Summary

THIS CHAPTER REVIEWS THE equipment and strategies for cardiopulmonary bypass (CPB) in infants and children, focusing on how they differ compared with CPB in adults. We review the effects of CPB on the key organ systems and discuss specific management issues that occur in daily practice.

Basic Aspects of Cardiopulmonary Bypass

The basic principles of CPB remain unchanged from when they were first introduced in the 1950s: the CPB machine assumes the functions of the heart and lungs during the time necessary to complete either an intracardiac or an extracardiac repair. A basic bypass circuit (Fig. 19.1) consists of an oxygenator, heat exchanger, and venous reservoir; pump heads for perfusion, cardiotomy suction, and cardioplegia; and appropriate tubing, cannulas, and monitoring and alarm devices.[1] Major differences exist between pediatric and adult CPB, stemming from anatomic, metabolic, and physiologic differences in these age groups (Table 19.1).

THE CIRCUIT AND CANNULAS

Unfortunately, the circuit size cannot be reduced proportionately to the patient's size; this disproportion commonly leads to hemodilution and dilutional coagulopathies in children. Surgical procedures require extremes of temperature, hemodilution, and changes in flow rates. Because of the smaller vascular structures and greater flow rates (150–200 mL/kg per minute) in infants and children compared with flow rates of 2.2 to 2.4 L/minute per meter squared in adults, selection of appropriately sized cannulas is critical to maintain these flows. Shear stress is significant in small cannulas and several-fold greater than needed for activation of blood cells and platelets, leading to a disproportionately exaggerated systemic inflammatory response syndrome (SIRS).

Bypass Circuit

Technical advances in the field of oxygenator construction and size, including the reduction of priming volumes to as small as 45 mL for neonatal oxygenators, have allowed marked reductions

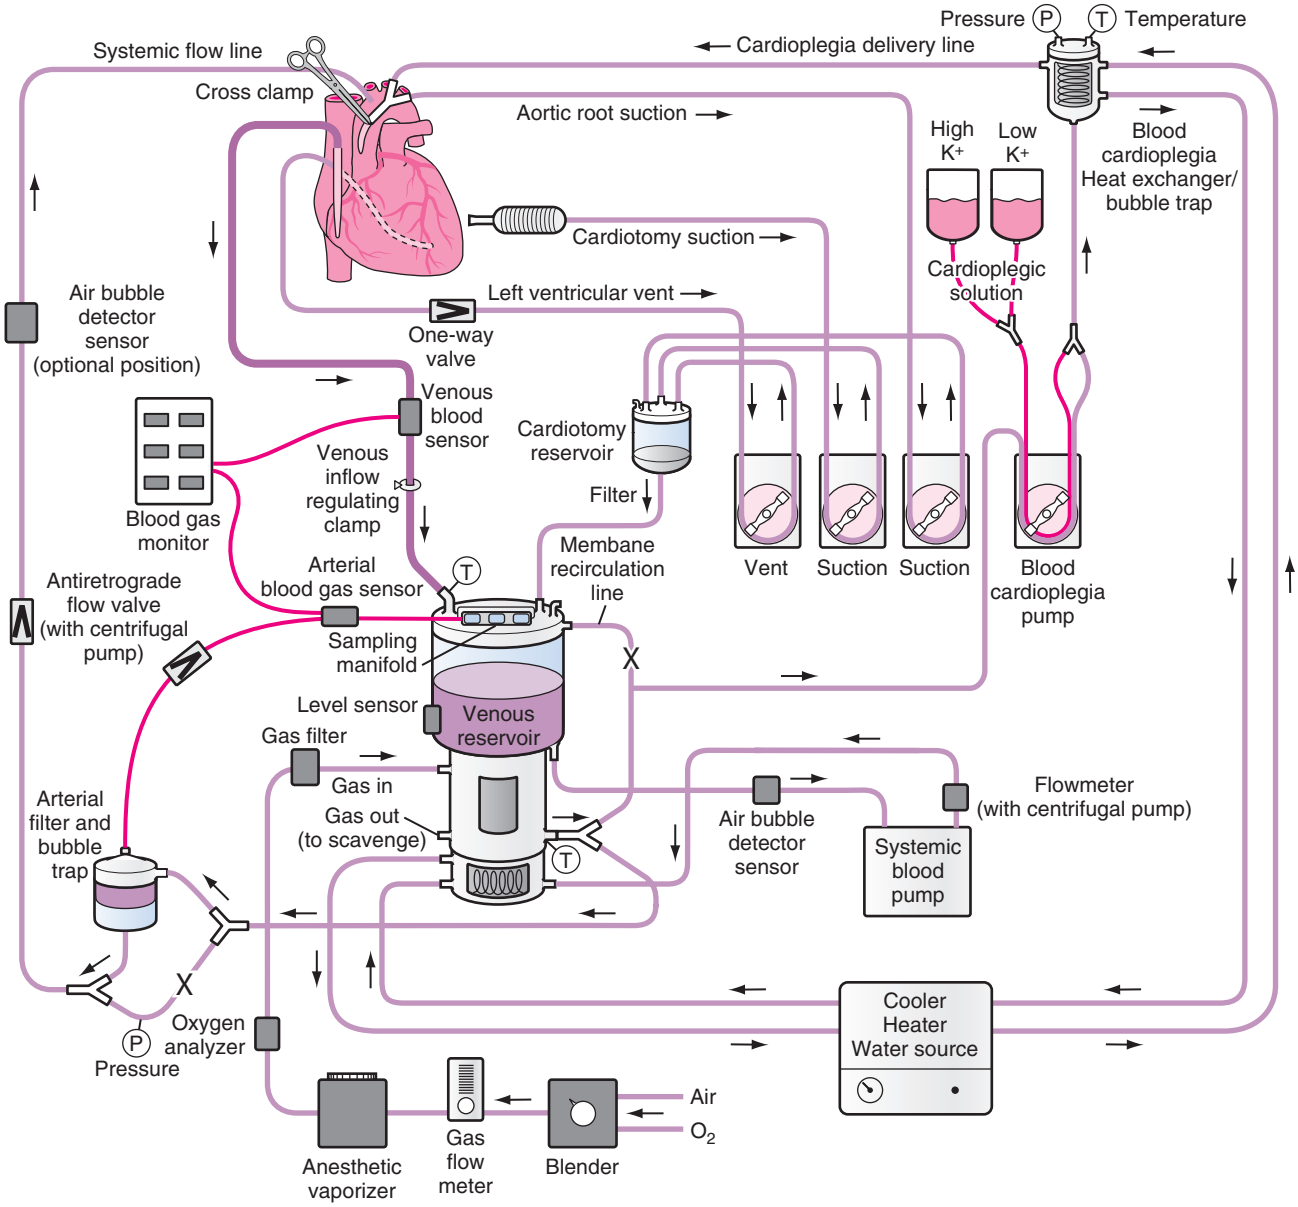

FIGURE 19.1 Schematic diagram of a cardiopulmonary bypass circuit. This scheme depicts a membrane oxygenator with integral hard-shell venous reservoir and external cardiotomy reservoir. Many circuits have the cardiotomy reservoir, venous reservoir, and oxygenator integrated into one single unit. The systemic blood pump may be either a roller or centrifugal pump. Most pediatric venous cannulations are bicaval with two separate venous cannulas instead of the single venous cannula depicted here. Carbon dioxide can also be added to the inspired gas to facilitate pH-stat blood gas management. *Arrows* indicate direction of flow; *P*, pressure sensor; *T*, temperature sensors; *X*, placement of tubing clamps. (From Hessel EA, Hill AG. Circuitry and cannulation techniques. In: Gravlee GP, Davis RF, Kurusz M, Utley JR, eds. *Cardiopulmonary Bypass: Principles and Practice*. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2000:69–97.)

of circuit volumes over the past decade. Also, tubing sizes can be reduced to $\frac{3}{16}$-inch diameters, which in combination with shorter length tubing, can allow the reduction of priming volumes to the range of 100 to 150 mL for neonates. A summary of the Texas Children's Hospital sizing chart is shown in Table 19.2.

Heparin-Coated Versus Noncoated Circuits

Young children are more susceptible to the adverse effects of CPB than adults, and the inflammatory response to CPB may have serious consequences for neonatal and pediatric patients.[2,3] This is in part related to the surface area of the CPB circuit, which is large relative to the infant and child's blood volume. For example, a 3-kg neonate with a blood volume of 90 mL/kg has a total blood volume of approximately 270 mL, and with an average priming volume in many centers of 350 mL (120% of the neonate's estimated blood volume), the CPB circuit volume thus causes greater than 100% dilution. A 70-kg adult with 70-mL/kg blood volume has an approximately 5000-mL blood volume, and

TABLE 19.1 Comparison of Pediatric Versus Adult Cardiopulmonary Bypass

	Child	Adult
Hemodilution	3–15 × adult	Moderate
Perfusion pressure	30–40 mm Hg	Moderate (>50–80 mm Hg)
	Wide flow rates (0–200 mL/kg per minute)	Narrow range (CI 2.0–2.4 L/m^2 per minute)
Blood gas management	pH-stat (P_{CO_2} 20–80 mm Hg or greater)	α-stat (P_{CO_2} 30–45 mm Hg)
Cannulation techniques	Variable	Predictable
Aortopulmonary collaterals		Uncommon
Temperature ranges	Variable	DHCA occasionally
Glucose management		Predictable
Inotropic response	Negative	Positive
Perfusion circuit	Per kilogram weight	Standard
Parameters	Hematocrit often >55%–60%	
	P_{O_2} 40–80 mm Hg	±
	Sa_{O_2} 75%–85%	
	Ultrafiltration (MUF/CUF)	± Ultrafiltration

CI, cardiac index; *CUF*, conventional ultrafiltration; *DHCA*, deep hypothermic circulatory arrest; *MUF*, modified ultrafiltration.

TABLE 19.2 Cardiopulmonary Bypass Circuit Prime Volume and Constituents at Texas Children's Hospital

Patient Weight	Prime Volume	Prime Constituents
<8 kg	350 mL	Whole blood or PRBC + FFP + crystalloid prime[a]
8–15 kg	650 mL	100 mL albumin 25% ± PRBC + crystalloid prime[a]
15–25 kg	900 mL	100 mL albumin 25% + crystalloid prime[a]
15–25 kg	1200 mL	Crystalloid prime[a]

FFP, fresh frozen plasma; *PRBC*, packaged red blood cells.
[a]Crystalloid prime: ½ normal serum + PlasmaLyte + $CaCl_2$ + KCl.

with a CPB circuit prime of 1500 mL, this results in less than 33% dilution. Contact of blood with the surface of the circuit also plays an important role for activation of coagulation and fibrinolysis. Heparin-coated biocompatible bypass systems reduce this activation in children weighing less than 10 kg undergoing CPB.[4] They also reduce the activation of factor XII and the complement system.[5,6] This results in less production of kallikrein and bradykinin, which in turn reduces the secretion of tissue plasminogen activator from endothelial cells. One study has documented more bleeding with a conventional, non–heparin-coated circuit compared with a heparin-coated circuit.[6] Overall, children who underwent surgery while supported with heparin-coated circuits have significantly less inflammatory mediator release and fewer consequences thereof, such as prolonged postoperative ventilation and duration of stay in the intensive care unit (ICU).[7]

CARDIOPULMONARY BYPASS PUMPS

The two pumps used most commonly for CPB are roller pumps and centrifugal pumps. Roller pumps have the advantages of simplicity, low cost, ease and reliability of flow calculation, and the ability to pump against increased resistance without reducing flow.[8] Disadvantages include the need to assess occlusiveness, spallation or fragmentation of the inner tubing surface (potentially producing particulate arterial emboli), potential for pumping large volumes of air, and ability to create large positive and negative pressures. Compared with roller pumps, centrifugal pumps offer the advantages of less air pumping potential, less ability to create large positive and negative pressures, less blood trauma, and virtually no spallation. Disadvantages of centrifugal pumps include a greater cost, the lack of occlusiveness (creating the possibility of accidental patient exsanguination), and afterload-dependent flow that requires constant flow measurement. In the setting of short-term CPB for cardiac surgery, it remains uncertain whether the selection of a roller pump over a centrifugal pump, or of any specific centrifugal pump over another, has clinical importance. Pulsatile perfusion may prove to be beneficial in the future, but further outcome data and technical improvements are needed.[9]

CARDIOPULMONARY BYPASS PRIME

The optimal priming fluid in cardiac surgery is a topic of enduring debate. Crystalloid solutions, colloids, and mixtures of both are used. Children appear to benefit from a colloid prime. If crystalloid is used for priming, it should not contain lactate or dextrose because CPB induces a metabolic acidosis[10] that is iatrogenic, not splanchnic, in provenance.[11] The addition of lactate to the prime increases the serum concentration of lactate postoperatively and should be avoided.[12] Hyperchloremic metabolic acidosis is the second contributing component of a metabolic acidosis on CPB. This is often only detected by measuring the strong ion difference via the Stewart approach to the acid-base homeostasis.[13] Both acidifying events are attenuated by the dilutional hypoalbuminemia induced by the pump prime. Because a hyperchloremic acidosis of a mild degree seems to be well tolerated and not associated with a poor outcome, no intervention seems necessary. Understanding the nature of CPB-associated acidosis, however, is likely to prevent unnecessary investigations or interventions.

