pulmonary veins drain to the SVC territory via the left brachiocephalic vein through an ascending vertical vein (Fig. 17.9A).
- In cardiac TAPVD, the pulmonary veins connect to the right atrium through the coronary sinus (see Fig. 17.9B).
- In infracardiac TAPVD, the pulmonary veins drain to the IVC territory through a common vein, which traverses the diaphragm (see Fig. 17.9C).
- In mixed TAPVD, any combination of the previously mentioned three types may occur (see Fig. 17.9C).

Infants with obstructed anomalous pulmonary venous drainage, pulmonary hypertension, and reduced pulmonary blood supply usually present early with cyanosis and tachypnea. The degree of cyanosis depends on the size of an existing ASD and the associated right-to-left shunt, as well as on the degree of mixing of systemic and pulmonary venous blood. Children without pulmonary venous obstruction and pulmonary hypertension usually have few symptoms.

Anesthesia Considerations

- The patient may be a neonate.
- Heart failure can occur.
- Pulmonary edema may be present.
- There is a risk of pulmonary hypertension preoperatively and postoperatively; nitric oxide may be required.
- Circulatory arrest may be used, and profound hypothermia may be required.
- Coagulopathy may occur after bypass.
- Antifibrinolytics are often used.

As previously mentioned, there is a risk of pulmonary hypertension, for which inhaled nitric oxide may be necessary. However, it should be used with caution in these patients. In fact, children with obstructive lesions at the atrial level before surgery or patients with a poorly compliant left ventricle may be unable to tolerate an acute increase in pulmonary venous return; the use of inhaled nitrous oxide could thus result in paradoxical pulmonary hypertension.[424,425]

Hypoplastic Left Heart Syndrome

The incidence of HLHS in the United States is about 2 cases per 10,000 live births. In Europe, this figure is probably reduced because many mothers with a prenatal diagnosis of HLHS opt for pregnancy termination.

The anatomic features of HLHS (Fig. 17.10) include the following:

- Hypoplastic left ventricle
- Mitral stenosis or atresia
- Aortic stenosis or atresia
- Hypoplastic aortic arch
- Duct-dependent circulation

The prognosis for infants who are born with HLHS has improved dramatically. Previously, virtually all of these infants died of this condition, but in some centers, most children now survive at least into childhood.[426] The longer-term outlook has not been fully determined, and many hurdles remain.

The diagnosis of HLHS is usually made in the prenatal period, although it can be difficult and is sometimes missed. At birth, neonates present with tachypnea, tachycardia, and cyanosis, and a systolic murmur can be heard.

Surgical Palliation

The aim of surgery is to convert the anatomy of the HLHS into a single-ventricle–type circulation in which the right ventricle becomes the single systemic ventricle and the pulmonary blood flow is supplied passively from the SVC and IVC (i.e., Fontan circulation). This is done by a series of three operations known as Norwood stage I, Norwood stage II (also called superior cavopulmonary connection, bidirectional Glenn or hemi-Fontan), and Norwood stage III (Fontan).

NORWOOD STAGE I. The Norwood stage I operation is performed in the neonatal period. It involves reconstructing the aortic arch so that it arises from the pulmonary trunk. The pulmonary valve becomes the neoaortic valve. The branch pulmonary arteries are disconnected from the pulmonary trunk, and a new source of pulmonary blood supply is provided by a shunt from the subclavian artery (i.e., Blalock-Taussig shunt) or from the right ventricle (i.e., Sano modification) (Fig. 17.11).[427] If the ASD is restrictive, it is enlarged to allow for unobstructed pulmonary venous return into what becomes a common atrium, then draining across the interatrial septum through the right side into the right ventricle. The important physiologic principles of the Norwood stage I operation are

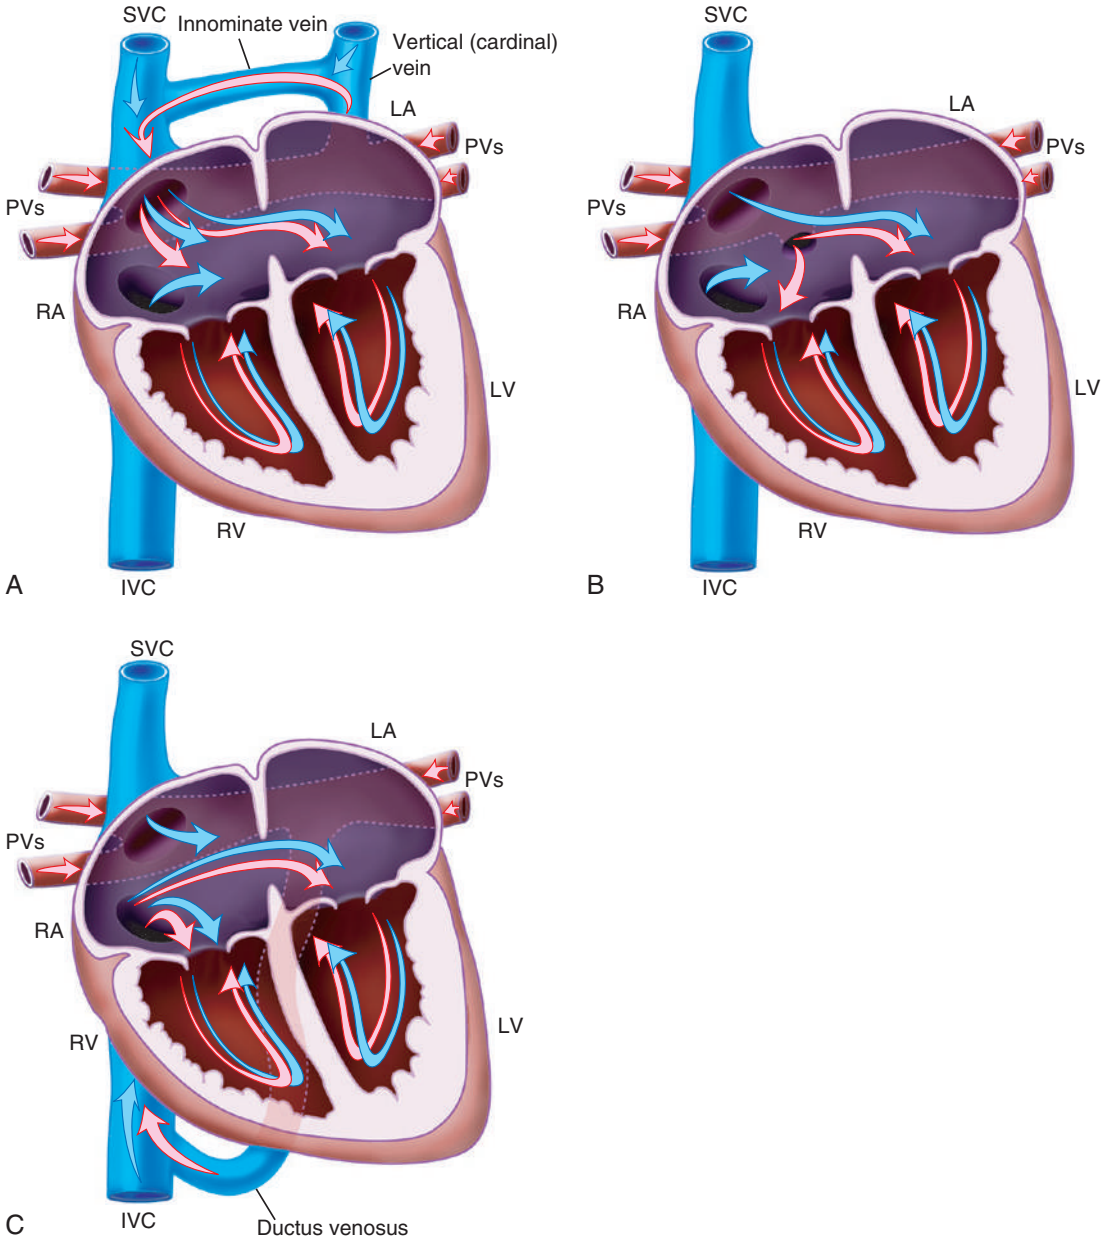

FIGURE 17.9 A, In the diagram of a supracardiac total anomalous pulmonary venous connection (TAPVC), the main arteries are removed. The pulmonary veins (*PVs*) drain through the innominate vein to the right atrium (*RA*), and there is an atrial septal defect (ASD). The result is a left-to-right shunt. These children are cyanotic. The veins may also be obstructed, leading to pulmonary hypertension. **B,** In the diagram of an intracardiac TAPVC, the PVs drain to the RA. There is a ventricular septal defect, and the effect is to create a left-to-right shunt. The veins may also be obstructed, which can lead to pulmonary hypertension. **C,** In the diagram of an infracardiac TAPVC, the PVs drain through the ductus venosus to the RA. An ASD exists, and the circulation results in a right-to-left shunt; the child is blue. The veins may also be obstructed. *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle; *SVC,* superior vena cava. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals.* Milwaukee, WI: Maxishare; 2005.)

unobstructed pulmonary venous return with unrestrictive interatrial communication; unobstructed systemic blood flow and adequate coronary perfusion; and controlled source of pulmonary blood flow.

NORWOOD STAGE II. The Norwood stage II (superior cavopulmonary connection, bidirectional Glenn or hemi-Fontan) operation takes place at about 6 months of age. It involves taking down the shunt that was created at the first operation and creating a new connection from the SVC to the pulmonary arteries (i.e., a bidirectional or Glenn shunt). The result is a pulmonary blood supply that is provided by systemic venous blood from the SVC. Flow is passive and depends on pulmonary artery pressures remaining low, since its driving force is the pressure gradient between the SVC (connected to the pulmonary arteries, upstream from the lungs) and atrial pressure (pressure downstream from the lungs). The gradient between these two pressures is called the

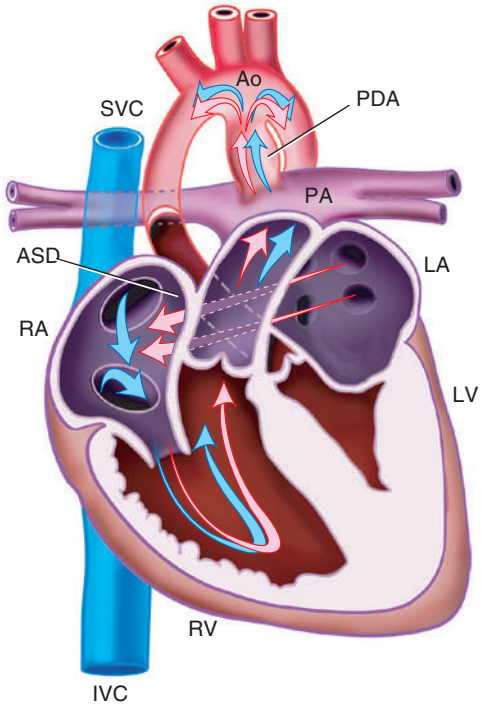

FIGURE 17.10 Diagram of hypoplastic left heart syndrome shows a very small left ventricle (*LV*), mitral valve, aortic valve, and aortic arch. Pulmonary venous blood drains to the left atrium (*LA*), then through an atrial septal defect (*ASD*) to the right atrium (*RA*), and from there through the right ventricle (*RV*) to the pulmonary artery (*PA*). A patent ductus arteriosus (*PDA*) provides blood to the systemic circulation. *Ao,* aorta; *IVC,* inferior vena cava; *SVC,* superior vena cava. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals.* Milwaukee, WI: Maxishare; 2005.)

transpulmonary gradient, and any obstruction between these two sites (for example, pulmonary hypertension) will result in inadequate pulmonary blood flow. The infants remain cyanotic with arterial saturations in the mid-80s because desaturated blood from the IVC continues to flow into the heart and the systemic circulation (Fig. 17.12).

NORWOOD STAGE III. The Norwood stage III (Fontan) operation converts the anatomy into a Fontan circulation. The surgery involves connecting the IVC through an extracardiac or intracardiac conduit to the pulmonary artery. This creates a single-ventricle or Fontan circulation (Fig. 17.13). The single right ventricle pumps blood to the systemic circulation, and the pulmonary blood supply is provided by passive flow by systemic venous blood from the SVC and IVC. The PVR must remain low because any increase will dramatically reduce pulmonary blood flow. It is common for a small hole (i.e., fenestration) to be created between the conduit and the right atrium so that if the PVR rises, blood will be directed to the right atrium and allow cardiac output to be maintained. In this situation, the child becomes cyanotic, but cardiac output is maintained, a much safer situation than a state of low cardiac output. Postoperatively, increased systemic venous pressure may cause pleural effusions, an enlarged liver, or protein-losing enteropathy. Later, if PVR remains consistently low, the fenestration can be closed with a transvenous device.

The long-term problem for these children is that the morphologic right ventricle, which then becomes the systemic ventricle, fails over time. The only recourse is heart transplantation.[428,429]

Anesthesia Considerations

NORWOOD STAGE I.

- The anesthesiologist must understand the anatomy and physiology of HLHS.
- Balance between systemic and pulmonary circulations is maintained by balancing PVR and SVR. If the PVR decreases, blood flow will be directed away from the systemic circulation and there will be pulmonary overcirculation. This results in hypotension and systemic hypoperfusion with increasing acidosis. If PVR increases, cyanosis will increase. Before anesthesia, these infants are best managed spontaneously breathing in room air with a prostaglandin E_1 infusion to maintain ductal patency. However, if mechanical ventilation is required, it is important to maintain normal to high $PaCO_2$ and very low FIO_2, usually with air. Even though oxygen saturations as read by pulse oximetry have traditionally been used as a guide to balancing the circulation, there is evidence that, when considered in isolation, they are a poor reflection of such a balance. As such, systemic venous saturations should also be used to provide an estimate of tissue oxygen delivery.[183,185,430,431] NIRS monitoring can also be used as a continuous indicator of the adequacy of oxygen delivery to the brain.
- Air should be available for transfer to and from the ICU; alternatively, a self-inflating bag can be used.
- Venous access is gained through the femoral or umbilical veins. The internal jugular vein is avoided because narrowing of the SVC would jeopardize a future Glenn shunt.
- High-dose opioid technique is preferred.
- Profound hypothermia may be required.
- Postoperative myocardial dysfunction is common, and inotropes are required.
- Balancing systemic and pulmonary blood flow remains an issue after bypass and estimating the relative systemic and pulmonary blood flows is not always straightforward. Some centers use the long-acting α-adrenergic blocker phenoxybenzamine after bypass to reduce SVR variability, allowing greater concentrations of oxygen to be used and an overall increase in oxygen delivery.[432] The alternative approach is to combine an inodilator such as milrinone with a vasopressor such as dopamine or epinephrine to achieve a similar effect. The authors' preference is to deliver a bolus dose of milrinone (0.5 μg/kg over 20 minutes during rewarming), followed by an infusion of 0.3 μg/kg per minute, in combination with a continuous infusion of epinephrine, 0.05 to 0.1 μg/kg per minute.
- Coagulopathy is likely to occur after bypass.
- Antifibrinolytics are often used.
- The sternum is frequently left open, and closure may be delayed for several days.

NORWOOD STAGE II.

- The procedure is carried out with CPB.
- Cardioplegia is not used. The heart remains beating, and inotropes are seldom required.
- Venous access is achieved through the femoral veins. However, only a single side should be used because femoral bypass is occasionally required. A short temporary cannula is useful as an additional monitor in the internal jugular vein. It reflects the pulmonary artery pressure after anastomosis of the SVC to the pulmonary artery. It is removed early in the postoperative period to avoid any possibility of thrombosis in the SVC.
- This is repeat surgery, and external defibrillator pads should be attached.
- Antifibrinolytics may be used.

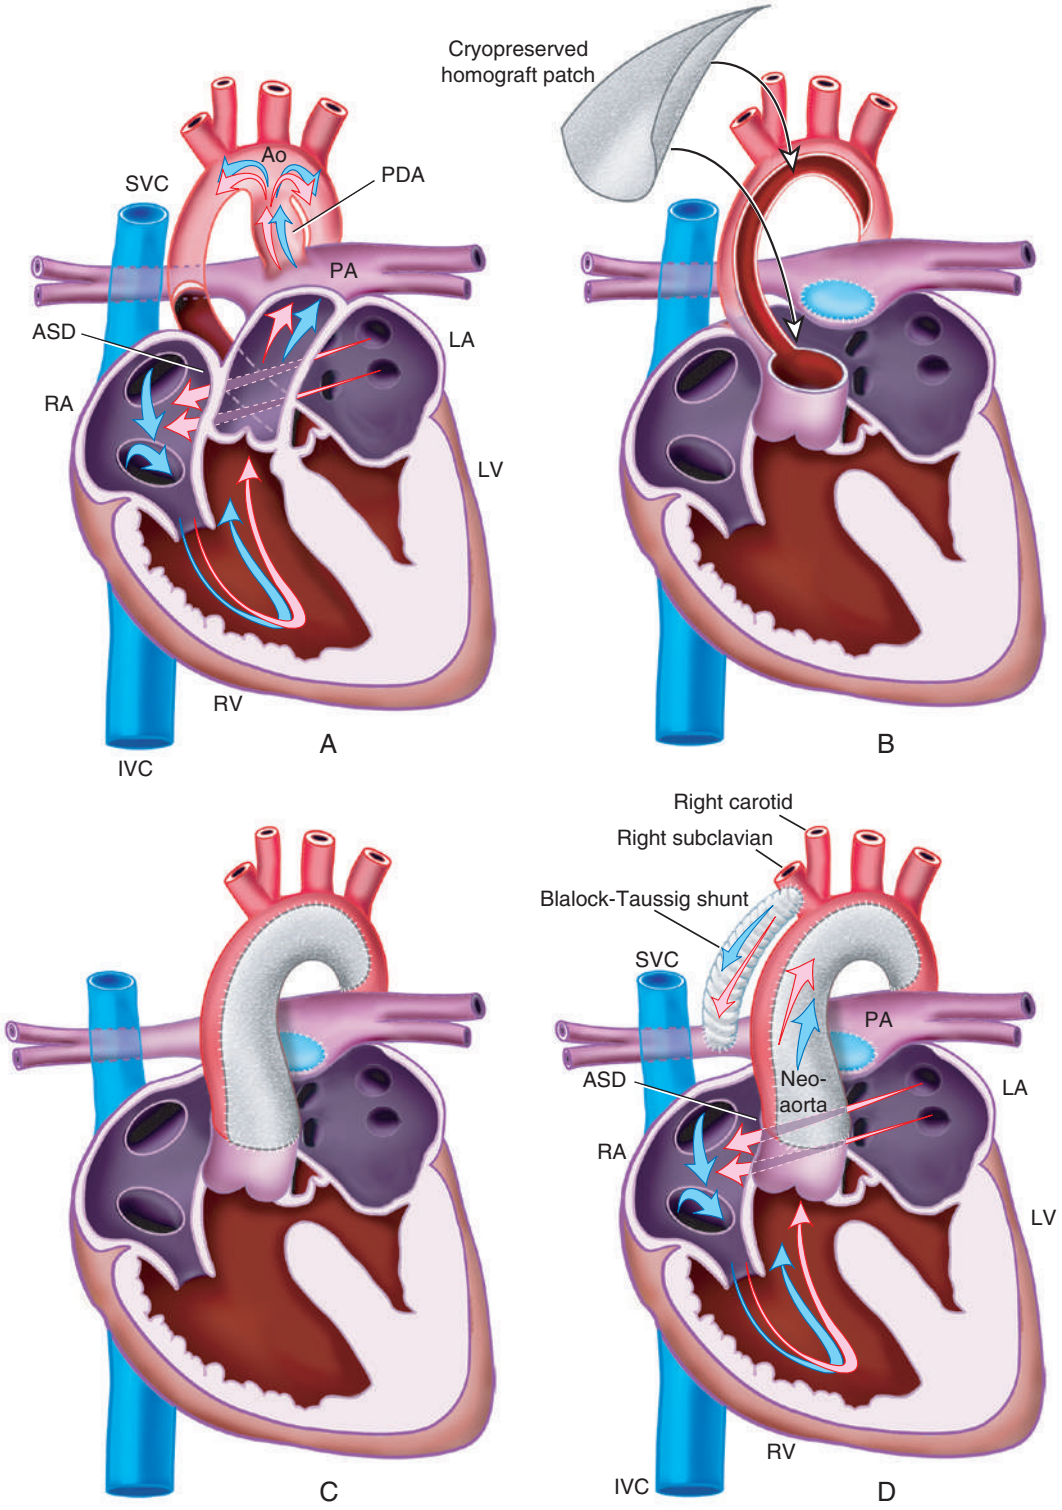

FIGURE 17.11 Diagram of the Norwood stage I operation. **A,** The main pulmonary artery (*PA*) is disconnected from the right ventricle (*RV*). **B** and **C,** The aortic arch is reconstructed with homograft and connected to the RV, which becomes a single ventricle. **D,** Pulmonary blood is then supplied by a Blalock-Taussig shunt from the subclavian artery to the PA. The children remain cyanotic. *Ao,* aorta; *ASD,* atrial septal defect; *IVC,* inferior vena cava; *LA,* left atrium; *LV,* left ventricle; *PDA,* patent ductus arteriosus; *RA,* right atrium; *SVC,* superior vena cava.. - The aim is early extubation; positive intrathoracic pressure reduces flow in the Glenn shunt.
- Infants should be nursed with the head up at 30 degrees after surgery, to improve flow in the Glenn shunt and reduce the possibility of edema in the SVC territory.

NORWOOD STAGE III.

- Surgery is carried out with CPB but usually without cross-clamping the aorta.
- PVR must remain low postoperatively, careful management of the lungs is important to minimize atelectasis, and inhaled nitrous oxide is occasionally required.[433]
- Milrinone is a good choice if inotropes are needed because of its beneficial effects on PVR.
- Early extubation is beneficial in terms of hemodynamics.
- Large amounts of fluid may be required in the early postoperative period.

AORTIC STENOSIS

Obstruction to the LVOT can occur at the valvular, subvalvular, or supravalvular areas or in various combinations, and it occurs commonly, accounting for up to 10% of CHD.[434,435] Congenital valvar aortic stenosis is frequently associated with a bicuspid valve. Severe critical aortic stenosis in neonates occurs in approximately 10% of cases and requires urgent treatment. Supravalvular aortic stenosis may be associated with Williams syndrome.[436]

Despite the many anatomic varieties of aortic stenosis, the resulting pathophysiology remains essentially the same. There is an increasing imbalance between myocardial oxygen supply and demand. Coronary blood flow is impaired due to low coronary perfusion pressure, while workload on the left ventricle is increased, leading to subendocardial ischemia, left ventricular hypertrophy, and a risk of left ventricular failure. The risk of sudden death is always present, especially with Williams syndrome.[437] The age at which the child presents is a risk factor; younger children are most at risk. Two-thirds of those presenting in the first 3 months of life will require inotropic or ventilatory support before treatment of the stenosis.[438] Approximately 5% of Williams syndrome patients may suffer a cardiac arrest during anesthesia.[439]

Treatment Options

Treatment options depend on the patient's age and the type and severity of the lesion. In neonates with critical aortic stenosis, an urgent valvuloplasty is required. It can be performed surgically using CPB, but it typically is performed using transluminal balloon angioplasty in the cardiac catheterization laboratory.[440] Complications in this age group include ventricular fibrillation, aortic incompetence, or residual aortic stenosis.

In the older child, several surgical approaches may be used, depending on the anatomy. Transluminal balloon valvuloplasty commonly is performed in older patients. The most common complications of valvuloplasty are aortic incompetence and residual aortic stenosis. Valve replacement with a mechanical valve or bioprosthetic valve is delayed as long as possible because of the long-term problems associated with the anticoagulation needed with a mechanical valve and because of the inevitable calcification of the bioprosthetic valve. An alternative surgical option is the Ross procedure, which involves moving the pulmonary valve into the aortic valve position and using a homograft in the pulmonary position. The need for reoperation with the Ross procedure is

reduced because the systemic valve (i.e., neoaortic valve) grows with the child and calcification of the homograft in the pulmonary position is slow. There is no need for anticoagulation.[441–443] More recently, there has been an interest in the possibility of aortic valve repair for aortic stenosis (rather than replacement) by use of a reconstruction technique with pericardial patch, thus avoiding the potential problems associated with valve replacement.[444–446]

Anesthesia Considerations

- A crucial aim of anesthesia is to maintain the balance of oxygen supply and demand. This involves maintaining a normal heart rate (no tachycardia or bradycardia), maintaining SVR and diastolic blood pressure to preserve coronary perfusion, avoiding hypertension, and avoiding myocardial depression.
- Anesthesia for neonates with aortic stenosis having surgery with CPB is similar to other neonatal cardiac surgery.
- For transluminal balloon valvuloplasty:
  - The catheter crossing the aortic valve and inflation of the balloon can lead to dramatic cardiovascular changes. Cardiac output decreases, myocardial ischemia occurs, and bradycardia is common. In neonates, ventricular fibrillation may occur after passing the wire across the valve. The anesthesiologist must be prepared to resuscitate the neonate quickly, and drugs, particularly epinephrine, should be immediately available.
  - It is possible the child will remain ventilated after the procedure because ventricular function can remain poor for some time.
  - Arterial access is needed by the cardiologist for the procedure, but pressure is not always displayed. An independent arterial line is very useful.
  - Occasionally, adenosine is given to slow or stop the heart at the time of balloon inflation to prevent damage to the valve by the inflated balloon being expelled through it. However, this practice is not universal.

Coarctation of the Aorta

Coarctation of the aorta is discrete narrowing of the aorta, and it accounts for about 5% of CHD. The lesion is often isolated with no other associated abnormalities. This type of lesion, however, may occur in association with other CHD, such as aortic arch, valve abnormalities, or VSD. The coarctation may be preductal, juxtaductal, or postductal, depending on the relationship to the ductus arteriosus. The most common form presenting in the neonatal period is the preductal type. Preductal coarctation is associated with minimal collateral circulation below the coarctation and requires prostaglandin to maintain ductal patency. Juxtaductal and postductal coarctations are characterized by the development of collateral vessels that supply the area below the coarctation. This is important because the spinal cord is supplied by these collaterals, which supply the spinal cord during aortic cross-clamping.

In practical terms, children with coarctation of the aorta can be classified in two groups. One group presents in the neonatal period with preductal coarctation with few collaterals, very poor left ventricular function, and possible heart failure. The second group of children (usually older than 1 year of age) have well-developed collaterals and better left ventricular function. Femoral pulses are often weak, and patients usually have a progressive acidosis. Differences between the systolic systemic blood pressures in the right arm (proximal to the stenosis) and legs (distal to the stenosis) may indicate the presence of a coarctation of the aorta.

Anesthesia Considerations

NEONATAL REPAIR.

- These infants are sick, with poor left ventricular function. They should be treated very carefully, and the anesthesiologist should not be misled by an infant who looks reasonably well.
- Some infants are already intubated and ventilated, and may be on inotropic support.
- IV access often is established to give prostaglandin E_1; this IV line can also be used to administer induction agents. The authors' preference is to give incremental doses of fentanyl (up to 5 μg/kg) and then a muscle relaxant and to supplement this with a very low dose of inhalation agent (e.g., isoflurane [0.3% to 0.5%]). This can be omitted if hypotension ensues.
- Inotropes may be required before surgery, and they should be available.
- Ideally, the arterial line should be placed in the right arm (right radial or axillary arteries) to allow continuous blood pressure measurement during arterial cross-clamping. The left subclavian may be partially obstructed during the repair. Some have advocated an arterial line below the coarctation to measure perfusion pressure during cross-clamping, but this may be very difficult in practice because femoral pulses are usually absent.
- A central venous line should be placed.
- Surgery usually takes place through a left thoracotomy without the use of CPB. The lung is retracted, and ventilation may be problematic. The endotracheal tube must fit snugly and have a minimal leak because a tracheal tube with a large leak may make ventilation very difficult. Alternatively, a cuffed endotracheal tube can be used.
- Paraplegia may occur in about 1% of cases and is thought to result from hypoperfusion during aortic cross-clamping.[447,448] To reduce the chance of spinal cord damage, infants should be cooled to 34°C or 35°C before the cross-clamp is applied, although this approach is not evidence-based. Normocarbia and upper limb blood pressure should be maintained, and the anesthesiologist should resist the temptation to lower blood pressure while the cross-clamp is applied. Low-dose anticoagulation may be requested. A short cross-clamp time is thought to be important.
- Epidural anesthesia is occasionally used but controversial, especially if anticoagulation is to be used, owing to the risk of neurologic damage.
- Postoperative hypertension may be a problem, since ventricular remodeling after relief of the obstruction is not immediate; a degree of left ventricular hypertrophy is to be expected for some weeks to months; in the immediate postoperative period, a vasodilator such as sodium nitroprusside may be required.

ANESTHESIA FOR THE OLDER CHILD.

- These children usually are not as sick as the neonates with this heart defect.
- Issues about vascular lines are similar to those in neonatal repair.
- Careful IV induction with a combination of fentanyl and an induction agent of choice is standard. Etomidate is a good anesthetic because of its cardiovascular stability.
- Although a collateral blood supply is present, the spinal cord remains at risk during the cross-clamping, and the same precautions taken with neonates should be taken with these children.
- An oral cuffed tracheal tube is useful because early extubation is the norm.
- Postoperative hypertension is a common problem, and good analgesia combined with sodium nitroprusside and β-blockers

is usually required. Up to 30% of children eventually develop long-term hypertension that will require therapy.

Some of these children are managed with balloon angioplasty with or without stent placement. Rupture of the aorta is a risk in these patients, and the institution in which the procedure is undertaken should be in a position to deal with this possibility, with a rescue plan clearly established.

Interrupted Aortic Arch

Interrupted aortic arch is a rare anomaly, accounting for less than 1% of CHD. In this condition, disruption occurs between the ascending aorta and descending aorta (Fig. 17.14). The three types depend on where the disruption takes place. It is a duct-dependent systemic circulation, since a PDA is required to supply the descending aorta. A VSD is also common. An interrupted aortic arch is frequently associated with chromosome 22q11 deletion and results in the aforementioned DiGeorge syndrome (see Table 17.4).[449]

These children are often small for gestational age and are started on a prostaglandin infusion to maintain ductal patency. They are often sick with progressive acidosis and poor cardiac output. There is increasing pulmonary blood flow as the duct closes. Surgical repair depends on the presence of associated lesions, particularly a VSD. In the single-stage repair, the arch is reconstructed and the VSD is closed. The two-stage repair involves repair of the aortic arch and banding of the pulmonary artery to limit blood flow to the lungs. The VSD is closed at a later date. Either way, deep hypothermic circulatory arrest is likely to be used. Some centers use selective regional perfusion to try and limit neurologic injury.[450] The early and late mortality rates are high. Greater mortality rates correlate with small size, preoperative acidosis, and associated cardiac lesions.[451]

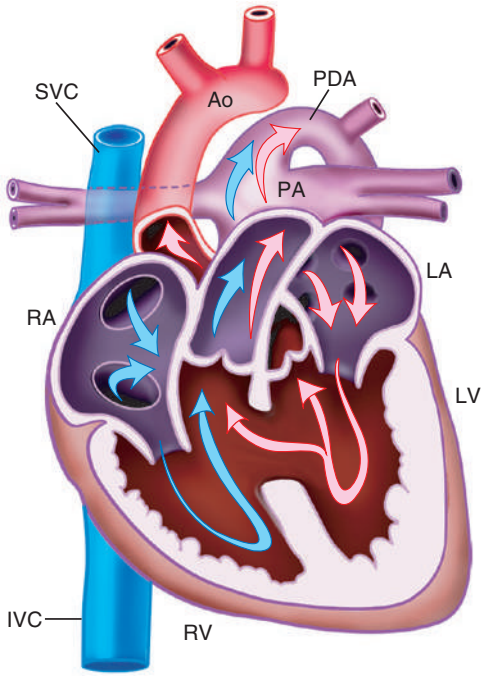

FIGURE 17.14 Diagram of an interrupted aortic arch. The patent ductus arteriosus (*PDA*) supplies the body below the interruption. *Ao,* aorta; *ASD,* atrial septal defect; *LA,* left atrium; *LV,* left ventricle; *PA,* pulmonary artery; *RA,* right atrium; *RV,* right ventricle. (Modified from May LE. *Pediatric Heart Surgery: A Ready Reference for Professionals*. Milwaukee, WI: Maxishare; 2005.)