The avoidance of dextrose is especially important during complex repairs using deep hypothermic cardiac arrest in which the risk of neurologic injury is substantive. The additives in banked blood, namely, glucose in citrate-phosphate-dextrose (CPD) storage solutions, also need to be considered as a source of glucose (together with the increased plasma concentrations of potassium in stored blood). We use a balanced electrolyte solution, such as PlasmaLyte, for the crystalloid component of our prime.

The proportionally large volume of the bypass circuit compared with the child's blood volume has a significant impact on the coagulation factors and cellular components. Platelet count decreases and coagulation factors, including fibrinogen, are diluted after bypass thereby contributing to a coagulopathy. The fibrinogen concentration at the end of bypass correlates with the 24-hour chest drainage in children who weigh less than 8 kg.[14] This occurs more frequently in infants and neonates in whom the plasma concentrations of hemostatic proteins decrease postoperatively

by 56% immediately upon initiation of bypass[15]; younger age represents the single most important risk factor for coagulopathy and bleeding complications.[16]

One approach to offset this dilutional coagulopathy is the addition of whole blood to the circuit prime. Proponents cite two theoretical advantages: (1) improved hemostasis and (2) decreased SIRS with less edema formation and less organ dysfunction. However, one study challenged these perceived advantages when the researchers reported that the use of fresh whole blood actually increased perioperative fluid requirements, leading to a more prolonged duration of mechanical ventilation and ICU stay than in the single component group.[17] The only advantage of whole blood prime was fewer donor exposures, a problem we obviate by matching packed red blood cells (PRBCs) and fresh frozen plasma (FFP) from the same donor.[18] One retrospective analysis of donor exposures using fresh whole blood concluded that donor exposures were reduced in patients younger than 2 years of age compared with published reports using component therapy.[19] Unfortunately, fresh whole blood is frequently unavailable. However, when a commitment to use fresh whole blood for pediatric cardiovascular surgery exists, it is possible to build a sustainable operating protocol to provide this resource. An alternative approach is to use FFP in the prime.[20] Some investigators determined that the use of FFP led to greater fibrinogen concentrations at the end of surgery. On average, children in the FFP group needed 1.3 fewer donor exposures and tended to need fewer PRBCs. The reduced donor exposure was primarily the result of fewer transfusions of cryoprecipitate.[20] FFP may be safely substituted by 5% albumin in the prime in children with less complex repairs and acyanotic lesions.[21] Whenever possible, we prefer fresh blood that is less than 5 days old. Fresh PRBCs are presumably more balanced metabolically than stored PRBCs; the former contain less potassium, greater concentrations of glucose, reduced concentrations of lactate, and a greater pH.[22] Also, postoperative morbidity increases with increasing age of red blood cells.[23] Pulmonary complications, acute renal failure, and increased infection rates were among the main complications associated with increased red blood cell storage time. As far as potassium concentrations and acid-base balance are concerned, PRBC priming can be safely performed with stored PRBCs if the priming solution is circulated for 20 minutes before the initiation of CPB.[24]

Depending on the size and age of the child and the complexity of the repair, a target hematocrit is chosen. Based on the child's blood volume and the prime volume, homologous blood is added using the following calculation:

$$\begin{aligned}\text{Prime PRBC volume (mL)} = &[\text{Target hematocrit}] \\ &\times [\text{Patient blood volume (mL)}] \\ &+ \text{Prime volume (mL)}] \\ &- [\text{Patient PRBC volume (mL)}]\end{aligned}$$

The average prime volume of the circuits in use at Texas Children's Hospital is shown in Table 19.2. Other prime additives are heparin, antifibrinolytics, antiinflammatory agents (corticosteroids), antibiotics, vasodilators, and, sometimes, diuretics (mannitol, furosemide). At the end of the case and before separation from bypass, a blood gas sample should be analyzed to ensure the electrolytes (including calcium and magnesium ions), glucose, and hematocrit are within a desired range. Acid-base changes and sodium concentration are corrected with sodium bicarbonate and wash solutions, and residual lactate is washed out using hemofiltration.

ANTIFIBRINOLYTIC AGENTS

Aprotinin

Inhibitors of serine proteases regulate and prevent uncontrolled activation of thrombin, coagulation factors, complement products, kallikrein, trypsin, elastase, and cathepsin among others of these potent enzymes (see Chapter 20). Of the serine protease inhibitors, the broad-spectrum agent aprotinin is the most widely studied in both experimental and clinical settings. Aprotinin is derived from bovine lung. It inhibits plasmin, kallikrein, trypsin, and other proteases, resulting in both antiinflammatory and antifibrinolytic effects and maintenance of glycoprotein homeostasis.

The first use of aprotinin in pediatric cardiac surgery was reported in 1990[25]; a high-dose regimen was administered to 28 children that included those undergoing a reoperation or surgery for transposition of the great arteries or endocarditis. No reduction in blood loss or drainage was observed; there were no adverse effects, and the time to chest closure from the end of cardiopulmonary bypass was reduced.

Despite the expense of aprotinin, follow-up studies reported more favorable results. Its use has reduced overall costs, from a reduced number of blood products used, operative time, duration of postoperative ventilation, and hospitalization.[26,27] This was confirmed in a comparative analysis among antifibrinolytic medications.[28] However, this benefit was observed only in complex repairs and the use of a high-dose regimen.[29] The lesser effect of a low-dose regimen may be attributable to the dilutional effects in pediatric surgery compared with the adult population.[30] Pediatric lung transplantation has been studied as a potential target group for the use of aprotinin.[31] As in most high-risk groups, a significant benefit was found for children with repeat operations (defined as repeat sternotomies or repeat transplantations), either with a high- or a low-dose regimen. This is consistent with our experience. Also, in general, infants younger than 6 months of age and those with repeat sternotomies benefit from a high-dose regimen of aprotinin[32] compared with reduced doses, despite greater drug costs. Economic studies have shown a cost-effective benefit of aprotinin in repeat cardiac procedures.[26,27]

Aprotinin influences the inflammatory response to CPB in children.[33] There has been a decrease in the duration of postoperative mechanical ventilation[34] and an improved PaO_2/FIO_2 (ratio of arterial oxygen concentration to the fraction of inspired oxygen, or P/F ratio), as an indicator of an attenuated reperfusion injury of the lung.[35] The clinical relevance of its antiinflammatory action remains unclear but points toward significant antiinflammatory properties.

Although a standard dosing regimen has yet to be defined in children, pediatric studies have demonstrated decreases in operative time after CPB, in exposure to donor blood products, and in postoperative chest tube drainage.[34] In vitro plasma concentrations of aprotinin have been related to antifibrinolytic and antiinflammatory activity at concentrations of 50 to 125 kallikrein inhibitor units (KIU)/mL and 200 KIU/mL, respectively.[26,36,37] Anaphylactic and anaphylactoid reactions may occur with aprotinin, and a test dose should be given before administration of the loading dose or addition of aprotinin to the CPB circuit. In a retrospective review of 681 children, reactions occurred in 1% of first exposures, 1.3% of second exposures, and 2.9% of more frequent exposures.[38]

We used aprotinin for complex neonatal repairs, such as arterial switch operations or Norwood procedures, as well as for most reoperative procedures and organ transplantations.[39,40] The drug is currently unavailable in the United States and Europe because of safety concerns in adults, who presented with a different profile

of complications after cardiac surgery than children. Aprotinin has been shown to be safe and effective in the neonate.[41] Furthermore, serious questions have been raised regarding the statistical method used in the sentinel study that questioned the safety of aprotinin. Aprotinin continues to be used in Australia and New Zealand and has been reintroduced for adult coronary artery bypass graft surgery in Canada. Our dosing regimen is based on a 60,000 KIU/kg loading dose by the intravenous (IV) route and in the pump prime. The aprotinin infusion (7000 KIU/kg per hour) is started before skin incision. This infusion rate maintains the blood concentrations until the end of surgery at which time it is discontinued, just before leaving the operating room. Regimens based on body surface area are also used, along with a CPB prime dose that is based on the priming volume designed to achieve a plasma level above 200 KIU/mL. An example of one such calculation is a 0.85 to 1.7 $\times$ 10^6 KIU/m^2 loading dose both into the patient and the bypass prime, and an infusion of 2.0 to 4.0 $\times$ 10^5 KIU/m^2 per hour.[26]

The Lysine Analogs: Aminocaproic Acid and Tranexamic Acid

Despite meticulous surgical technique, it is still frequently difficult to achieve adequate hemostasis after CPB, particularly in neonates. ε-Aminocaproic acid (EACA) and tranexamic acid (TXA) are analogs of the amino acid lysine that exert their antifibrinolytic effects by interfering with the binding of plasminogen to fibrin, thereby preventing the activation of the active plasmin (see Chapter 20). TXA may also improve hemostasis by preventing plasmin-induced platelet activation. Both EACA and TXA exercise some antiinflammatory properties, but not to the same extent as aprotinin. In one study, EACA reduced bleeding postoperatively in 25 of 71 children undergoing cardiac surgery on CPB but only benefited children with cyanotic heart disease.[42] The empirical EACA loading dose was 75 mg/kg followed by an infusion of 15 mg/kg per hour, with an additional 75 mg/kg was added to the CPB prime. A larger loading dose of 150 mg/kg that was followed by an infusion of 30 mg/kg per hour of EACA has also been studied. In the latter case, intraoperative blood loss was reduced, although postoperative blood loss did not differ between the treatments.[43] Blood coagulation measured with a thromboelastograph showed less fibrinolysis with EACA. The clearance of EACA is reduced in neonates compared with children and adults; dosing requirements in neonates were approximately half of those for children and adults. A regimen of 40 mg/kg as a loading dose, 30 mg/kg per hour infusion, and a pump prime concentration of 100 mg/L effectively maintained the plasma concentration in excess of 50 mg/L in 90% of neonates undergoing cardiac surgery using cardiopulmonary bypass.[44] Dosing regimens for EACA at Texas Children's Hospital are displayed in Table 19.3. A recent meta-analysis established the efficacy of EACA in pediatric cardiac surgery.[45]

TXA compares favorably with EACA but confers a particular benefit in children with cyanotic heart disease alone.[46] Those with acyanotic defects and those who required repeat sternotomies did not benefit from TXA, although that dosing regimen only included a single 50 mg/kg loading dose before incision. In children, the TXA plasma concentration between the peak of the loading dose and the end of CPB decreased 80% when it was not followed by a continuous infusion.[47]

Although less efficient than aprotinin, EACA and TXA are equally effective in reducing perioperative blood loss in pediatric cardiac surgery.[48] Given their safety profile, they may be even more appealing in the future. Further studies are needed to delineate their pharmacokinetic profiles and their efficacy. We use EACA based on simulation results from a study in children and adults.[49] An initial loading dose of 75 mg/kg over 10 minutes followed by an infusion rate of 15 mg/kg per hour complemented a 75-mg/kg dose in the pump to maintain serum concentrations in excess of the therapeutic concentration (assumed to be 130 μg/mL) in more than 95% of children.

TABLE 19.3 ε-Aminocaproic Acid Dosing (Texas Children's Hospital)

Age (Weight)	Loading Dose to Patient	Infusion Dose	Loading Dose to Bypass Circuit
<30 days (3.5 kg)	40 mg/kg	30 mg/kg per hour	0.1 mg/mL of CPB prime volume
1 months–12 years (3.5–40 kg)	75 mg/kg	15 mg/kg per hour	75 mg/kg
>12 years (>40 kg)	5 g	1 g/hour	5 g

Special Coagulation and Hematologic Problems

HEPARIN-INDUCED THROMBOCYTOPENIA

The use of unfractionated heparin for anticoagulation for CPB in adults produces antiheparin antibodies in 25% to 50% of patients within 10 days postoperatively. In a small minority of these patients, high-titer immunoglobulin G (IgG) platelet-activating antibodies form and make immune complexes with heparin and platelet factor 4 (PF4).[50] This results in activation of platelets (via their Fc receptors) and formation of procoagulant platelet microparticles, leading to thrombin generation and thrombosis. Thus the major problem in heparin-induced thrombocytopenia (HIT) is thrombocytopenia that occurs several days after heparin exposure accompanied by thrombosis, often in major vessels or structures. HIT appears to be less common, of milder course, and probably underrecognized in neonates and children. About 1% of children exposed to CPB have PF4 antibodies when tested before their second exposure to CPB, and actual HIT is much less common.[51] When HIT is suspected, either PF4 enzyme-linked immunosorbent assay or a functional assay for HIT can be used to make the diagnosis; if positive, no further heparin should be given. If CPB is necessary, alternatives to heparin, such as the direct thrombin inhibitors argatroban, lepirudin, and bivalirudin, may be used. None of these agents is approved for use in children for anticoagulation for CPB, but case reports and small series have documented their successful use when HIT is diagnosed.[52–54] The partial thromboplastin time (PTT), activated clotting time (ACT), and a specialized clotting time called the *ecarin clotting time* can be used to follow anticoagulation with these agents, but there is no reversal agent for them. Thus, treatment of post-CPB bleeding involves only administration of blood products and coagulation factors.

ANTITHROMBIN III DEFICIENCY

Heparin produces anticoagulation by combining in a 1:1 ratio with antithrombin III (ATIII), which then binds to and inhibits thrombin, leading to anticoagulation. Of adult patients, 4% to 13% have a resistance to normal doses of heparin for CPB; most instances occur because of a partial deficiency of ATIII, rendering heparin less effective at producing anticoagulation.[55] In children this is often unknown, and the first suspicion of ATIII deficiency may occur when the standard heparin dose of 300 to 400 units/kg fails to adequately anticoagulate before CPB; that is, the ACT remains less than 300 seconds. The usual response is to apply another dose of heparin from a different vial and remeasure the ACT, but if the ACT is still not adequately prolonged, a diagnosis of ATIII deficiency may be suspected. Infants younger than 6 months of age and children with congenital heart disease have decreased ATIII concentrations.[56] Therefore heparin may not achieve adequate anticoagulation, and disorders in hemostasis and thrombosis and an exaggerated inflammatory response may occur. In this case, blood can be sent for ATIII levels, but to proceed with CPB, the ATIII must be increased. This can be accomplished in two ways: (1) by supplementing ATIII with 75 units/kg of recombinant ATIII and ensuring that the ACT is adequately prolonged before proceeding with CPB, or (2) by adding FFP (which has ample concentrations of ATIII) to the CPB prime or administering it to the child before bypass.[55,57]

In the presence of reduced baseline concentrations of ATIII, the total dose of heparin, the amount of thrombin that was generated during bypass, and the fibrinogen that was consumed and fibrinolysis that was produced increased in infants undergoing cardiac surgery with CPB. This can exacerbate after bypass coagulopathy and transfusion requirements.[58,59]

RECOMBINANT FACTOR VIIA FOR MASSIVE HEMORRHAGE

Recombinant factor VIIa (rFVIIa) was originally approved for use in patients with hemophilia who possess inhibitors to factors VIII or IX, and was shown to be effective in treating bleeding in these patients with doses of 90 μg/kg (see also Chapter 10).[60] Endogenous factor VII circulates at small concentrations in the plasma. At a site of tissue or blood vessel injury, tissue factor (TF) is exposed, and the extrinsic coagulation pathway is activated by the binding of factor VII to TF, resulting in the activation of factor X to factor Xa, leading to the generation of thrombin from prothrombin, with further activation of platelets and the coagulation cascade.[61] Large concentrations of rFVIIa activate the extrinsic pathway at the site of injury, theoretically without inducing systemic hypercoagulability. However, thrombotic complications are increased after its use. rFVIIa also activates platelets, adding to the potential benefit of this agent in significant hemorrhage. Thus this therapy seems appropriate for the treatment of surgical bleeding; a very complete review of the off-label uses of rFVIIa in pediatric cardiac surgery patients found no evidence to support the routine or prophylactic use of the therapy.[61a] However, rFVIIa may be beneficial as a rescue therapy for severe life-threatening refractory bleeding; the authors caution against the use of rFVIIa in children at risk for thromboembolic complications.[62] A dose of 45 to 90 μg/kg, repeated every 2 hours, has been used. rFVIIa cannot produce hemostasis alone and should only be administered after the transfusion of sufficient amounts of platelets, plasma, and fibrinogen to form the substrate for hemostasis.

FIBRINOGEN CONCENTRATE

Fibrinogen concentrate is an alternative to cryoprecipitate to replace fibrinogen after CPB. Compared with cryoprecipitate, fibrinogen concentrate, which is lyophilized and purified human plasma fibrinogen, has an improved safety profile because it has undergone viral inactivation and is devoid of microparticles that can cause vasoreactivity. In addition, fibrinogen concentrate contains a known amount of fibrinogen, and cryoprecipitate varies in the amount of fibrinogen per unit. One randomized pilot trial found no difference in the safety and efficacy of fibrinogen concentrate compared with cryoprecipitate when managing bleeding in children undergoing CPB.[63] The dose of fibrinogen concentrate may be empiric (70 mg/kg), based on either the laboratory fibrinogen concentration or thromboelastometry.

SICKLE CELL DISEASE

Sickle cell disease (SCD), one of the most common hemoglobinopathies among patients of African American or West Indian origin (with a prevalence of 0.2%–0.3% in that population), is the result of the substitution of valine for glutamic acid in position 6 of the β-hemoglobin chain. Normal adult hemoglobin is referred to as HbA, whereas hemoglobin containing the mutant β-hemoglobin chains is referred to as HbS. SCD is represented by a homozygous genotype (HbSS) with fractional concentrations of HbS in the range from 70% to 90%. Sickle cell trait, on the other hand, is a heterozygous manifestation (HbAS) with a prevalence of 8% to 10% in the same population. The definitive diagnosis of any sickle cell hemoglobinopathy is confirmed by hemoglobin electrophoresis (see Chapter 10).

Children with SCD are at particular risk for perioperative complications.[64,65] Sickling can be triggered by hypoxia, dehydration, acidosis,[66] hypothermia, stress, and infections. Hypoxia opens a Ca^{2+}-activated K^+ channel (Gardos channel) that causes intracellular dehydration.[67] Chain formation occurs that leads to increased blood viscosity with vasoocclusion. Opening of the Gardos channel, which is an important mechanism of sickle cell dehydration, depends on temperature, with greater potassium efflux at reduced temperatures.[68] Shrinkage of sickle erythrocytes may also result from activation of a K^+/Cl^- cotransport pathway under acidotic conditions.[69] Activation of this pathway can be blocked by increasing the abnormally low level of intracellular magnesium in sickled erythrocytes. The use of magnesium and hydroxyurea in the perioperative period therefore seems to be reasonable.[70]

CPB, particularly for more complex surgical procedures, may involve periods of low flow or even circulatory arrest, as well as hypothermia with consequent local vasoconstriction, hypoxemia, and acidosis. There is some evidence that CPB can be safely undertaken in SCD.[71] Flow conditions are an important determinant of sickle erythrocyte adherence to endothelium. Under low-flow conditions, the adhesion of sickled cells to endothelium increases with contact time in the absence of endothelium activation or adhesive proteins, whereas under low-flow conditions in venules, sickle cell adhesion occurs only after endothelial activation. During CPB, both low-flow conditions and endothelial activation may occur. Multiple triggers of sickling are likely to occur during CPB, and close attention should be paid to the conduct of all aspects of bypass.

In the past, routine exchange transfusion has been recommended to prevent these complications.[72] More recent experience provides evidence that not all children require an exchange transfusion.[73] The growing evidence of the harmful effects of blood transfusion adds to the need to carefully reconsider routine exchange transfusion.[74] For uncomplicated bypass surgery without periods of cardiac arrest, the omission of exchange transfusion has led to good outcomes.

Guidelines have been proposed for the perioperative management of children with sickle cell disorders.[73] It is essential to avoid hypothermia using tepid or warm CPB in its stead; blood

transfusion only for a decrease in hematocrit to less than 20%; maintenance of intravascular volume and body temperature while on CPB; the avoidance of vasopressors; the use of postoperative multimodal pain therapy; and early incentive spirometry to prevent pulmonary complications.[75] In our practice, we use cerebral near-infrared spectroscopy (NIRS) to help determine an acceptable lower limit of hemoglobin for the individual child.

For children undergoing hypothermia, successful management with[76] and without[77] partial or complete exchange transfusion on bypass has been reported. Exchange transfusion can be performed preoperatively or on initiation of CPB.[78] For exchange transfusion during CPB, the extracorporeal circuit is primed with blood and the usual components. When CPB is commenced, the child's blood volume is drained into storage bags and separated. The platelet-rich plasma is reinfused at the end of CPB, and the concentrated sickle cells are discarded. Platelet and plasma sequestration in conjunction with exchange transfusion reduces the need for postoperative transfusion and protects the platelets from the negative effects of CPB.[79]

There seems to be no consensus as to a suitable target concentration of HbS. Reducing the absolute level of HbS may provide a greater benefit than targeting a particular ratio of HbA to HbS because the remaining sickle cells are still 100% at risk for sickling.[80] In SCD, exchange transfusion has been shown to favorably affect cerebral tissue oxygenation.[81] Exchange transfusion decreases both the proportion and absolute amount of HbS, but it does not remove every cell that may sickle. It may also improve hypoxic pulmonary vasoconstriction.[81] In this context, these children may benefit from continuous hemofiltration to reduce inflammatory mediators and improve pulmonary recovery.[82] Inhaled nitric oxide also has been recommended as an adjunct to prevent sickle cell crisis. It may improve the binding of oxygen, thereby reducing the formation of sickle cells; reduce pulmonary hypertension; and improve pulmonary function without adverse effects on normal hemoglobin.[83]

A Perspective on Blood Preservation: Cardiopulmonary Bypass in Jehovah's Witness Patients

Jehovah's Witnesses differ from other religious groups in their conscious objection to the therapeutic infusion of blood and blood components. They uniformly refuse the transfusion of red blood cells, and some individuals also refuse platelets and plasma, as well as predonated autologous blood. Individual choices that can be made are the acceptance of fractions of blood, such as albumin and globulins, dialysis, cell savage, and acute isovolemic hemodilution (see Chapters 5 and 12).