Anesthesia Considerations

- The patient is a small, sick neonate.
- DiGeorge syndrome should be identified preoperatively, especially regarding the potential for hypocalcemia and the need for irradiated blood products; in case of uncertainty about 22q11 deletion status, it is prudent to proceed as if it is present.
- High-dose opioid technique is standard.
- Ideally, blood pressure should be monitored above and below the interruption, but this is often difficult in practice.
- Deep hypothermic circulatory arrest may be used.
- Coagulopathy is likely to occur after bypass.
- An antifibrinolytic is frequently used.
- Anticipate poor renal function postoperatively.
- There is a risk of postoperative pulmonary hypertensive crises.

These infants are likely to require repeat operations to deal with recurrent LVOTO, which may occur at any level. Restenosis of the repaired aortic arch can often be treated by transluminal balloon dilation.

Transport and Transfer to a Pediatric Intensive Care Unit

After surgery is completed, cardiac surgical patients need a period of intensive care. The first phase of this care is transport of the children from the operating room to the pediatric intensive care unit (PICU). This is a potentially hazardous time and requires good organization, teamwork, and appropriate equipment. Guidelines exist for the safe transport of these children.[452]

Transport to the PICU can be subdivided into a preparatory phase, transport phase, and stabilization phase.[453] During the preparatory phase, the estimated time of arrival in the PICU is communicated with the PICU. The bed space is prepared, ventilator and monitors are configured in an appropriate way, and any additional interventions that may be required are made ready. In the authors' institution, a form is sent to the PICU that indicates the child's age and weight, the ventilator settings that will be required, the number of transducers that will be required, and the infusions that are running. After arrival in the PICU, two basic tasks need to be completed: transfer of technology and transfer of information. It is better to allow the technology transfer to occur before the information handover. This includes ensuring that all the monitors are connected and working appropriately, that the ventilator is connected and delivering adequate ventilation, that all infusions are working, and that drains and urinary catheter are all in place with baseline readings documented. After this has been accomplished, a single handover of information should be done with all of the appropriate personnel present, and it should include information given by the anesthesiologist and surgeon. In our institution, a checklist is followed to ensure that no important information is omitted. It is important to avoid a large number of information handovers between individuals rather than a single, comprehensive handover with all the relevant personnel present.

ACKNOWLEDGMENT

The authors wish to thank Paul R. Hickey, Richard L. Marnach, Dolly D. Hansen, Robert W. Reid, and Frederick A. Burrows for their prior contributions to this chapter.

ANNOTATED REFERENCES

Bettex DA, Pretre R, Jenni R, Schmid ER. Cost-effectiveness of routine intraoperative transesophageal echocardiography in pediatric cardiac surgery: a 10-year experience. *Anesth Analg*. 2005;100:1271-1275.

Bettex and coworkers showed in a retrospective study of 580 pediatric patients undergoing cardiac surgery that the use of routine intraoperative transesophageal echocardiography (TEE) was cost effective. They identified 33 children who required a second bypass run on the basis of the intraoperative TEE. The authors estimate that the savings per child were in the range of $690 to $2130.

Hoffman TM, Wernovsky G, Atz AM, et al. Prophylactic intravenous use of milrinone after cardiac operation in pediatrics (PRIMACORP) study. Prophylactic Intravenous Use of Milrinone After Cardiac Operation in Pediatrics. *Am Heart J*. 2002;143:15-21.

In this large, multicenter, prospective, randomized, double-blind study, it was shown that the use of milrinone in high doses (75 μg/kg bolus over 60 minutes, followed by an infusion at a rate of 0.75 μg/kg per minute) in infants undergoing complex congenital cardiac operations reduced the incidence of low cardiac output syndrome in the postoperative period.

Kern FH, Morana NJ, Sears JJ, Hickey PR. Coagulation defects in neonates during cardiopulmonary bypass. *Ann Thorac Surg*. 1992;54:541-546.

Kern and colleagues showed that hemodilution is an important factor in the development of post-bypass coagulopathy in neonates. They showed that platelets and coagulation factors were dramatically reduced as soon as the neonate was placed on cardiopulmonary bypass (CPB) and were not significantly reduced further during CPB.

Malviya S, Voepel-Lewis T, Siewert M, et al. Risk factors for adverse postoperative outcomes in children presenting for cardiac surgery with upper respiratory tract infections. *Anesthesiology*. 2003;98:628-632.

These investigators have shown that children with an upper respiratory tract infection at the time of cardiac surgery are at risk for more complications in the postoperative period and have a longer stay in the intensive care unit. These children need very careful assessment before surgery, and the risk/benefit ratio for the child must be considered.

Mangano DT, Tudor IC, Dietzel C. The risk associated with aprotinin in cardiac surgery. *N Engl J Med*. 2006;354:353-365.

Mangano and associates reported a large observational study in adult patients undergoing revascularization surgery. They reported an increase in renal failure, myocardial infarction, heart failure, stroke, and encephalopathy. This study has been criticized for not being randomized. These effects have not been shown in children, but it has created an unease about the use of aprotinin in children. It is important that well-designed, independent, large studies are carried out in children to establish the role of aprotinin.

Naik SK, Knight A, Elliott M. A prospective randomized study of a modified technique of ultrafiltration during pediatric open-heart surgery. *Circulation*. 1991;84(suppl):III422-III431.

Naik and colleagues were the first to report the use of modified ultrafiltration (MUF) after cardiopulmonary bypass in children. Beneficial effects included reduced total body water, higher hematocrit, higher blood pressure, less postoperative bleeding, and a reduced requirement for inotropes. MUF is now used in many centers worldwide and has a number of benefits.

Pasquali SK, Li JS, He X, et al. Comparative analysis of antifibrinolytic medications in pediatric heart surgery. *J Thorac Cardiovasc Surg*. 2012;143:550-557.

The Society of Thoracic Surgeons Congenital Heart Surgery Database (2004-2008) was linked to medication data from the Pediatric Health Information Systems Database. A total of 22,258 children were included in the study. Aprotinin (vs. no drug) was associated with a reduction in combined hospital mortality/bleeding requiring surgical intervention overall (odds ratio [OR], 0.81; 95% confidence intervals [CI], 0.68–0.91) and in the redo sternotomy subgroup (OR, 0.57; 95% CI, 0.40–0.80). There was no benefit in neonates and no difference in renal failure requiring dialysis in any group. In comparative analysis, there was no difference in outcome for aprotinin versus aminocaproic acid recipients. Tranexamic acid (vs. aprotinin) was associated with significantly reduced mortality/bleeding requiring surgical intervention overall (OR, 0.47; 95% CI, 0.30–0.74) and in neonates (OR, 0.30; 95% CI, 0.15–0.58). These observational data suggest aprotinin is associated with reduced bleeding and mortality in children undergoing heart surgery with no increase in dialysis. Comparative analyses suggest similar efficacy of aminocaproic acid and improved outcomes associated with tranexamic acid.

Williams GD, Ramamoorthy C. Brain monitoring and protection during pediatric cardiac surgery. *Semin Cardiothorac Vasc Anesth*. 2007;11:23-33.

This article reviews brain monitoring modalities available during pediatric cardiac surgery. Its emphasis is on ways of reducing brain injury during cardiopulmonary bypass and deep hypothermic circulatory arrest in children. Neuroprotective stategies are discussed, including selective cerebral perfusion during deep hypothermic circulatory arrest, management of acid-base balance, the degree of hemodilution, blood glucose management, and antiinfammatory therapy.

Zhou G, Feng Z, Xiong H, et al. A combined ultrafiltration strategy during pediatric cardiac surgery: a prospective, randomized, controlled study with clinical outcomes. *J Thorac Cardiovasc Surg*. 2013;27:897-902.

The combined use of ultrafiltration of the prime solution, zero-balance ultrafiltration, and a modified ultrafiltration (MUF) strategy was associated with modest improvements in pulmonary function compared with the combination of coventional and MUF strategies in the early postoperative period, but the principal clinical outcomes are similar.

THE CARDIOVASCULAR SYSTEM plays a dominant role within the human body: a centrally located "powerhouse" provides oxygen and nutrients via an extensive network of vessels and capillaries throughout the body. All other organ systems depend on its normal development and function. At birth, and especially in the first few hours of life, the heart and the vascular system have to adapt to the extrauterine conditions. Prematurity, congenital defects, complications during labor and delivery, and many other factors can prevent or delay the necessary changes and cause significant morbidity.

A thorough understanding of the fetal circulation, the changes at birth, and the age-specific characteristics is important for the safe management of neonates, infants, and especially the growing number of preterm and small-for-gestational-age (SGA) infants who come to our diagnostic suites and operating rooms. Given the complex embryology and difficult transition from fetal to extrauterine life, it is amazing that more than 90% of neonates are delivered without any special interventions and that congenital heart defects occur in only 7 to 10 of every 1000 live births.[1] (A detailed discussion of the embryologic development is beyond the scope of this chapter; the interested reader is referred to the excellent review by Van Praagh[2] or Langman's classic embryology textbook.[3])

Congenital heart defects are among the most common birth defects. In the United States, approximately 32,000 infants are born every year with congenital heart disease (CHD); a significant number require urgent interventions in the catheterization laboratory or surgical procedures during the neonatal period. In addition, CHD is often associated with other, noncardiac anomalies, and many of these children will present for procedures outside the cardiac operating room. Pediatric anesthesiologists have to be able to classify and recognize the pathophysiologic effects of CHD on the cardiovascular system of the neonate or infant and the potential impact of anesthesia and surgical manipulations.

With recent advances in surgical techniques, critical care, and anesthesia management, 85% of all infants with CHD are now expected to reach adulthood. Anesthesiologists will increasingly encounter children with "repaired" or "palliated" CHD presenting for noncardiac procedures. Chapter 23 addresses specific long-term problems and anesthetic considerations for various repaired heart defects, but a few conditions deserve additional discussion: the basic changes in the exercise physiology of repaired heart defects, the characteristics of the Fontan physiology after single ventricle palliation, and the altered physiologic responses in the transplanted heart.

Many conditions require pharmacologic support with cardiovascular drugs, some of which can have significant age-specific effects. Well-controlled drug studies in infants and children are rare; dosing is often based on long-standing experience or extrapolation from adult data. Understanding the basic pharmacology of the most commonly used cardiovascular drugs and the special considerations for infants and children is essential for successful perioperative care. This chapter will help the pediatric anesthesiologist to understand the complexity of the neonatal cardiovascular system, the implications of CHD, basic pharmacologic considerations, and will provide the necessary tools to develop a safe management plan.

Cardiovascular Physiology

FETAL CIRCULATION

In utero, the placental gas exchange provides the fetus with poorly oxygenated blood; the partial pressure of oxygen (P_{O_2}) in the umbilical vein is approximately 30 mm Hg, and in the umbilical arteries it is approximately 16 mm Hg. The fetal lungs are fluid

filled and only minimally perfused (10%–15% of the cardiac output). The normal postnatal circulation can be described as a serial circuit: two pumps, the right ventricle (RV) and left ventricle (LV), support two different resistance systems, the pulmonary and systemic vasculatures, one after the other. In contrast, the fetal circulation is better explained by the concept of a parallel circuit: both ventricles provide systemic blood flow and a variety of fetal shortcuts or connections allow for mixing of oxygenated and deoxygenated blood (Fig. 18.1).[4,5] Oxygenated blood from the placenta returns via the umbilical vein to the portal venous system, where 30% to 50% of the blood flow is shunted across the *ductus venosus* to the inferior vena cava (IVC), bypassing the liver and thereby maintaining higher oxygenation and velocity. The rest of the umbilical venous blood passes through the hepatic microcirculation into the suprahepatic IVC.

The IVC blood entering the right atrium (RA) is a mixture of bloodstreams with different velocities and saturations: the low-velocity, deoxygenated venous return from the lower body and hepatic veins and the high-velocity, oxygenated umbilical venous blood from the ductus venosus. Valve-like tissue in the RA (eustachian valve) and the Chiari network preferentially direct the high-velocity bloodstream from the IVC across the *foramen ovale* into the left atrium (LA), bypassing the RV and pulmonary vessels. In the LA, the oxygenated blood mixes with the minimal amount of venous return from the pulmonary circulation and is then ejected by the LV into the ascending aorta and the major vessels of the aortic arch. This blood, with a saturation of 65% to 70%, provides the oxygenation for the growing heart and brain.

Most of the venous return from the superior vena cava (SVC) and about 20% of the IVC blood flow (mainly the low-velocity,

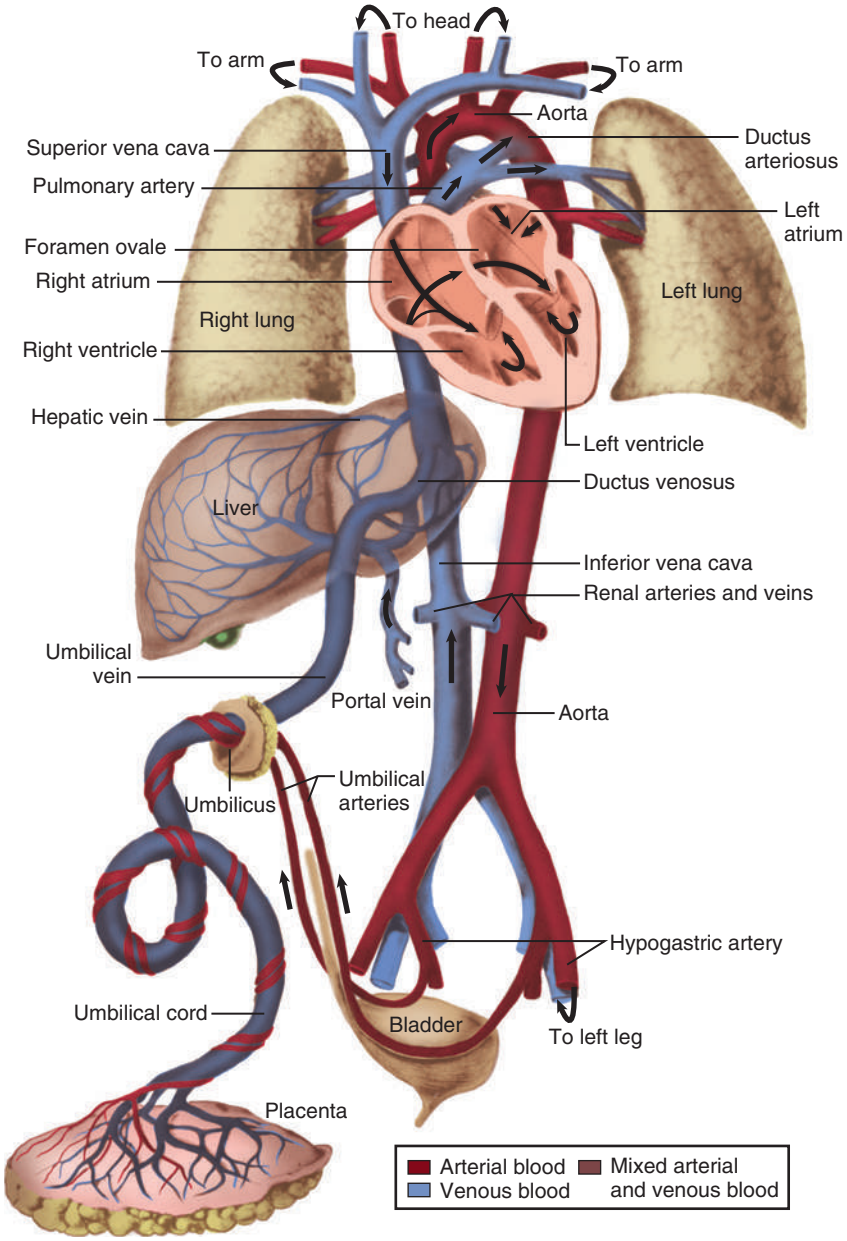

FIGURE 18.1 Course of the fetal circulation in late gestation. Notice the selective blood flow patterns across the foramen ovale and the ductus arteriosus. (From Greeley WJ, Berkowitz DH, Nathan AT. Anesthesia for pediatric cardiac surgery. In: Miller RD, ed. *Anesthesia*. 7th ed. Philadelphia: Churchill Livingstone; 2010, Fig. 83.1.)

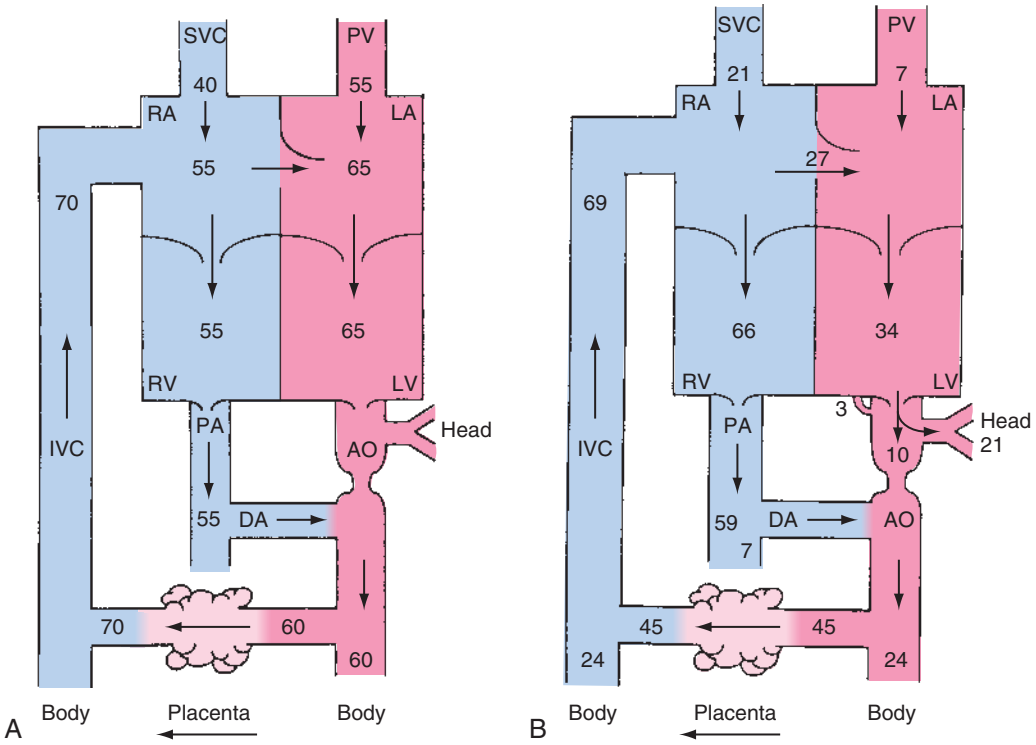

FIGURE 18.2 Fetal circulation in the late-gestation lamb. **A,** The numbers indicate the percentage of oxygen saturation. Oxygen saturation is greatest in the inferior vena cava *(IVC),* representing flow that is primarily from the placenta. The saturation of the blood in the heart is slightly greater on the left side than on the right side. **B,** The course of the circulation. The numbers represent the percentage of combined ventricular output. Some of the return from the IVC is diverted by the crista dividens in the right atrium *(RA)* through the foramen ovale into the left atrium (*LA*), where it meets the pulmonary venous return *(PV),* passes into the left ventricle *(LV),* and is pumped into the ascending aorta. Most of the ascending aortic flow goes to the coronary, subclavian, and carotid arteries, with only 10% of combined ventricular output passing through the aortic arch (indicated by the narrowed point in the aorta) into the descending aorta *(AO).* The remainder of the IVC flow mixes with return from the superior vena cava *(SVC)* and coronary veins (3%), passes into the RA and right ventricle *(RV),* and is pumped into the pulmonary artery *(PA).* Because of the increased pulmonary resistance, only 7% of the blood passes through the lungs *(PV),* with the rest passing through the ductus arteriosus *(DA)* to the AO and then to the placenta and lower half of the body. (Modified from Rudolph AM. *Congenital Diseases of the Heart.* Chicago: Year Book Publishers; 1974:1-48; and from Freed MD. Fetal and transitional circulation. In: Fyler DC, ed. *Nadas' Pediatric Cardiology.* Philadelphia: Mosby-Year Book; 1992:57-61.)

deoxygenated part) reach the RV and are pumped into the pulmonary artery (PA), where the high pulmonary resistance in the nonexpanded lung redirects 90% of the blood flow into the descending aorta via the *ductus arteriosus*. The bulk of the blood flow in the descending aorta is generated by the RV, with minor contributions from the LV. The blood has a saturation of only 55% to 60%; two-thirds of it returns to the placenta for oxygenation, and the rest is distributed to the intestines, the kidneys, and the lower part of the body (Fig. 18.2).

The fetal circulation has to support a growing fetus in a relatively cyanotic atmosphere (highest oxygen saturation, 65% to 70%). This difficult task is further complicated by the parallel circuit, which creates increased workload for the RV, and the limitations of the fetal shortcuts, which add additional volume load by incomplete shunting of oxygenated and deoxygenated blood. Initially, our understanding of the fetal circulation was based mainly on experimental animal data, but recent advances in ultrasound technology have facilitated assessment and monitoring of fetal cardiovascular parameters, especially stroke volume and cardiac output, under various conditions throughout the gestational period. RV stroke volume has been found to increase from about 0.7 mL at 20 weeks to 7.6 mL at 40 weeks, and LV stroke volume increases from 0.7 mL to 5.2 mL. The combined fetal cardiac output of both ventricles is estimated to be 400 to 425 mL/kg per minute, with an RV dominance because of the increased volume load. At 38 weeks, the RV provides approximately 60% of the combined cardiac output (E-Table 18.1).[6–8] Intrauterine growth restriction and placental compromise are associated with redistribution of cardiac output and relative changes in the size of the foramen ovale.[9] A functional placenta, the fetal cardiovascular high-output state, greater hemoglobin concentrations, and additional alterations in oxygen binding and release (hemoglobin F, increased 2,3-diphosphoglycerate [2,3-DPG]) are all necessary to provide adequate tissue oxygenation for the developing fetus.

Until recently, CHD was thought to be relatively well tolerated in utero, but growing evidence suggests that fetal cardiovascular defects can induce intrinsic autoregulatory changes in cerebral perfusion and thereby compromise brain development.[10–12] Ultrasound and magnetic resonance imaging demonstrate that 25% to 40% of neonates with CHD have neurologic abnormalities before any surgical intervention.[13,14]

E-TABLE 18.1 Combined Cardiac Output and Distribution in Human Fetuses During the Second Half of Pregnancy

	PERCENTAGE OF COMBINED CO AT GESTATIONAL AGE		
	20 Weeks	**30 Weeks**	**38 Weeks**
Combined CO	210 mL/minute	960 mL/minute	1900 mL/minute
Left ventricle	47%	43%	40%
Right ventricle	53%	57%	60%
Foramen ovale	34%	18%	19%
Lungs	13%	25%	21%
Ductus arteriosus	40%	32%	39%

CO, cardiac output.

Data from Rasanen J, Wood DC, Weiner S, Ludomirski A, Huhta JC. Role of the pulmonary circulation in the distribution of human fetal cardiac output during the second half of pregnancy. *Circulation* 1996;94:1068–1073.

TRANSITIONAL CIRCULATION

At birth, a variety of humoral, biochemical, and physiologic changes occur abruptly. First, the placental circulation is eliminated shortly after the lungs expand. Second, expansion of the lungs to a normal functional residual capacity (FRC) results in an optimal geometric relationship of the pulmonary microvasculature. Third, air entering the lungs causes the alveolar P_{CO_2} to decrease and the alveolar P_{O_2} to increase. These three factors act in concert to markedly reduce pulmonary vascular resistance (PVR).[5,15,16] The net effect is a considerable increase in pulmonary blood flow, which augments pulmonary venous return to the left heart. Along with elimination of the placenta and the low-resistance umbilical circulation, the LV is suddenly subjected to increased volume and afterload (Table 18.1). Typically, LV end-diastolic pressure, and thus LA pressure, increases enough to exert hydrostatic pressure on the septum primum, resulting in functional closure of the foramen ovale. In contrast to the increased stress for the LV, the RV is relatively unloaded by the transition to extrauterine life.

The three fetal connections (ductus arteriosus, ductus venosus, and foramen ovale) close over a variable period after birth. The ductus arteriosus functionally (but not anatomically) closes in 58% of normal full-term infants by day 2 after birth and in 98% by day 4.[17] Although many substances (such as eicosanoids) have been implicated in initiating constriction of the ductus, initial constriction probably occurs primarily in response to the increased arterial oxygen tension[18,19] and the reduction in circulating prostaglandins that follow separation of the placenta.[20] The response to oxygen is age dependent: term neonates usually demonstrate effective constriction of the smooth muscles in the ductal tissue when exposed to oxygen, whereas preterm infants respond poorly and often require medical (prostaglandin inhibitor) or even surgical therapy. Additional catecholamine-induced changes in PVR and systemic vascular resistance (SVR) and other substances such as acetylcholine contribute to ductal closure. Within 2 to 3 weeks, functional constriction is followed by a process of ductal fibrosis, leaving a band-like structure, the ligamentum arteriosum.[21,22] With ligation of the umbilical vein, the portal pressure falls, triggering functional closure of the ductus venosus. This process rarely requires more than 1 to 2 weeks; by 3 months only fibrous tissue, the ligamentum venosum, is left.

The foramen ovale is functionally closed when the LA pressure exceeds the RA pressure, but it remains anatomically patent in most infants, in 50% of children younger than 5 years of age, and in 25% to 30% of adults.[23] Echocardiographic studies have confirmed right-to-left shunting via the foramen ovale in healthy infants emerging from general anesthesia, and this can be a significant cause of persistent arterial desaturation at that time despite ventilation with 100% oxygen.[24]

TABLE 18.1 Hemodynamic Changes at Birth

Right Ventricle	Left Ventricle
Decreased Afterload:	**Increased Afterload:**
Decreased pulmonary vascular resistance	Placenta eliminated
Ductal closure	Ductal closure
Decreased Volume Load:	**Increased Volume Load:**
Eliminated umbilical vein return	Increased pulmonary venous return
Output diminished 25%	Output increased almost 50%
	Transient left-to-right shunt at ductus

NEONATAL CARDIOVASCULAR SYSTEM

Compared with the adult, the neonatal myocardium is immature and incompletely developed (Table 18.2). Differences in cytoarchitecture and metabolism account for many of the functional limitations. The neonatal heart contains fewer muscle cells and more connective tissue than the adult myocardium. Contractile elements represent only 30% of the total cardiac mass, in contrast to 60% in the adult.[25] The ratio of surface area to mass and water to collagen content are greater in neonates than older children. There are fewer myofibrils within the muscle cells, and they tend to be less organized (i.e., not parallel to the long axis of the cell). The sarcoplasmic reticulum and the T-tubule network, both important components of rapid and effective calcium regulation, are incompletely developed, and the immature myocardium relies substantially on the calcium flux through the sarcolemma to initiate and terminate contraction.[26–28] One practical consequence

TABLE 18.2 Characteristic Differences Between the Immature and the Adult Myocardium

	Immature Myocardium	Adult Myocardium
Cytoarchitecture	Fewer mitochondria and sarcoplasmic reticula Poorly formed T-tubules Limited contractile elements and increased water content Dependence on extracellular calcium for contractility	Organized mitochondrial rows, abundant SR Well-formed T tubules Increased number of myofibrils with better orientation Rapid release and reuptake of calcium via SR
Metabolism	Carbohydrates and lactate as primary energy sources Increased glycogen stores and anaerobic glycolysis for ATP Decreased nucleotidase activity, retained ATP precursors Better tolerance to ischemia with rapid recovery of function	Free fatty acids as primary source for ATP Limited glycogen stores and glycolytic function Increased 5′-nucleotidase activity, rapid ATP depletion Less tolerance to ischemia
Function	Decreased compliance Limited CO augmentation with increased preload Decreased tolerance to afterload Immature autonomic innervation: parasympathetic dominance, incomplete sympathetic innervation	Normally developed tension Able to improve CO with increased preload and to maintain CO with increasing afterload

ATP, adenosine triphosphate; *CO,* cardiac output; *SR,* sarcoplasmic reticulum.

Data from Mossad EB, Farid I. Vital organ preservation during surgery for congenital heart disease. In: Lake CL, Booker PD, eds. *Pediatric Cardiac Anesthesia.* 4th ed. Philadelphia: Lippincott, Williams & Wilkins; 2005:266–290; and DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, eds. *Anesthesia for Cardiac Surgery.* 3rd ed. Malden, MA: Blackwell Publishing; 2008:167–251.

of this disorganized and immature myocardium is a greater degree of contractile dysfunction in the infant exposed to substances that decrease extracellular ionized calcium, such as citrate (blood products) and albumin; there is also increased sensitivity to inhalational anesthetics and calcium channel blockers.

Reduced numbers of underdeveloped mitochondria and maturational differences in various signaling pathways and related messenger systems are also characteristic of the neonatal myocardium. Immature mitochondrial enzyme activity for fatty acid transport may explain the primary use of carbohydrates and lactates as energy sources and might be a reason for the greater anaerobic tolerance and faster recovery after periods of ischemia. A variety of developmental changes in contractile proteins occur from fetal through early postnatal life, including changes in pH, calcium sensitivity, and adenosine triphosphate (ATP) hydrolyzing activity. The key features of the immature cardiac function are summarized in Table 18.2.

The increased amount of noncontractile tissue in the neonate decreases ventricular compliance and limits the response to an increased preload. Compliance of both ventricles progressively increases during fetal life and the postnatal period, so that maximal stroke volume occurs at a significantly reduced atrial pressure in the neonate compared with the fetus (Figs. 18.3 and 18.4).[29–31] The high metabolic rate of the neonate (oxygen consumption, 6-8 mL/kg per minute, compared with 2-3 mL/kg per minute in the adult) requires a proportional increase in cardiac output. The neonatal heart meets this demand, in part, by a greater heart rate (HR).[32,33] The cardiac output is commonly described as depending primarily on HR owing to a fixed stroke volume, but echocardiographic studies in human fetuses and neonates have demonstrated the capacity to increase stroke volume (Fig. 18.5)[34] In fact, the neonate uses both tachycardia and stroke volume adjustments to meet metabolic demand. On the other hand, neonates exhibit exquisite sensitivity to pharmacologic agents that produce negative inotropic or chronotropic effects. At birth, both ventricles are equal in mass and connected via a common septum. Increased pressures in one ventricle shifts the septum, decreasing compliance of the other ventricle. The net effect is a reduction in cardiac output. Neonates and infants often present with biventricular failure as a result of this interventricular dependence.

Immature autonomic regulation of cardiac function persists throughout the neonatal period. Both sympathetic and parasympathetic innervation of the heart can be demonstrated at birth. However, evidence suggests that development of the sympathetic nervous system is incomplete at both the postganglionic nerve-receptor level and the receptor-effector level.[35] The sympathetic system reaches maturity by early infancy, whereas the parasympathetic system reaches maturity within a few days after birth.[36] The relative imbalance of these two components of the autonomic nervous system at birth may account for the clinical observation that neonates are predisposed to marked vagal responses to a variety of stimuli.