Acute isovolumic reduction of hemoglobin to a concentration of 5 g/dL has been well tolerated in healthy children under anesthesia in one study and does not appear to reduce tissue oxygenation significantly.[84] Reduction of oxygen delivery to 7 to 8 mL/kg per minute under resting conditions does not increase the oxygen debt. This degree of anemia is compensated for, in part, by an increased extraction, an increase in cardiac index, and a subsequent decrease in systemic vascular resistance.[85,86] In a retrospective study of the morbidity associated with reduced concentrations of hemoglobin in Jehovah's Witness patients, the hemoglobin concentration of those who died was less than 5 g/dL.[87] A safe limit of hemodilution in children has not been established. Hemodilution in acyanotic children up to 50% appears to be well tolerated and safe,[88] although in cyanotic children, hemodilution probably should not exceed 40%. If this level of hemodilution is exceeded, hemodynamic instability and inadequate oxygen delivery can occur. Evidence suggests that hematocrit concentrations of 21.5% in infants on CPB significantly increase adverse psychomotor developmental outcomes compared with concentrations of 27.8%.[89]

The most important and simplest strategy to avoid transfusion in the setting of cardiac surgery is to limit blood loss. Unnecessary and reduced amounts of blood removed for testing and sampling reduce the blood loss.[90] Pharmacologic agents, such as aprotinin, TXA and EACA, reduce the risk of perioperative blood loss.[91] The administration of erythropoietin in the cardiac surgery setting has been shown to reduce the risk of exposure to allergenic blood.[92] Preoperative recombinant erythropoietin is an acceptable strategy to Jehovah's Witnesses to augment the red cell concentration. This strategy requires that oral iron (2–6 mg/kg of elemental iron in 2–3 divided doses) and vitamin C are started about 6 weeks before surgery followed by twice weekly erythropoietin (50–100 IU/kg) intramuscularly about 3 weeks before surgery. Hemoglobin concentrations should be tracked to ensure that the concentration does not exceed 15 to 20 g/dL as venous thromboembolism may occur. Some Jehovah's Witnesses refuse albumin, a constituent in the preparation of erythropoietin that is supplied in glass ampoules. In the latter case, a lyophilized preparation of erythropoietin, which is albumin-free, may be used. The cost of erythropoietin can be substantial, and one cost analysis suggested that its use in cardiac surgery is not cost-effective.[93]

Intraoperative recovery of blood with a cell salvage device is also acceptable to many Jehovah's Witnesses. This involves the removal by suction of blood from the operative field followed by washing, filtering, and return of red blood cells to the patient. A randomized controlled trial of intraoperative cell salvage in cardiothoracic surgery demonstrated a reduction in RBC transfusion and an increase in postoperative hemoglobin.[94]

Acute normovolemic hemodilution involves the preoperative removal of a volume of blood from the patient with the simultaneous administration of crystalloid or colloid to maintain circulating volume.[95] The collected blood is then reinfused during the operation. Some Jehovah's Witnesses find this process acceptable, especially if the blood remains in continuity with the patient throughout. Acute normovolemic hemodilution has other advantages, including lower costs, because the blood does not need compatibility testing; reduced the possibility of administrative error; and achieved patient time-saving (see also Chapters 10 and 12). The development of artificial red cell substitutes could potentially obviate the need for compatibility testing, as well as vastly reduce infection risks, with none of the immunomodulatory side effects of allogeneic blood.[96] Some of these products would also be acceptable to Jehovah's Witness families. Substitutes include perfluorocarbons, hemoglobin solutions, intramolecular cross-linked hemoglobin, and liposome-encapsulated hemoglobin. None of these has reached clinical practice. Lastly, autologous retrograde priming has been used in Jehovah's Witness patients and can further reduce the hemodilutional effects of the prime.[95,97] For this purpose, priming of the arterial line of the CPB circuit is accomplished with the patients' own blood.

Modern bypass circuits reduce the priming volumes to less than 200 to 300 mL. Main components that are amenable to volume reduction on a regular circuit are the size and length of the lines, small oxygenators and arterial filters, and priming the hemofilter for modified ultrafiltration with blood from the venous line after

CPB. Line volumes, for example, may vary from 1.73 mL per 10 cm of a 3/16-inch tubing to 0.75 mL per 10 cm of a 1/8-inch tubing. The limiting factor, however, is the necessary flow. For a 3/16-inch arterial line, a maximum flow of 1.8 L/minute was established as the point at which the Reynolds number reaches a critical value indicating turbulent flow, which may damage RBCs. Modified ultrafiltration at the end of CPB through a fluid warmer line to prevent heat loss or continuous ultrafiltration has been used. The venous line and the reservoir are emptied before discontinuation of bypass, the field is suctioned, and all blood is retransfused through the arterial line. Decannulation is achieved and protamine is given as usual. Crystalloid cardioplegia solution should be evacuated from the field by an external sucker to prevent dilution of the pump volume.

Postoperative care involves minimal blood sampling, and only on special indications. Noninvasive monitoring allows uncomplicated weaning from the ventilator.[98] The first report of successful outcomes in Jehovah's Witness children with congenital cardiac defects was in 1985[99]; 110 children older than 6 months of age successfully underwent operation, with a perioperative mortality rate of 5.3%. Only one death was attributed to blood loss. A weight less than 5 kg is considered by some as a contraindication for open-heart surgery and palliative procedures were advocated in the past.[100] For some lesions, however, no palliation is possible. The development of miniaturized circuits, preoperative optimization, use of antithrombolytic drugs, vacuum-assisted drainage to allow smaller tubing and cannula sizes, as well as the use of modified ultrafiltration, enabled the safe expansion of surgery into the neonatal population. Individualized heparin level–based anticoagulation management further results in a reduction of coagulation problems, blood loss, and transfusion requirements.[101] The addition of desmopressin, 0.3 μg/kg, is thought by some to improve platelet activity and stimulate the release of von Willebrand factor after protamine infusion, although this is not evidence-based.

In one study, when center-specific blood conservation strategies were used, bloodless cardiac surgery was most successful in children greater than 18 kg in weight, followed by those 6 to 18 kg in weight. All 73 patients less than 6 kg in weight had transfusions during their hospitalization.[102]

All of the aforementioned considerations are important in approaching the Jehovah's Witness patient; however, at Texas Children's Hospital, Jehovah's Witness children are not treated differently with regard to blood transfusion practice than any other child. Cerebral NIRS is used to help determine the safe hemoglobin level for the individual child at all phases of surgery. Consent for blood transfusion in this situation is a complicated issue, because the legal status of children differs from that of an adult. Each institution must develop a legal informed consent process for blood transfusion for Jehovah's Witness children, in consultation with local legal authorities, social work and ethnic groups, and representatives of the Jehovah's Witness faith (see Chapter 5). Currently, we have a release of liability form for the parents to sign stating that he or she requests that no blood products be used, but acknowledges they may be needed to treat his or her child. The parent further agrees to release and hold harmless the physicians and hospital for any liability associated with blood transfusion. This form was developed in conjunction with the local Jehovah's Witness church representatives, and in our practice this has been accepted by more than 95% of parents and has obviated the need for more extreme measures, such as temporary child protective services custody during the perioperative period, which was our former practice.

Myocardial Protection

Myocardial protection during cardiac surgery has evolved over the years, and the concept of chemical cardioplegia was introduced in 1955.[103] Before the popular use of chemical cardioplegia, topical cardiac hypothermia was used. In the late 1970s and early 1980s, the concept of cold hyperkalemic blood cardioplegia was introduced.[104] Potassium concentrations in cardioplegic solutions ranging from 12 to 30 mEq/L are typically used to achieve cardiac standstill within 1 to 2 minutes under hypothermic conditions, with greater concentrations or induction times required for normothermic conditions. Myocardial edema after bypass and global ischemia can be reduced by a number of strategies that involve modifying the conditions of delivery and composition of cardioplegia solutions as they affect the movement of intracellular and interstitial fluid. In contrast to studies in adults, most studies conducted in neonates have shown little difference between blood and crystalloid cardioplegia.[105,106] Hypothermia also decreases myocardial oxygen consumption. The benefits of this approach appear to be optimal at myocardial temperatures between 24°C and 28°C. However, there is growing evidence that warm, intermittent blood cardioplegia may be advantageous to either cold crystalloid or cold blood cardioplegia.[107] The benefits of blood cardioplegia are more pronounced in younger, cyanotic children who require longer aortic cross-clamping. For acyanotic children, the cardioplegic technique is probably not as critical.[108] Avoidance or reduction of myocardial edema occurs by limiting the pressure of cardioplegia infusions and by providing moderately hyperosmolar cardioplegia solutions that contain blood. Buffering the acidosis that results from ischemia is achieved by including tromethamine, histidine-imidazole, or both in the cardioplegia solution. Close management of myocardial calcium balance to avoid extremes of intracellular hypercalcemia or hypocalcemia, especially during reperfusion, is very important.[109,110] The addition of magnesium may solve this dilemma by preventing damage from greater cardioplegic calcium concentrations by its action as a calcium antagonist.[110,111] This prevents mitochondrial calcium overload as a consequence of reperfusion injury. Magnesium also prevents the influx of sodium into the postischemic myocardium, which is exchanged for calcium during reperfusion.

Every cardiac program has its own philosophy regarding cardioplegia and myocardial protection. At Texas Children's Hospital, plain crystalloid cardioplegia is used. The prime blood gas and electrolytes should mimic physiologically the child's arterial blood gas as closely as possible. If whole blood or packed cells are added to the prime, the target hemodilution range should be 28% to 30%; the prime should be recirculated continuously and warmed between 35.0°C and 36.5°C before initiation of bypass. In neonates and infants, albumin is added to the cardioplegic solution to maintain an appropriate colloid osmotic pressure. This may decrease edema formation of the arrested heart. In children undergoing circulatory arrest, long cross-clamp times, and large pump suction return cases, 20 mg/kg methylprednisolone is used, up to a maximum of 500 mg, to reduce the production of inflammatory mediators that result in myocardial dysfunction. Table 19.4 summarizes the Texas Children's Hospital protocols for cardioplegia and myocardial protection.

Phases of Cardiopulmonary Bypass

Surgical cases requiring CPB are divided into several basic phases.

TABLE 19.4 Cardioplegia Solution

CARDIOPLEGIA BASE SOLUTION (385 ML)

Concentration		Contents	
Sodium chloride BP	3.54 g/L	Sodium	23 mmol
Anhydrous glucose BP	6.65 g/L	Potassium	15 mmol
Potassium chloride	2.92 g/L	Calcium	0.35 mmol
Mannitol	6.54 g/L	Chloride	39 mmol
Calcium chloride	135 mg/L	Glucose	2.52 g
		Mannitol	2.48 g
		Approximate pH 4.5	
		275 mOsm/L	

CARDIOPLEGIA BUFFER SOLUTION

Concentration		Contents	
Sodium carbonate	9.37 g/L	Sodium carbonate	0.28 g
Sodium bicarbonate	27.0 g/L	Sodium bicarbonate	0.81 g

USES OF CARDIOPLEGIA SOLUTION DURING CARDIOPULMONARY BYPASS

Children Weighing <10 kg
385 mL Cardioplegia base solution
26 mL Cardioplegia buffer solution
100 mL 25% Albumin
Note: This is usually delivered at a pressure of 30 mm Hg for newborns and 30–40 mm Hg for older infants.
Children weighing >10 kg
385 mL Cardioplegia base solution
100 mL 0.9% Sodium chloride
10 mL 25% Mannitol
5 mL 8.4% Sodium bicarbonate
Note: This is usually delivered at a pressure of 30–60 mm Hg. A good guide is to note the end-diastolic pressure of each child before bypass. This will be a guide to the normal filling pressure of the coronary arteries. When aortic incompetence is present, the CPS flow may need to be increased.

ADMINISTRATION OF CARDIOPLEGIA SOLUTION

For All Patients:	
Temperature	8°C–12°C
Initial dose	110 mL/m^2 per minute for 4 minutes
Subsequent doses	110 mL/m^2 per minute for 2 minutes

Note: Following the initial dose, cardioplegia is delivered every 20 minutes during the cross-clamp period unless otherwise indicated by the surgeon. The perfusionist will remind the surgeon of the need for cardioplegia and keep track of the time. Because of the nature of the surgical procedure, it may be necessary to deliver cardioplegia directly into the coronary ostia via a handheld delivery system. In this case, the surgeon will direct the perfusionist. Close attention should be paid to the delivery line pressures.

EXAMPLES OF PRIMES

Neonate: Whole Blood, if Available, Otherwise Reconstituted	
Whole blood	225 mL
PlasmaLyte A	50 mL
0.45% NaCl	125 mL
Heparin	2500 units
$NaHCO_3$	5 mEq
$CaCl_2$	250 mg
Pediatric: Packed Red Blood Cells	
PRBCs	250 mL
Plasmalyte A	300 mL
0.45% NaCl	75 mL
25% Albumin	100 mL
Heparin	3500 units
$NaHCO_3$	20 mEq
$CaCl_2$	300 mg
Adult: Crystalloid Prime	
PlasmaLyte A	700 mL
0.45% NaCl	600 mL
25% Albumin	100–200 mL (volume varies depending on the size of the patient)
5% Dextrose	40 mL
Heparin	5000 units
$NaHCO_3$	40 mEq
$CaCl_2$	300 mg
KCl	2.4 mEq

BP, the material conforms to the specifications and procedures outlined in the British Pharmacopoeia; *CPS*, cardioplegia solution; *PRBCs*, packed red blood cells.