PULMONARY VASCULAR PHYSIOLOGY

At birth, pulmonary vascular development is incomplete. Lung sections demonstrate a diminished number of arterioles, and the arterioles exhibit thick medial muscularization (Fig. 18.6).[37–39] The pulmonary vasculature matures during the first few years of life. During this period, arterioles proliferate faster than alveoli, and the medial smooth muscle thins and extends more distally in the vascular tree. PVR continues to decrease as long as pulmonary

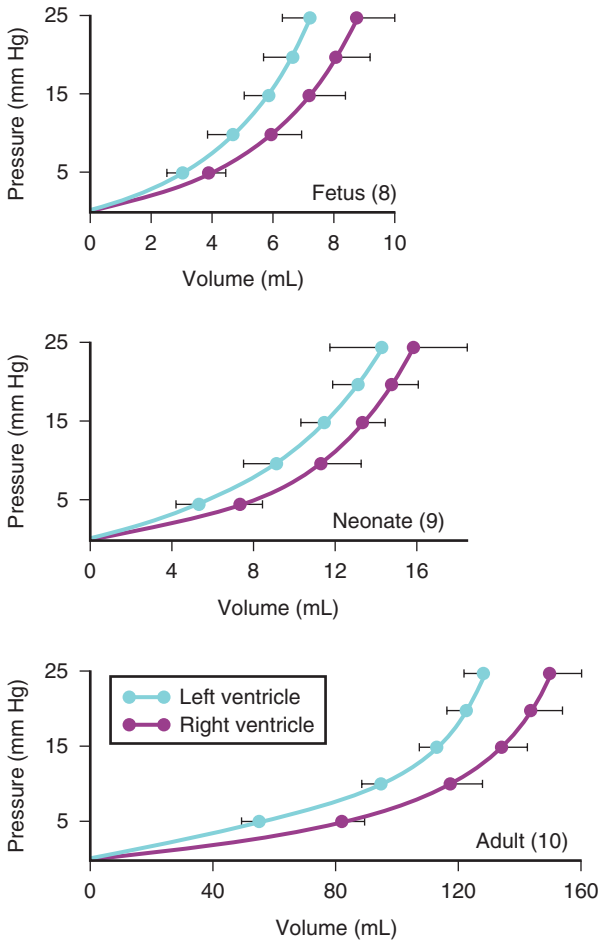

FIGURE 18.3 Comparison of ventricular pressure–volume curves for fetal, neonatal, and adult sheep. Differences between ventricles are significant only in adult sheep. Notice that the right and left ventricles have similar compliance curves in the neonates, making the physiologic relationship between ventricles more intimate (i.e., infants tend to develop biventricular failure). (From Romero T, Covell J, Friedman WF. A comparison of pressure-volume relations of the fetal, newborn and adult heart. *Am J Physiol.* 1972;222:1285–1290.)

mechanics and alveolar gas composition remain favorable, with a significant decrease occurring immediately after birth as the result of lung expansion and oxygenation. Progressive remodeling of the pulmonary vasculature facilitates further decreases in PVR (assuming normal physiology) during the first 2 to 3 months of life; by 6 months of age, the PVR has almost reached adult levels.[39]

The fetal pulmonary vasculature is extremely reactive to a number of stimuli. Hypoxia, acidosis, increased levels of leukotrienes, and mechanical stimulation (e.g., coughing on an endotracheal tube) can cause significant and prolonged increases in PVR (e.g., reactive pulmonary hypertension). On the other hand, acetylcholine, histamine, bradykinin, prostaglandins, β-adrenergic catecholamines, and nitric oxide (NO) are strong vasodilators.[37] In the first days after birth, many pathophysiologic conditions can trigger severe and sustained increases in PVR[40,41] and prevent the normal adjustment to extrauterine life (E-Table 18.2). The acute load imposed on the RV can induce diastolic dysfunction and promote right-to-left shunting via the foramen ovale. Once PVR exceeds the SVR, a right-to-left shunt develops through both the ductus arteriosus and the foramen ovale. This situation is called *persistent fetal circulation*,[42] and it can result in a life-threatening hypoxemia

E-TABLE 18.2	Conditions Prolonging Transitional Circulation
Prematurity	Sepsis

Congenital heart disease	Prolonged stress

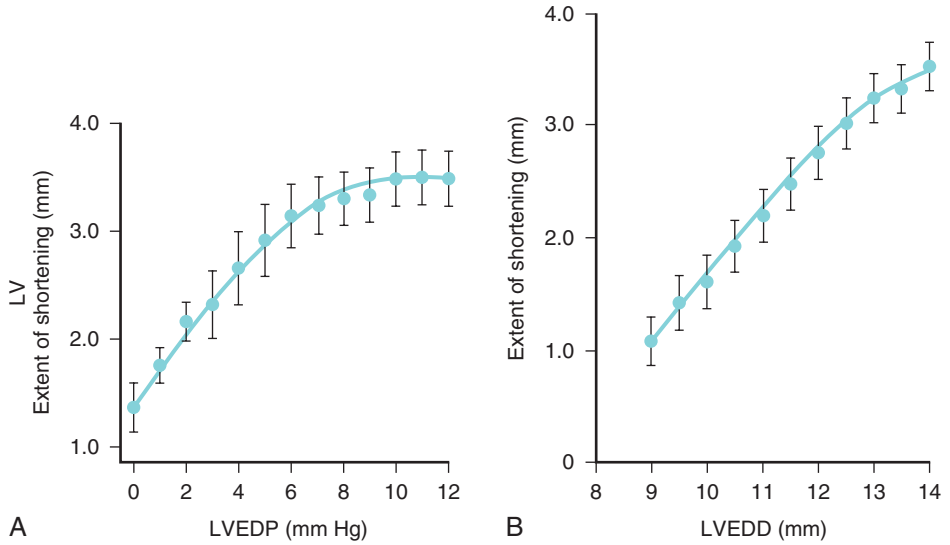

FIGURE 18.4 Frank-Starling relationship in fetal lamb model (gestational age, 135 ± 5 days). **A,** The relationship between left ventricular end-diastolic pressure *(LVEDP)* and shortening in a chronically instrumented fetal lamb model. Although myocardial performance improves with increasing LVEDP, the effect achieves a plateau at 10 mm Hg. **B,** In the same model, the relationship between left ventricular end-diastolic diameter *(LVEDD)* and left ventricular shortening. Taken together, these experiments support the capacity, albeit blunted, of the fetal heart to change stroke volume on the basis of volume loading conditions. Each point and vertical bars represent mean ± standard error. (From Kirkpatrick SE, Pitlick PT, Naliboff J, et al. Frank-Starling relationship as an important determinant of fetal cardiac output. *Am J Physiol.* 1976;231:495–500.)

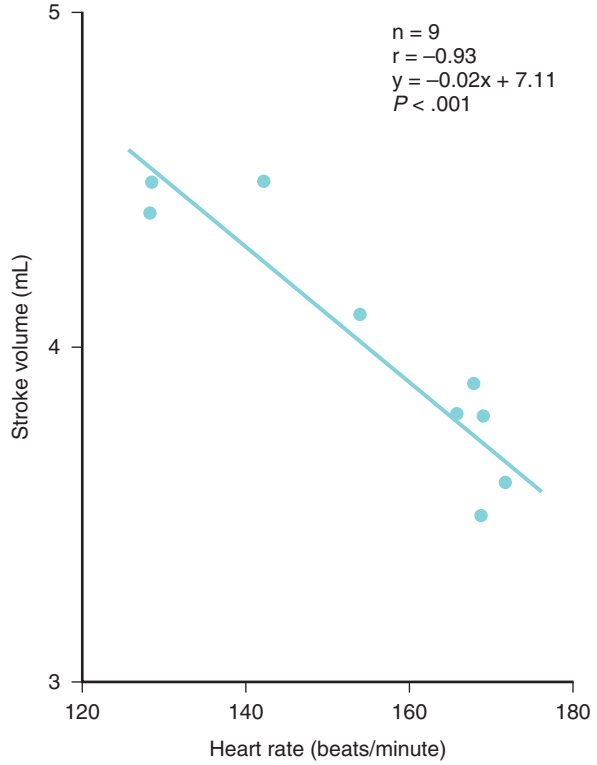

FIGURE 18.5 Doppler echocardiographic comparison of the effect of spontaneous changes in heart rate on stroke volume in a normal human fetus in utero, illustrating decreased stroke volume with increased heart rate. These observations confirm the ability of the fetal heart to change stroke volume under normal physiologic conditions. (From Kenny J, Plappert T, Doubilet P, et al. Effects of heart rate on ventricular size, stroke volume, and output in the normal human fetus: a prospective Doppler echocardiographic study. *Circulation* 1987;76:52–58.)

that may require inhaled NO,[43–47] sildenafil,[48] or extracorporeal support (i.e., extracorporeal membrane oxygenation)[49,50] (see Chapter 21) to provide oxygenation and sustain life.

Pulmonary vascular occlusive disease (PVOD) describes the structural changes in the pulmonary vasculature after long-standing exposure to abnormal pressures and flow patterns in utero and after birth. Lung biopsies demonstrate thickened muscle layers in the small pulmonary arteries, intimal hyperplasia, scarring, and thrombosis as well as a decreased number of distal (intraacinar) arteries.[38] Over time, these changes lead to a progressive and ultimately irreversible obstruction to pulmonary blood flow with increases in PVR and PA pressures. The very muscularized pulmonary arteries are also extremely sensitive to pulmonary vasoconstrictors, which can easily trigger a pulmonary hypertensive crisis.

Many cardiac defects are associated with abnormal pulmonary flow patterns and can be categorized into three basic groups:

- *Exposure of the pulmonary vasculature to systemic arterial pressures and high flow:* The classic example is a large, nonrestrictive ventricular septal defect (VSD) with rapid progression of PVOD.
- *Exposure of the pulmonary vasculature to high flow without increased pressure:* Large atrial septal defects (ASDs) and small, restrictive patent ductus arteriosus (PDA) defects fall into this category. PVOD develops much more slowly in this setting.
- *Obstruction of pulmonary venous drainage resulting in increased PA pressures:* Pulmonary vein stenosis (e.g., total anomalous pulmonary venous return [TAPVR], cor triatrium) or increased LA pressures (e.g., mitral atresia, congenital aortic stenosis, severe coarctation) can cause backpressure in the pulmonary vasculature and induce PVOD.

The muscle tone in the pulmonary arteries is regulated by numerous factors, and various therapeutic interventions can be used to manipulate the PVR (Table 18.3)[16]:

- *Arterial oxygen tension (PaO_2):* Alveolar as well as arterial hypoxia increases PVR. A PaO_2 value less than 50 mm Hg, especially

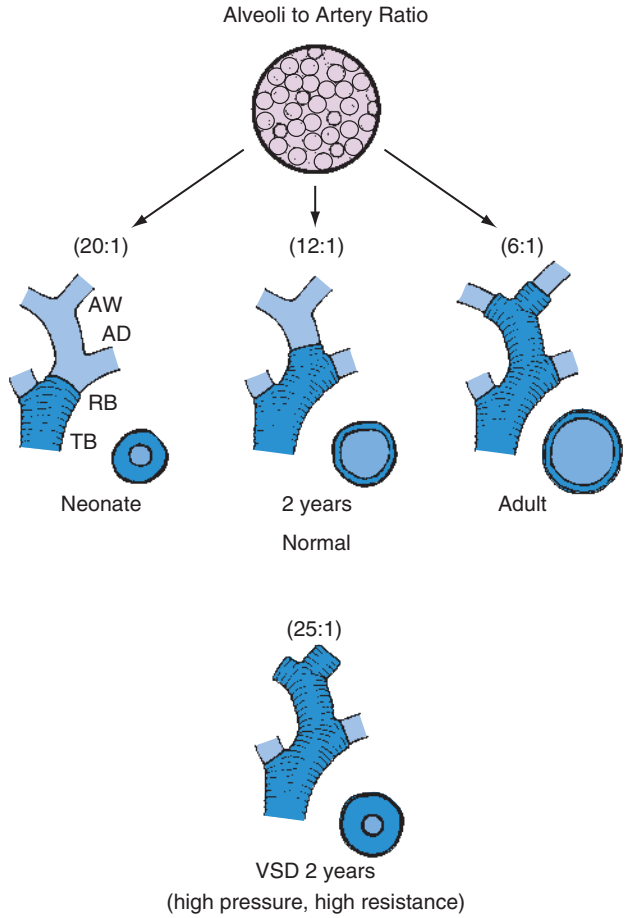

FIGURE 18.6 Peripheral pulmonary artery development. The normal pattern of pulmonary vascular development and that of a 2-year-old child with pulmonary vascular changes accompanying a large ventricular septal defect (VSD). Rabinovitch and colleagues characterized the pulmonary vasculature morphometrically in three respects: vessel thickness, muscular extension, and the ratio of alveoli to arteries seen on lung biopsy specimens. The normal neonate exhibits thick vascular smooth muscle, but this extends only as far as the arterioles accompanying the respiratory bronchiole. In neonates, the alveoli/artery ratio is 20:1. In the first few months of life, the vessels thin substantially and proliferate relative to the alveoli, so that by the age of 2 years, the normal child has an alveoli/artery ratio of 12:1 and thin muscles extending to the arteries associated with alveolar ducts. In the normal adult, the alveoli/artery ratio is 6:1 and muscle extends all the way to the arteries in the alveolar wall. In contrast, in the 2-year-old child with a large VSD, the vessel numbers are markedly diminished (alveoli/artery ratio, 25:1), and persistent neonatal muscle thickness extends all the way to the alveolar wall. *AD,* artery at alveolar duct; *AW,* artery at alveolar wall; *RB,* respiratory bronchiole; *TB,* artery at terminal bronchiole. (From Steven JM, Nicolson SC. Congenital heart disease. In: Miller RD, series editor. *Atlas of Anesthesia.* Vol 7. In: Greeley WJ, volume editor. *Pediatric Anesthesia* Orlando, FL.: Harcourt Publishers; 1998:6.6; modified from Rabinovitch M, Haworth SG, Castaneda AR, et al. Lung biopsy in congenital heart disease: a morphometric approach to pulmonary vascular disease. *Circulation.* 1978;58:1107–1122.)

when associated with an acidic pH (<7.4), leads to significant pulmonary vasoconstriction. On the other hand, increased inspired oxygen can lead to pulmonary vasodilation and overcirculation.

- *Arterial carbon dioxide tension ($PaCO_2$):* Hypercapnia increases PVR, independent of the blood pH. In contrast, hypocapnia induces alkalosis and thereby decreases PVR. Reliable pulmonary vasodilation can be achieved with a $PaCO_2$ of 20 to 33 mm Hg and a pH of 7.5 to 7.6.
- *pH:* Respiratory and metabolic acidosis increase PVR; alkalosis reduces PVR.
- *Lung volumes:* PVR is optimized at a lung volume close to the FRC; larger volumes compress small intraalveolar vessels, and smaller volumes can cause atelectasis and vascular collapse.
- *Stimulation of the sympathetic nervous system:* Catecholamine surges from stress, pain, or light anesthesia can trigger significant increases in PVR.
- *Vasodilators:* Most intravenous (IV) agents used for pulmonary vasodilation also affect the systemic circulation and induce hypotension. Alternatively, inhaled substances such as NO or prostacyclin can provide a more selective pulmonary vasodilation (see "Cardiovascular Pharmacology").

In summary, the pulmonary vasculature undergoes a complex maturation process that can be influenced by a multitude of external factors and congenital heart defects. Persistent fetal circulation and PVOD are examples of inadequate adaptation and development. In cases of increased PVR, ventilator strategies using greater inspired oxygen concentrations, lung volumes close to the FRC, and interventions aiming for a PaO_2 greater than 60 mm Hg, a $PaCO_2$ of 30 to 35 mm Hg, and a pH of 7.5 to 7.6 can improve pulmonary blood flow.

TABLE 18.3 Manipulations of Pulmonary Vascular Resistance

Increasing PVR	Decreasing PVR
PEEP	No PEEP
High airway pressures	Low airway pressures
Atelectasis	Lung expansion to FRC
Low FIO_2	High FIO_2
Respiratory and metabolic acidosis	Respiratory and metabolic alkalosis
Increased hematocrit	Low hematocrit
Sympathetic stimulation	Blunted stress response (deep anesthesia)
Direct surgical manipulation	Nitric oxide
Vasoconstrictors: phenylephrine	Vasodilators: milrinone, prostacyclin, others

FIO_2, fraction of inspired oxygen; *FRC,* functional residual capacity; *PEEP,* positive end-expiratory pressure; *PVR,* pulmonary vascular resistance.

Incidence and Prevalence of Congenital Heart Disease

CHD can be defined as *"a gross structural abnormality of the heart or intrathoracic great vessels that is actually or potentially of functional significance."*[51] This definition covers a wide array of defects, which are among the most common congenital malformations. However, the precise incidence of CHD, both collectively and by individual anatomic subset, varies depending on definition, method of case identification, and epoch (E-Table 18.3). Including all categories of CHD, large epidemiologic surveys place the prevalence between 4 and 50 cases per 1000 live births.[52–55] When stratified according to trivial, moderate, and severe forms, the incidence for moderate and severe forms of CHD has been relatively consistent, at about 6 per 1000 live births.

E-TABLE 18.3 Incidence of Congenital Heart Disease per Million Live Births

Modified from Hoffman JL, Kaplan S. The incidence of congenital heart disease. *J Am Coll Cardiol.* 2002;39:1890–1900.

Anatomic diagnoses within the population of infants with CHD vary according to the method used to identify cases. In 2002, Hoffman and Kaplan compiled 62 epidemiologic studies published after 1955 and investigated the potential causes for the wide variability in the reported incidence of CHD.[56] More recent studies based mainly on prenatal and postnatal echocardiographic screening data often include a large number of trivial lesions (e.g., tiny VSDs, nonstenotic bicuspid aortic valve, "silent" PDA) for which no interventions may be required; other data collections, such as the New England Regional Infant Cardiac Program (NERICP), a registry of children with CHD who died or required catheterization or surgery during the first year of life, are clearly biased toward more severe forms of CHD.[1]

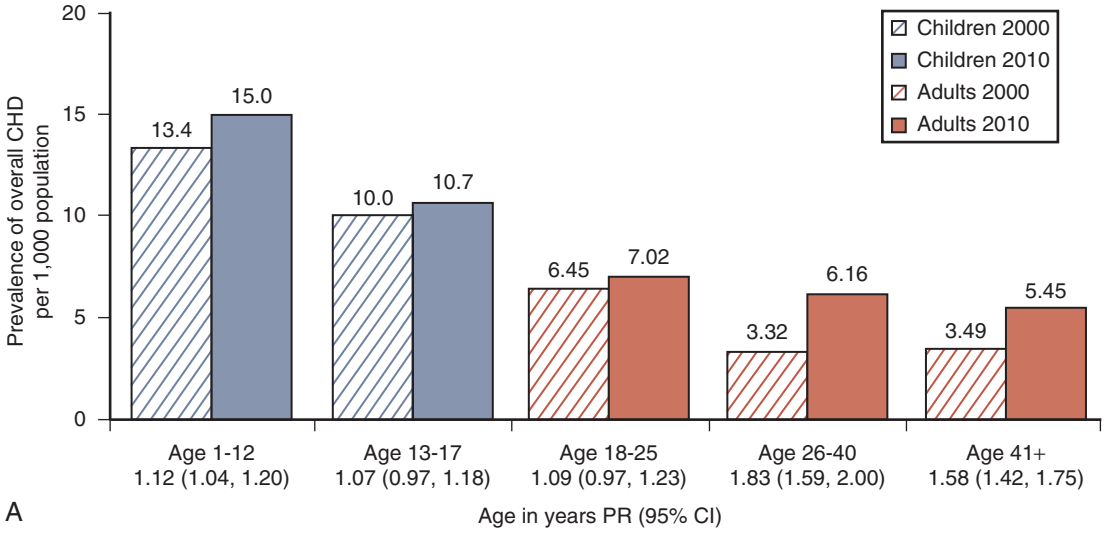
The increasing availability of prenatal diagnostic methods may influence the relative prevalence of reported lesions as well as their outcome. When fetal echocardiography is used, the apparent shift toward more complex lesions may reflect technical limitations in identifying simple defects.[57] In addition, evaluation in utero skews the results because it includes fatally malformed fetuses that will not survive to term. The prevalence of CHD among spontaneous abortions reaches 20% and remains as large as 10% among stillborn infants.[58] In one study, 50% of women whose children were given a prenatal diagnosis of CHD elected to terminate the pregnancy, particularly when presented with complex heart lesions.[57]

On the other hand, female infants with severe CHD have a mortality rate that is 5% less than similarly affected male infants,[1] and with increased survival rates more females will reach childbearing age, where they continue to have reduced mortality.[59] The recurrence risk of CHD for their offspring is about 3% to 4%.[60,61]

A study from Canada examined the changing epidemiology of CHD with respect to prevalence and age distribution in the general population between 1983 and 2010.[62] The prevalence of all categories of CHD in 2010 was ~13 per 1000 in children (<18 years of age) and ~6 per 1000 in adults. For the subcategory of severe CHD, the prevalence was ~1.8 per 1000 in children and ~0.62 per 1000 in adults. In 2010, 60% of all patients with severe CHD were adults, compared with 49% in 2000 and 35% in 1985. Between 1983 and 2010 the prevalence of CHD has been steadily increasing for both children and adults but at a different pace: from 1985 to 2000 the increase for severe CHD was 85% in adults and 22% in children compared with 57% for adults and 11% for children from 2000 to 2010. The median age of all patients with severe CHD was 11 years in 1985, 17 years in 2000 and 25 years in 2010, reflecting the fact that more children with CHD were surviving to adulthood (E-Fig. 18.1). Improved survival may be attributed to improved prenatal care, early diagnostic imaging, and major advances in pediatric cardiac care, particularly for those with severe CHD; these improved outcomes will continue to influence the future demographic profile. The growing number of adolescents and adults with CHD will require long-term follow-up with experienced cardiologists and access to specialized care facilities; this will require a thorough understanding of their underlying pathophysiology by all members of the adult care team, including anesthesiologists.

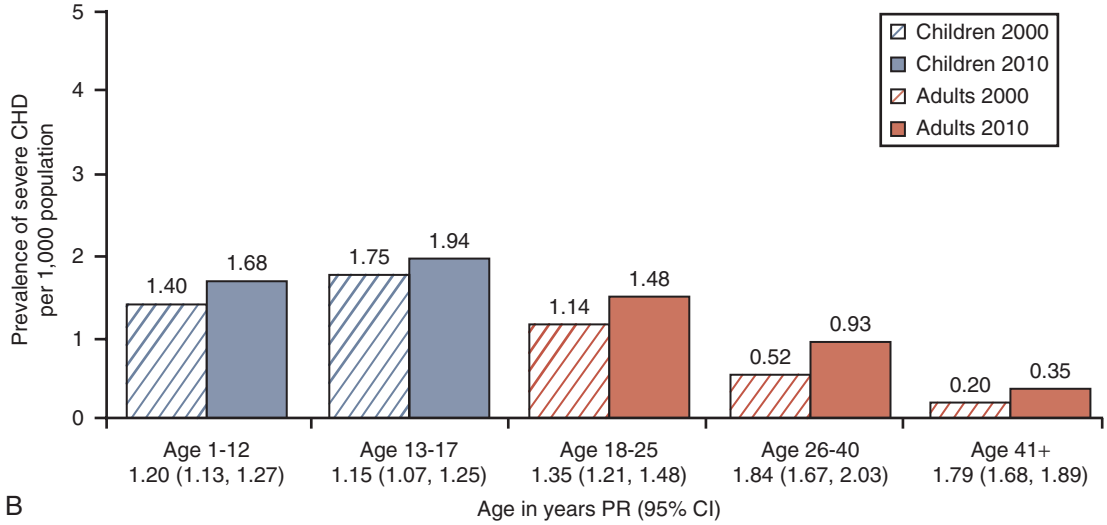
Pathophysiologic Classification of Congenital Heart Disease

CHD consists of an almost endless array of anatomic and functional variants. Many different classification systems have been introduced, some using a segmental approach to anatomic features, others by examining the amount of pulmonary blood flow (cyanotic versus acyanotic) or the common physiologic characteristics (e.g., volume versus pressure overload).[63–73] Several of these classifications are discussed in Chapter 16. However, certain defects are better described using the concepts of shunting (physiologic, anatomic, simple or complex), intercirculatory mixing, and single ventricle physiology, which are presented in the following sections.



SHUNTING

Shunting occurs when blood return from one circulatory system (systemic or pulmonary) is recirculated to the same system, completely bypassing the other circulation. For example, if deoxygenated blood from the systemic veins flows directly to the aorta, the result is a right-to- left shunt with recirculation of deoxygenated blood in the systemic circulation. In contrast, redirection of oxygenated blood from the pulmonary veins to the PA causes a left-to-right shunt with recirculation of oxygenated blood within the pulmonary circulation. The terms *physiologic* and *anatomic* are often used to describe shunting. Basically, any kind of recirculation of blood within one circulatory system is called *physiologic shunting*. In most cases, physiologic shunting is caused by an anatomic shunt (i.e., a communication between the cardiac chambers or the great vessels), but physiologic shunting can also exist by itself, as in the classic transposition physiology.



To really understand the pathophysiology of shunting and its implications, it is important to introduce the concepts of effective and total systemic/pulmonary blood flows. *Effective blood flow* is the quantity of venous blood from one circulatory system that reaches the arterial system of the other circulatory system. Effective *pulmonary* blood flow is the volume of systemic venous blood reaching the pulmonary circulation, whereas effective *systemic* blood flow is the volume of pulmonary venous blood reaching the systemic circulation. Effective pulmonary blood flow and effective systemic blood flow are always equal, no matter how complex the lesions. *Total blood flow*, on the other hand, is the sum of recirculated and effective blood flow and a measure of the workload of the circulatory system. Total systemic and pulmonary blood flows are not equal. Even in healthy patients there is a small amount of normal physiologic shunting (e.g., thebesian cardiac veins, bronchial vessels), but with CHD the difference can be quite substantial. Physiologic shunting or recirculation should be viewed as a noneffective, superfluous load added to the essential nutritive blood flow (effective blood flow).

Anatomic shunts are communications between the two circulatory systems, either within the heart or at the level of the great vessels. They can be divided into simple and complex shunts, depending on the presence of additional outflow obstructions. In *simple shunts* without any additional outflow obstruction, the size of the communication (the so-called shunt orifice) determines the flow characteristics. For small orifices (restrictive shunts) with large pressure gradients across the communication, the size of the opening essentially regulates the amount of shunting. Changes in SVR or PVR have little influence. In contrast, for large orifices or nonrestrictive shunts (also classified as *dependent shunts*), the quantity and direction of blood flow are controlled by the respective outflow resistances (i.e., the ratio of SVR to PVR) (Table 18.4 and Fig. 18.7).

Complex shunts are defined by an additional outflow obstruction, which can be at various levels within the ventricle, valves, or great vessels and is often described as subvalvular, valvular,

A

B

E-FIGURE 18.1 Change in prevalence ratios of congenital heart disease in Quebec, Canada, from 2000 to 2010 for all **(A)** and severe **(B)** congenital heart disease (CHD) stratified by age. *CI,* credible interval; *PR,* prevalence ratio. (From Marelli AJ, Ionescu-Ittu R, Mackie AS, Guo L, Dendukuri N, Kaouache M. Lifetime prevalence of congenital heart disease in the general population from 2000 to 2010. *Circulation*. 2014;130(9):749–756.)

or supravalvular. These obstructions can be fixed (e.g., valvular stenosis) or variable (e.g., dynamic infundibular obstruction by muscle bundles). Shunt flow and direction are determined by the combined resistance across the outflow obstruction and the pulmonary/systemic vascular beds. For severe obstructions downstream, SVR or PVR will have little influence on the shunt. Tetralogy of Fallot (TOF) is a good example of a complex shunt lesion. The amount of right-to-left shunt and therefore the amount of cyanosis are influenced by the degree and type of right ventricular outflow tract obstruction (RVOTO). This is especially evident in the setting of a dynamic infundibular obstruction, where changes in preload, contractility, and HR can lead to significant decreases in pulmonary blood flow and increased shunting (Table 18.5).

TABLE 18.4 Characteristics of Simple Shunts (Without Additional Outflow Obstruction)

	Restrictive (Small Shunt Orifice)	Nonrestrictive (Large Shunt Orifice)
Examples	Small ASD, VSD, or PDA; modified Blalock-Taussig shunt	Large VSD, PDA, CAVC
Pressure gradient across shunt	Large	Small or none
Direction and magnitude of shunt	Independent of PVR/SVR	PVR/SVR dependent
Influence of pharmacologic and ventilatory interventions	Minimal	Large

ASD, atrial septal defect; *CAVC,* common atrioventricular canal; *PDA,* patent ductus arteriosus; *PVR,* pulmonary vascular resistance; *SVR,* systemic vascular resistance; *VSD,* ventricular septal defect.

INTERCIRCULATORY MIXING

The concept of intercirculatory mixing is often used to explain the unique physiology in children with transposition of the great arteries (TGA). In this cardiac defect, the aorta arises from the RV, transporting deoxygenated blood back to the right heart, and the PA originates from the LV, returning oxygenated blood to the pulmonary circulation (see Fig. 17.6). Unless there is some mixing of blood via an ASD, VSD, or PDA, this defect will result in a complete separation of the two systems, a parallel circulation with 100% physiologic shunting, or recirculation of oxygenated and deoxygenated blood that is incompatible with life once the fetal ductus arteriosus has closed. Effective pulmonary blood flow (i.e., deoxygenated blood reaching the pulmonary vascular bed for oxygenation) has to be provided by some form of right-to-left shunt; effective systemic blood flow (i.e., oxygenated blood returning to the systemic circulation) must be achieved by a left-to-right shunt. Intercirculatory mixing is the combined systemic and pulmonary effective blood flow and is only a small portion of the total blood flow. The bulk of the respective systemic and pulmonary total blood flows consists of recirculated blood (Fig. 18.8). Usually the total blood flow and the volume in the pulmonary system are two to three times greater than in the systemic circulation.