PREBYPASS PERIOD

This phase begins with surgical incision and lasts through initial dissection and preparation for cannulation. During this period transesophageal echocardiography (TEE) is performed to confirm the diagnosis and establish a basis for postbypass comparison.

CANNULATION AND INITIATION OF BYPASS

After sternotomy and mediastinal dissection, the aorta is cannulated, along with either the right atrium, if single venous drainage is planned, or the superior and inferior venae cavae for bicaval venous drainage. After a large dose of heparin (300-400 units/kg) is administered intravenously, the adequacy of the anticoagulation is measured using the ACT *before initiating CPB*. The target ACT is usually 480 seconds. High ACTs are maintained during CPB with the addition of heparin to the prime as needed, because larger doses of heparin lead to a reduced degree of consumptive coagulopathy, which translates into reduced blood product requirements.[101] Other methods of measuring anticoagulation include the Hepcon system (a plasma heparin concentration assay), which may allow for more accurate titration of heparin and protamine dosages since ACT is prolonged by hypothermia, hemodilution, platelet dysfunction, and low coagulation factor levels.[112,113] The thromboelastogram may also be used as a baseline measure of the coagulation system and then repeated during and after bypass, with heparinase added to more objectively assess each child's anticipated need for coagulation factors.[114,115] An improved preservation of the hemostatic system with subsequent reduction in blood loss and transfusion requirements has been demonstrated after maintenance of high heparin levels during CPB.[116] The additional maintenance of high ATIII

concentrations may further contribute to a reduction of hemostatic activation.[117]

In most centers, bicaval cannulation is used for all but the smallest children (<2 kg) to prevent venous return from interfering with the surgical field. A gradual transition to full CPB is then performed to minimize myocardial stress, using a prime that has essentially the same composition as the child's blood with regard to temperature, pH, calcium, potassium, and hematocrit. CPB flows of 150 mL/kg per minute are used for infants weighing less than 10 kg, and 2.4 L/minute per meter squared is used for children weighing more than 10 kg. Flow rates may be reduced during periods of hypothermia (see later), although many centers now prefer to maintain greater flows throughout the bypass period. Misplaced cannulas can lead to significant morbidity. Obstruction of the inferior vena cava (IVC) by a misplaced IVC cannula can lead to increased venous pressure, which causes ascites and decreased perfusion pressure in mesenteric, hepatic, and renal vascular beds. Misplacement of the cannula in the superior vena cava can result in cerebral edema from inadequate venous drainage and a subsequent reduction in cerebral blood flow, potentially resulting in ischemia. Arterial cannula misplacement can also occur. If the cannula inadvertently slips beyond the takeoff of the right innominate artery, preferential perfusion to the left side of the brain can be observed. This can be detected on the NIRS monitor, which may be an important monitor, particularly in pediatric cardiac surgery.[118]

The presence of any anomalous systemic-to-pulmonary shunts can lead to shunting of blood away from the systemic circulation, through the pulmonary circuit, and then through the venous cannula to the CPB machine. Thus, the systemic perfusion is shunted away from the body in a futile circuit back to the CPB machine. Anatomic lesions where such shunting can occur include an unrecognized patent ductus arteriosus and large aortopulmonary collaterals, as found in pulmonary atresia. Bypass flow needs to be increased to compensate for these shunts until they can be controlled.

COOLING PHASE

Systemic cooling is used frequently in pediatric cardiac surgery, but normothermia is used with increasing frequency in modern practice for selected cases.[119] Hypothermia is classified as mild (30°C–36°C), moderate (22°C–30°C), or deep (17°C–22°C). In general, the coldest temperatures are used for more complex operations that carry a greater potential for requiring periods of low-flow bypass or circulatory arrest. Cooling is primarily achieved extracorporeally through the heat exchanger in the bypass circuit; some surgeons may request that ice be applied to the head to prevent brain rewarming during circulatory arrest.

AORTIC CROSS-CLAMPING AND INTRACARDIAC REPAIR PHASE

The aorta is cross-clamped, with the heart then rendered asystolic after infusion of cardioplegia solution into the aortic root.

DEEP HYPOTHERMIC CIRCULATORY ARREST OR SELECTIVE CEREBRAL PERFUSION PHASE

If circulatory arrest is to be used, it is initiated after a slow cooling period of at least 20 minutes, and an attempt is made to limit the total duration of deep hypothermic circulatory arrest (DHCA) to less than 40 minutes. Special bypass techniques (see later) have been developed to avoid the necessity of using DHCA and may also be performed during this time.

REMOVAL OF AORTIC CROSS-CLAMP AND REWARMING PHASE

After completion of the intracardiac repair and de-airing of the heart, the aortic cross-clamp is removed, allowing reperfusion of the myocardium. Optimally, normal sinus rhythm and myocardial contractility are restored during this time, while the child is slowly rewarmed. During rewarming, surgery is completed, inotropic and vasoactive agents are started, the trachea is suctioned, and ventilation begins. Hemofiltration and blood transfusion are used to achieve the desired hematocrit. Left atrial and/or pulmonary artery monitoring lines, if indicated, are placed at this time, as are temporary atrial and ventricular pacing wires. If the child is incompletely rewarmed before separation from CPB, a significant afterdrop with precipitous postbypass reduction in core body temperature can occur. This can lead to vasoconstriction, shivering, increased oxygen consumption, and acidosis. However, postischemic hyperthermia can lead to delayed neuronal cell death.[120] Mild degrees of hypothermia and certainly the avoidance of hyperthermia are essential in the perioperative period.[121] In children, rectal temperature mostly reflects peripheral temperature. One study showed that the temperature of the foot was more sensitive than the temperature of the hand.[122] Another study revealed that for anatomic or physiologic reasons, temperature gradients in the toes develop more readily than those in the fingers.[123] Several endpoints have been proposed, such as nasopharyngeal temperatures greater than 35.0°C, bladder temperature greater than 36.2°C, or skin temperatures greater than 30°C[124,125]; we use an endpoint of 35.5°C rectal temperature.[126]

SEPARATION FROM BYPASS

The child's core body temperature, hematocrit, and metabolic variables should be optimized before attempting separation from CPB. Careful observation for air in the systemic ventricle, confirmation with the TEE, and concurrent inspection of electrocardiogram (ECG) changes should continue throughout the weaning process, with the child in the Trendelenburg position and the aortic root vented. While fluid volume is gradually added to the child by reducing the outflow to the venous reservoir until optimal filling pressures are achieved, CPB flow is then slowly reduced to zero. If inotropic support is anticipated to separate from CPB, infusions should be initiated before beginning separation.

POSTBYPASS PERIOD

This phase lasts until chest closure and transfer to the ICU have been accomplished. During this time, modified ultrafiltration (MUF) may be performed for 10 to 15 minutes after cessation of CPB. Cardiac function and the quality of the surgical repair are assessed using TEE, and if found to be satisfactory, protamine is administered to neutralize residual heparin. The usual dose of protamine is 1.0 to 1.3 mg/100 units of heparin given at the onset of bypass. Limiting protamine to this dose prevents an overdose with its associated effects on platelet function (reduction of the interaction of glycoprotein Ib receptor interaction with von Willebrand factor).[127] If the ACT remains increased or prime blood is given back to the child, an additional 10% of the initial dose of protamine is added and the ACT is rechecked, keeping in mind that high ACT values after bypass may be related to factors other than the presence of residual heparin.[128]

Early use of heparinase-assisted thrombelastography or protamine titration ACT will allow a diagnostic separation of residual

heparin effect. However, particularly in infants, the administration of protamine and the persistent treatment of a suspected incomplete heparin reversal should not distract and delay the treatment of other commonly associated postbypass coagulopathies, such as thrombocytopenia, platelet dysfunction, hypofibrinogenemia, and other coagulation factor deficiencies. The child should be transferred to the ICU only after adequate hemostasis has been established since ongoing bleeding increases surgical mortality.[129]

Protamine reactions occur much less frequently in children younger than 16 years of age, approximately 1.8% to 2.9%.[130] Independent risk factors are a female gender, a larger protamine dose, and smaller heparin doses. Type I reactions or effects during administration are rare and adding calcium does not change the hemodynamic consequences of injection.[131] Fortunately, severe anaphylactic reactions (type II) or catastrophic pulmonary vasoconstriction (type III) are rare but have been observed.[132] Administering the protamine over 5 or more minutes reduces the severity and precipitous nature of any protamine reaction.

Unstable neonates and small infants may have their sternums temporarily left open, with surgical closure planned 24 to 72 hours later when cardiac function has improved and myocardial edema has diminished.

Because CPB can have a multitude of adverse physiologic effects, attempts are made to minimize both the duration of CPB and ischemic (aortic-clamp) time; thus, as much of the surgery as possible is performed outside of these phases. In general, physiologic responses to bypass are more extreme with decreasing age and size of the child. The neonate experiences a greater degree of hemodilution and colder temperatures on bypass and frequently requires longer aortic cross-clamp times, all of which can result in a greater inflammatory response. Table 19.5 summarizes clinical management issues during the major phases of CPB.

TABLE 19.5 Checklist for Bypass Management

Before CPB

1. Check temperature; maintain normothermia during induction and preparation.
2. Supplement premedication.
3. Ensure noninvasive monitoring: blood pressure, ECG, pulse oximetry, stethoscope.
4. Perform inhalational induction after preoxygenation; intravenous induction, if cannula is in place.
5. Peripheral intravenous placement(s)
6. Neuromuscular blockade and ventilation
7. Intubation and mechanical ventilation according to shunt lesion (CO_2, O_2 control)
8. Monitoring:
   a. Arterial line and central venous line
   b. ECG electrodes
   c. Bladder catheter
   d. Temperature probes
   e. TEE probe (in infants >3 kg)
9. Positioning
10. Deepening of anesthetic level
11. Antifibrinolytics and corticosteroids, as indicated
12. Heparin, 300–400 units/kg, before arterial cannulation
13. Check activated clotting time 400–480 seconds.
14. Supplement anesthetics on initiation of bypass.

During CPB

1. Stop ventilation and drips when full flow is reached.
2. Inspect head perfusion.
3. Evaluate quality of perfusion (perfusion pressure, central venous pressure, diuresis, arterial blood gases, temperature gradient).
4. Prepare for separation.
   a. Drips (inotropic drugs, calcium)
   b. Pacemaker
   c. Blood products
5. Set and control temperature and rewarming (heating blanket, room temperature).
6. Zero transducers
7. Check arterial blood gases in preparation for discontinuation of CPB; correct abnormalities.
8. Suction and ventilate.

After CPB

1. Separate when
   a. Temperature >35.5°C
   b. Stable rhythm or pacing
   c. Heart contracting well
2. Fine-tune blood pressure; consider direct blood pressure measurement for hypotension at the aortic cannula; volume ± drips.
3. Consider modified ultrafiltration.
4. Check arterial blood gases.
5. Evaluate with transesophageal echocardiography for residual defects and intracardiac air bubbles.
6. Give protamine, 1–1.3 mg/100 IU of initial heparin.
7. Check activated clotting time and arterial blood gases.
8. Chest closure and recheck arterial blood gases.
9. Transport to the intensive care unit.

CPB, cardiopulmonary bypass; *ECG*, electrocardiogram; *TEE*, transesophageal echocardiography.

Particular Aspects of Management on Cardiopulmonary Bypass

PH-STAT VERSUS α-STAT MANAGEMENT

Some degree of hypothermia is used for nearly every cardiac operation to slow the metabolism and oxygen consumption of all organs, particularly the brain and heart.[133] During cooling, the carbon dioxide contained in blood becomes more soluble and its partial pressure decreases. The $PaCO_2$ sensed by the body decreases as body temperature decreases, with the result that at a core temperature of 17°C to 18°C, if pH and $PaCO_2$ have not been corrected for temperature, the body experiences a pH of about 7.6 and $PaCO_2$ of 15 to 18 mm Hg (Fig. 19.2).[134] This very low $PaCO_2$ causes cerebral vasoconstriction, particularly during the cooling phase of bypass, which in turn leads to less cerebral blood flow, less efficient brain cooling, and less cerebral protection at a given temperature.[135] Because blood samples are normally heated to 37°C before measurement of pH, $PaCO_2$, and PaO_2, the use of pH-stat management indicates that blood gases are being corrected for the child's actual body temperature by increasing the $PaCO_2$ during bypass, as it is measured at 37°C, so that the body experiences a $PaCO_2$ of approximately 40 mm Hg and a pH of 7.4 at all temperatures. Conversely, α-stat management means not correcting the blood gases for temperature, as if the child's blood was always at 37°C, with the goal of pH 7.4 and $PaCO_2$ 40 mm Hg. In the early days of CPB, pH-stat was used to preserve cerebral blood flow at all ages.[134] Subsequently, in

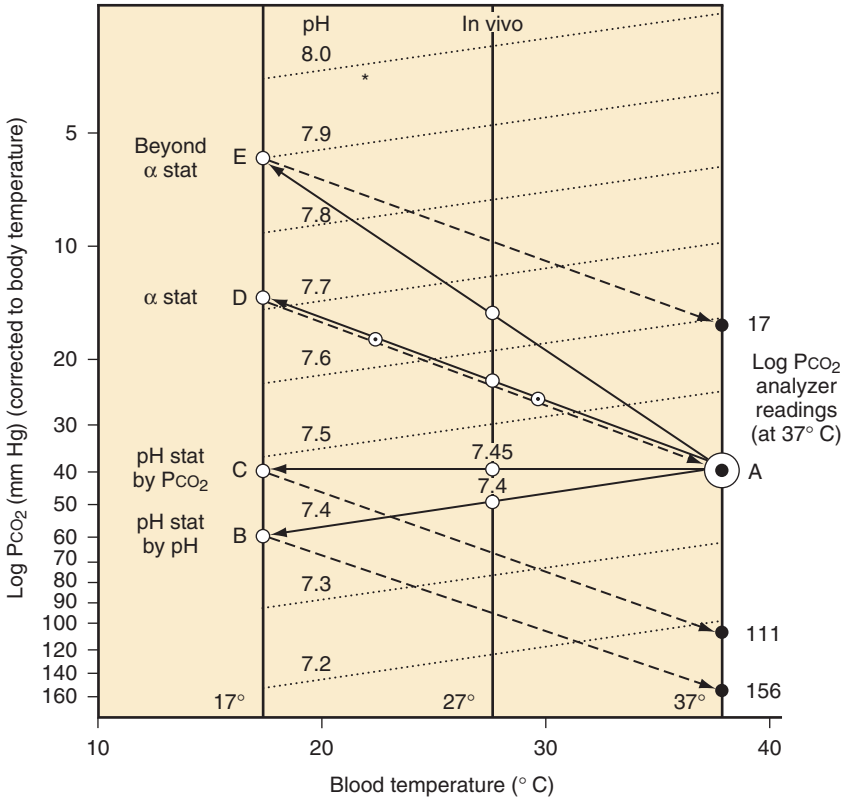

FIGURE 19.2 pH and P_{CO_2} changes when blood temperature is varied between 17°C and 37°C. Point **A** is the starting point, with pH 7.4 and P_{CO_2} 40 mm Hg at 37°C. Points **B, C, D,** and **E** are the conditions the brain experiences at 17°C with various blood gas management strategies. pH-stat management (correcting the pH and P_{CO_2} for temperature) results in an acid-base environment that is neutral, whereas α-stat management (not correcting for temperature) results in a very alkalotic environment at 17°C. Warming the blood sample (as is done for blood gas measurement) results in very high P_{CO_2} values when pH-stat is used. The pH of blood becomes slightly more alkalotic with cooling, owing to the decreased dissociation of hydrogen ions. (From Jonas RA. Carbon dioxide, pH, and oxygen management. In: Jonas RA, DiNardo J, Lawson PC, et al, eds. *Comprehensive Surgical Management of Congenital Heart Disease*. London: Arnold Publishers; 2004:151–160.)

the 1970s and 1980s, randomized controlled studies in adults confirmed that acute, post-CPB neurologic problems were worse with pH-stat management.[136] α-Stat management was, therefore, adopted for both adult and pediatric CPB. However, studies in a neonatal pig model have challenged this conclusion, proving that neurologic outcomes, both behavioral and neuropathologic, are significantly worse when α-stat management is used in infants.[135,137]

Advantages of pH-stat CPB have been shown to include:

- A decreased brain metabolic rate[138]
- An increased rate of brain cooling and reperfusion,[139] thereby providing better protection through more even and faster cooling and rewarming secondary to increased CBF[139,140]
- Molecular effects of altered Pa_{O_2} and pH, including changes in cerebral oxygenation and brain enzyme activity, as well as decreased brain electrical activity[140-142]
- Decreased oxyhemoglobin affinity[143]
- Increased cortical oxygenation before arrest (through hypercapnic capillary vasodilation) and decreased oxygen metabolic rate, providing slower deoxygenation compared with α-stat management (~10 vs. ~7 minutes).[135,144] Cortical anoxia occurs at 36 minutes with pH-stat management versus 24 minutes for α-stat management.

In cyanotic infants with aortopulmonary collaterals, pH-stat management significantly improves brain oxygenation as measured by NIRS oximetry.[145] A retrospective study of 16 infants revealed worse neurodevelopmental outcomes with α-stat management.[146] In a randomized prospective trial of pH- versus α-stat management in 182 infants younger than 9 months of age, there was a strong trend toward improved outcomes with pH-stat management, including earlier return of electroencephalographic activity, fewer seizures, and improved psychomotor development index.[147] Another study examined the effects of α-stat and pH-stat on developmental and neurologic outcomes after deep hypothermic CPB in infants.[148] Psychomotor Development Index scores of 110 patients did not differ significantly between the groups ($P = 0.97$). The results of the Mental Development Index scores were dependent on diagnosis. In all but the ventricular septal defect subgroup, the pH-stat group did not have statistically greater Mental Development Index scores. Abnormalities on the electroencephalogram ($P = 0.77$) and neurologic examination ($P = 0.70$) were similar with the two methods of blood gas management. The authors concluded that the use of α-stat or pH-stat strategy is not consistently associated with improved or impaired early neurodevelopmental outcomes in infants undergoing deep hypothermic CPB.[148] One reason for the differing results between pediatric and adult studies is that the

increased cerebral blood flow produced by pH-stat management and the presence of atherosclerotic plaques in adults lead to microcerebral atherosclerotic plaque emboli. Emboli occur much less frequently in children, and the primary cause of neurologic injury from CPB in children is hypoxic-ischemic[149]; thus, the increased cerebral blood flow observed on CPB with pH-stat management lessens this risk in children. Interestingly, this putative mechanism has been recently challenged by a study involving a controlled microembolic load and DHCA in pigs that revealed that pH-stat was still associated with improved outcomes when compared with α-stat.[150] pH-Stat also improves oxygen delivery by counteracting the pH- and hypothermia-associated leftward shift in the oxyhemoglobin dissociation curve. Studies have also revealed a decrease in peak postoperative troponin levels, reduced ventilator dependence, and reduced ICU stays with pH-stat versus α-stat.[151] Most programs specializing in surgery for congenital heart defects currently use pH-stat management. This necessitates careful attention to $PaCO_2$ during all phases of bypass, and possibly reducing the sweep gas flow into the CPB oxygenator (to decrease the efficiency of CO_2 removal), and often adding inspired CO_2 to the sweep gas of the bypass circuit, particularly in small infants.

HEMATOCRIT ON BYPASS

The relatively small total blood volume in infants, along with the volume required to prime the CPB circuit, means that adding blood to the CPB prime is mandatory. However this practice is institution specific; many centers add either whole blood, PRBCs with FFP (for children <8 kg), or PRBCs alone (for children <12 to 15 kg) to ensure that the hematocrit on bypass is not less than 20%. As a result of increased transfusion-related concerns from bloodborne viral disease transmission during the 1980s and 1990s, and given that a low hematocrit is thought to be necessary to ensure adequate blood flow through capillary beds (because the blood viscosity increases at low temperatures), hematocrits of 20% or less on CPB with deep hypothermia were frequently tolerated.[152] There is increasing evidence that the practice of extreme hemodilution is detrimental to neurologic outcome in children. In a newborn pig model, one group of investigators determined that the incidence and degree of hypoxic-ischemic brain injury after a period of DHCA was significantly greater with a hematocrit of 20% versus one of 30%, regardless of whether pH- or α-stat strategy was used.[153] In another newborn pig model, using intravital microscopy of pial capillaries during deep hypothermic CPB, a hematocrit of 30% did not impair cerebral microcirculation when compared with a hematocrit of 20%.[154] Finally, in a prospective randomized trial of CPB hematocrit of 20% versus 30% at Boston Children's Hospital, children in the lower hematocrit group demonstrated significantly reduced psychomotor development index scores 1 year after surgery.[89] In a follow-up study of hematocrit 25% versus 35%, the same group did not observe a difference in neurodevelopmental outcomes.[155] However, when they combined all children from both hematocrit trials, they found that a hematocrit less than 24% was associated with poorer psychomotor index scores 1 year after surgery.[156] The hypoxic-ischemic damage most likely occurs during the cooling and rewarming phases of bypass, when cerebral oxygen metabolism is not suppressed, yet hematocrit and, thus, oxygen delivery, are reduced. Therefore, many centers are now maintaining greater hematocrits on CPB (at least 25%), which either means using more donor blood products or using hemofiltration to increase the hematocrit during bypass. The current quantifiable risk of viral transmission through blood product transmission in the United States is 1 in 1.9 million units for human immunodeficiency virus, 1 in 1,000,000 for hepatitis B virus, and 1 in 1.7 million units for hepatitis C virus.[157,158] The risk/benefit ratios therefore favor the greater hematocrit approach, a definitive change from previous practice patterns. Balanced against this practice of a greater hematocrit on CPB is the finding that greater transfusion of blood products in the intraoperative and early postoperative periods is associated with a greater duration of mechanical ventilation in infants undergoing two-ventricle repairs.[159] Additional studies are required to optimize strategies for the use of blood products in infants and children undergoing CPB.