The arterial saturation (Sa_{O_2}) is influenced by the volumes and saturations of recirculating and effective systemic blood

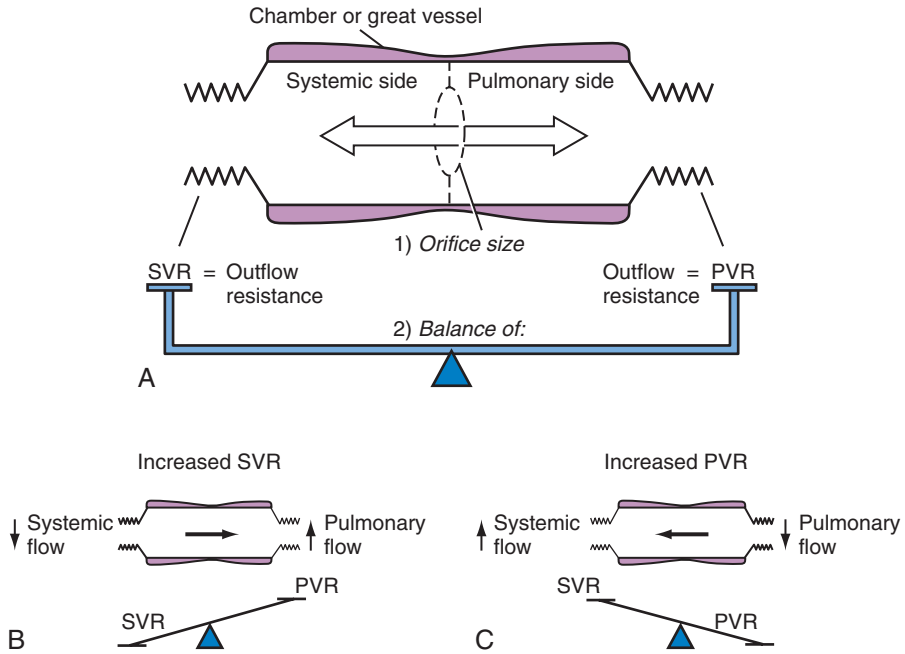

FIGURE 18.7 Influence of orifice size and the ratio of pulmonary vascular resistance *(PVR)* to systemic vascular resistance *(SVR)* on the magnitude and direction of a simple shunt. **A,** PVR and SVR are balanced, resulting in equal pulmonary and systemic blood flows. **B,** PVR is reduced relative to SVR, resulting in an increase in pulmonary blood flow and a decrease in systemic blood flow. **C,** PVR is elevated relative to SVR, resulting in a decrease in pulmonary blood flow and an increase in systemic blood flow. (Modified from DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, eds. *Anesthesia for Cardiac Surgery.* 3rd ed. Malden, MA: Blackwell Publishing; 2008:167–251.)

flows and can be calculated with the use of the following equation:

$$\text{Aortic saturation} = [(\text{Systemic venous saturation} \times \text{Recirculated blood flow}) + (\text{Pulmonary venous saturation} \times \text{Effective blood flow})] \div [\text{Total systemic venous blood flow}]$$

TABLE 18.5 Characteristics of Complex Shunts (With Additional Outflow Obstruction)

	Partial Outflow Obstruction	Complete Outflow Obstruction
Examples	TOF, VSD/PS, VSD/coarctation	Tricuspid or mitral atresia, Pulmonary or aortic atresia
Shunt magnitude and direction	Relatively fixed	Totally fixed
Dependence on PVR/SVR ratio	Inversely related to obstruction	Independent
Pressure gradient across shunt	Dependent on shunt orifice and degree of obstruction	Dependent only on shunt orifice

PS, pulmonary stenosis; *PVR*, pulmonary vascular resistance; *SVR*, systemic vascular resistance; *TOF*, tetralogy of Fallot; *VSD*, ventricular septal defect.
Modified from DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, eds. *Anesthesia for Cardiac Surgery.* 3rd ed. Malden, MA: Blackwell Publishing; 2008:167–251.

Increasing the intercirculatory mixing will improve the arterial saturations, and in severely cyanotic neonates with TGA, intact ventricular septum, and inadequate atrial communication, a balloon atrial septostomy (balloon dilation of an existing patent foramen ovale or small ASD, either echo-guided at the bedside or under fluoroscopy in the catheterization laboratory) can be lifesaving. Additional measures to improve systemic and pulmonary venous saturations (e.g., blood transfusion, inotropic support, ventilatory strategies) can help to stabilize the arterial saturation.

SINGLE VENTRICLE PHYSIOLOGY

Single ventricle physiology defines the circulation present in a wide variety of complex cardiac defects. It is characterized by complete mixing of systemic and pulmonary venous blood return at either the atrial or the ventricular level; the mixed blood is then distributed to both systemic and pulmonary circulations in parallel. The defects can consist of one anatomic single ventricle with severe hypoplasia and inflow or outflow obstruction of the other one (hypoplastic left heart syndrome [HLHS] or pulmonary atresia with intact ventricular septum) or even two well-developed ventricles with atresia of the outflow tract or severe obstruction (TOF with pulmonary atresia, interrupted aortic arch). In some lesions, a PDA is the only source of systemic or pulmonary blood flow; these are called duct-dependent circulations. In others, intracardiac communications provide adequate blood flow to both circulations (Table 18.6).

Irrespective of the anatomic features, in single ventricle physiology the ventricular output (delivered by one or two ventricles)

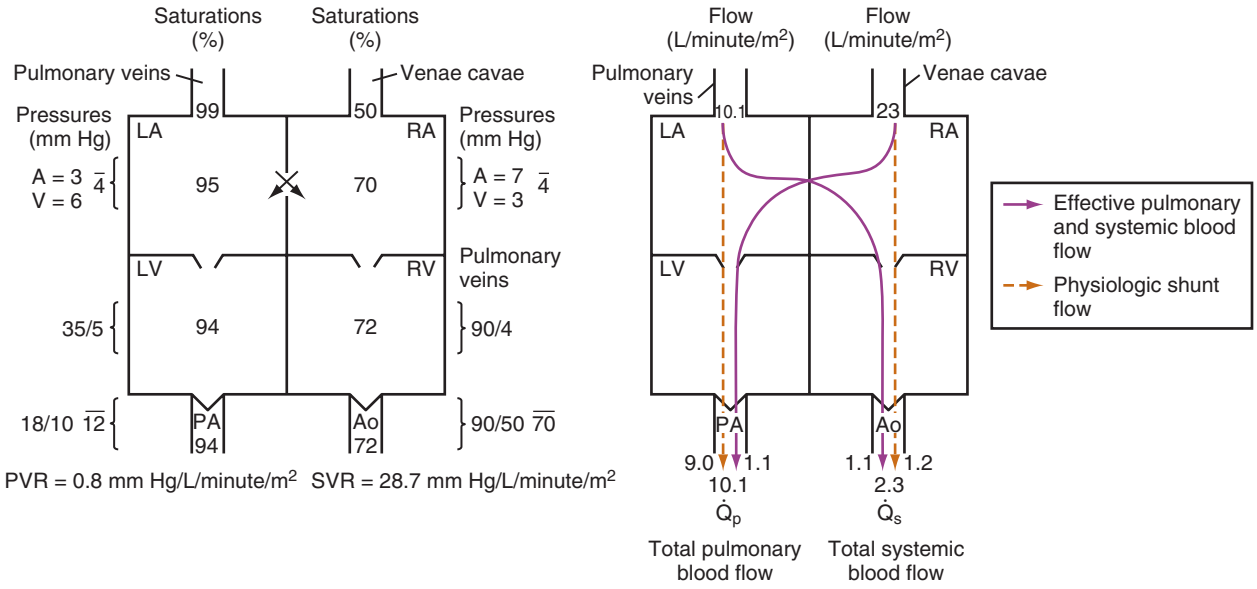

FIGURE 18.8 Saturations, pressures, and blood flows in transposition of the great arteries with a nonrestrictive atrial septal defect and a small left ventricular *(LV)* outflow tract gradient. Intercirculatory mixing occurs at the atrial level. Effective pulmonary and effective systemic blood flows are equal (1.1 L/minute per m^2) and are the result of a bidirectional anatomic shunt at the atrial level. The physiologic left-to-right shunt is 9.0 L/minute per m^2; this represents blood recirculated from the pulmonary veins to the pulmonary artery *(PA)*. The physiologic right-to-left shunt is 1.2 L/minute per m^2; this represents blood recirculated from the systemic veins to the aorta *(Ao)*. Total pulmonary blood flow ($\dot{Q}_P$ = 10.1 L/minute per m^2) is almost five times greater than the total systemic blood flow ($\dot{Q}_S$ = 2.3 L/minute per m^2). The bulk of pulmonary blood flow is recirculated pulmonary venous blood. In this depiction, pulmonary vascular resistance *(PVR)* is low (approximately 1/35 of systemic vascular resistance [*SVR*]) and there is a small (17 mm Hg peak to peak) gradient from the LV to the PA. These findings are compatible with the high pulmonary blood flow depicted. *LA*, left atrium; *RA*, right atrium; *RV*, right ventricle. (From DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, eds. *Anesthesia for Cardiac Surgery.* 3rd ed. Malden, MA: Blackwell Publishing; 2008:167–251.)

TABLE 18.6 Examples of Single Ventricle Physiology

Congenital Heart Defect	Aortic Blood Flow From	Pulmonary Blood Flow From
Hypoplastic left heart syndrome	PDA	RV
Neonatal critical aortic stenosis	PDA	RV
Interrupted aortic arch	Proximal LV, distal PDA	RV
Tetralogy of Fallot with pulmonary atresia	LV	PDA, MAPCAs
Pulmonary atresia with intact septum	LV	PDA
Tricuspid atresia 1B (VSD and PS)	LV	LV through VSD to RV
Truncus arteriosus	LV and RV	Aorta
Double inlet left ventricle, no TGA	LV	LV through VSD to bulboventricular foramen

LV, left ventricle; *MAPCAs,* major aortopulmonary collateral arteries; *PDA,* patent ductus arteriosus; *PS,* pulmonary stenosis; *RV,* right ventricle; *TGA,* transposition of the great arteries; *VSD,* ventricular septal defect.
Modified from DiNardo J, Zwara DA. Congenital heart disease. In: DiNardo J, Zwara DA, eds. *Anesthesia for Cardiac Surgery.* 3rd ed. Malden, MA: Blackwell Publishing; 2008:167–251.

is the sum of the pulmonary and systemic blood flows. The distribution of the respective flows depends on the relative outflow resistances into the two parallel circulations. Oxygen saturations in the aorta and PA are equal. The severity and location of anatomic obstructions and the ratio of PVR to SVR determine the balance of flows to the two circulations

The following equation illustrates the various factors that influence the arterial saturation (SaO_2) in a single ventricle physiology:

$$\text{Aortic saturation} = [(\text{Systemic venous saturation} \times \text{Total systemic venous blood flow}) + (\text{Pulmonary venous saturation} \times \text{Total pulmonary venous blood flow})] \div [(\text{Total systemic venous blood flow} + \text{Total pulmonary venous blood flow})]$$

Accordingly, three major variables determine arterial saturation and the initial management options for patients with single ventricle physiology:

- *The ratio of pulmonary to systemic blood flow ($\dot{Q}_{pulm}/\dot{Q}_{sys}$).* With high $\dot{Q}_{pulm}/\dot{Q}_{sys}$, a greater percentage of the blood in the ventricle (or ventricles) is oxygenated because more fully saturated pulmonary venous blood is entering the heart to mix with desaturated systemic venous return. Saturations greater than 85% can be achieved only by significant pulmonary overcirculation. $\dot{Q}_{pulm}/\dot{Q}_{sys}$ can be influenced by careful manipulations of the PVR/SVR ratio.
- *Systemic venous saturation ($S_{sys}vO_2$):* For a given $\dot{Q}_{pulm}/\dot{Q}_{sys}$ and pulmonary venous saturation ($S_{pulm}vO_2$), any decrease in $S_{sys}vO_2$ causes a decrease in arterial saturation. Oxygen delivery and consumption are the basic determinants for SvO_2. Adequate oxygen delivery depends on cardiac output and arterial oxygen content and thus on hemoglobin levels and arterial saturation. All measures that increase oxygen delivery (e.g., transfusion to increase the hematocrit to 0.45-0.50 or decrease oxygen consumption (e.g., adequate analgesia and sedation during painful procedures) improve arterial saturations.
- *Pulmonary venous saturation ($S_{pulm}vO_2$):* Normally the blood in the pulmonary veins should be fully saturated ($S_{pulm}vO_2$ = 100%) on room air, but lung disease, $\dot{V}/\dot{Q}$ mismatch, or large intrapulmonary shunts can cause pulmonary venous desaturation. $\dot{V}/\dot{Q}$ mismatch usually responds to therapy with increased inspired oxygen, whereas intrapulmonary shunts are refractory to oxygen therapy. Pulmonary venous desaturation will decrease arterial saturations.

Special Situations

EXERCISE PHYSIOLOGY IN THE CHILD WITH REPAIRED CONGENITAL HEART DISEASE

Children with CHD, including those with lesions considered repaired, exhibit an array of abnormalities elicited during exercise testing consistent with reduced exercise capacity (E-Table 18.4). It is worthwhile to review the various exercise testing abnormalities to gain insight into the limitations imposed by the presence of congenital heart lesions.

Oxygen consumption ($\dot{V}O_2$) is equal to the product of cardiac output and O_2 extraction. O_2 extraction is equal to the arterial-venous oxygen content difference. Peak $\dot{V}O_2$ is the greatest measure of $\dot{V}O_2$ obtained during a progressively more difficult exercise test. $\dot{V}O_2$ at rest is defined as 1 metabolic equivalent energy expenditure unit or 1 MET (approximately 3.5 mL O_2/kg per minute).[74] A typical elite endurance athlete can reach 20 to 22 METs, or 70 to 77 mL O_2/kg per minute, at peak exercise. Activities of daily living require at least 4 METs or 14 mL O_2/kg per minute. Peak $\dot{V}O_2$ is the best overall assessment of the capabilities of the cardiovascular system, but determination of normal values is difficult owing to the effects of age, gender, effort, and body composition (e.g., adipose tissue) on peak $\dot{V}O_2$. Nonetheless, peak $\dot{V}O_2$ has been demonstrated to be a reliable predictor of hospitalization and mortality in patients with a wide variety of congenital heart lesions.[75]

During exercise, the HR normally increases linearly with increases in $\dot{V}O_2$. Normal peak HR is generally defined (in beats per minute [beats/minute]) as 220 minus age in years. In children with chronotropic incompetence, which is defined as the inability to increase HR to greater than 80% of the predicted value at peak exercise, the relationship between HR and $\dot{V}O_2$ is depressed. Chronotropic incompetence is an indicator of poor prognosis and is most commonly the result of sinus node dysfunction. By comparison, well-trained endurance athletes have a normal peak HR and a depressed HR/$\dot{V}O_2$ relationship, because they can generate a larger-than-normal stroke volume increase as exercise progresses. The inability to increase stroke volume (discussed later) during exercise results in an increased HR/$\dot{V}O_2$ relationship as a compensatory mechanism.

The *oxygen pulse* is the quantity of oxygen delivered per heartbeat. The peak O_2 pulse is calculated by dividing the peak $\dot{V}O_2$ by the peak HR. Because peak $\dot{V}O_2$ = cardiac output × O_2 extraction and because O_2 extraction remains remarkably constant over a wide range of exercise, O_2 pulse is proportional to stroke volume. Determination of normal peak O_2 pulse is hampered by the same factors that confound determination of normal peak$\dot{V}O_2$. In addition, O_2 pulse overestimates stroke volume in the presence of erythrocytosis and underestimates it in the presence of anemia or reduced arterial O_2 saturation. O_2 pulse is reduced in patients with impaired ventricular function, severe valvular regurgitation, or pulmonary vascular disease.[75] It is also uniformly reduced in those with Fontan physiology as a consequence of the inability of this circulation to augment systemic ventricular preload during exercise.[76]

E-TABLE 18.4 Cardiopulmonary Exercise Testing Abnormalities in Pediatric Patients With Various Forms of Congenital Heart Disease[a]

Defect	↑ Peak $\dot{V}O_2$	↓ Peak HR	↓ Peak O_2 Pulse	↑ $\dot{V}_E/\dot{V}CO_2$	↓ VAT

[a]This table assumes that the patient is not receiving β-blocker or other antiarrhythmic therapy that might impair the chronotropic response to exercise.
Peak HR, heart rate at peak exercise; *peak O_2 pulse,* oxygen pulse at peak exercise; *peak $\dot{V}O_2$* oxygen consumption at peak exercise; *PR,* pulmonary regurgitation after valvuloplasty; *PVOD,* pulmonary vascular obstructive disease; *TOF,* tetralogy of Fallot; *$\dot{V}E/\dot{V}CO_2$,* slope of the linear portion of the minute ventilation vs. carbon dioxide production curve; *VAT,* ventilatory anaerobic threshold; *+,* rarely present; *++,* sometimes present; *+++,* often present; *++++,* usually present.

The *respiratory exchange ratio* (RER) is defined as the ratio $\dot{V}CO_2/\dot{V}O_2$ (ratio of the volume of CO_2 produced per minute to the volume of oxygen consumed per minute). A normal resting RER is between 0.67 and 1.0, depending on the precise composition of protein, carbohydrates, and fat in the diet. As exercise intensifies, anaerobic metabolism commences and the lactate threshold is reached; buffering of lactic acid with bicarbonate causes the carbon dioxide production ($\dot{V}CO_2$) to increase out of proportion to oxygen consumption ($\dot{V}O_2$), resulting in an increased RER. An RER of 1.09 or greater is thought to indicate the onset of anaerobic metabolism and to be consistent with a good effort.[74,75] Because RER increases only if anaerobic metabolism occurs, exercise limitation and low $\dot{V}O_2$ owing to musculoskeletal problems or poor effort are associated with an RER less than this threshold.

The *ventilatory anaerobic threshold* (VAT) is used to identify the onset of anaerobic metabolism that occurs before $\dot{V}O_2$ peaks and is relatively effort and motivation independent. As aerobic exercise progresses, minute ventilation ($\dot{V}_E$) increases in direct proportion to $\dot{V}CO_2$ and $\dot{V}O_2$. When anaerobic metabolism commences and CO_2 production increases as lactic acid is buffered, $\dot{V}_E$ increases accordingly. VAT is the point at which $\dot{V}_E/\dot{V}O_2$ and $\dot{V}_E/\dot{V}CO_2$ diverge, with $\dot{V}_E$ increasing in proportion to $\dot{V}CO_2$ but out of proportion to $\dot{V}O_2$. An important characteristic of successful endurance athletes is the ability to reach and sustain effort at an anaerobic threshold that is a large percentage (80%–85%) of peak $\dot{V}O_2$.

Ventilation efficiency can be assessed with the use of the $\dot{V}_E/\dot{V}CO_2$ slope. This relationship is defined as $863 \bullet \dot{V}CO_2/[PaCO_2 \bullet (1 - V_D/V_T)]$, where V_D/V_T is the ratio of physiologic dead space to tidal volume.[77] The $\dot{V}_E/\dot{V}CO_2$ slope can be thought of as the number of liters of ventilation required to eliminate 1 L of CO_2. Normal children have a $\dot{V}_E/\dot{V}CO_2$ slope of less than 28.[75] To maintain a normal $PaCO_2$ during exercise, children with increased V_D/V_T and reduced ventilatory efficiency have a greater than normal increase in $\dot{V}_E$ and therefore a steeper $\dot{V}_E/\dot{V}CO_2$ slope. Increased V_D/V_T is the consequence of either reduced V_T in the setting of a normal V_D or pulmonary flow maldistribution and subsequent $\dot{V}/\dot{Q}$ mismatch that increases V_D. The latter is the major source of inefficient ventilation and steepening of the $\dot{V}_E/\dot{V}CO_2$ slope in children with cardiac disease.

In children with PA stenosis, (e.g., repaired TOF), pulmonary hypertension, or increased LA pressure from any cause (e.g., LV systolic or diastolic dysfunction, mitral valve disease), an increase in the $\dot{V}_E/\dot{V}CO_2$ slope is associated with increased mortality. When pulmonary stenosis is corrected in children with TOF, the $\dot{V}_E/\dot{V}CO_2$ slope and peak $\dot{V}O_2$ improve.

Children with Fontan physiology also exhibit an increase in $\dot{V}_E/\dot{V}CO_2$ slope. These children have inherent nonhomogeneous pulmonary perfusion at rest owing to the lack of pulsatile pulmonary blood flow. In addition, there is poor recruitment of the distal pulmonary vasculature during exercise. The presence of a Fontan fenestration further contributes to this increase in the $\dot{V}_E/\dot{V}CO_2$ slope by allowing mixed venous blood high in CO_2 to be shunted into the systemic circulation. This produces, via central chemoreceptor stimulation, an increase in $\dot{V}_E$ out of proportion to $\dot{V}CO_2$.[78] Fontan fenestration closure eliminates this right-to-left shunt and reduces the $\dot{V}_E/\dot{V}CO_2$ slope but does not improve the peak $\dot{V}O_2$.[78] The reason is that the primary limitation to increases in $\dot{V}O_2$ during exercise in Fontan patients is the inherent inability of the pulmonary vascular bed to substantially increase surface area, flow, and preload delivery to the systemic ventricle.

FONTAN PHYSIOLOGY

Francis Fontan, a French cardiac surgeon, described a new treatment for complex cardiac malformations with only one ventricle in 1971.[79] To decrease the chronic volume overload for the single ventricle and normalize oxygenation, he separated the systemic and pulmonary circulations by directly connecting the systemic venous return (SVC and IVC) to the PA, without a pumping chamber. This created a circulation wherein pulmonary blood was driven solely by a nonpulsatile pressure gradient across the pulmonary vascular bed, with the single ventricle being the sole source of kinetic energy. All other shunt connections were interrupted. The original indication was tricuspid atresia, but over the years the classic Fontan technique has been modified in many ways and is now used for various complex cardiac lesions with single ventricle physiology, such as HLHS, double-inlet RV, and pulmonary atresia with intact septum (see also Chapters 17 and 23).[80–85]

It is impossible to create a Fontan circulation at birth; high PVR and small vessel sizes prevent adequate pulmonary blood flow. In the neonatal period, palliative procedures such as stage I Norwood operation with aortic arch reconstruction, atrial septostomy, and aortopulmonary shunts (modified Blalock-Taussig shunt) or the Sano modification of the Norwood procedure (RV-to-PA conduit) aim for balanced systemic and pulmonary blood flows, allowing the infant to grow for several months despite cyanosis and volume load on the ventricle. At the age of 3 to 6 months, an intermediate procedure called the bidirectional Glenn operation or superior cavopulmonary anastomosis, is performed. The SVC is connected directly to the PA, providing nonpulsatile pulmonary blood flow, whereas the IVC remains connected to the heart. As a result, the volume load on the ventricle is significantly reduced, but oxygenated and deoxygenated blood still mix and the saturations remain in the low 80% range. By the age of 1 to 5 years, most of these children are ready for the Fontan circulation. With adequate growth and maturation of the pulmonary vascular bed, the resistance should be small enough to allow the complete separation of the systemic and pulmonary flows. The IVC is now also connected to the PA, most often via a lateral tunnel in the atrium or an extracardiac conduit, with or without a small fenestration (small opening in the baffle or conduit connecting the systemic venous return with the common atrium of the single ventricle). The fenestration can provide a residual right-to-left shunt in case of sudden increases in PVR, maintaining ventricular preload and function. This seems to facilitate the adaptation to the new loading conditions, shorten the recovery time, and decrease the incidence of early complications. The fenestration often occludes spontaneously, or it is closed during a cardiac catheterization and hemodynamic evaluation with a special device (Fig. 18.9; see also Figs. 17.11 through 17.13).[86–89]

The Fontan operation has dramatically improved the mortality rates for children with single ventricles, but the success comes at a price: chronic systemic venous hypertension and congestion have been implicated in a multitude of potential early and long-term complications, including arrhythmias, residual right-to-left shunts, coagulopathies with increased risk for thrombosis and stroke, lymphatic dysfunction with pleural effusions, and protein-losing enteropathy.[90–95] Late cardiac failure and poor functional outcome remain risks for patients with Fontan circulations. The anatomy of the single ventricle and the type of Fontan connection influence the duration of freedom from complications. Children with systemic RVs and the classic atriopulmonary Fontan procedure (RA directly anastomosed to the PA) tend to have a shorter duration of freedom from complications than those

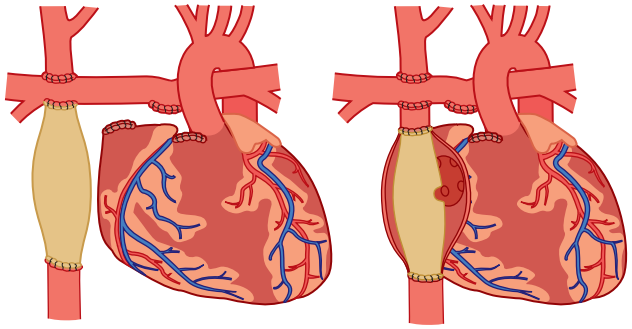

FIGURE 18.9 Fontan modifications: extracardiac conduit *(left)* and lateral tunnel with fenestration *(right)*. (Courtesy of Children's Hospital of Boston.)

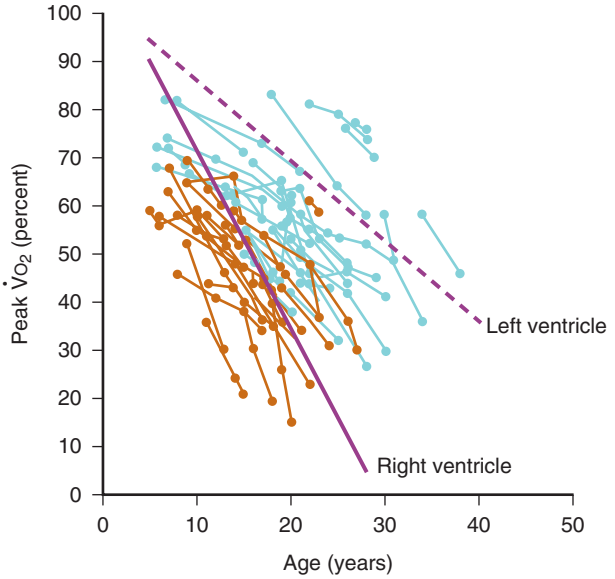
with systemic LVs and newer Fontan modifications (E-Figs. 18.2 and 18.3).[96]

Inherent limitations of the Fontan circulation, such as altered control of cardiac output with decreased hemodynamic response to stress and reduced exercise tolerance, have been documented (Fig. 18.10).[97–105] Even at rest, cardiac output is usually only 70% (range, 50%- 80%) of normal for body surface area. Cardiac output is classically determined by four factors: preload, contractility, HR, and afterload. Over a physiologic range, cardiac output improves with increased preload, contractility, and HR and with decreased afterload. For the Fontan circulation, the determinants of cardiac output are more complex (Fig. 18.11).[100,106,107] The classic determinants of cardiac output are less effective, while other factors, such as transpulmonary gradient and PVR, must be considered. The following mechanisms regulate cardiac output in children with Fontan physiology.

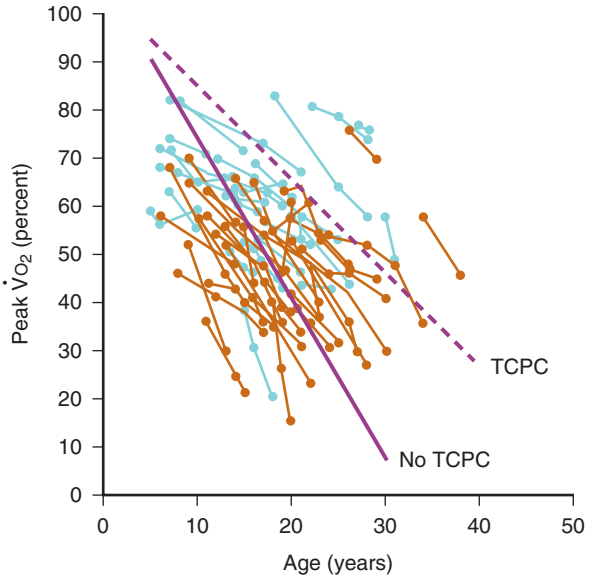
- *Preload:* The RV usually provides the kinetic energy to distend the pulmonary vasculature and create a preload reservoir for the LV, thereby enabling an increase in cardiac output up to fivefold or greater with exercise.[106,108] The lack of a pre-pulmonary pump leads to a significant decrease in available pulmonary blood volume and, consequently, reduced or absent LV preload reserve.[100,109,110]
- *Contractility:* During the staged palliation, the single ventricle typically develops from a volume-overloaded and dilated ventricle to a hypertrophied, underfilled ventricle.[111,112] Although the contractile response to β-adrenergic stimulation seems to be preserved, the resulting increase in cardiac output is diminished, most likely owing to limited preload reserve.[103,110]
- *Heart rate and rhythm:* Within the physiologic range, atrial pacing at different HRs does not alter cardiac output because there is a simultaneous decrease in stroke volume.[113] Normalization of HR increases the reduced cardiac output associated with severe bradycardia or tachycardia.[114] During exercise testing, Fontan patients demonstrate chronotropic incompetence, a blunted HR response to exercise. This is likely the result of autonomic dysfunction or abnormal reflex control. In contrast to the HR, cardiac rhythm is of utmost importance. Ectopy or loss of atrioventricular (AV) synchronization compromises ventricular filling and decreases the transpulmonary gradient.[115]
- *Afterload:* The Fontan circulation is characterized by increased afterload, which is a physiologic response to decreased cardiac output and occurs because a single ventricle is ejecting into two large resistance beds (systemic and pulmonary vascular) arranged in series.[100,110,116,117] Autonomic regulation and activation of various endocrine systems increase the systemic venous resistance and help to maintain adequate perfusion pressures and venous tone. Because of the limited preload reserve, attempts at afterload reduction often result in significant hypotension. On the other hand, excessive afterload, such as that which occurs with residual aortic arch obstruction, is poorly tolerated.
- *Transpulmonary flow:* Transpulmonary flow is directly proportional to the gradient between the systemic venous pressure (usually between 10 and 15 mm Hg, rarely >20 mm Hg) and the preventricular atrial pressure, which is determined by the functional status of the AV valve, the ventricle, the rhythm, and the potential presence of outflow obstruction. Transpulmonary flow is inversely proportional to the resistance over the Fontan circuit. This resistance is largely determined by PVR, but mechanical obstruction such as stenosis or thrombosis may also play a role. The geometry of the cavopulmonary connections is also important in that turbulent flow produces energy loss and a reduction in effective driving pressure. It has been suggested that PVR is the key determinant of transpulmonary flow, delivery of pulmonary venous flow to the systemic ventricle, and, consequently, cardiac output (Fig. 18.12).[100,118–128]

In conclusion, the Fontan circulation can be described as a serial circulation with a single kinetic energy pump. Increased systemic venous pressures are necessary to create the transpulmonary pressure gradient that drives flow across the pulmonary vascular bed; however, these increased pressures simultaneously increase the ventricular afterload. Cardiac output depends on an adequate preload and low PVR. Decreased cardiac output at rest and limited exercise tolerance are characteristics of the Fontan circulation.



PHYSIOLOGY OF THE TRANSPLANTED HEART

According to the International Society for Heart and Lung Transplantation (ISHLT), children younger than 18 years of age account for about 13% of all heart transplantations. Every year, approximately 450 cardiac transplants in children are reported to this voluntary registry, mainly from centers in Europe and North America.[129] Major indications are cardiomyopathies, CHD, and a growing number of retransplantations, especially in older children. The median survival time (the time at which 50% of recipients are still alive) has improved over the years, mainly because of reduced early posttransplant mortality. Survival time is currently 20.6 years for infants, 17.2 years for children aged 1 to 5 years, 13.9 years for children aged 6 to 10 years, and 12.4 years for teenagers. Ninety-four percent of transplant recipients describe a normal functional status with no limitations during physical activity.[129]



As survival continues to improve, more and more children with transplanted hearts will present to operating rooms and sedation suites for diagnostic studies and general procedures. A basic understanding of the physiologic changes in the transplanted heart and the implications of current immunosuppressive therapy are important for safe management.

Physiology of the Denervated Heart

After transplantation, the function of the surgically denervated heart depends primarily on an intact Frank-Starling mechanism and stimulation from circulating catecholamines. The classic Frank-Starling mechanism describes the ability of the cardiac muscle to increase contractility in response to stretch or tension

E-FIGURE 18.2 Change in peak oxygen uptake $\dot{V}O_2$ over time in individual Fontan patients according to the presence of a morphologically right ventricle *(orange circles)* or left ventricle *(blue circles). Solid* and *dashed lines* indicate the average of the individual slopes of decrease of peak $\dot{V}O_2$ in patients with morphologically right versus left ventricle, respectively. (From Giardini A, Hager A, Pace Napoleone C, Picchio FM. Natural history of exercise capacity after the Fontan operation: a longitudinal study. *Ann Thorac Surg*. 2008;85:818–821.)