FLOW RATES ON BYPASS

The traditional practice in many institutions has been to decrease CPB flows, particularly during hypothermia, to reduce the volume of blood returning to the surgical field and allow more efficient completion of the surgery, particularly in small infants. This concept has been questioned in recent years owing to the inability to determine the safe low-flow bypass rate in the individual child. One report studied 28 neonates who underwent the arterial switch operation with α-stat blood gas management during CPB.[160] At 14°C to 15°C, bypass flow was sequentially reduced from 150 mL/kg per minute to 50 mL/kg per minute, and then further decreased in increments of 10 mL/kg per minute until circulatory arrest was initiated (to 0 mL/kg per minute). All neonates had detectable cerebral blood flow by transcranial Doppler (TCD) at CPB flows above 20 mL/kg per minute, but one had no detectable perfusion at 20 mL/kg per minute, and eight had none at 10 mL/kg per minute, leading the authors to conclude that 30 mL/kg per minute was the minimum acceptable flow in this population. A neonatal pig model determined that, at normothermia, bypass flows of at least 150 to 175 mL/kg per minute were necessary to ensure full oxygenation of all end organs and tissues.[161] Clinical studies of a high-flow bypass strategy, which included flows of 150 mL/kg per minute at all phases of bypass except during DHCA, minimal use of DHCA, and α-adrenergic receptor blockade with phenoxybenzamine to produce long-duration systemic vasodilation, demonstrated excellent short- and long-term clinical and neurodevelopmental outcomes; no child scored outside normal ranges for testing performed at a mean age of 9 years.[162] This strategy also has led to excellent early results for the Norwood operation, with an early perioperative survival of 83% for cases carried out from 1993 to 1999.[163] During the same era, one report documented that 26.7% of children who had arterial switch procedures had neurologic abnormalities, and 55% had at least one abnormal area on neurodevelopmental testing (performed at a mean of 10 years) when DHCA and low-flow bypass had been used.[163]

Vasoconstriction and increased vascular resistance, resulting in uneven regional organ perfusion, are among the undesired side effects of CPB. Endogenous catecholamine production and the alkaline α-stat CPB technique, if used, are responsible for these effects. To be able to run full flow during hypothermic CPB without significant hypertension, vasodilators are often used. Agents currently used to provide systemic vasodilation and more even cooling and rewarming include phentolamine, nitroprusside, or nitroglycerin. Phenoxybenzamine, which is no longer available, was used as part of a treatment strategy after stage 1 palliation for hypoplastic left heart syndrome and has been associated with improved outcomes.[164,165] Phenoxybenzamine was more effective than sodium nitroprusside in improving peripheral circulation, as shown by temperature gradients intraoperatively.[166] Greater

CPB flows are associated with an improved oxygen delivery, which can improve patient outcome.[167]

Phentolamine is a nonselective competitive α_1 and α_2 catecholamine receptor blocker. It has a half-life of 19 minutes and is eliminated mainly by the kidneys. Through postsynaptic α_1 and α_2 receptor inhibition it has a vasodilating and hypotensive effect that can improve cardiovascular variables and metabolic acidosis during CPB management.[168] In children receiving phentolamine, increasing lactate concentrations at the end of the CPB period show a steady state toward the end of the surgery, whereas lactate continues to increase in patients who did not receive phentolamine.[169] These findings suggest that the use of phentolamine limits lactic acid production during the hypothermic period and aids the disposal of lactic acid from tissues. Seelye and associates called the physiologic state after hypothermia the "oxygen debt repayment" period in infants.[169] Although it has a beneficial effect on CPB management, the potential harmful effects of phentolamine, especially on the brain, have still not been fully elucidated. One study provided evidence that phentolamine increases S100B protein and a parameter indicative of altered cerebrovascular resistance, the pulsatility index in the middle cerebral artery, in infants given phentolamine during open-heart surgery.[170]

Nitroprusside has been used as an easily titratable agent with direct arterial smooth muscle relaxant properties through production of nitric oxide and enhancement of the cyclic guanosine monophosphate (GMP) pathway. One study examined the effect of perioperative sodium nitroprusside in 25 neonates undergoing an arterial switch operation.[171] In comparison to the prebypass values, a similar increase in the concentration of S100B protein was found 2 hours after the termination of CPB in the sodium nitroprusside–treated and nontreated neonates, which decreased over the subsequent 48 postoperative hours. However, reduced postbypass serum levels of S100B protein were found in the sodium nitroprusside–treated group after 24 and 48 hours of treatment.

Nitroglycerin has been used with the same success. The only proven benefit over other agents is its nitric oxide donation capacity.[172] In Japan, high-dose chlorpromazine has been used as part of a low-resistance strategy during CPB for the Norwood procedure.[173]

We routinely use phentolamine, 0.1 to 0.2 mg/kg, to provide normal CPB flow and mean arterial pressure in the range of the diastolic pressure. If hypotension develops during bypass, the flow should be increased up to 150% of predicted; also one should examine the acid-base status in conjunction with cerebral oxygenation and mixed venous saturations. Often, severe hemodilution with oxygen debt is the cause and should be treated as such. After exclusion, we treat the hypotension carefully with vasoconstrictors, knowing that normal systemic pressures will not restore splanchnic hypoperfusion[174] and that vasoconstrictors will often lead to a greater base excess. Excessive α-adrenergic receptor blockade can be antagonized by vasopressin.[175] One study demonstrated that vasoconstrictor treatment results in the administration of more sodium bicarbonate to treat the acidosis and is associated with a later time to extubation and return of bowel function.[176] In conclusion, α-adrenergic receptor blockade during bypass should be considered because of its benefits for tissue perfusion, but carefully executed and balanced against potential drawbacks afterwards.

CONVENTIONAL ULTRAFILTRATION AND MODIFIED ULTRAFILTRATION

Ultrafiltration involves placing a hemofilter (similar to that used for continuous arteriovenous or venovenous hemofiltration in the ICU) in the CPB circuit and has become the standard of care for nearly all programs that specialize in surgery for congenital heart defects.[177] Conventional ultrafiltration (CUF) is performed during CPB, with the filter placed between the arterial and venous sides of the CPB circuit. The hemofilter has thousands of fibers with pores, which allow water, electrolytes, and small molecules to be filtered out of the blood. Suction is applied to the hemofilter on CPB, and an ultrafiltrate of plasma is produced. Advantages of ultrafiltration include the ability to increase the hematocrit, fibrinogen, plasma proteins, and platelet count,[178,179] without necessitating further blood transfusion, the ability to remove excess free water and sodium (which contribute to excess intravascular volume, tissue edema, pulmonary and myocardial edema), as well as the ability to correct acid-base and electrolyte imbalances and to remove small molecules, such as interleukins and tumor necrosis factor-α (TNF-α) in particular,[180] which are involved in the postbypass inflammatory process.[181,182] This improves systolic and diastolic function of the myocardium and reduces endothelial dysfunction in the systemic and pulmonary vasculature.[182,183] Pulmonary function is better preserved, probably owing to a slight reduction in interleukin 6 (IL-6) and thromboxane B_2,[184] even though this is not a consistent finding.[185,186] Endothelin-1, another mediator of pulmonary damage and hypertension, is not reduced by any filtration method.[186] Clinically, however, any ultrafiltration method seems to benefit children, especially those undergoing complex repairs, neonates, and children with preexisting pulmonary hypertension.[185]

MUF is performed for 10 to 15 minutes immediately after the conclusion of CPB. It can be performed in an arteriovenous manner with a hemofilter placed between the aortic cannula and the IVC cannula, or in a venovenous fashion using bicaval cannulation or an internal jugular venous catheter.[187] It was developed in 1991[188] as an alternative method to reduce the side effects of CPB. CUF during bypass is often limited by the minimal venous reservoir levels and requires the addition of crystalloid or colloid to be able to continuously remove cytokines during ultrafiltration. During MUF, blood passes out of the aorta, through the hemofilter, and is returned through the IVC cannula. The theoretical advantage of MUF over CUF is that only the child's blood volume is filtered, yielding a more efficient system for achieving the goals outlined previously. The disadvantages are that the child remains heparinized, and body temperature may decrease during the process (unless the circuit is modified to include the heat exchanger).[189] It also requires extra time, an aortic cannula is needed that can obstruct the aorta in small infants, and acute intravascular volume shifts may occur at a time when the child is prone to hemodynamic instability. Opposite to the expected effects of fluid removal, MUF actually increases arterial pressures despite decreasing filling pressures and improving myocardial performance.[190]

There is increasing evidence that the use of ultrafiltration reduces bypass-related postoperative morbidity. Outcome studies have demonstrated that ultrafiltration improves myocardial and pulmonary function, lessens tissue edema, allows faster weaning from mechanical ventilation, and decreases the need for inotropic support.[191] In that aspect it may be as efficient as the perioperative application of steroids.[192] Unfortunately, the reduction of inflammatory transmitters is only temporary, because the levels of cytokines are similar after 24 hours.[193]

Although each method has its proponents, and some centers perform both techniques in the same children, controlled comparative studies revealed no difference in outcome between MUF and CUF.[191,194] We routinely use a balanced ultrafiltration technique

for all cases on CPB because it removes fluids and cytokines, as well as reduces lactate, which can aggravate reperfusion injury.[195]

Prebypass Anesthetic Management

The objectives of the anesthetic management of children before bypass include maintenance of normal sinus rhythm and ventricular function and avoidance of extreme increases in heart rate, ventricular contractility, and pulmonary vascular resistance (PVR). Special attention should be given to maintaining adequate coronary perfusion. Methods for accomplishing these objectives are lesion-specific and may include the maintenance of PVR with controlled hypoventilation and delivery of a low fraction of inspired oxygen to avoid pulmonary overcirculation, diastolic runoff, and coronary hypoperfusion in patients with a large left-to-right shunt (truncus arteriosus, aortopulmonary window, large patent ductus arteriosus, central shunt). Vasoactive and inotropic infusions and temporary snaring of the pulmonary artery may be required to achieve these goals. The duration of the prebypass period varies greatly, particularly in children who have had previous surgery, and maintaining hemodynamic stability for prolonged periods of time can be challenging. Adequate anesthetic depth should be ensured to avoid increases in sympathetic stimulation and hypercyanotic spells, and temperature homeostasis should be maintained to avoid cardiac arrhythmias, especially when the duration of the pre-CPB surgical dissection is protracted. For children undergoing repeat sternotomy, blood products with an appropriate-capacity blood warmer should be readily at hand in case of emergent need.

Neonates and children who have been receiving total parenteral nutrition preoperatively receive an infusion of 5% or 10% dextrose before CPB, with frequent monitoring of glucose concentrations to avoid hypoglycemia or hyperglycemia. Older children receive PlasmaLyte, a balanced electrolyte solution, at a reduced maintenance rate, allowing the administration of 5% albumin, if necessary, for volume augmentation.

The placement of purse-string sutures before cannulation, as well as the actual cannulation of the great vessels before CPB, can often precipitate arrhythmias, hypotension, and arterial desaturation, especially in small infants and children. It is common for volume replacement to be necessary during placement of the cannula; if the aortic cannula is already in place, it is our practice to coordinate the administration of fluid volume between the anesthesiologist and perfusionist while the surgeon completes cannulation. Calcium chloride (10 mg/kg) is also frequently useful to support hemodynamics at this time.

Anesthesia on Cardiopulmonary Bypass

CHANGES IN PHARMACOKINETICS

The initiation of CPB introduces additional volume to the intravascular space (hemodilution). Hemodilution and altered protein concentrations greatly affect drug distribution and consequent plasma concentrations. Plasma protein binding,[196] hypotension, hypothermia,[197] pulsatility,[198] isolation of the lungs from the circulation, altered hepatic and renal function, ultrafiltration, and uptake of anesthetic drugs by the bypass circuit are other major factors that affect pharmacologic responses.[199,200] Drugs in the blood exist in the free (unbound and therefore the active form) or plasma-bound (inactive form bound to protein, e.g., albumin) forms and therefore are subject to marked changes with alterations in plasma protein levels. CPB alters all these factors, which makes description of pharmacokinetic parameters during CPB problematic. The greatest changes occur within 5 minutes of initiation of CPB. The addition of the prime volume immediately reduces the protein concentration, and the ratio of bound-to-free drug in the circulation changes. Hemodilution occurs, and free drug concentrations are also reduced owing to dilution; this reduces the amount of drug available for interaction with the receptors. Most studies show a reduction in total drug concentration in plasma with little change in unbound drug concentration over time, whereas on CPB other than the transient (<5 minutes) reduction at initiation of CPB,[201] it would appear that the greatest risk for unwanted "lightening of anesthesia" is within this time frame, and additional doses of fentanyl, muscle relaxant, and midazolam are generally administered just before or with the onset of CPB. The explanation for why unbound drug concentrations are sustained during CPB is that the volume of distribution for most anesthetic agents is large relative to the volume of the CPB prime and serves as a huge reservoir for drug after IV administration. A decrease in the plasma concentrations of medications as a result of hemodilution shifts drugs down their concentration gradient from tissue to plasma. Hypothermia contributes to the changes in plasma concentrations, primarily by depressing enzyme function and slowing drug clearance by approximately half for every 10°C reduction in temperature. When normothermia is reestablished, reperfusion of tissues might lead to washout of drug sequestered during the hypothermic CPB period. This may explain the secondary increases in plasma concentrations of opioids reported during the rewarming phase. pH-stat management also affects the degree of ionization and protein binding of certain medications, leading to increased unbound drug. During CPB, the lungs are out of circuit and medications that are taken up by the lungs (e.g., opioids) are sequestered during CPB. These medications are released when systemic reperfusion is established and concentrations are transiently increased. The volume of distribution of many drugs is expanded because of the priming volume of the bypass circuit, especially with neonates and small infants, where the priming volume is often greater than the child's blood volume. Medications may be taken up by various components of the CPB circuit itself. Renal dysfunction associated with CPB reduces the clearance of drugs such as cephalosporin antibiotics, TXA, EACA, and milrinone.