E-FIGURE 18.3 Change in peak oxygen uptake $\dot{V}O_2$ over time in individual Fontan patients according to the type of Fontan surgery. *Orange circles* indicate atriopulmonary or atrioventricular connections; *blue circles* refer to intracardiac or extracardiac total cavopulmonary connection (*TCPC*). The *dashed* and *solid lines,* respectively, indicate the average of the individual slopes of decrease of peak $\dot{V}O_2$ in patients with and without a TCPC. (From Giardini A, Hager A, Pace Napoleone C, Picchio FM. Natural history of exercise capacity after the Fontan operation: a longitudinal study. *Ann Thorac Surg*. 2008;85:818-821.)

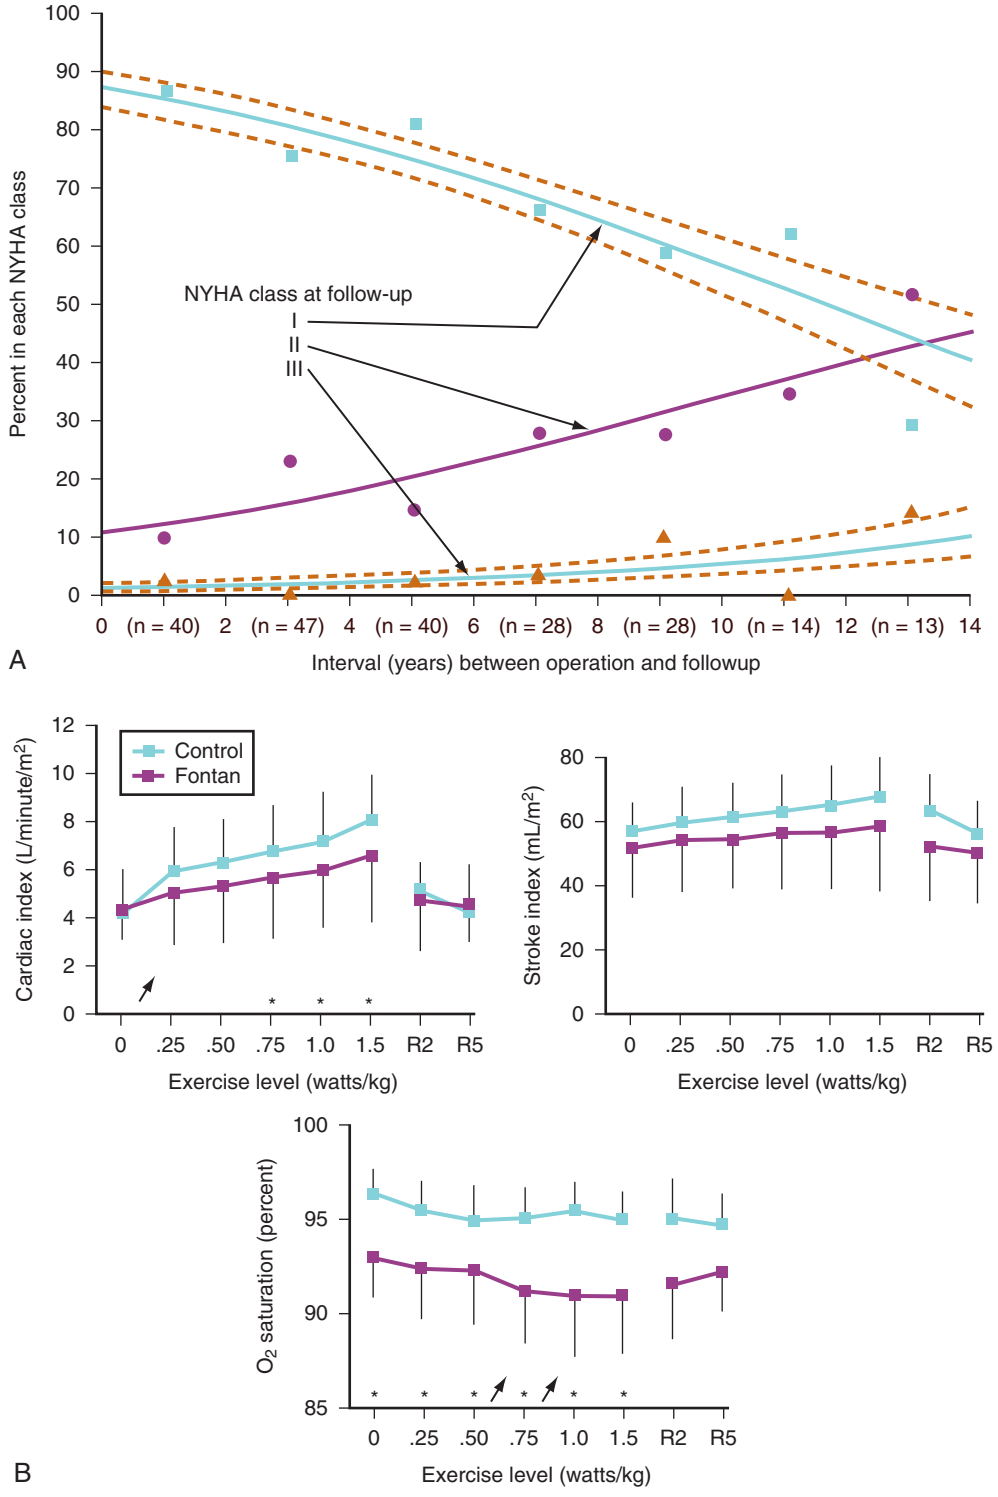


FIGURE 18.10 **A,** Symptomatic outcomes of 334 survivors of Fontan operations who were monitored for 1 month to 20 years. The graph illustrates the changes since surgery in patients assessed as New York Heart Association (NYHA) classification I *(blue squares),* II *(purple circles),* or III *(brown triangles).* Although most children exhibited good functional status (NYHA class I) immediately after surgery, mild functional limitations evolved over time. Broken lines indicate 70% confidence intervals. **B,** Results of exercise studies (cardiac index, stroke index, and oxygen saturation vs. exercise level) of 42 children after Fontan operation *(purple squares)* compared with normal control subjects *(blue squares).* Although the protocol was designed to achieve modest targets, significant differences emerged in the capacity of Fontan children to increase cardiac output with exercise, and systemic arterial oxygen saturation remained below normal throughout. The primary reason for the inability to increase cardiac output appears to be an inability to increase pulmonary blood flow and, consequently, systemic ventricular filling. Potential reasons for decreased arterial saturation include intrapulmonary shunting owing to arteriovenous malformations and ventilation/perfusion imbalance. *Arrows* indicate a significant difference ($P < .05$) in values between consecutive exercise levels. (**A** from Fontan F, Kirklin JW, Fernandez G, et al. Outcome after a "perfect" Fontan operation. *Circulation* 1990;81:1520–1536; **B** from Gewillig MH, Lundstrom UR, Bull C, et al. Exercise responses in children with congenital heart disease after Fontan repair: patterns and determinants of performance. *J Am Coll Cardiol.* 1990;15:1424–1432. Reprinted with permission from the American College of Cardiology.)

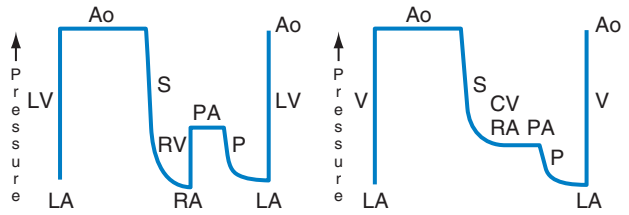

FIGURE 18.11 In the normal cardiovascular circulation *(left),* the pulmonary circulation *(P)* is connected in series with the systemic circulation *(S).* The right ventricle *(RV)* maintains a right atrial *(RA)* pressure that is lower than the left atrial *(LA)* pressure and provides enough energy for the blood to pass through the pulmonary resistance. In the Fontan circuit *(right),* the systemic veins are connected to the pulmonary artery *(PA)* without a subpulmonary ventricle or systemic atrium (the RV is not present on the right). In the absence of a fenestration, there is no admixture of systemic and pulmonary venous blood, but the systemic venous pressures are markedly increased. *Ao,* aorta; *CV,* caval veins; *LV,* left ventricle; *V,* single ventricle. (e.g., increasing cardiac output with increases in venous return). Afferent and efferent denervation has multiple effects on circulatory control mechanisms and leads to physiologic changes, including an increase in the resting HR and a blunted response to stress and exercise. Despite excellent physical activity, exercise testing easily demonstrates that heart transplant recipients can usually achieve only 60% to 70% of normal capacity. In the transplanted heart, exercise-induced increase in cardiac output is initially caused by an increase in stroke volume, a highly preload-dependent process. Tachycardia occurs only later, in response to circulating catecholamines.[130] Further details of the altered physiology are summarized in Table 18.7.[130] The incidence, timing, and extent of sympathetic reinnervation are still being investigated, but the

TABLE 18.7 Physiology of the Transplanted Heart

Increased filling pressures (LVEDP 12 mm Hg 4–8 weeks after transplantation)
Low-normal left ventricular ejection fraction
Restrictive physiology (stiff heart)
Increased afterload
Afferent denervation No angina during ischemia Altered cardiac baroreceptors and mechanoreceptors Less stress-induced increase in systemic vascular resistance Increased blood volume due to decreased natriuresis and diuresis
Efferent denervation Resting tachycardia (loss of baseline vagal tone) Impaired chronotropic response to stress (dependent on circulating catecholamines) Altered response to medications No heart rate response to atropine, glycopyrrolate, and digitalis Possible severe bradycardia or cardiac arrest with neostigmine Exacerbated response to calcium channel blockers, β-blockers, adenosine Exacerbated response to direct acting sympathetic agents Decreased response to indirect-acting agents such as dopamine and ephedrine
Electrophysiology High incidence of sinus node dysfunction in immediate postoperative period, normal AV node Shift to β_2-receptors
Possible sympathetic reinnervation: timing and extent variable Enhanced contractile response and exercise tolerance Higher peak heart rates during exercise

positive effects on cardiac performance have been clearly demonstrated.[131] During standardized exercise testing, transplant recipients with evidence of reinnervation show improved endurance with greater peak HRs and better contractile function.

Chronic denervation also causes an altered response to many medications. Atropine, glycopyrrolate, digoxin, and pancuronium have no chronotropic effect on the denervated heart. Sympathomimetics that act indirectly, such as ephedrine and dopamine, have a blunted response, whereas direct-acting adrenergic agents, such as epinephrine, isoproterenol, and dobutamine, can cause exaggerated effects and should be carefully titrated.[132] A single-center retrospective study did not find any negative effects of neostigmine in patients with heart transplants,[133] but several case reports have described profound bradycardia and even cardiac arrest after neostigmine was used for reversal of neuromuscular blockade.[134–137] Neostigmine has been shown to produce an atropine-sensitive, dose-dependent bradycardia in both recent (<6 months) and remote (>6 months) cardiac transplants. Direct stimulation of postganglionic nicotinic cholinergic receptors with denervation hypersensitivity, a direct effect of the old sinoatrial node on the pacemaker cell of the new sinoatrial node, and parasympathetic reinnervation have been postulated as potential mechanisms.[138–140] Avoidance of neuromuscular blockade, use of short-acting neuromuscular blocking agents without reversal, and use of edrophonium for reversal have all been suggested.[136,137] Edrophonium

seems to have less effect on the HR in this population than neostigmine.[141]

The denervated heart is also extremely sensitive to adenosine. The magnitude and duration of the effects on the AV node are three to five times greater, and the initial and subsequent doses should be reduced by 50%.[142] Calcium channel blockers and β-blockers are associated with exaggerated bradycardia and hypotension. The lack of reflex tachycardia can also lead to profound hypotension with the use of direct vasodilators such as nitroglycerine, nitroprusside, or hydralazine; therefore initial doses of these medications should also be reduced.

Transplant Morbidity

Children who have undergone cardiac transplantation continue to experience morbidity associated with immunosuppressive therapy. Rehospitalization for treatment of infections and episodes of rejection is common, especially during the first year (~42%). Acute rejection episodes are a major threat. With the latest immunosuppressive regimens, the incidence has decreased from almost 30% during the first year in 2008 to 15% in 2014.[129] Rejection is thought to be associated with the development of cardiac allograft vasculopathy (CAV) or coronary artery disease, which is a major cause of morbidity and graft failure. Indeed, 10 years after transplantation, ~16% of infants, ~27% of children 1 to 10 years of age, and ~37% of adolescents have CAV.[129] Most centers include annual coronary angiography or intravascular echocardiography as a part of regular rejection surveillance. Children with CAV present the same anesthetic challenges as adults with severe coronary artery disease and ischemic heart disease. Aggressive immunosuppressive therapy with induction and maintenance regimens carries its own risks.[143] A detailed discussion is beyond the scope of this chapter but, in general, monoclonal or polyclonal T-cell antibodies (OKT3, ATG) and specific interleukin-2 receptor antagonists (basiliximab, daclizumab) are used for the induction phase and various combinations of corticosteroids, calcineurin inhibitors (cyclosporine, tacrolimus, FK506), mechanistic target of rapamycin inhibitors (mTOR inhibitors: sirolimus, everolimus) and antiproliferative agents (azathtioprine, mycophenolate mofetil) are used for maintenance. Adverse effects are common and include neurotoxicity with seizures, hypertension, liver and renal dysfunction, hyperlipidemia, diabetes, gingival hypertrophy, hypertrichosis, bone marrow suppression, and posttransplantation lymphoproliferative disease.[144]

Several excellent review articles describe the anesthetic management of children with heart transplants (see also Chapter 23).[145–148] A thorough preoperative evaluation with attention to episodes of rejection, presence of coronary artery disease, and organ dysfunction; a detailed medication history with investigation of major side effects; consideration of the denervated physiology; and appropriate choice of anesthetic drugs and other medications are essential components of a sensible anesthetic plan for those with a transplanted heart.

Cardiovascular Pharmacology

RATIONAL USE OF VASOACTIVE DRUGS

Many factors influence the selection of appropriate inotropic and vasopressor therapies, including the clinical situation, underlying cardiac abnormalities, and perfusion requirements of other organs. The major goal is to improve tissue oxygenation. Oxygen delivery is principally dependent on cardiac output and oxygen content. In addition to an increased cardiac output (i.e., optimal HR, preload, contractility, and afterload), adequate hemoglobin concentration and oxygen saturation values are important components. On the other hand, a careful balance of pulmonary and systemic blood flows can be crucial for certain congenital heart defects.

Catecholamines and catecholamine-like agents remain the most commonly used inotropic and vasoconstrictor drugs. It is likely that improvements in cardiac output in neonates in response to drugs such as dopamine or dobutamine are the result of increases in both HR and contractility. Some evidence exists in infants and young children after cardiac surgery that the increases in cardiac output produced by dopamine and dobutamine may be more related to a positive chronotropic effect than to an increase in the intrinsic contractile state.[149–151] With few exceptions, drugs that primarily increase afterload, such as α-adrenergic agonists, have limited use in children. Large increases in afterload without corresponding improvements in contractile state are often poorly tolerated by infants and children, particularly in the context of significant underlying contractile dysfunction.

PRACTICAL CONSIDERATIONS FOR THE USE OF VASOACTIVE AGENTS

Commonly used drugs, their doses, and a summary of their effects on selected cardiac functions are presented in Table 18.8; most of this information has been empirically derived from studies in adults. Limited direct information regarding the effects of commonly used vasoactive drugs in children at different ages and in various pathophysiologic states is available. Neonates, infants, and small children demonstrate unique responses to inotropic and vasoactive drugs primarily because of age-specific pharmacokinetics; differences in receptor types, number, and function; and a variability in drug delivery. Important variations in the volume of distribution and measured plasma concentrations have been observed in children receiving inotropic agents. As much as a 10-fold range in plasma concentration has been reported for a given infusion rate.[152–154]

Substantial pharmacodynamic variability (i.e., variability in the serum concentration required to produce the desired effect) can also be observed. Some of these differences are related to receptor maturation and function. For example, it appears that β-adrenergic receptors have a high density in the term neonate and young infant but their coupling to adenyl cyclase may be incomplete.[35,155] In addition to developmental changes, which are to some extent controlled by thyroid hormone, β-receptor, and adenyl cyclase activities are diminished in response to sustained administration of exogenous β-agonists and also as a result of increased endogenous catecholamine concentrations, which are often seen as a complication of moderate to severe heart failure and other forms of severe stress (e.g., sepsis).[156–158]

In the neonatal myocardium, chronic catecholamine exposure may upregulate adrenergic receptor number or function, or both, perhaps mimicking the normal developmental program of increasing sympathetic nervous system activity as term approaches.[159] With further maturation in early postnatal life, β-adrenergic receptor density declines. The impacts of various pathophysiologic states on these processes have been incompletely identified. For example, congestive heart failure, cardiopulmonary bypass (CPB), and ischemic reperfusion all lead to decreased β-receptor and adenyl cyclase expression and activity.[160–163] On the other hand, the myocardium of infants with TOF exhibits increased β-receptor density and greater receptor-stimulated adenyl cyclase activity with increased gene and protein expression.[164,165]

One must pay particular attention to technical issues when administering vasoactive infusions to infants. Infusions are often

TABLE 18.8 Inotropics and Vasopressors

Agent	Intravenous Dose	Comments
Dopamine	2–20 μg/kg per minute infusion	Primary effects at β_1, β_2, and dopamine receptors, somewhat related to dose; lower doses (2–5 μg/kg per minute) can increase contractility and can also have a direct dopaminergic receptor effect to increase splanchnic and renal perfusion; increasing doses increase contractility via β-effects and increase likelihood of α-mediated vasoconstriction; effects depend on endogenous catecholamine stores.
Dobutamine	2–20 μg/kg per minute infusion	Relatively selective β_1 stimulation; also potential β_2 stimulation, tachycardia, and vasodilation, especially at higher doses (>10 μg/kg per minute); may be less potent than dopamine, especially in immature myocardium; no significant α-adrenergic effects; tachydysrhythmias perhaps more likely than with dopamine; effects are independent of endogenous catecholamine stores.
Epinephrine	0.02–2.0 μg/kg per minute infusion	Primary β-effects to increase contractility and vasodilation at lower doses (0.02–0.10 μg/kg per minute); increasing doses (>0.1 μg/kg per minute) are accompanied by increased contractility and increased α-mediated vasoconstriction; may be best choice to augment contractility and perfusion, especially in situations of severely compromised ventricular function, shock, or anaphylaxis.
Isoproterenol	0.05–2.0 μg/kg per minute infusion	Pure, nonselective β-agonist; significant inotropic, chronotropic (β_1 and β_2), and vasodilatory (β_2) effects; may be an effective pulmonary vasodilator in some children; tachycardia and increased myocardial oxygen consumption may be dose limiting; tachydysrhythmias may also occur; bronchodilator.
Norepinephrine	0.05–2 μg/kg per minute infusion	Primary effects on α_1-, α_2-,and β_1-receptors, no significant clinical effects on β_2. Increased systemic blood pressure and cardiac output (α_1 and β_1) as well as improved pulmonary blood flow (α_2). Less tachycardia. Mainly used for treatment of septic shock and pulmonary hypertension.
Phenylephrine	1–10 μg/kg bolus, 0.1–0.5 μg/kg per minute infusion Preterm and term infants may require as much as a 30 μg/kg bolus (see Chapter 17)	Pure α-mediated vasoconstriction; no increase in contractility.
Vasopressin	0.0003–0.002 U/kg per minute	Induces intense vasoconstriction via V_{1a} receptors in the vascular endothelium. May cause vasodilation via V_2 receptors in specific tissues (release of nitric oxide and vasodilating prostaglandins). Used for the treatment of vasodilatory shock, refractory hypotension, and pulmonary arterial hypertension. Careful when programming syringe pumps: multiple dosing forms (U/minute, U/kg per hour, U/kg per minute, or mU/kg per minute).
Amrinone	0.75–1 mg/kg repeated twice, maximum 3 mg/kg Neonates and infants may require loading doses of 2–4 mg/kg and infusions of 10 μg/kg per minute	Increases cyclic adenosine monophosphate by phosphodiesterase inhibition; positive inotropy, positive lusitropy, and smooth muscle vasorelaxation; hypotension; reversible thrombocytopenia.
Milrinone	50–75 μg/kg loading dose, 0.5–1.0 μg/kg per minute infusion	Similar to amrinone (antiplatelet effects may be less).
Calcium chloride Calcium gluconate	10–20 mg/kg per dose (slowly) 30–60 mg/kg per dose (slowly)	Positive inotropic and direct vasoconstricting effects; inotropy is significant only if ionized calcium is low and/or ventricular function is depressed by other agents; can slow sinus node; increases electrophysiologic abnormalities from hypokalemia and digoxin.
Digoxin	Total digitalizing dose (TDD): Premature: 20 μg/kg Neonate (1 mo): 30 μg/kg Infant (<2 yr): 40 μg/kg Child (2–5 yr): 30 μg/kg Child (>5 yr): 20 μg/kg Maintenance: 2.5–5 μg/kg q12 hour	TDD given in divided doses: ½ TDD followed by ¼ TDD q8–12 hour ¾ × 2; increases cardiac contractility; slows sinus node and decreases atrioventricular (AV) node conduction; long half-life (24–48 hours) that is prolonged by renal dysfunction; numerous drug interactions; toxicity includes supraventricular tachycardia, AV block, ventricular dysrhythmias; symptoms include drowsiness, nausea, vomiting; toxicity exacerbated by hypokalemia.

specifically prepared as very concentrated, nonstandardized solutions to minimize the amount of volume infused; hence, the potential for dose or concentration error is substantial. One study at a tertiary care children's hospital demonstrated that the actual concentration of prepared solutions varied significantly.[166] Because of the high concentration of these drugs relative to the child's size, small errors (either in calculation or in infusion pump flow rate) can have a large impact on the actual amount of drug delivered. The extremely small infusion rates can also lead to a delay in drug delivery and effect (see Chapters 8 and 52). Confirming that the pump drive mechanism is actually delivering drug at the distal end of the infusion tubing, connecting the infusion tubing as close to the child as possible, and using a carrier infusion to "push" the medication at a constant rate are important steps to

ensure the safety and effectiveness of drug infusions. The rate of the carrier infusion is also crucial. Most standard infusion setups require rates in excess of 5 mL/hour to effect rapid (less than ~10 minutes) changes in the concentration of drug delivered to the infant and therefore preclude all attempts of fluid restriction.

VASOACTIVE DRUGS

Dopamine

Dopamine continues to be the most frequently used inotropic agent in neonates, infants, and children. It has activity at α-, β-, and dopaminergic receptors. Dopamine augments cardiac contractility through two mechanisms. First, it directly stimulates cardiac β_1-receptors and provokes norepinephrine release from cardiac sympathetic nerve terminals. Second, circulating concentrations of endogenous epinephrine and norepinephrine increase during dopamine infusions, leading to the suggestion that at least some of the effects of a dopamine infusion are indirectly mediated via induced release of endogenous catecholamines.[167] Because of its indirect effects, particularly the release of myocardial norepinephrine stores, the response to dopamine may be diminished in children with congestive heart failure or other relatively long-standing forms of hemodynamic stress.

Activity at dopaminergic receptors in the kidney and gastrointestinal tract can lead to improved perfusion of these organ systems. The evidence that dopamine specifically and selectively improves renal perfusion via stimulation of renal dopaminergic receptors (i.e., as opposed to a nonspecific and generalized improvement in cardiac output that might occur with any positive inotrope) is conflicting.[168–172] Regardless of the mechanism, most evidence indicates that renal blood flow and perfusion are increased by dopamine, even at very large doses.

As in the case with other inotropes, pharmacokinetic studies of dopamine have shown wide variability in serum concentration in neonates and children.[173,174] Because of variability in the plasma concentration for a given infusion rate, as well as the wide range of serum concentrations necessary to produce a given effect, doubling or halving a dopamine infusion rate may be a logical approach to bracketing the optimal dose. The frequent practice of changing the infusion rate by small proportions (i.e., 5% to 10%) may be inconsistent with our current understanding of the pharmacokinetics and pharmacodynamics of most inotropes.

Neonates have classically been considered to have a greater dependence on HR, a reduced myocardial compliance, and a relative resistance to inotropic effects of exogenous catecholamines. Nonetheless, there is substantial echocardiographic evidence that small dopamine infusion rates (≤5 μ/kg per minute) increase myocardial contractility before significant increases in HR.[175,176] Evidence regarding the effects of dopamine in sick preterm infants is also somewhat controversial.[169,177–181] There may be a relative dissociation between its effects on the renal and mesenteric beds in these infants, such that a portion of the increase in arterial blood pressure during a dopamine infusion may result from mesenteric vasoconstriction and an actual decrease in mesenteric blood flow.

Although it is generally accepted that large infusion rates (>10 to 15 μg/kg per minute) of dopamine cause substantive vasoconstriction, studies have shown that both cardiac output and renal blood flow improve, even at very large doses (≥20 μg/kg per minute) in neonates and infants.[182,183]

The effects of dopamine on PVR are variable. Both minimal effect and increased PVR have been observed.[151,184–190] The effects of dopamine on PVR most likely depend on the dose as well as the underlying state of the vascular endothelium and smooth muscle. Vasoconstriction may be more likely after ischemia-reperfusion and in the presence of hypoxia. Conversely, the presence of vasodilators, such as nitroprusside, or α-adrenergic blockers, such as phenoxybenzamine, can prevent increased PVR in response to dopamine.[191,192] Overall, dopamine remains the drug of choice in most infants and children, owing to its beneficial effects on mesenteric and renal blood flow, lesser chronotropic effects than some other agents, and a somewhat reduced arrhythmogenic potential.

Dobutamine (Dobutrex)

Dobutamine is a structural analog of isoproterenol. It was developed to provide relatively selective β-adrenergic receptor stimulation. Its inotropic and α-adrenergic effects are somewhat less potent than those of dopamine. Dobutamine does possess significant β_2-adrenergic receptor agonist properties, accounting for its peripheral vasodilatory properties. Substantial vasodilation and tachycardia occur at larger infusion rates (≥10 μg/kg per minute).[150,193–196] The tendency toward tachycardia and tachyarrhythmia may be greater in neonates than in older children or adults. There is some evidence from immature animal models that the efficacy of dobutamine is reduced, perhaps because of greater circulating catecholamine concentrations and alterations in β-receptor expression and function.[149,150,197–199]

Because the actions of dobutamine do not depend on endogenous catecholamine stores, the drug may be more effective in increasing cardiac output in patients with severe congestive heart failure or cardiogenic shock.[200,201] In children with normal LV function, dobutamine increases LV relaxation. It also improves diastolic relaxation by decreasing end-systolic wall stress.[202] Evidence indicates that dobutamine improves LV contractility in neonates with LV dysfunction, dispelling the notion that there is relative resistance in neonates.[203] Dobutamine does not selectively improve renal or mesenteric blood flow independently of its effect on increasing cardiac output. The improvement in cardiac output with dobutamine is related to both an increased contractility and decreased SVR via vasodilation. Pulmonary vasodilation in the presence of an increased PVR may also occur.[199]

As is the case with dopamine, exponential increases in serum concentrations are required to produce linear improvements in cardiac index. There is also substantial pharmacokinetic variability in the plasma concentrations of dobutamine.[153,204,205] Tolerance may occasionally develop.[206] In one animal study, high-dose dobutamine infusion was associated with significant dysfunction of platelet aggregation after hypoxia and reoxygenation.[207]

Isoproterenol (Isuprel)

Isoproterenol is a pure, nonselective β-adrenergic agonist.[208] It increases HR and contractility and vasodilates mesenteric and renal vessels and skeletal muscle. Isoproterenol is also a fairly effective vasodilator of the pulmonary circulation.[209] The tachycardia, which almost always accompanies its use, and greater contractility cause an increase in myocardial oxygen consumption, which is usually well tolerated. However, these changes may be limiting in compromised hearts. The pulmonary vasodilation produced by isoproterenol may be useful in settings in which tachycardia is either unimportant or somewhat beneficial.[210] Systemic vasodilation induced by isoproterenol can be sufficiently profound as to cause systemic hypotension.[189,211] The positive chronotropic effects of isoproterenol may be useful in children with bradycardia.[212] The drug is increasingly used in electrophysiology suites to facilitate the detection of abnormal conduction

pathways in infants and children under general anesthesia.[213] Isoproterenol is also a potent bronchodilator. Prolonged use or large doses of isoproterenol and other catecholamines may be associated with the development of myocardial fibrosis.[214]

Epinephrine (Adrenaline)

Epinephrine has α-, β_1-, and β_2-adrenergic agonist effects. Data derived mainly from studies in adults indicate that lower doses of 0.02 to 0.1 μg/kg per minute are associated with predominantly β-adrenergic effects. In this range, increases in HR and systolic blood pressure and reduced diastolic blood pressure owing to skeletal muscle vasodilation predominate. Doses between 0.1 and 0.2 μg/kg per minute have mixed α- and β-effects. At larger doses, α-adrenergic–induced vasoconstriction is significant, and hence there is reduced skin, muscle, renal, and mesenteric blood flow. Compared with pure α-agonists, epinephrine provides significant inotropic effect. The effects of epinephrine do not depend on endogenous tissue catecholamine stores. Based on experience, epinephrine seems to be effective in children who do not respond to dopamine or dobutamine, particularly those with significant dysfunction of the systemic ventricle in the immediate postoperative period. The addition of moderate vasoconstriction to increased contractility may be advantageous to maintain myocardial perfusion and may also increase both systemic and pulmonary blood flow in children with shunt-dependent circulations. Important adverse effects include dysrhythmias (usually ventricular) and, at larger doses, regional ischemia and hypoperfusion as the result of vasoconstriction.

Pharmacokinetic studies have shown a linear relationship between serum concentration and infusion rate, but again there is significant variability in the individual response to a specific concentration.[215,216] In infants and children with postoperative low cardiac output syndrome, increased concentrations of glucose and of lactate have been reported after 1 to 2 hours of an epinephrine infusion of 0.1 μg/kg per minute.[215]

Norepinephrine (Levophed)

Norepinephrine is often indicated as a first- or second-line treatment for severe hypotension associated with septic shock, but it has also been used in the treatment of persistent pulmonary hypertension of the newborn and other forms of pulmonary hypertension.[217–222] This endogenous adrenergic agent activates both α- and β-receptors. Compared with epinephrine, it seems to be equally effective on β_1-receptors, slightly less on α_1-receptors, and has no clinically significant effects on β_2-receptors. Norepinephrine has been shown to increase systemic blood pressure as well as cardiac output, oxygen delivery, and splanchnic perfusion in animal models and clinical studies.[223,224] It causes less tachycardia than epinephrine. Through activation of α_2-receptors and release of NO, norepinephrine reduces PVR and can improve pulmonary blood flow.[184,225–228] Norepinephrine has a very rapid onset of action with a duration of effect of only 1-2 minutes. It is metabolized by catechol-O-methyltransferase and monoamine oxidase, the inactive metabolites are eliminated in the urine. Pharmacokinetic data are mainly derived from adult studies; the few available pediatric reports emphasize the wide interindividual variability and the need for careful titration. The initial dose of 0.05 to 0.1 μg/kg per minute has to be slowly increased to the desired effect, usually in a range of 0.1 to 2 μg/kg per minute. In a small prospective observational study in term neonates, the majority responded to a mean dose of 0.5 ± 0.4 μg/kg per minute, with a range of 0.2 to 7.1 μg/kg per minute.[219] A retrospective study in children in septic shock reported mean initial doses of 0.5 ± 0.4 μg/kg per minute to 2.5 ± 2.2 μg/kg per minute, with a maximum individual dose of 10.5 μg/kg per minute.[217] Norepinephrine may be administered via peripheral venous access (and is recommended to avoid delays in treatment) until central access can be established, but some institutions report IV infiltrates in up to 15% of children on vasoactive infusions especially during transport. Accordingly, ongoing vigilance is important.[229] Other side effects include arrhythmias and hypertension, which usually respond to dose reductions.

Phenylephrine (Neosynephrine)

Phenylephrine is a pure α-adrenergic agonist. As such, its major function is to cause peripheral vasoconstriction. It has no β-adrenergic or inotropic effect and therefore does not increase contractility. It may be temporarily used to improve afterload, systemic blood pressure, and, therefore, critical organ blood flow. But without concurrent inotropic support, an isolated acute increase in afterload is often poorly tolerated, particularly by a compromised ventricle. There are a at least three situations in which phenylephrine can be extremely useful. The first is to increase systemic afterload and decrease right-to-left shunting in children with TOF and dynamic RVOTO (tet spell). This pure α-adrenergic effect is particularly important in this situation, since any additional increase in contractility would worsen the outflow obstruction. Second, phenylephrine is also beneficial in cyanotic children who depend on a systemic-to-PA shunt for pulmonary blood flow and adequate oxygenation. The increased afterload may increase flow across the shunt and improve pulmonary blood flow. Third, acute hypotension in children with hypertrophic obstructive cardiomyopathy or critical aortic stenosis increases the outlet obstruction; phenylephrine increases afterload attenuating the severity of the obstruction.[230–233]

Vasopressin (Pitressin)

Arginine vasopressin is a peptide secreted by the pituitary gland. Secretion is promoted by angiotensin II and increased stimulation from hypothalamic osmoreceptors; increased activity from cardiopulmonary baroreceptors and increased levels of natriuretic peptide inhibit the secretion of vasopressin. Vasopressin acts at the tissue level by binding to specific receptors. It causes vasoconstriction via vasopressin$_1$ (V_{1a}) receptors and renal reabsorption of water, renal secretion of renin, and synthesis of renal prostaglandins via vasopressin$_2$ (V_2) receptors. In addition, vasopressin may mediate vasodilatation via V_2 receptors by increasing the release and synthesis of NO and vasodilating prostaglandins. Vasopressin also sensitizes baroreceptors and therefore may cause vasodilatation by decreasing sympathetic activity. Normally, vasopressin acts primarily via V_2 receptors in the kidney to promote water retention. However, during extreme hypotension, vasopressin may act via V_{1a} receptors in the vascular endothelium to induce intense vasoconstriction.

In adults, vasopressin has been shown to be beneficial in the treatment of vasodilatory shock and during cardiopulmonary resuscitation.[234] A few pediatric case reports and small observational studies have demonstrated improved blood pressure and accelerated weaning of inotropic support with low-dose vasopressin.[235–238] However, a multicenter, randomized, controlled trial in children with vasodilatory shock did not confirm these findings. Low-dose vasopressin (0.0005-0.002 U/kg per minute) had no beneficial effects compared with placebo; there was even a suggestion of increased mortality.[239] Further studies are necessary

to establish the effectiveness and safety of vasopressin in children. Currently its role as a "rescue" medication for the treatment of catecholamine-resistant vasodilation during or after congenital cardiac surgery[240,241] and for refractory hypotension in extremely low–birth-weight (ELBW)[242] infants is being investigated. In 2013, a Cochrane Review found no eligible studies to analyze the effects of vasopressin and its analogues on refractory hypotension in neonates.[243] All available evidence for a role of vasopressin in children is based on case reports, small case series and three randomized controlled trials in older children.[239,244,245] A small pilot study in 20 infants, published in 2015, compared vasopressin and dopamine as the primary treatment for hypotension in ELBW infants. Vasopressin appeared to be safe and effective, but this interpretation must be tempered by the small sample size.[223,246,247] The prophylactic use of low dose vasopressin (0.0003 U/kg per minute) in the early postoperative phase after the Norwood or arterial switch procedure has been reported to decrease catecholamine and fluid requirements.[248] Refractory pulmonary hypertension is another potential indication for vasopressin and its analogues. In animal studies and in vitro experiments with human tissue, vasopressin causes pulmonary vasodilation via endothelium-dependent release of NO or by direct activation of smooth muscle receptors.[249–252] This vascular response seems to be age and disease specific and could explain the conflicting results in the literature. Several case reports and case series describe the successful use of vasopressin for this indication, but further studies are necessary to assess appropriate dosing and safety.[253–256] Extrapolated from adult data, pediatric dosing algorithms currently range from 0.0003 to 0.002 U/kg per minute. Careful attention to the infusion rate is important, especially when programming syringe pumps. The literature and common reference tools often cite the doses in units per minute (U/minute), units per kilogram per hour (U/kg per hour), units per kilogram per minute (U/kg per minute), or even milliunits per kilogram per minute (mU/kg per minute), which can be quite confusing and readily lead to dosing errors.

Phosphodiesterase Inhibitors

Phosphodiesterase inhibitors, which include amrinone, milrinone, and enoximone, are the most commonly used non–catecholamine-mediated inotropic agents. Their mechanism of action is also relatively straightforward. Phosphodiesterases degrade cyclic adenosine monophosphate (cAMP) to 5′-AMP. Phosphodiesterase inhibitors prevent this degradation and therefore increase levels of cyclic nucleotides, primarily cAMP. The increased concentration of this secondary messenger leads to an increase in calcium availability and thus increased contractility. Because the response is related to an increase in cAMP and not purely to inhibition of phosphodiesterase, the greatest effect occurs if initial levels of cAMP exceed normal values. In this way, synergy exists with β-agonists.[257] The absence of adrenergic stimulation minimizes effects on HR, rhythm, and dependency on endogenous tissue catecholamine stores. In addition to positive inotropic effects, these drugs also have significant lusitropic properties (i.e., diastolic relaxation) and promote peripheral vasodilation.[258–260] Phosphodiesterase drugs may also have substantial antiinflammatory properties that are currently not well understood.[261–263]

Amrinone (Inocor, Wincoram, Cordemcura)

Amrinone produces significant increases in myocardial contractility and reduces ventricular afterload.[259,264,265] As with all phosphodiesterase inhibitors, there has been an ongoing debate about the relative contribution of systemic vasodilation and afterload reduction relative to the increased cardiac contractility as the primary underlying mechanism for improving cardiac output. Amrinone improved cardiac performance in neonates and infants after cardiac surgery such as the arterial switch procedure and in older children after the Fontan operation.[260,264,266] Pharmacokinetic data in children suggest that the loading and infusion doses for amrinone need to be approximately twice those reported for adults.[267] In addition to differences in volume of distribution and clearance (both greater in infants), binding of amrinone to the oxygenator membrane needs to be considered if the loading dose is administered during CPB.[268] Overall, these data suggest that loading doses of 2 to 4 mg/kg and infusion rates starting in the range of 10 μg/kg per minute may be indicated in the neonate and infant.[268] Large bolus doses of amrinone can cause significant systemic hypotension, particularly in the period immediately after cardiac surgery. From a practical standpoint, it may be best to administer the loading dose of amrinone slowly over 1 hour. Caution is also indicated because the elimination half-life of amrinone is large (3–15 hours). Other side effects include thrombocytopenia, which is reversible, occasional drug-related fever, and increased hepatic enzymes.[269]

Milrinone (Primacor)

Several studies have demonstrated improved cardiac output and outcome from the use of milrinone after cardiac surgery in neonates and infants and with other states associated with ventricular dysfunction.[270–275] Renal clearance is the primary route of elimination and the maturation of milrinone clearance closely follows that of the glomerular filtration rate. A clearance of 9 L/hour per 70 kg is reported in adults with congestive heart failure and we might anticipate that clearance in premature neonates is reduced to 10% of this value because of a corresponding immaturity of renal function in this cohort. This has been confirmed in 26-week postmenstrual age infants who had a clearance of 0.96 L/hour per 70 kg.[276] Milrinone has a larger volume of distribution and greater clearance (expressed per kilogram) in children compared with adults; adjustments to bolus dosing and infusion rates have therefore been recommended.[270,275] Unlike amrinone, milrinone does not bind to the CPB circuit and has less deleterious effect on platelet function. Loading doses of 50 to 100 μg/kg (typically 75 μg/kg) and initial infusion rates of 0.50 to 1.0 μg/kg per minute have been recommended.[270,273] Neonates with HLHS who underwent stage I palliation exhibited reduced renal clearance in the immediate postoperative period, and dose adjustments should be considered (i.e., infusion rates of 0.2 μg/kg per minute).[277] Milrinone increases cardiac output, reduces cardiac filling pressures, and reduces afterload; its effects are typically not associated with tachyphylaxis and are independent of β-adrenergic receptor density or activity. An initial multicenter, double-blind, placebo-controlled trial demonstrated that prophylactic use of high-dose milrinone significantly reduced the development of low cardiac output syndrome relative to placebo after cardiac surgery in high-risk pediatric subjects.[272] In 2011, a survey of European hospitals performing open heart surgery showed that milrinone was used in 70% of all drug regimens.[278] Several limited small studies reported that milrinone and the calcium sensitizer, levosimendan, were equally effective in preventing low cardiac output syndrome.[279–281] In addition, a recent Cochrane Review found no significant mortality advantage for prophylactic milrinone in the available literature (only five eligible studies).[282] Milrinone is also increasingly used to improve oxygenation in neonates

with persistent pulmonary hypertension who are unresponsive to therapy with NO.[283,284] Animal studies have shown that IV or inhaled milrinone enhances the response of the pulmonary vasculature to iloprost and prostacyclin.[285,286] Potential side effects of milrinone include hypotension, tachycardia, tachyarrhythmias, and platelet dysfunction.[287]

Enoximone (Perfan)

Enoximone is a phosphodiesterase inhibitor that has been used extensively in Europe but is not currently available in the United States. Its properties are similar to those of the other members of its class.[258,288] Improvements in indirect indexes of cardiac function, such as mixed venous oxygen saturation, ventricular filling pressures, and systemic arterial blood pressure, were observed in infants treated with enoximone after cardiac surgery. In addition, the length of hospital stay was reduced.[289] Enoximone was also useful to support cardiac function and potentially reduce PVR in children after cardiac transplantation.[290]

Digoxin (Digitek, Digox, Lanoxicaps, Lanoxin)

Digoxin can act as an inotropic agent; however, its effectiveness in children with congestive heart failure caused by large left-to-right shunts has been questioned. The clinical picture in such children often improved without echocardiographic evidence of increased contractility, and frequently progressive ventricular dilatation was observed.[291,292] Use of digoxin to improve RV dysfunction owing to pulmonary hypertension or as part of a multimodal therapy during the interstage phase for infants with single ventricle physiology has also been debated.[293]

Digoxin has both direct and indirect effects. Its direct effects are mediated by inhibition of the membrane sodium-potassium adenosine triphosphatase (ATP) and thereby outward sodium ion flux. The resulting increased intracellular sodium concentration stimulates the membrane sodium-calcium exchanger, producing increased intracellular calcium and positive inotropic effect. The indirect effects of digoxin are mediated by stimulation of the parasympathetic nervous system. The parasympathetic effects of digoxin result in slowing of atrial and AV node conduction. The drug can also be used to slow down the ventricular response in atrial flutter and atrial fibrillation and to treat supraventricular tachycardia (SVT) (see later discussion).

Because digoxin has a slow distribution phase after oral administration and a long elimination half-life (up to 1–2 days in neonates and young infants), a loading dose is usually administered (see Table 18.8). Renal dysfunction can significantly prolong the elimination half-life. Therapeutic digoxin concentrations are between 0.5 and 2.0 ng/mL. IV and oral dosing regimens are the same, although the onset of electrophysiologic effects from IV dosing is much more rapid (5–20 minutes).

Many drugs interact with digoxin and influence its pharmacokinetics. It should be assumed that almost any drug administered along with digoxin can affect the absorption and clearance, usually necessitating a reduction in dose.[294,295] The likelihood of digoxin toxicity increases with serum concentrations greater than 3 ng/mL.[296,297] Symptoms of toxicity include drowsiness, nausea, and vomiting. Various conduction abnormalities and SVT are the most frequent cardiac rhythm manifestations of digoxin toxicity in infants and young children. Older children and adults are more likely to experience AV block, ventricular dysrhythmias, junctional tachycardia, and premature ventricular contractions. Hypokalemia, specifically intracellular potassium depletion (often a result of long-standing diuretic use), exacerbates the proarrhythmogenic effects of digoxin.

CALCIUM

The role, mechanisms of action, and potential for deleterious consequences of IV calcium continue to be controversial.[298] It is the ionized calcium concentration that is important for myocardial function. Calcium is a positive inotrope, particularly when administered in the presence of ionized hypocalcemia. It may also improve ventricular contractility when LV function is depressed by inhalational agents, β-adrenergic blockade, or disease (e.g., sepsis).[299,300] In the presence of a normal myocardium and normal ionized calcium concentrations, the effects of IV calcium on contractility are much more modest.[301] Extracellular calcium levels also play an important role in the regulation of peripheral vascular resistance. A calcium-sensing receptor has been identified on vascular cell walls.[302]

There is evidence in adults that the primary effect of calcium administered after cardiac surgery is to increase SVR and mean arterial pressure with little or no effect on intrinsic myocardial contractility.[298,303] In fact, the increase in afterload, if not accompanied by a corresponding increase in contractility, may only serve to decrease stroke volume and cardiac output. Calcium may cause or exacerbate reperfusion injury and cellular damage by mechanisms that include activation of calcium-dependent proteases and phospholipases and organelle damage caused by cellular calcium overload.[304,305] These concerns are particularly relevant in children immediately after cardiac surgery. IV calcium may also attenuate the β-adrenergic effects of concurrently administered epinephrine.[298]

The role of IV calcium administration in neonates and young infants, both alone and after cardiac surgery, is more complicated. Preterm and term neonates have erratic calcium handling and are prone to ionized hypocalcemia.[306,307] The neonatal myocardium is more sensitive to ionized hypocalcemia than the adult myocardium, owing to reduced intracellular calcium stores, immaturity of sarcoplasmic reticulum calcium-handling mechanisms, and greater dependency on transmembrane calcium flux for excitation-contraction coupling.[308] Furthermore, the need to administer substantial volumes of citrated and albumin-containing blood products (both of which bind calcium) and other fluids after CPB increases the likelihood of ionized hypocalcemia.[309] The most prudent approach includes awareness of the greater dependency of the immature myocardium on extracellular calcium, monitoring of ionized calcium concentrations, and careful administration to maintain normal, or at most mildly increased, ionized calcium concentrations. This approach is particularly needed in neonates and in those with diminished LV function. Administration of large bolus doses of calcium immediately on reperfusion of the heart after a period of ischemia is probably ill-advised because of the potential to exacerbate reperfusion injury and even to cause myocardial contracture.

Extravasation of calcium can cause local venous irritation and significant tissue necrosis. Although it has been suggested that calcium gluconate may cause less harm in this regard than calcium chloride, we recommend that both forms be administered via a centrally positioned catheter whenever possible. Both forms of calcium increase ionized calcium concentrations similarly when equal amounts of elemental calcium are administered (3 : 1 calcium gluconate to calcium chloride).[310] Calcium may cause significant slowing of AV conduction and should be administered cautiously in children with sinus bradycardia or junctional rhythm. Care must also be exercised when administering calcium to children who are receiving digoxin, particularly in the presence of concurrent hypokalemia, because IV calcium exacerbates the potential for digoxin-induced dysrhythmias in this setting.

TRIIODOTHYRONINE (THYROXINE)

Triiodothyronine hormone (T_3) is essential for the maturation of sarcolemmal calcium channels, myosin, actin, and troponin. In addition, hypothyroid rats demonstrate reduced numbers of β-receptors and reduced density of stimulatory secondary messenger protein with an increase in inhibitory secondary messenger protein density. T_3 is mostly produced by monodeiodination of thyroxine. This process is inhibited by surgery, hypothermia, catecholamines, propranolol, and amiodarone; therefore postoperative T_3 levels are often reduced.[311–313]

T_3 replacement therapy acts via two pathways, intranuclear and extranuclear. Intranuclear effects include an increase in mitochondrial density and respiration, an increase in contractile protein synthesis, and an upregulation in β-adrenoceptors. Extranuclear effects include an improvement in glucose transport, increased stimulation of L-type calcium channels with subsequent calcium mobility, and increased efficiency in calcium reuptake with subsequent improvement in diastolic relaxation.

Endocrine function is compromised after cardiac surgery. Infants younger than 3 months of age with low T_3 concentrations on intensive care admission after cardiac surgery have a more complicated intensive care course. Low cortisol concentration is common in the early postoperative period but is not associated with postoperative complications.[314] A randomized, double-blind, placebo-controlled study of T_3 administration in children undergoing simple or complex cardiac surgery demonstrated that myocardial function was better and length of stay in the intensive care unit was decreased in the T_3 group.[315] T_3 improved contractility without any associated increase in oxygen consumption. In addition, the T_3 group demonstrated no delay in recovery of thyroid function secondary to exogenous administration. The dose of T_3 used was 2 μg/kg on day 1 followed by 1 μg/kg on days 2 through 12. A randomized, double-blind, placebo-controlled study of T_3 administration in neonates undergoing the Norwood procedure or repair of interrupted aortic arch and VSD closure demonstrated only more rapid achievement of negative fluid balance.[316] Many follow-up studies have been flawed by small numbers and significant patient heterogenicity; thus routine postoperative T_3 replacement therapy remains controversial.[317–320]

CALCIUM-SENSITIZING AGENTS

Levosimendan (Simdax, Simendan)

Calcium-sensitizing agents represent a relatively new class of drugs with inotropic properties. Levosimendan has been in clinical use since 2000 and is one of the best studied drugs in this class. It provides positive inotropy, lusitropy, vasodilation and cardioprotection via two distinct mechanisms: calcium sensitizing and opening of K^+-channels. Levosimendan binds to troponin C and seems to maintain the calcium-binding site of troponin C in its active conformation. This shifts the calcium binding–concentration relationship toward increased binding (i.e., more binding at reduced intracardiac calcium concentrations). Contraction is thereby enhanced for a given cytosolic calcium concentration. In contrast to other types of inotropic agents, myocardial contractility is greater with minimal increase in oxygen demand. The concept of increasing the sensitivity to calcium rather than the cellular calcium concentration is also attractive because it reduces the deleterious effects of increased calcium concentrations on oxygen consumption, mitochondrial function, and activation of various calcium-dependent proteases and phospholipases (e.g., during ischemia-reperfusion).

Levosimendan has also been shown to stimulate membrane and mitochondrial ATP-sensitive potassium (K_{ATP}) channels; the former dilates the coronary, pulmonary, and the systemic vasculature. Opening mitochondrial K_{ATP} channels is likely to be an important mechanism of pharmacologic (and anesthetic) preconditioning and potential cytoprotection. Interestingly, and for reasons that are not entirely clear, levosimendan has either no effect or a positive effect on lusitropy (diastolic relaxation). At much larger doses than clinically used, it does inhibit phosphodiesterase III. Compared with other inotropic agents (e.g., dopamine, amrinone, milrinone), its effectiveness as a positive inotrope is maintained in the depressed myocardium.[287,321,322] The safety of levosimendan has been well established in adults; headaches, hypokalemia, and tachycardia are the most common side effects. A reported possible increased incidence of atrial fibrillation is controversial.[323,324]

Clinical effects include improved cardiac output, reduced ventricular filling pressures, and decreased PVR during the acute treatment of adult patients with either stable or decompensated heart failure.[323–326] However, initial mortality studies failed to show any improvements in short- or long-term prognosis for acute heart failure with levosimendan compared with dobutamine or placebo[327]; a meta-analysis of 45 studies in a wide variety of settings reported potential advantages.[328] Other investigations demonstrated improved cardiac performance after cardiotomy and bypass, including beneficial responses in adult patients who appeared to be poorly responsive to other inotropes.[329–334] Beneficial effects were also found with levosimendan pretreatment directly before bypass.[335]

Current recommendations suggest a 6- to 12-μg/kg loading dose followed by an infusion of 0.05 to 0.2 μg/kg per minute for 24 hours. Although the elimination half-life is approximately 1 hour, effects are mediated through changes in structural calcium sensitivity that may last for 7 to 9 days. At least one metabolite (OR-1896) has prolonged (approximately 80 hours) effects and this may, in part, account for observations of sustained benefit after drug discontinuation.[336]

There are limited data available regarding the use of levosimendan in children or immature animal preparations. Most of the evidence in children stems from observational studies, case reports, or registry inquiries.[279,337–349] These reports suggest that levosimendan is well tolerated, improving cardiac output and reducing afterload in children with low cardiac output syndrome.[337] Only a few randomized controlled trials have been published: two studies compared levosimendan with milrinone in children after congenital cardiac surgery and concluded that levosimendan is safe and at least as effective as milrinone.[279,280] Another study compared levosimendan with a standard treatment with milrinone and dopamine and came to the same conclusion.[350] The most recent investigation examined pulmonary artery pressures and the response to levosimendan or dobutamine during pediatric cardiac surgery. The results showed that levosimendan was superior.[351] These early data and the drug's mechanism of action suggest the need for further studies in children and a likely indication for use in infants and children with decreased myocardial performance from cardiac surgery, myocarditis, and sepsis.[287,337,352] Its widespread clinical application is significantly limited due to the high cost of the drug and the restricted availability. Currently levosimendan is only approved in 12 European countries, Asia, South America. and Australia. The use in children (<18 years) is off-label, under compassionate care, and requires informed consent.[287]

B-TYPE NATRIURETIC PEPTIDE AND NESIRITIDE (NATRECOR)

B-type natriuretic peptide (BNP) and its N-terminal precursor (NTpBNP) are members of the natriuretic peptide family. These peptides are released from the heart in response to pressure and

volume overload and play an important role in maintaining fluid balance and hemodynamic stability. BNP is secreted from cardiac ventricles in response to increased stimulation of cardiac stretch receptors and increased wall tension. It acts mainly via natriuretic peptide receptors (NPRs) that are present in large vessels and kidneys. Once stimulated, NPRs promote diuresis, natriuresis, and vasodilation and inhibit the renin-angiotensin-aldosterone system. BNP is used as a marker for heart failure in adults and as a monitor for the response to anticongestive heart failure therapies.[353] These markers are also increasingly used to diagnose cardiovascular disease in neonates, infants, and children. The concentrations of NTpBNP are often markedly increased immediately after birth but decrease during the first week of life. Age-adjusted cut points and reference values have been suggested.[354,355] Post hoc analysis of a large multicenter heart failure trial (Pediatric Carvedilol Trial) tried to establish prognostic cutoff values. In children with moderately symptomatic heart failure from cardiomyopathy or CHD, a BNP greater than or equal to 140 pg/mL was associated with worse outcomes.[356] Disease-specific cutoff points and their prognostic value, especially for congenital heart defects, are still under investigation.[357–359]

Nesiritide is a recombinant form of BNP and therefore acts via NPRs to promote diuresis, natriuresis, and vasodilation. Early investigations in the adult population suggested that nesiritide may be beneficial for patients with decompensated heart failure; it seemed to improve cardiac output, reduce pulmonary capillary occlusion pressure, and dilate arterial and venous vessels with only minimal increase in HR or myocardial oxygen consumption.[360–362] However, a large multicenter study found no significant advantages of nesiritide and only recommended its use as an individualized case-based therapy.[363] Empirical perioperative nesiritide or milrinone infusions were not associated with improved early clinical outcomes after Fontan surgery.[364] Although nesiritide reduces mean arterial pressure in children after cardiac surgery and has been used as adjunct therapy in children with biventricular failure, more extensive studies are required before its usefulness and safety in children can be determined.[365–372]

β-BLOCKING AGENTS

There are several indications for the use of β-blockers in children, including control of hypertension (both acutely in a perioperative period and chronically), treatment of cyanotic spells and RVOTO in TOF, reduction of left ventricular outflow tract obstruction (LVOTO) in hypertrophic cardiomyopathy, control of HR in thyrotoxicosis and pheochromocytoma, and control of SVT (see later discussion).[373–377] In contrast to the situation in adults, the use of β-blockers to treat chronic heart failure in children is controversial.[378] Important distinctions include β-receptor subtype selectivity, variability in half-life and metabolism, and intrinsic sympathomimetic activity. Even "selective" β-blockers lose their selectivity at increased plasma concentrations. Although the mechanism is incompletely understood, β-blocker use in children is associated with hypoglycemia.[379] Consequently, vigilance should be exercised during periods of fasting and illness as reflex adrenergic responses to hypoglycemia may be blunted.

Propranolol (Inderal, InnoPran)

Propranolol is one of the most frequently used β-blockers in children. Typical oral doses start at 0.25 to 0.5 mg/kg every 6 hours, titrated every 3 to 5 days; the usual dose is 2 to 4 mg/kg per day. A sustained-release form is available for older children who are able to swallow pills. IV propranolol is administered at doses of 0.01 to 0.1 mg/kg over several minutes; this may be increased if necessary (maximum dose 1 mg in infants, 3 mg in children). Sinus bradycardia and hypotension can be serious complications, particularly in infants or after IV administration. Propranolol may also cause conduction disturbances at the AV node and worsen pump function in congestive heart failure. Other important adverse effects include fatigue, depression, and lethargy. Interactions with the β_2-receptor may also exacerbate bronchospasm.[380] Propranolol is primarily metabolized in the liver. Significant population variability in its kinetics has been noted. Metabolism is also affected by factors that alter hepatic blood flow because it has perfusion limited clearance. Its major metabolite, 4-hydroxypropranolol, is also active.[374]

Atenolol (Tenormin)

The use of atenolol has been increasing in children.[377,381,382] Compared with propranolol, it is more selective for the β_1-adrenergic receptor subtype; the elimination half-life is 8 to 12 hours. There is little hepatic biotransformation, and there are no active metabolites. The typical starting dose is 0.8 to 1.5 mg/kg per day in one or two doses daily, with an upper limit in the range of 2 mg/kg per day. No IV form is available. Atenolol does not cross the blood-brain barrier, so some of the limiting adverse effects common to propranolol are absent. At large doses, β_1 selectivity is probably lost, leading to the potential to exacerbate bronchospasm and hypoglycemia.

Esmolol (Brevibloc)

Esmolol is a relatively selective β_1-adrenergic blocker with several unique features. Its onset is fast, it can easily be titrated to a desired endpoint, and its effects are rapidly terminated through metabolism by red blood cell and plasma esterases.[383,384] The drug has been particularly useful for the acute control of perioperative hypertension and for treatment of SVTs (see later discussion). Loading doses between 100 and 500 μg/kg given over 1 to 5 minutes are followed by maintenance infusions of 50 to 100 μg/kg per minute. If the desired response is not achieved, the infusion rate is then doubled every 5 minutes until a desired response is achieved.

Specific data on pediatric dosing are limited at present.[385] One study investigated the pharmacokinetics of esmolol therapy after an episode of stimulated or spontaneous SVT. The results were similar to the findings in the adult population.[386] Esmolol has been investigated to control blood pressure immediately after coarctation repair using 3 different bolus doses: 125 μg/kg, 250 μg/kg, and 500 μg/kg IV infused over 10 to 20 seconds, each followed by an infusion that consisted of the same dose as in the bolus every minute.[387] Blood pressure response and adverse events were similar among the groups. Clearance in neonates was twice that in older children (281 mL/kg per minute vs. 126 mL/kg per minute), consistent with other drugs cleared by plasma esterases (e.g., remifentanil).[387] The current maximum loading dose recommended is 500 μg/kg followed by an infusion rate of 25 to 300 μg/kg per minute.[388] A major potential adverse effect of esmolol is hypotension, particularly during bolus therapy. As noted earlier, esmolol rapidly distributes and has a very small elimination half-life (7-10 minutes) that is unaffected by organ blood flow or disease. Therefore, hypotension is usually short-lived, but therapy with vasopressors may occasionally be required until it resolves.[389,390]

Labetalol (Normodyne, Trandate)

Labetalol has nonselective β-adrenergic blocking properties and is also a selective α-adrenergic receptor blocker. The ratio of α- to

β-blockade efficiency is 1 : 3 and 1 : 7 after oral and IV administration, respectively. The primary use of labetalol in children is to control hypertension. The drug has been given by IV to treat hypertensive crisis, to control hypertension after aortic coarctation repair, and as an adjunct to induce controlled hypotension during surgery.[391–394] Typical doses are 0.1 to 0.4 mg/kg given every 5 to 10 minutes until the desired effect is achieved with infusions of 0.25 to 1 mg/kg per hour. The elimination half-life of labetalol is 3 to 5 hours.

Carvedilol (Coreg)

Carvedilol is a nonselective β-blocker with additional vasodilator and some antioxidant properties.[395,396] The ratio of α_1 to β_1 blockade is 1 : 1.7. It is primarily used for the treatment of heart failure. In adults, significant benefit has been demonstrated, including reduced mortality, reduced hospital stay, improved New York Health Association (NYHA) functional class, and a somewhat reduced progression of the clinical disease.[397] However, a randomized, double-blind, placebo-controlled, multicenter study of children and adolescents with symptomatic systolic heart failure found no significant differences in outcome between carvedilol and placebo during an 8-month follow-up period.[398] Nevertheless, carvedilol is often prescribed after an episode of acute decompensation in patients with cardiomyopathy.[399] Carvedilol may have differential effects based on ventricular morphology, and further studies are necessary.[400–403] A retrospective review of the initial experience with carvedilol therapy in children showed that adverse effects—mainly dizziness, headaches, and hypotension—were common (>50%) but well tolerated.[404] The ideal dose in children has not yet been determined. Pharmacokinetic simulation studies suggest that larger doses[405] than those used in adults are warranted, although clinical experience in small patient populations favors smaller doses and gradual dose adjustments with frequent echocardiographic and BNP monitoring.[403]

VASODILATORS

Vasodilators are used in children to control blood pressure during and after surgery, to treat systemic and pulmonary hypertension, and to decrease afterload on either the systemic or the pulmonary ventricle, thereby improving pump function. Vasodilators are also administered during CPB to reduce SVR, improve regional perfusion, and facilitate rapid and even core cooling and rewarming.

Vasodilators can be divided into pharmacologic groups. Direct-acting nitrosovasodilators such as sodium nitroprusside (SNP) and nitroglycerin (NTG) are the most commonly used cardiovascular medications. These drugs relax vascular smooth muscle to cause vasodilation by directly (SNP) or indirectly (NTG), releasing NO that subsequently activates smooth muscle soluble guanylyl cyclase to form cyclic guanosine monophosphate (cGMP). Nicardipine is a dihydroxypyridine calcium channel blocker that is highly selective for calcium channels in the coronary and peripheral vasculature. It is an effective vasodilator with minimal effects on HR and contractility and is often used as a longer-acting alternative to SNP. Hydralazine is another direct-acting smooth muscle vasodilator that is occasionally given to children to reduce blood pressure. Selective α-adrenergic blockers, such as phentolamine and phenoxybenzamine, are occasionally used to reduce blood pressure and SVR in the perioperative period. The classic indication is the treatment of pheochromocytoma, but they are also frequently given during hypothermic CPB.

Ventricular "remodeling" and long-term blood pressure control is often achieved with angiotensin-converting enzyme (ACE) inhibitors. Prostaglandin E_1 (PGE_1) is a direct-acting vasodilator primarily used to maintain the patency of the ductus arteriosus in duct-dependent circulations. In contrast, prostacyclin and inhaled NO are vasodilators with relatively selective effects on the pulmonary vasculature. Commonly used vasodilators and antihypertensive agents are summarized in Table 18.9.

Sodium Nitroprusside (Nipride, Nitropress)

The primary indication for SNP is the rapid and reliable reduction of afterload and blood pressure before, during, and after a wide variety of procedures. For example, it is used to control intraoperative and postoperative hypertension in children with aortic coarctation and other forms of LVOTO. The reduction in afterload may improve performance of a dysfunctional ventricle, particularly in combination with a positive inotropic agent.[406,407] The ability of nitroprusside to successfully treat pulmonary hypertension is variable and may be age dependent.[408–412]

SNP is an extremely potent vasodilator that acts directly on smooth muscle to cause dilation.[413,414] Its effects reduce cardiac preload as well as afterload. Onset of effect is fast (within minutes), and offset is similarly rapid; the effect ends within 1 to 2 minutes after termination of the infusion. Because of its potency, it should always be administered using an infusion pump in conjunction with continuous direct arterial pressure monitoring. The starting dosage is 0.3 to 1 μg/kg per minute. This can be increased or decreased to achieve the desired effect. The titration of nitroprusside to achieve specific blood pressure goals can be rather frustrating and often results in large blood pressure swings.[415] A recent multicenter, randomized, double-blinded dose-ranging trial developed a population-based pharmacokinetic/pharmacodynamic model and presented dosing guidelines. A starting dose of 0.3 μg/kg per minute, small dose adjustments, and slow weaning are recommended to avoid significant hypotension or rebound hypertension.[416,417] The hypotensive effects of nitroprusside are potentiated by hypovolemia, inhalation anesthetics, and drugs that inhibit the reflex responses to direct vasodilation (e.g., increase in sympathetic tone, renin release), such as propranolol and ACE inhibitors.

Adverse effects of SNP include cyanide and thiocyanate toxicities, rebound hypertension, inhibition of platelet function, and increased intrapulmonary shunting via attenuation of hypoxic pulmonary vasoconstriction. Rebound hypertension is most likely caused by activation of the aforementioned reflex mechanisms. This effect is minimized by slowly tapering the infusion rather than abruptly discontinuing it. Toxicity may occur when more than 10 μg/kg per minute of SNP is administered, if tachyphylaxis develops within 30 minutes, or if there is immediate resistance to the drug. A blood cyanide concentration of approximately 500 μg/dL has been linked to a death in a child,[418] but subsequent studies showed that increased concentrations of cyanide were not necessarily associated with the clinical signs of cyanide toxicity.[419,420] Cyanide and thiocyanate toxicities are rare but may be more likely in neonates and young infants and in those with impaired hepatic or renal function.[418,421]

Cyanide is produced from the metabolism of SNP. Free cyanide is then conjugated with thiosulfate by rhodanase in the liver to produce thiocyanate. A major mechanism of cyanide toxicity is binding to cytochrome oxidase in the mitochondrial electron transport chain, which prevents mitochondrial respiration and ATP production. Signs of toxicity include tachyphylaxis and an increase in mixed venous oxygen saturation and metabolic acidosis. In children who have received prolonged (>24 hours)

TABLE 18.9 Antihypertensives and Vasodilators[a]

Drug	Intravenous Dose	Comments
Propranolol	0.01–0.1 mg/kg slowly	Nonselective β-blockade; bradycardia, hypotension, worsening of myocardial pump function; atrioventricular block; hypoglycemia; bronchospasm; depression; fatigue
Labetalol	0.1–0.4 mg/kg per dose; 0.25–1.0 mg/kg per hour infusion	Nonselective β-blockade; selective α-blockade; ratio of α- to β-blockade is 1:7 for intravenous form; doses (0.1 mg/kg) can be repeated every 5–10 minutes until desired effect is achieved; side effects are similar to those of propranolol.
Esmolol	100–500 μg/kg loading dose (over 5 min); 50–250 μg/kg per minute infusion	Relatively selective β-blockade; short elimination half-life (7–10 minutes); hypotension, especially during bolus administration; if less than desired response after 5 minutes, can repeat or double bolus dose, followed by doubling infusion rate; non–organ-based metabolism by plasma and red blood cell esterases; infusion concentrations >10 mg/mL may predispose to venous sclerosis; dilute infusion at high rates increases risk of volume overload.
Sodium nitroprusside	Start at 0.3–1.0 μg/kg per minute infusion; maximum 6–10 μg/kg per minute	Potent direct smooth muscle relaxation; dilates both arteriolar resistance and venous capacitance vessels; hypotension potentiated by hypovolemia, inhalation anesthetics, other antihypertensives; variable pulmonary vasodilation; potential cyanide toxicity; reflex tachycardia; check cyanide and thiocyanate levels if >4 μg/kg per minute is infused or drug is used longer than 2–3 days.
Nitroglycerin	0.5–10 μg/kg per minute infusion	Direct smooth muscle relaxation; predominantly dilates venous capacitance vessels, modest effects on arterial resistance at larger doses; weak antihypertensive effects; variable pulmonary vasodilation; used to facilitate cooling and rewarming during cardiopulmonary bypass.
Nicardipine	Start at 0.5–1 μg/kg per minute infusion; maximum 4–5 μg/kg per minute	Dihydroxypyridine calcium channel blocker: primary effects on coronary and peripheral vasculature, predominantly vasodilation, minimal effects on heart rate and contractility. Hypotension potentiated by inhalational agents. Potentiation of neuromuscular blockers. Prolonged effects after discontinuation.
Phentolamine	0.05–0.1 mg/kg dose; 0.5–5 μg/kg per minute infusion	Selective α-blocker, produces mainly arteriolar vasodilation; some direct vasodilation with mild venodilation.
Enalaprilat	5–10 μg/kg per dose q8–24 hours	Long duration of effect; angioedema, renal failure, hyperkalemia; potential problematic hypotension with anesthetic agents (see text).
Hydralazine	0.1–0.2 mg/kg bolus q6 hours	Maximum 20 mg/dose; direct-acting smooth muscle (predominantly arteriolar) vasodilation; long effective half-life; tachyphylaxis; reflex tachycardia; lupus-like syndrome; drug fever; thrombocytopenia.
Prostaglandin E1	0.05–0.1 μg/kg per minute infusion	Direct smooth muscle relaxation, relatively specific for ductus arteriosus; variable pulmonary and systemic vasodilation; apnea in neonates.

[a]All drugs should be started in the lower dose range and titrated to effect.

or large-dose infusions of nitroprusside and in those with organ dysfunction, it may be advisable to measure blood cyanide concentrations.[420,422–425] Serum thiocyanate concentrations may also be measured. Thiocyanate concentrations may increase if renal function is abnormal. Central nervous system (CNS) dysfunction can occur when thiocyanate concentrations reach 5 to 10 mg/dL. Treatment of cyanide toxicity consists of IV infusion of sodium nitrite, 6 mg/kg (maximum dose 300 mg) over 5 minutes, and sodium thiosulfate, 250 mg/kg or 7 g/m^2 (maximum dose 12.5 g) over 15 minutes. In children with abnormal renal function in whom stimulating the production of thiocyanate from thiosulfate may be contraindicated, administration of hydroxocobalamin has been recommended.[426,427]

Nitroglycerin (Nitronal, Nitro-Bid)

Nitroglycerin is primarily a venodilator that acts on venous capacitance vessels. It has a substantially smaller effect on arteriolar smooth muscle, and its ability to attenuate an increased PVR is variable. Compared with nitroprusside, it is a poor antihypertensive agent. It has a brief half-life and no significant toxic metabolites. Similar to nitroprusside, it may increase intrapulmonary shunting and cause platelet dysfunction. Nitroglycerin is typically administered in doses of 0.5 to 3.0 μg/kg per minute. Effects occur within 2 minutes after nitroglycerin is started and resolve within 5 minutes after discontinuation. Mild decreases in blood pressure may be observed at doses exceeding 2 to 3 μg/kg per minute. In case of prolonged simultaneous infusions of nitroglycerin and nitroprusside, methemoglobin and cyanmethemoglobin levels can accumulate.[428]

Nitroglycerin is frequently used during CPB to facilitate rapid and effective cooling and rewarming and to improve tissue blood flow. Nitroprusside and nitroglycerin differ substantially with regard to their effects on the microcirculation. Because nitroprusside primarily reduces arteriolar tone and dilates precapillaries, it decreases microvascular blood flow and tissue perfusion more than nitroglycerin does, particularly in the presence of reduced arterial blood pressure (e.g., during CPB).[429] In contrast, nitroglycerin dilates precapillaries and postcapillaries with equal efficacy, thereby maintaining stable or enhanced capillary perfusion.[430,431]

Nicardipine (Cardene)

Nicardipine was the first available IV dihydroxypyridine calcium channel blocker and has been used to treat hypertension in children of all ages for over 20 years. Compared with nifedipine, nicardipine has a greater selectivity for calcium channels in the coronary and peripheral vasculature, resulting in predominant vasodilation and only minimal effects on HR and contractility.[432,433] Many adult studies investigated nicardipine for perioperative blood pressure

control,[434–437] but only limited pediatric data are available, derived mainly from small case series and observational reports.[438–441] Nicardipine has been successfully used to control hypertension in preterm infants and neonates.[439,442,443] Given as a continuous infusion at an initial rate of 0.5 to 1 μg/kg per minute, the rate is slowly increased every 15 to 30 minutes until the target blood pressure is reached. Usual doses range from 1 to 3 μg/kg per minute, with a maximum dose of 4 to 5 μg/kg per minute[438,444,445]; 50% of the maximum change occurs within 45 minutes. In one retrospective study in children, it took an average of 2.7 ± 2.1 hours (range 0.5–9 hours) to achieve blood pressure control with this dosing regimen.[438] An alternative high-dose approach has been described, starting with an initial dose of 5 to 10 μg/kg per minute and followed by a smaller maintenance dose of 2 to 3 μg/kg per minute (range 1–5 μg/kg per minute) once the blood pressure is well controlled.[446,447] Nicardipine is extensively metabolized in the liver (cytochrome P450, isoenzyme CYP3A4) and excreted in urine and feces. An adult two-compartment pharmacokinetic model revealed an α-half-life of 2.7 minutes, a β-half-life of 44.8 minutes, and a slow terminal phase (γ-half-life) of 14.4 hours, contributing to the prolonged effects of nicardipine. After discontinuing the infusion, the antihypertensive effects decrease by 50% within the first 30 minutes but can be present for up to 50 hours. Clearance is affected by hepatic dysfunction. Commonly seen adverse effects are mild reflex tachycardia, flushing, nausea and vomiting, or phlebitis at the infusion site.[438] In contrast to nitroprusside, there is no tachyphylaxis, and nicardipine can be administered for extended periods of time without accumulation of toxic metabolites. Interactions with inhalational anesthetic agents and neuromuscular-blocking drugs should be considered during intraoperative use.[448] Inhalational anesthetics blunt the baroreflex mediated increase in HR and increase the hypotensive effects of nicardipine[449]; the effects of depolarizing and nondepolarizing neuromuscular-blocking drugs will be potentiated by the calcium channel blocker and should be closely monitored.[450] In the United States, due to the limited availability and high costs of nitroprusside, nicardipine is increasingly used as a substitute.

Phentolamine (Regitine, OraVerse) and Phenoxybenzamine (Dibenzyline)

Both phentolamine and phenoxybenzamine are α-adrenergic blocking agents with little selectivity for α-receptor subtypes. Their primary effect is to decrease resistance on the arterial side of the circulation, although both possess weak venodilating capabilities. Phentolamine is usually administered by infusion at 0.5 to 5 μg/kg per minute, whereas phenoxybenzamine is administered orally initially 0.2 mg/kg once daily, then slowly increased every 4 days by 0.2 mg/kg per day. The usual maintenance dose is 0.4 to 1.2 mg/kg per day divided in three doses. The elimination half-life of phenoxybenzamine is much greater than that of phentolamine. Some cardiovascular centers have found the potent arteriolar-dilating effects of phenoxybenzamine and its prolonged elimination half-life to be advantageous, especially to provide adequate vasodilation during deep hypothermic CPB.[451–455]

Angiotensin-Converting Enzyme Inhibitors

ACE inhibitors are administered to children with increasing frequency.[456–458] In the perioperative setting, they are given to control blood pressure after aortic coarctation repair or to relieve LVOTO. In addition, ACE inhibitors are given on a more long-term basis to reduce afterload on the systemic ventricle and to improve ventricular performance in children with congestive heart failure or single ventricle physiology.[293,399,459] Among the growing number of ACE inhibitors, captopril, enalapril, and lisinopril are most often used in children, although data in children are scant. Adverse effects common to all ACE inhibitors include angioedema, acute renal failure, and hyperkalemia; case reports of substantive complications have been published.[460–462] Cyanosis and coadministration of furosemide are independent risk factors for acute kidney injury in children undergoing cardiac surgery who were treated with ACE inhibitors.[463]

The contribution of ACE inhibitors to anesthetic-induced hypotension remains controversial.[464–468] Angiotensin receptor–blocking agents such as losartan and lisinopril can produce significant and refractory hypotension with standard anesthetic induction techniques.[469] Because of the potential risk for substantive refractory hypotension that is usually unresponsive to volume expansion and requires substantial vasoconstrictor treatment, it is our practice to discontinue long-acting ACE inhibitors 1 day before surgery.

Captopril (Capoten)

Captopril has a relatively brief elimination half-life (<2 hours); clearance is by metabolism in the liver (captopril-cysteine disulfide and the disulfide dimer) and excretion by the kidney.[470] Oral dosing in neonates is 0.05 to 0.1 mg/kg every 8 to 24 hours, titrated up to 0.5 mg/kg every 6 to 24 hours. Infants initially receive 0.15 to 0.3 mg/kg every 6 to 8 hours. This can be titrated toward a maximum dose of 6 mg/kg per day in four divided doses. Oral dosing in older children is 0.3 to 0.5 mg/kg every 6 to 12 hours. The brief duration of effect, necessitating more frequent dosing, has led to increased use of the longer-acting ACE inhibitors (enalapril and lisinopril) in children.

Enalapril (Vasotec, Epaned)

Enalapril is metabolized in the liver to its active form, enalaprilat. Enalapril is the only ACE inhibitor currently available in the United States that has an IV formulation. It can be given orally, once or twice daily, with daily doses ranging between 0.1 and 0.5 mg/kg. The IV dose is 0.005 to 0.01 mg/kg per dose, one to three times a day.[456] Both enalapril and lisinopril are eliminated by the kidney. The duration of their hypotensive actions averages 24 hours but can extend to 30 hours.

Losartan (Cozaar)

Losartan blocks selectively angiotensin II type 1 (AT1) receptors. In children, it is used mainly in the treatment of proteinuria and hypertension associated with renal disease and seems to be well tolerated.[471–475] Lorsartan may also help to slow the rate of aortic root dilation in patients with Marfan syndrome.[476]

Hydralazine (Apresoline)

In the past, hydralazine was frequently used for long-term blood pressure control in children, but has been largely replaced by ACE inhibitors. In contrast to its effect in adults, its ability to decrease pulmonary hypertension in children was disappointing.[477] Hydralazine directly relaxes smooth muscle without known effects on receptors. It reduces cardiac afterload but may cause significant reflex tachycardia. With long-term use, it may also cause fluid retention, requiring concurrent administration of a diuretic. Oral dosing is in the range of 0.75 to 1 mg/kg per day divided in 2 to 4 doses and is slowly increased over 3 to 4 weeks to a maximum dose of 5 mg/kg per day for infants and 7.5 mg/kg per day for children. In the perioperative setting, it is occasionally used by

the IV route to control blood pressure and reduce afterload. IV doses are administered as a bolus of 0.1 to 0.2 mg/kg not to exceed 20 mg. The effects of IV hydralazine on PVR are variable.[477,478] Tachyphylaxis to the antihypertensive effects of IV hydralazine may occur. Important adverse effects include a drug-related fever, rash, pancytopenia, and lupus-like syndrome. The elimination half-life of the drug is approximately 4 hours, but the effective biologic half-life may be substantially longer because of significant binding of the drug to vascular smooth muscle.[479]

Prostaglandin E_1 (Alprostadil, Prostin)

The major indication for PGE_1 is to establish or maintain patency of the ductus arteriosus in neonates. It is best able to reopen a closing ductus in neonates up to 1 to 2 weeks of age but may occasionally be effective even in older infants.[21,480]

Ductal patency is important and often lifesaving for duct-dependent circulations–those in which either the lower body is supplied by right-to-left ductal flow (e.g., interrupted aortic arch, critical aortic stenosis, HLHS) or the PDA is the sole provider of pulmonary blood flow (e.g., pulmonary atresia, tricuspid atresia, severe TOF). Adverse effects of PGE_1 include systemic hypotension, apnea, increased risk of infection, leukocytosis, gastric outlet obstruction, and CNS irritability.[481–483] PGE_1 infusions usually start at 0.05 µg/kg per minute and may be increased to 0.1 µg/kg per minute or more; maintenance infusions range from 0.003 to 0.01 µg/kg per minute.[484,485] The risk of apnea may be related to the infusion rate. Tracheal intubation and ventilation are often required with infusion rates greater than 0.05 µg/kg per minute.[486,487] Prophylactic treatment with aminophylline was found to be effective in reducing the apnea risk.[488] Caffeine may also prove useful for those with apnea. PGE_1 has also been used to treat primary or acquired pulmonary hypertension with varying degrees of success.[489–492]

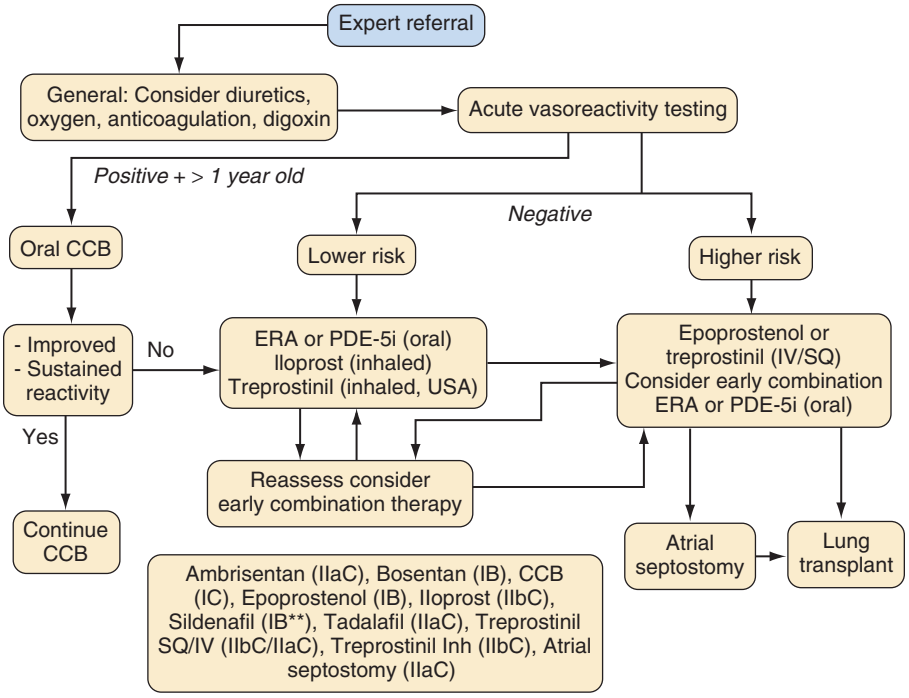
Inhaled Nitric Oxide (Inomax)

An important development in the treatment of pulmonary hypertension is inhaled NO gas, which can be delivered directly to the pulmonary circulation. NO is an endothelium-derived relaxing factor that acts on guanylate cyclase in vascular smooth muscle.[493] Endogenous NO is produced by endothelial cell NO synthase. NO synthases convert the amino acid L-arginine into NO and the by-product L-citrulline. NO then diffuses into the subjacent vascular smooth muscle. It produces relaxation by acting on smooth muscle guanylate cyclase to produce cGMP, which acts on a series of protein kinases and reduces intracellular calcium levels to inhibit muscle contraction (see Fig. 37. 3A and B). Diffusion of NO in the other direction from the endothelial cell into the blood vessel lumen can decrease the adhesiveness of white blood cells and platelets. NO in the blood is rapidly bound by oxyhemoglobin, which is then oxidized to methemoglobin. From this reaction, NO is inactivated and nitrite and nitrate are released in the blood. Red blood cell methemoglobin is subsequently reduced back to hemoglobin. The rapid binding and inactivation of NO in the blood means that inhaled NO has a minimal effect on the systemic circulation and functions as a very specific pulmonary vasodilator.

Significant reductions in PVR from inhaled NO have been demonstrated in adults with mitral stenosis, in neonates with persistent pulmonary hypertension of the neonate, in lung transplant recipients, and in children after surgical repair of a variety of CHDs.[494–498] The efficacy of inhaled NO is in large part related to the ability to deliver it into the alveolus, which is in close proximity to the pulmonary vascular smooth muscle.

Inhaled NO has found several indications in children with CHD. In the cardiac catheterization laboratory, it is used to assess the reactivity of the pulmonary vasculature in children with pulmonary hypertension. This can help distinguish between children with fixed pulmonary vascular obstructive disease and those with a reversible component to pulmonary hypertension, thereby facilitating therapeutic management and operative planning.[499–501]

In the postoperative period after the repair of CHD, NO can be used to reduce PVR and improve cardiopulmonary performance.[502–504] Experience thus far suggests that children with two ventricles who have increased LA pressure or its pathophysiologic equivalent (e.g., mitral stenosis, severe congestive heart failure, cardiomyopathy, large left-to-right shunt, TAPVR) are more likely to respond to NO in the postoperative period. Some children who do not respond to NO immediately after CPB in the operating room demonstrate significant reductions in PVR with NO several hours later. NO is administered in concentrations of 1 to 80 ppm in oxygen via a special delivery device attached to the ventilator or oxygen delivery system. Inspired gas is monitored for toxic nitrogen oxides; during long-term therapy with NO, blood methemoglobin concentrations should be assessed on a regular basis.[505]



Prostanoids

Members of the prostacyclin and prostaglandin families are often classified as *prostanoids*. All prostanoids are potent vasodilators and inhibitors of platelet aggregation. Since the 1980s, they have been used in the treatment of PA hypertension and are part of the official treatment guidelines (E-Fig. 18.4, E-Table 18.5),[506–509] even though they are not selective pulmonary vasodilators. Common adverse effects include flushing, hypotension, headache, jaw pain, skin rash, nausea and diarrhea, and nonspecific musculoskeletal pains. Tolerance can develop over time, requiring increasing doses.[510] In the United States, only three prostanoids are currently approved by the Food and Drug Administration (FDA): epoprostenol (Flolan), treprostinil (Remodulin), and iloprost (Ventavis). Beraprost is an oral prostacyclin analog licensed in Japan and still being investigated.

Epoprostenol (Flolan, Veletri)

Continuous IV infusion of epoprostenol has been used effectively for many years in children with PA hypertension of any cause. It improves hemodynamics by reducing PA pressure, increasing cardiac output, increasing oxygen transport, and improving symptoms such as exercise capacity and dyspnea.[511] It has been used with excellent results in the treatment of primary pulmonary hypertension and irreversible acquired pulmonary hypertension in CHD; in children awaiting heart, lung, or heart-lung transplantation; in children with primary pulmonary hypertension; in neonates with persistent pulmonary hypertension; and in pulmonary hypertensive crises.[512–520] The fact that children who were initially nonresponders may respond after prolonged use of NO suggests that its mechanism of action involves a degree of remodeling, although no absolute mechanism has been elucidated.

Unfortunately, epoprostenol is chemically unstable at room temperature and has a half-life of 6 minutes or less; it requires cooling for storage, continuous IV infusion via a central venous catheter, and a specific delivery system. Rapid and unintended decreases in the rate, dislodgments or occlusions of the central venous catheter, or pump malfunctions can lead to severe and life-threatening rebound pulmonary hypertension.[521,522] The infusion is usually started at 1 to 2 ng/kg per minute and gradually increased over several months to doses between 30 and 80 ng/kg per minute.

In patients with pulmonary venous disease, IV epoprostenol can worsen the pulmonary edema; it can also increase the ventilation/perfusion mismatch in patients with pneumonia and thereby negatively affect oxygenation. In the acute setting, epoprostenol is increasingly used in the inhaled form to benefit from the selective pulmonary vasodilation and reduction of ventilation/perfusion mismatch.[510,523–525] Some centers have used inhaled epoprostenol as an alternative to the rather expensive NO, although the currently available delivery systems are far from ideal and may alter the delivered tidal volumes.[510]

Treprostinil (Remodulin)

Treprostinil was first introduced in 2002, initially only for continuous subcutaneous infusion, but later also for IV infusion in patients who could not tolerate the pain at the subcutaneous infusion site. The hemodynamic effects are similar to those of epoprostenol, with fewer adverse effects.[526–529] IV infusions of treprostinil are started at 1 to 2 ng/kg per minute and slowly increased over several weeks to 40 ng/kg per minute, occasionally even higher doses (80-120 ng/kg per minute) are used. One pediatric study confirmed the effectiveness of IV treprostinil in children.[530] Since 2009, inhaled treprostinil has been used for long-term outpatient management. Because of the relatively short half-life, it must be administered every 6 hours.[531–534] More recently a sustained release oral form of treprostinil has been investigated. In adults, it showed some promising effects in treatment-naïve patients but failed to demonstrate significant long-term improvements in more advanced disease stages.[535–538] Side effects were common and included headaches, nausea, diarrhea, and flushing. The initial dose for adults is 0.25 mg every 12 hours or 0.125 mg every 8 hours. If more than two doses are missed (prolonged NPO status owing to gastrointestinal symptoms or surgical procedure), appropriate treatment with subcutaneous or IV treprostinil has to be initiated. Pediatric data are not yet available.

Iloprost (Ventavis)

Iloprost, approved by the FDA in 2004, is another prostaglandin I_2 analog that can be delivered by IV or via an ultrasonic nebulizer. It has a very brief elimination half-life of only 7 to 9 minutes, although its clinical efficacy is greater, with a half-life of 20 to 25 minutes. Frequent nebulized treatments (6 to 9 times each day) are required.[539] In adult studies, iloprost was shown to be beneficial in patients with PA hypertension of any cause, idiopathic PA hypertension, or chronic thromboembolic pulmonary hypertension. These patients demonstrated improvements in hemodynamics and in subjective parameters such as quality of life scores.[540–542] Studies in children are scarce and have involved only small numbers of patients, although numerous case reports are encouraging.[510,543–550] Long-term effects and compliance are still under investigation.[551] When iloprost and NO were compared in children with CHD, the two agents produced similar effects.[552] In one study, combination therapy using both systemic and inhaled prostacyclin analog showed promise.[553] It has also been successfully used in the perioperative management of CHD patients with pulmonary hypertension[554] and for the postoperative transition from inhaled NO to an inhaled prostacyclin.[555] A study in lambs demonstrated an enhanced effect of prostacyclin and iloprost when combined with milrinone.[286]

Beraprost (Careload)

Beraprost sodium is an oral prostacyclin analog that is chemically more stable and has a prolonged elimination half-life but nevertheless requires dosing three to four times per day, reaching its peak blood concentration at 30 minutes. Two double-blind studies showed no significant long-term benefit, but there may still be a role for this drug in combination therapy, because improvements have been observed in the exercise capacity of children with idiopathic PA hypertension.[556,557] Case reports of successful long-term treatment with beraprost and of combination therapy using oral beraprost and inhaled prostacyclin have been published.[553,558–560] Another case series described the use of beraprost for the treatment of persistent pulmonary hypertension in newborns.[561]

Endothelin Receptor Antagonists

Endothelin 1 is a potent vasoconstrictor that is thought to be a key factor in the pathogenesis of PA hypertension. There are two known receptors on which it acts: endothelin A and endothelin B. Endothelin A receptors are present on smooth muscle cells, and agonist action causes vasoconstriction; endothelin B receptors are present on endothelial cells, and agonist action causes both relaxation and vasoconstriction through different pathways. In addition, endothelin B receptors are involved in the clearance of endothelin.

Bosentan (Tracleer)

Bosentan is an oral, nonselective endothelin-receptor antagonist. Adult studies have shown long-term benefit in patients with PA hypertension. It can also improve exercise capacity in adolescent and adult patients with a Fontan circulation.[562] Bosentan can cause abnormal liver function test results, although no severe liver dysfunction has been reported in adults.[563–567] Two studies in children showed both short-term reduction in PA pressure and PVR and longer-term improvement in symptoms and stabilization of the disease process.[511,568] In addition, three studies have suggested that the dose for children weighing more than 10 kg could largely follow adult guidelines, with the total daily dose not exceeding 125 mg. There is growing evidence, although few controlled studies, suggesting that bosentan is an effective and well-tolerated therapy in children.[569–571] Compared with the results in adult studies, hepatic dysfunction was less frequently reported but was still the most common adverse effect.[572–575]

Ambrisentan (Letairis)

Ambrisentan is a selective endothelin A receptor antagonist that has been extensively studied in the adult population.[576–578] It seems to be associated with an increased incidence of peripheral edema but a lower risk for liver dysfunction.[579,580] The pediatric experience is limited but ambrisentan could be a safe and effective treatment alternative for some children with pulmonary arterial hypertension.[581]

Sildenafil (Viagra)

Sildenafil is a selective inhibitor of phosphodiesterase type 5, the isoform that is responsible for hydrolysis of cGMP in the pulmonary vasculature. By preventing the breakdown of cGMP, sildenafil increases cGMP concentrations and potentiates the pulmonary vasodilation caused by endogenous NO.[582–584] Sildenafil can also have positive effects on the ventricular contractility in patients with pulmonary hypertension because phosphodiesterase type 5 is highly expressed in the hypertrophied human right ventricle.[585] It has a long-standing track record in the adult population.[586–591] In the pediatric population, sildenafil is currently used as an adjunctive agent during weaning from NO, in the treatment of PA

hypertension, for patients with congenital diaphragmatic hernia, for the perioperative management of patients after cardiac surgery, and also for persistent pulmonary hypertension of the newborn.[48,592–603] The benefit of combining oral sildenafil with inhaled iloprost for the treatment of severe pulmonary hypertension has also been demonstrated.[604] Most of the pharmacokinetic data for sildenafil are derived from adult studies with oral dosing. Sildenafil is rapidly absorbed; the bioavailability is 38% to 41% in the fasted state; and the maximum plasma concentration is achieved after 0.5 to 2.5 hours. It is highly metabolized in the liver into active metabolites. With a half-life of only 2 to 4 hours, sildenafil is relatively short-acting. Clearance decreases in patients with severe renal or hepatic dysfunction. Compared with healthy volunteers, patients with pulmonary hypertension have reduced clearance and greater bioavailability.[605–610] In adult patients, a 10-mg IV bolus and a 20- mg oral tablet have comparable effects.[611] According to in vitro studies, plasma concentrations of 50 to 400 ng/mL are necessary to provide a 50% to 90% inhibition of phosphodiesterase 5 activity.[612,613] Only a few pediatric pharmacokinetic studies are available. Children (1–17 years of age) with PA hypertension given oral sildenafil had a relatively high oral clearance.[614] Investigations in neonates demonstrated a larger volume of distribution, greater elimination half-life, and a rapidly increasing age-dependent metabolic clearance over the first month of postnatal life.[615,616] Oral therapy usually begins with 0.25 to 0.5 mg/kg every 4 to 6 hours with increasing doses as tolerated.[598,617,618] The IV use of sildenafil has been investigated in premature infants, neonates with persistent pulmonary hypertension, and children after congenital cardiac surgery.[48,619–622] Case reports of sublingual use of sildenafil have also been published.[623] Sildenafil seems to be well tolerated; the most commonly reported adverse effects are headache, fever, respiratory infections, vomiting, and diarrhea,[614] but serious adverse events such as pulmonary hemorrhage, stridor or hypotension have been occasionally observed.[572,614,624] In 2012, the results of a randomized, double-blind, placebo-controlled clinical trial (STARTS-1) investigating three different dose regiments of oral sildenafil for treatment-naïve children with pulmonary arterial hypertension were published. Body weight–adjusted groups were treated for 16 weeks with placebo, small- (10 mg tid), medium- (10-40 mg tid), or large-dose (20-80 mg tid) sildenafil. The effect was greater with the medium- and large-dose ranges.[614] A follow-up study (STARTS-2) after 2 years of treatment found an increased risk of mortality for the large-dose group,[625] which triggered the release of an FDA warning against the chronic use of sildenafil for children aged 1 to 17 years. The European Medicines Agency warned only against the use of large doses. The current controversy among pediatric cardiologists regarding the safety of sildenafil was fueled by several publications, which questioned the START-2 results.[624,626–628] In 2014, the FDA issued another statement clarifying that the risk-benefit profile of sildenafil might be acceptable for selected children in special situations. Oral phosphodiesterase 5 inhibitors are currently still part of the treatment guidelines for pulmonary hypertension in children.[506,508]

Cialis is another selective phosphodiesterase 5 inhibitor. Compared with sildenafil, it has a greater duration of action, which permits once-daily dosing. The initial experience in pediatric patients is promising.[629,630]

ANTIARRHYTHMIC AGENTS

Antiarrhythmic agents have been traditionally categorized according to the Vaughan Williams classification, which is based on the presumed primary mechanism of action. For example, class I agents are sodium channel blockers. They are also called membrane-stabilizing agents because of their ability to decrease the excitability of the plasma membrane. Class I drugs can be subdivided into class IA, IB, or IC agents depending on their effects on the cardiac action potential (Table 18.10). Many antiarrhythmic drugs have multiple mechanisms of action and are therefore difficult to classify. Commonly used IV antiarrhythmic agents for children are described in Table 18.11.

Procainamide (Pronestyl)

Procainamide is one of the most commonly used class IA agents in children. It has sodium channel and moderate potassium channel blocking activities (class III effect). Its major effect is to delay repolarization. This effect is more pronounced at faster HRs. IV procainamide is used to treat SVT associated with the Wolff-Parkinson-White syndrome, atrial flutter, and ventricular dysrhythmias unresponsive to lidocaine.[631–634] It may also be effective in postoperative junctional ectopic tachycardia.[635,636] In addition, electrophysiologists use it as a "procainamide challenge" to unmask the characteristic electrocardiographic changes of Brugada syndrome.[637]

Procainamide is the only class IA agent that is still clinically used in children, mainly for short-term IV therapy. A loading dose of 3 to 10 mg/kg is given over 30 to 60 minutes to infants

TABLE 18.10 Vaughan Williams Classification of Antiarrhythmic Drugs

Class	Mechanism	Examples
I	Sodium channel blockers	
IA	Increase length of action potential	Procainamide Quinidine Disopyramide
IB	Decrease length of action potential	Lidocaine Mexiletine Phenytoin
IC	No effect on length of action potential	Flecainide Propafenone
II	β-Blockers	Propranolol Atenolol Metoprolol Esmolol
III	Potassium channel blockers	Amiodarone Sotalol Bretylium Ibutilide Dofetilide Dronedarone
IV	Calcium channel blockers	Verapamil Diltiazem
V	Other or unknown mechanism	Adenosine Digoxin Magnesium sulfate

TABLE 18.11 Intravenous Antiarrhythmic Agents

Agent (Vaughan Williams Class)	Dose	Comments
Procainamide (IA; sodium ± potassium channel blockade; antivagal effects)	Infant (<1 year): 3–10 mg/kg loading dose over 30 minutes Child (>1 year): 5–15 mg/kg loading dose over 30 minutes All ages, infusion rate: 20–80 μg/kg per minute	Used to treat SVT due to WPW, atrial flutter, junctional ectopic tachycardia (with patient hypothermia), lidocaine-resistant ventricular dysrhythmias; hypotension and negative inotropy; lupus-like syndrome.
Lidocaine (IB; sodium channel blockade; speeds repolarization)	1 mg/kg bolus; then 20–50 μg/kg per minute	Used for ventricular dysrhythmias; CNS toxicity (apnea, seizures, abnormal sensations).
Phenytoin (IB)	1–3 mg/kg q5 minutes up to 15 mg/kg loading dose, then 5–10 mg/kg divided q6 hours	Drug must be infused slowly (>30 minutes) due to potential hypotension; antidysrhythmic profile similar to that of lidocaine; may be useful to treat digoxin-induced dysrhythmias.
Propranolol (II; β-adrenergic blockade; sodium channel blockade also)	0.01–0.1 mg/kg slowly	Nonselective β-blockade; used mainly to treat SVT; bradycardia, hypotension, worsening of myocardial pump function; AV block; hypoglycemia; bronchospasm; depression; fatigue.
Esmolol (II; B-receptor blockade)	100–500 μg/kg loading dose (over 5 minutes); 50–250 μg/kg per minute infusion	Used to treat SVT; relatively selective β_1 blockade; short elimination half-life (7–10 minutes); hypotension, especially during bolus; if less than desired response after 5 minutes, can repeat or double bolus dose, followed by doubling infusion rate; non–organ-based metabolism by plasma and red blood cell esterases; infusion concentrations >10 mg/mL may predispose to venous sclerosis; dilute infusion at high rates increases risk of volume overload.
Amiodarone (III; prolongs repolarization; adrenergic and calcium blockade)	1–2.5 mg/kg bolus over 5–10 minutes (total loading dose up to 5–6 mg/kg); 5–15 mg/kg per 24-hour infusion	Used for resistant reentrant atrial and ventricular dysrhythmias; may be useful for postoperative junctional ectopic tachycardia; hypotension with bolus IV administration; bradycardia; AV block; rare proarrhythmia and torsades de pointes; pulmonary fibrosis; hypothyroidism; controversial association with acute perioperative lung injury.
Verapamil (IV; calcium channel blockade)	0.1–0.3 mg/kg bolus (maximum 5 mg)	Used for SVT in older children and adults; potential for hypotension and asystole contraindicates use in children <1 year of age; bradycardia; AV block; may increase ventricular response rate in some children with WPW.
Adenosine	0.05–0.1 mg/kg rapid bolus followed by flush; may repeat with doses increasing in increments of 0.05 mg/kg q2 minutes (maximum dose 0.25 mg/kg or 12 mg, whichever comes first)	Increases potassium channel flux and inhibits slow inward calcium current; causes transient sinus bradycardia and AV block; transient hypotension; rarely causes ventricular ectopy or atrial fibrillation; bronchospasm; used to terminate SVT; used diagnostically to transiently produce AV block. Reduce dose by 50% in heart transplant patients or if given through a central line.
Digoxin	Total digitalizing dose (TDD)[a]: Premature: 15–25 μg/kg Neonate (<1 month): 20–30 μg/kg Infant (<2 years): 30–50 μg/kg Child (2–5 years): 25–35 μg/kg Child (>5 years): 15–30 μg/kg Child (>10 years): 8–12 μg/kg	TDD given in divided doses: ½ TDD followed by ¼ TDD q8-12 hours × 2; slows sinus node and decreases AV node conduction; used to slow ventricular response in atrial flutter and fibrillation and may also treat junctional tachycardia or SVT; variable effect on accessory pathways; long half-life (24–48 hours) that is prolonged by renal dysfunction; numerous drug interactions; toxicity includes SVT, AV block, ventricular dysrhythmias; toxicity symptoms include drowsiness, nausea, vomiting; toxicity exacerbated by hypokalemia.
Magnesium sulfate	25–50 mg/kg bolus; maximum single dose 2 g; 30–60 mg/kg per 24-hour infusion	May be first-line therapy for torsades des pointes; also used for refractory ventricular tachycardia and ventricular fibrillation; hypotension and respiratory depression may accompany IV bolus dosing—IV calcium is an antidote.

[a]Daily maintenance dose varies by age; consult pharmacy or cardiologist.
AV, atrioventricular; *CNS,* central nervous system; *IV,* intravenous; *SVT,* supraventricular tachycardia; *WPW,* Wolff-Parkinson-White syndrome.

younger than 1 year of age. Older children receive IV bolus doses of 5 to 15 mg/kg given over 30 to 60 minutes. After the bolus dose, an infusion is usually started at 20 to 80 μg/kg per minute. Infusion rates in excess of 100 μg/kg per minute are occasionally necessary, particularly in infants. Infusion rates are adjusted to achieve procainamide plasma concentrations of 4 to 10 μg/mL.[638] The first concentration should be measured 6 to 20 hours after initiation of the infusion. It is recommended to stop the infusion if hypotension occurs or the QRS widens by more than 50%. Procainamide can have substantial negative inotropic effects, which may be more pronounced in the ischemic/reperfused or otherwise damaged myocardium.

The clearance of procainamide depends 50% on hepatic (phase II acetylation) metabolism and 50% on the renal clearance of the unchanged drug. Metabolism in the liver to *N*-acetyl procainamide (NAPA), which has significant class III antiarrhythmic

effects,[639] depends on the individual's genetic polymorphism of *N*-acetyltransferase-2 as a slow or fast acetylator. In the past, procainamide and NAPA serum concentrations were added, with a therapeutic goal of 10 to 30 µg/mL. Today, only procainamide plasma concentrations are monitored. Oral procainamide therapy is complicated by unreliable absorption, the need for frequent dosing, potential proarrhythmogenic effects, and a wide spectrum of adverse effects. Typical doses are 15 to 50 mg/kg per day, divided every 4 to 6 hours. A sustained-release form (administered every 8–12 hours) is available for older children.

The majority of procainamide-related adverse effects depend on the plasma concentration and the duration of therapy. A systemic lupus erythematosus–like syndrome is common, manifested as fevers, pleural effusions, pericarditis, arthralgias, myalgias, and rashes. A considerable number of children demonstrate positive antinuclear antibodies with chronic therapy, but they do not necessarily require discontinuation of the therapy.

Lidocaine (Xylocaine)

Lidocaine is a member of the class IB antiarrhythmic agents, which include mexiletine and phenytoin. Proarrhythmogenia is less common with class IB agents. In addition to blocking fast sodium channels, they also reduce the duration of both the action potential and repolarization.[638] As with class IA agents, the effects of these agents may be greater at faster HRs. Lidocaine primarily affects cells inferior to the AV node. It produces its greatest effects on cells with the action potentials with the greatest duration and thereby balances ventricular repolarization.

Because of its rapid hepatic metabolism, lidocaine is available only in an IV formulation. It is indicated for the emergency treatment of ventricular dysrhythmias. Lidocaine is initially administered as an IV bolus of 1 mg/kg that can be repeated once within 5 to 10 minutes. Standard lidocaine infusion rates range from 20 to 50 µg/kg per minute.

The major adverse effects of lidocaine administration are well known to anesthesiologists. They primarily consist of CNS toxicity, which typically occurs at plasma concentrations in excess of 6 to 8 µg/mL. Mental status changes, abnormal taste or other sensations, apnea, and seizures may occur. Lidocaine doses should be reduced in children with reduced cardiac output because it has perfusion limited clearance. The administration of lidocaine to children with atrial tachydysrhythmias or a prolonged QT interval can increase the ventricular response rate.[640]

Phenytoin (Dilantin)

Phenytoin shares many similarities to lidocaine in terms of its antiarrhythmic effects, which are also restricted primarily to tissues inferior to the AV node and the bundle of His. Phenytoin primarily binds to sodium channels, maintaining them in the inactivated state. Very large concentrations may also affect calcium channels and automaticity. This drug is useful in treating refractory ventricular arrhythmias and especially digoxin-induced dysrhythmias.[641,642]

IV loading with phenytoin is achieved by a bolus dose of 1 to 3 mg/kg. For treatment of status epilepticus, larger loading doses (10–15 mg/kg) are used. IV maintenance is 5 mg/kg day divided into two to three doses. IV phenytoin must be administered extremely slowly (>30 minutes) owing to its potential to cause hypotension. The oral dose in infants and older children is 5 mg/kg per day given every 12 hours, after a total loading dose of 15 mg/kg that has been divided over 6 hours. Other typical adverse effects are well described from its use as an antiepileptic medication and include gingival hyperplasia, aplastic anemia, ataxia, and nystagmus. Phenytoin should be avoided in patients who are pregnant or who may become pregnant because of its significant teratogenic profile (fetal hydantoin syndrome).

Flecainide (Tambocor) and Propafenone (Rythmol)

Flecainide and propafenone are class IC agents. As such, they have potent sodium channel blocking activity. In adults, flecainide is used to treat various tachyarrhythmias, and it has a special role in the pharmacologic cardioversion of recurrent atrial fibrillation in patients with normal hearts ("pill in a pocket").[643,644] Flecainide has also been extensively evaluated in children in whom it is frequently used in the treatment and prevention of supraventricular tachyarrhythmias.[645–653] It blocks activated slow sodium channels but exerts less of an inhibitory effect on potassium channels. It appears to reduce the refractory time and decrease the automaticity in His-Purkinje cells. In contrast, the duration of the action potential and refractory period is prolonged in ventricular muscle, resulting in a greater duration of the QRS complex.

Clearance is achieved via renal excretion of the unchanged drug and by hepatic metabolism by CYP2D6; both are immature in neonates. Neonatal dosing starts at 2 mg/kg per day orally, divided every 12 hours and titrated to clinical response; monitoring of serum concentration is also advised. Infants over 1 month of age require 3 to 6 mg/kg per day. Oral dosing of flecainide may be more reliable when it is calculated on the basis of body surface area. Typical dosages in infants are in the range of 80 to 90 mg/m^2 per day, given in two divided doses (40–45 mg/m^2 every 12 hours). Older children receive 100 to 110 mg/m^2 per day (50–55 mg/m^2 every 12 hours). Loading doses are not used. Serum elimination half-life is age dependent: approximately 1 day in neonates, 12 hours in infants younger than 6 months of age, and 8 to 12 hours in older children and adults. Therapeutic trough concentrations are believed to be in the range of 200 to 1000 ng/mL. Alterations in diet can markedly affect drug absorption with oral dosing. IV flecainide is available outside the United States. A dose of 1 to 2 mg/kg given over 5 to 10 minutes has been used. Continuous infusions are not given because of its prolonged elimination half-life.

Flecainide has mild to moderate negative inotropic effects. Substantial proarrhythmogenic effects have been observed in children with atrial tachydysrhythmias or significant abnormalities of myocardial anatomy and function. Proarrhythmia was considerably increased in adult patients who received flecainide after myocardial infarction.[654] In children and adults with paroxysmal SVT, a slow but incessant SVT may result on initiation of therapy. As a result, it is recommended to closely monitor these patients when initiating therapy with flecainide. The efficiency and safety of class IC antiarrhythmic agents in children with an abnormal or damaged myocardium are unclear; many pediatric electrophysiologists would avoid these drugs in children with severe myocardial dysfunction, myocardial injury (e.g., immediately postoperatively), right- or left-sided hypertrophy (e.g., TOF), or aortic stenosis.[632,655] Nevertheless, a retrospective cohort study based on an administrative database from 43 pediatric tertiary care hospitals in the United States reported a trend towards increased use of flecainide in patients with CHD or cardiomyopathies (8.7% in 2011 compared with 4.6% in 2004) with a cardiac arrest rate comparable to other antiarrhythmic medications.[656]

The effects and risks of propafenone are similar to those discussed for flecainide. Propafenone can also control dysrhythmias that arise from automatic mechanisms and can be used to treat postoperative junctional ectopic tachycardia. Oral propafenone is administered at 200 to 600 mg/m^2 per day divided into three

doses (for children under 15 kg, 10–20 mg/kg per day and for children over 15 kg, 7–15 mg/kg per day). IV propafenone is not available in the United States. An IV loading dose of 0.2 to 1.0 mg/kg should be given slowly over 10 minutes. The initial dose may be doubled to achieve a maximum 2-mg/kg total loading dose. Infusion rates of 4 to 7 μg/kg per minute have been reported.[657–662]

Significant hypotension can occur with a bolus of propafenone. Hypotension has been attributed primarily to its negative inotropic effects. Like flecainide, propafenone is probably contraindicated in children with significant structural or metabolic myocardial abnormalities, such as those related to severe pressure or volume overload, ischemia-reperfusion, or myocardial infarction. In addition, propafenone has the potential for proarrhythmogenic effects. Propafenone is extensively metabolized in the liver, with significant interindividual variability. Its reported elimination half-life ranges from 4 to 18 hours. Serum concentrations of propafenone do not correlate well with the clinical response.[663]

β-Blockers

β-Blockers are class II antiarrhythmic agents. Mechanism of action, relevance of subtype selectivity, metabolism, and other features are described in the section on vasoactive drugs. Here we focus on their indications as antiarrhythmic agents. In children, propranolol, atenolol, and esmolol are the most frequently used β-blockers.[377]

Propranolol (Inderal)

Propranolol is probably the most widely studied β-blocking agent in children.[664] Its primary indication is the treatment and prophylaxis of SVT. Even infants seem to tolerate high-dose propranolol (up to 4 mg/kg per day) but require frequent weight-based dose adjustments to maintain effect.[665,666] In addition to nonselective β-blockade, propranolol has effects on the sodium channels and at high concentrations on calcium channels as well. It seems that conduction tissues of neonates are more sensitive to the drug than those of older children and adults.[642,667]

Atenolol (Tenormin)

Atenolol is a commonly used, longer-acting β-blocker[645,668,669] It has more selective effects on β-adrenergic receptors, although the risk of bronchospasm may not be completely eliminated with this drug. Atenolol does not cross the blood-brain barrier, which may be a reason for its lower incidence of depression, fatigue, and malaise compared with propranolol.[382,670]

Esmolol (Brevibloc)

Esmolol is increasing in popularity for the control of perioperative tachydysrhythmias in children.[632] Esmolol acts predominantly on the sinus and AV nodes. It does not appear to have significant antiarrhythmic effects in the His-Purkinje or ventricular conducting tissues. Pharmacokinetics and the efficacy to terminate SVTs were found to be similar in children and adults.[386]

Class III Agents

The primary class III agents are amiodarone, sotalol, and ibutilide. They prolong depolarization and therefore increase refractoriness. All of these drugs have numerous other properties, including membrane-stabilizing effects, calcium channel blockade, and adrenergic blockade.

Amiodarone (Cordarone, Pacerone)

In addition to prolonging refractoriness, amiodarone has sodium channel blocking and noncompetitive α- and β-adrenergic receptor blocking properties. It may also interfere with potassium channels and inhibit the release of myocardial norepinephrine. Oral amiodarone is absorbed quite slowly from the gastrointestinal tract and is metabolized in the liver to an active metabolite, desethylamiodarone. Because of its high lipid solubility and large volume of distribution, tissue concentrations are maintained for 2 to 3 months after discontinuation of therapy. There are increasing data demonstrating the efficacy and safety of oral and IV amiodarone for the treatment of dysrhythmias in infants and children.[671–675] In addition to resistant reentrant atrial and ventricular dysrhythmias, amiodarone may be effective in treating postoperative junctional ectopic tachycardia.[676–678] Amiodarone, in a dose of 5 mg/kg IV push, is also indicated for shock-resistant arrhythmias during cardiopulmonary resuscitation in infants and children.[679]

The loading dose for oral amiodarone is 10 to 15 mg/kg per day for 5 to 10 days. After the loading dose, long-term oral dosing is 2 to 5 mg/kg once daily. IV amiodarone is usually given in boluses of 1.0 to 2.5 mg/kg, reaching a total of 5 to 6 mg/kg, with each bolus administered over 5 to 10 minutes. In children with resistant dysrhythmias, the average loading dose was 6.3 mg/kg, with 50% of children requiring a continuous amiodarone infusion of 10 to 15 mg/kg per day.[673,680,681]

Hypotension is the most significant acute adverse effect of IV amiodarone therapy. The effects of amiodarone may be synergistic with those of other agents that depress sinus node and AV node function. Important cardiac dysrhythmias include bradycardia and AV block. Proarrhythmogenic effects and torsades de pointes may occasionally occur. Long-term oral amiodarone therapy can lead to progressive and irreversible pulmonary fibrosis; all patients taking amiodarone chronically are usually monitored with pulmonary function tests at regular intervals.[682–684] The high iodine content of amiodarone can affect thyroid function, resulting in either hyperthyroidism or hypothyroidism; therefore thyroid function tests are indicated periodically or at least annually. Other effects include drug deposits in the cornea, skin photosensitivity, and chemical hepatitis with increased liver transaminases. Coadministration of amiodarone with other antiarrhythmic agents may result in significant increases in the plasma concentrations of the other drugs.[671,673]

The incidence of perioperative organ dysfunction in children who receive either acute or long-term amiodarone therapy is controversial. A syndrome with similarities to the adult respiratory distress syndrome has been described, particularly in children exposed to high inspired oxygen concentrations who are undergoing thoracic surgery or CPB.[685–688] This finding led to the recommendation that amiodarone be discontinued for several weeks before elective surgery.[689] Subsequent studies failed to demonstrate a significantly increased incidence of injury to lungs or other organs in children undergoing surgery while receiving amiodarone. Because it is most frequently given to children with severe and life-threatening cardiac rhythm disturbances, the current recommendation is to continue amiodarone up to the time of surgery. However, it may be wise to attempt to limit the inspired oxygen concentration and other factors that may predispose the children receiving amiodarone to free radical and inflammatory injury.[690]

Dronedarone (Multaq)

Dronedarone is a non-iodinated analog of amiodarone that was developed to reduce the iodine-associated adverse effects of chronic amiodarone therapy. Like amiodarone, it inhibits sodium, potassium, and calcium currents. It is mainly indicated for maintenance of sinus rhythm in patients with atrial fibrillation

but is still undergoing investigations regarding its long-term safety profile.[643,691–693] After the initial drug approval, a high incidence of serious adverse events has been reported, including several cases of severe hepatocellular injury, which prompted the FDA to issue a warning in 2011.[694,695] Pediatric data are not yet available.

Sotalol (Betapace, Sorine, Sotylize)

Sotalol, a newer agent available in the United States, is a class III antiarrhythmic that also acts as a nonselective β-blocker. At small doses, the β-adrenergic blocking effects predominate; at larger doses, the class III effects become more important. Sotalol is indicated for a number of refractory tachydysrhythmias, including fetal supraventricular tachyarrhythmias.[696] Current oral dosing recommendations for children start at target doses of 2 and 4 mg/kg in neonates, 3 and 6 mg/kg for children up to 6 years, and 2 and 4 mg/kg, divided into three doses, for children older than 6 years of age.[697] The major adverse effects of sotalol include mild cardiodepression owing to its β-blocking ability and prolongation of the QT interval and torsades de pointes owing to its class III effects.[698] It should be avoided in children with asthma, heart failure, renal dysfunction, or QT interval prolongation. Sotalol may be used as an alternative to amiodarone in some children who are unable to tolerate the adverse effects associated with amiodarone. Adult studies have shown that sotalol is not as effective for pharmacologic conversion of atrial fibrillation compared with other strategies or medications, but it can be indicated for maintenance of sinus rhythm after an episode of atrial fibrillation, especially for patients with coronary artery disease.[644] It has also been recommended as an alternative to amiodarone for postoperative atrial fibrillation in cardiac patients, but for prophylaxis and rate control pure β-blockers are still preferred.[699–701] The pediatric experience with sotalol is steadily increasing, but most studies have been limited by small numbers.[377,632,702–706]

Ibutilide (Corvert)

Ibutilide is one of the more recently released intravenous class III antiarrhythmic drugs. It prolongs repolarization by increasing the slow inward sodium current and by blocking the late rectifier current. It can be given intravenously and has a fast onset. Ibutilide is currently indicated for the rapid pharmacologic conversion of atrial fibrillation and atrial flutter, although it may be more efficacious for the latter. As with other class III drugs, ibutilide can prolong the QT interval and can cause associated polymorphic ventricular tachycardia (torsades de pointes, which occur in 5%–8% of adults).[707,708] Because the elimination half-life of ibutilide is approximately 6 hours, the current recommendation is to observe children for several hours after an IV administration of this drug. Studies to date have used a bolus dose of 10 to 25 μg/kg administered over 10 minutes, which may be repeated once. Ibutilide has been successfully used in neonates,[709] children with CHD,[710] and in children with accessory pathways.[711]

Dofetilide (Tikosyn)

Dofetilide is another new class III antiarrhythmic drug that has been approved for treatment of atrial fibrillation and flutter.[644] It prolongs the effective refractory period by selectively blocking the rapid component of the delayed rectifier potassium current. The major adverse effect is the potential for torsade de pointes as a result of QT prolongation.[712,713] Dofetilide is currently available only for oral administration; IV formulations are still under investigation. It has been successfully used in adult patients with CHD, but pediatric data are still lacking.[714]

Verapamil (Calan, Covera, Isoptin, Verelan)

Verapamil is a member of the class IV antiarrhythmic agents, the calcium channel blockers. Its primary action is depression of sinus node and AV node function.[715] Oral doses range from 4 to 8 mg/kg per day divided into three doses. A sustained-release preparation is available for older children. IV doses range from 0.1 to 0.3 mg/kg with a maximum dose of 5 mg. The most important side effect of verapamil occurs in children younger than 1 year of age, in whom IV administration can cause severe hypotension and asystole.[716] In fact, the drug is now contraindicated in infants (<1 year of age) because of this complication. Other side effects include bradycardia, AV block, and increased ventricular response in some children with Wolff-Parkinson-White syndrome.

Verapamil has been shown to be effective in terminating most SVTs in older children and adults.[632,717,718] Verapamil is also used to relieve outflow obstruction in hypertrophic cardiomyopathy[719] and as an antihypertensive in some children. The negative inotropic and AV conduction effects of verapamil are potentiated by β-blockers and anesthetic agents.[720,721] IV calcium and β-adrenergic drugs such as isoproterenol have been given to reverse the depressive effects of verapamil and other calcium channel antagonists.[722,723]

Adenosine (Adenocard, Adenoscan)

IV adenosine has markedly changed the therapy for SVTs. Its electrophysiologic effects are multiple and include increased potassium channel flux and decreased slow inward calcium current. These effects result in sinus bradycardia and transient AV block and are mediated primarily by stimulation of the A1-purinergic receptor subtype. Its onset of action is within 10 to 20 seconds. Bradycardia, AV block, and hypotension last an additional 10 to 30 seconds.

The best response to adenosine is achieved when it is rapidly administered into the central circulation. The initial central venous dose is 50 μg/kg and the initial peripherally administered dose is 100 to 150 μg/kg given as a rapid bolus, followed by a fluid bolus given via a syringe to flush the medication into the circulation. If this is unsuccessful or the effect is not sustained, the procedure can be repeated with a double dose (up to a maximum of 300 μg/kg). In adults, the starting dose is 6 to 12 mg.[724,725] Adenosine can also be used as a diagnostic tool to differentiate between SVT and other dysrhythmias. The slower HR caused by the transient AV conduction block often allows the recognition of specific electrocardiographic features, such as delta waves in Wolff-Parkinson White syndrome.[726]

Other than the noted electrophysiologic changes, the major adverse effect from adenosine is transient hypotension. In children with an antegrade-conducting accessory pathway, adenosine can induce atrial fibrillation with a rapid ventricular response. Therefore it should be used only in an appropriate setting with electrocardiographic monitoring and available resuscitation equipment.[727] Dipyridamole and diazepam may inhibit the metabolism or cellular redistribution of adenosine. Either drug can significantly potentiate the effects of adenosine, resulting in more prolonged hypotension and AV node blockade.[728] Children with transplanted hearts can demonstrate prolonged bradycardia and asystole in response to adenosine. **The denervated heart is extremely sensitive to the AV node–blocking effects. It is recommended that the initial dose be reduced by 50% in these children.[142] This can be very important in the cardiac catheterization laboratory, where wire-induced supraventricular arrhythmias are common during surveillance biopsies.** Adenosine has been reported to cause bronchospasm in children both with and without known reactive

airway disease. It is usually mild and, if necessary, can be treated with IV aminophylline, which directly counteracts the receptor-mediated effects of adenosine.

Digoxin (Digitek, Digox, Lanoxicaps, Lanoxin)

Digoxin has antiarrhythmic as well as positive inotropic effects. Its basic pharmacology and therapeutic dosing were discussed earlier in the section on vasoactive drugs. As an antiarrhythmic agent, digoxin slows both atrial and AV node conduction. It slows the ventricular response in atrial flutter and fibrillation and may be used to treat children with junctional tachycardia and SVT.[377,632] Digoxin can have an unpredictable effect on the refractory period of accessory pathways[729,730] and is therefore relatively contraindicated in children with Wolff-Parkinson-White syndrome or other forms of SVT with accessory pathways. Digoxin easily crosses the placenta and remains the primary treatment for termination of fetal SVT.[731–733]

The dosing of digoxin in infants and children must be undertaken with care. Infants have greater myocellular concentrations of digoxin than adults.[291,734–736] The dosing schedule of digoxin, based on age, is shown in Tables 18.8 and 18.11. IV and oral dosing are essentially the same. The onset of effect is more rapid with IV dosing (5–10 minutes) than with oral dosing (1–2 hours). The elimination half-life of digoxin is prolonged, approaching 1 to 2 days in young infants. Significant renal dysfunction and congestive heart failure can extend the elimination half-life. There are no active metabolites of digoxin. Therapeutic digoxin concentrations are 0.5 to 2.0 ng/mL. To properly measure the blood concentration of digoxin, blood should be obtained either just before a dose or at least 6 hours after the preceding dose.

Cardiac injury (e.g., ischemia-reperfusion, myocarditis) may increase the sensitivity to digoxin. Toxicity is more likely in children whose plasma concentrations exceed 3 ng/mL.[296] Signs of toxicity include proarrhythmia, nausea, vomiting, and drowsiness. Infants and young children frequently manifest digoxin toxicity as SVT and AV node conduction disturbances, whereas adults are more prone to ventricular arrhythmias, premature ventricular contractions, AV blocks, and junctional tachycardias. Hypokalemia exacerbates the risk of digoxin toxicity. Many drugs interact with digoxin. As a rule, the administration of other drugs may require a reduction in the digoxin dosing.

Magnesium Sulfate

Magnesium plays an important role in many biologic processes. The catalytic actions of more than 300 enzymes, including those for ATP and DNA synthesis, depend on the presence of the Mg^{2+} ion, the physiologically active form. Myocardial conduction and contractility, transmembrane calcium flux, potassium transport, vascular smooth muscle tone, coronary reactivity, and NO synthesis are all regulated by magnesium. Only 1% of the total body magnesium is extracellular; 60% is found in bones and 39% is intracellular, especially in muscle cells. This distribution explains why serum concentrations of magnesium may be normal despite an underlying intracellular deficiency. Of the extracellular magnesium, 55% is in the active ionized form. Ionized magnesium is a better predictor of the intracellular magnesium status; age-specific reference values have been published.[737,738]

Magnesium sulfate is currently used for the correction of hypomagnesemia, for management of seizures and hypertension, for bronchodilation during status asthmaticus, and in the treatment of life-threatening arrhythmias. It is especially valuable in the treatment of long QT syndromes and torsades de pointes.[739,740] More recently, prophylactic magnesium supplementation during pediatric CPB has been advocated to reduce the incidence of postoperative junctional ectopic tachycardia.[741,742] The IV dose is usually 25 to 50 mg/kg over 10 minutes (0.2–0.4 mEq/kg), with a maximum single dose of 2 g. This dose can be repeated every 6 to 8 hours depending on renal function and serum concentrations. Because magnesium is excreted solely by the kidneys, renal insufficiency requires increasing the intervals between doses to avoid toxicity. The normal serum concentration of magnesium is 1.5 to 2.5 mEq/L. Concentrations greater than 5 to 7 mEq/L can lead to increasing CNS and cardiac depression, initially manifested as loss of deep tendon reflexes and muscle weakness, potentially leading to respiratory depression and cardiac arrest (at levels >15–20 mEq/L). IV calcium directly antagonizes magnesium-induced toxicity.