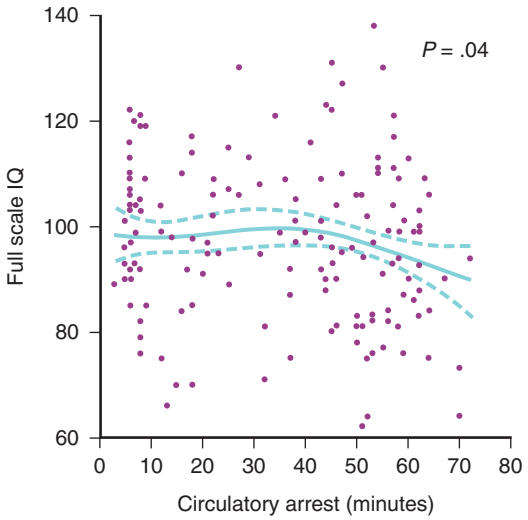
CHANGES IN PHARMACODYNAMICS

The pharmacodynamic effects of anesthetic agents are affected primarily via the central nervous system, which undergoes major changes during CPB. For example, hypothermia during CPB reduces anesthetic requirements. Hypothermia causes a host of other effects, including decreases in receptor affinity (e.g., decreased opioid receptor affinity[202] and nicotinic acetylcholine receptor sensitivity[203]), enhanced effects of neuromuscular receptor blocking drugs at the neuromuscular junction,[204,205] and alterations in tissue blood flow that may affect the response to catecholamines.[206]

CPB also affects the degree of ionization and protein binding (hence free or unbound drug concentrations) of weak acids and bases, as well as the electrolyte balance achieved by the blood gas management strategy used during CPB. Plasma concentrations of calcium, magnesium, and potassium decrease during CPB,[207,208] and these changes may lead to muscle weakness, dysrhythmias, and digitalis toxicity. The number of receptors available for interaction with a ligand will determine the subsequent magnitude of a drug effect. A reduction in the number of cardiac receptors has been observed in congestive heart failure, and defects in

receptor transduction, as well as impairment of synthesis and reuptake of norepinephrine occur.

Administration of β-adrenergic agonists in this condition has been associated with further reductions in β-receptor numbers, with diminished pharmacologic effect. Removal of β-adrenergic blockade may lead to β-adrenergic receptor upregulation and increased adrenergic responsiveness.[209] Changes in receptor density and function may occur very quickly and have been observed to occur during cardiac surgery. Many perfusionists, under the direction of the anesthesiologist, can also administer inhalation agents via a separate vaporizer mounted on the bypass machine. Alternatively, a propofol infusion can be used during bypass to maintain anesthetic depth. Anesthetic requirements decrease with systemic hypothermia,[210] but as rewarming is initiated, additional anesthetic drugs, including a benzodiazepine, are added to the bypass circuit to ensure that amnesia is maintained. Further work is required to elucidate the mechanisms and clinical implications of these acute changes in receptor density and function.



Special Techniques

MANAGEMENT OF DEEP HYPOTHERMIC CIRCULATORY ARREST

In the early days of cardiac surgery and CPB, hypothermia was used to improve intracardiac surgical exposure. In 1950, Bigelow and colleagues were the first to show that hypothermia decreases the metabolic rate.[211] Since then, we have discovered other advantages of hypothermia, including decreases in the inflammatory response of CPB,[212] decreases in blood loss,[213] myocardial protection,[214] and neuroprotection.[215] The last effect relates primarily to the decrease in the metabolic rate (by approximately 64%) that is achieved by cooling from 37°C to 27°C. The disadvantages of deep hypothermic circulatory arrest (DHCA) include a prolongation of CPB duration and a greater tendency toward postoperative bleeding.[216] Postoperative recovery, however, is not prolonged by hypothermia.[217] The rate of wound infection is uninfluenced by hypothermic bypass.[218]

Hypothermia during cardiac surgery gained widespread acceptance only after the 1959 development of a heat exchanger that could be integrated into the CPB machine.[219] DHCA involves cooling the child's body temperature during CPB to 17°C to 18°C, stopping the bypass machine, draining the blood from the child into a venous reservoir, and removing the cannulas from the heart. After the first reports of DHCA in the 1960s, this technique gained popularity in the 1970s and 1980s because of the bloodless field it provided, thus facilitating complex intracardiac and aortic repairs in neonates and small infants,[220] as well as reducing myocardial edema. However, it soon became evident that DHCA was associated with neurologic morbidity. Choreoathetosis, seizures, coma, and hemiparesis were all noted, especially with prolonged (>60-minute) DHCA. The incidence of these acute morbidities seemed to increase when α-stat management became the widely accepted standard. Long-term adverse neurodevelopmental outcomes have also been associated with long periods of DHCA, including abnormalities in mental development and in fine and gross motor skills.[221] The Boston Circulatory Arrest Study is a remarkable achievement in which 155 neonates undergoing the arterial switch operation from 1988 to 1992 were studied, with follow-up complete to 8 years of age.[222] The CPB protocol in those years included α-stat management, routine hemodilution to a hematocrit of 20%, and the absence of an arterial filter on the CPB circuit. A DHCA time longer than 40 minutes was associated with a significant increase in adverse long-term neurologic outcomes (Fig. 19.3). Although the 40-minute cutoff is now well accepted in surgery for congenital heart defects, a number of changes have subsequently been made to bypass protocols. Results from animal experiments using a neonatal pig model of DHCA, as well as data from the Boston Circulatory Arrest Study, led to the following recommendations for increasing the child's safety margin when using DHCA:

- Hematocrit of 30% should be the target.[89]
- Systemic hypothermia should be achieved slowly, over no less than 20 minutes.[223]
- pH-stat blood gas management should be used, at least for cooling (Fig. 19.4).[135,137]
- Core body temperatures of 17°C to 18°C should be used, and ice bags should be applied to the head.[224]
- DHCA should be divided into periods of less than 20 minutes, allowing a reperfusion period of at least 2 minutes between each segment of DHCA, to improve neurologic outcome.[225]
- Low-flow CPB is better than DHCA. Selective regional cerebral perfusion may be better than full-body low-flow CPB.[226]
- Normoxia should be maintained to decrease exacerbation of brain injury after DHCA.[227]

Variable	Cut-point estimate (minutes)	95% lower confidence limit (minutes)

FIGURE 19.3 Safe duration of circulatory arrest. From the Boston Circulatory Arrest Study, 155 8-year-olds who underwent arterial switch operation for D-transposition of the great arteries as neonates. Bypass protocol used α-stat pH management, with hematocrit of 20% and temperature of 18°C. Above 40 minutes DHCA, both mental and physical performance test scores at 8 years of age decreased significantly. (From Wypij D, Newburger JW, Rappaport LA, et al. The effect of duration of deep hypothermic circulatory arrest in infant heart surgery on late neurodevelopment: the Boston Circulatory Arrest Trial. *J Thorac Cardiovasc Surg.* 2003;126:1397–1403.)

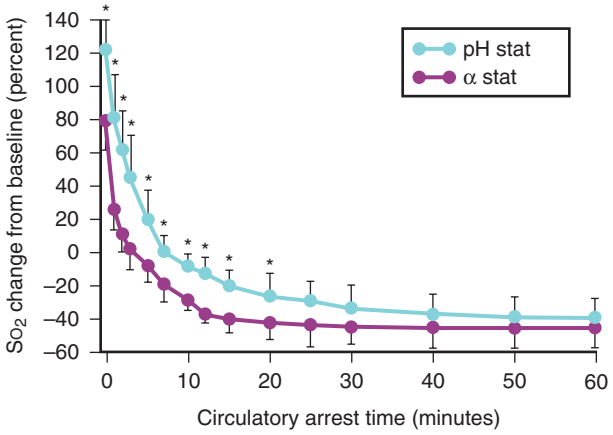

FIGURE 19.4 Cortical oxygen saturation (So_2) during deep hypothermic circulatory arrest in pH-stat and α-stat groups. The cortical So_2 half-life during arrest was significantly greater in the pH-stat than in the α-stat group. Mean ± SD, eight animals per group. *P < 0.05 between groups. (From Kurth CD, O'Rourke MM, O'Hara IB. Comparison of pH-stat and alpha-stat cardiopulmonary bypass on cerebral oxygenation and blood flow in relation to hypothermic circulatory arrest in piglets. *Anesthesiology* 1998;89:110–118.)

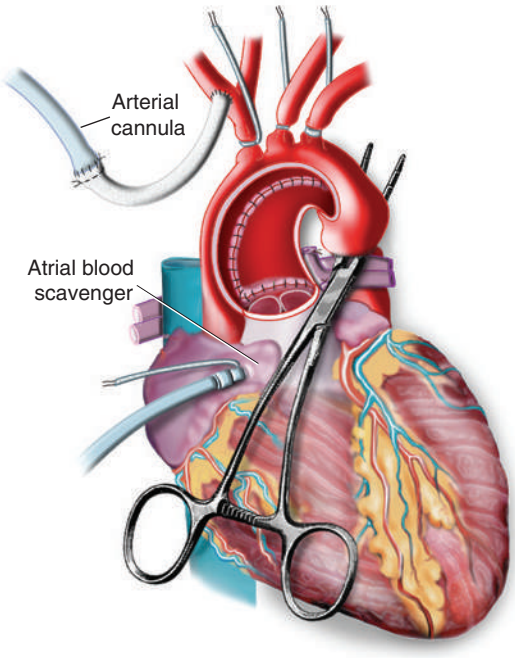

FIGURE 19.5 Selective cerebral perfusion for the Norwood stage 1 palliation for hypoplastic left heart syndrome. Arterial inflow for bypass is provided by a small polytetrafluoroethylene graft sewn to the right innominate artery. Instead of deep hypothermic circulatory arrest, flow is provided to the brain at low rates, while the brachiocephalic vessels and descending thoracic aorta are snared, providing a bloodless operating field. (From Pigula FA, Nemoto EM, Griffith BP, Siewers RD. Regional low-flow perfusion provides cerebral circulatory support during neonatal aortic arch reconstruction. *J Thorac Cardiovasc Surg.* 2000;119:331–339.)

Neurologic monitoring (see later discussion) may be useful in the individual child to aid in determining the safe duration of DHCA.[135,228]

Although there are situations in which DHCA must be used, many surgeons are avoiding it whenever possible, minimizing its duration and dividing the periods of its use, or using alternate methods, such as selective cerebral perfusion (see the following discussion).

REGIONAL CEREBRAL PERFUSION

Several novel CPB techniques have been developed to avoid the use of DHCA. The purpose of these techniques is to allow perfusion of the brain during critical periods of surgery, such as aortic reconstruction during the Norwood operation.[229,230] These techniques are collectively referred to as selective cerebral perfusion. Regional cerebral perfusion (RCP) is one variation in which a small Gore-Tex graft (W.L. Gore and Associates, Flagstaff, AZ) of 3 to 4 mm is sewn onto the innominate artery before initiation of CPB and is then used as the aortic cannula during CPB (Fig. 19.5). During aortic reconstruction, snares are placed around the brachiocephalic vessels and CPB flow is decreased, with the brain receiving perfusion only via the right carotid artery. In this way, a bloodless operative field is achieved, just as if DHCA was being performed, yet the brain is still receiving blood flow and oxygen, theoretically increasing protection from hypoxic ischemic brain injury. Another potential advantage of this technique occurs in neonates, who frequently have extensive arterial collaterals between the proximal branches of the aorta and the lower body via the internal mammary and long thoracic arteries. In this instance, the use of selective cerebral perfusion also provides some blood flow to the lower body, protecting renal, hepatic, and gastrointestinal systems from hypoxic damage as well.[231] This protection is, however, incomplete and RCP at 25°C is no more protective than DHCA.[232] Also, the ongoing perfusion prolongs the effective bypass time, leading to more cytokine release and capillary leakage, with worse pulmonary function, more weight gain, and decreased right ventricular function.[233]

One study described a cohort of 57 neonates undergoing RCP for stage 1 palliation of hypoplastic left heart syndrome and other aortic arch reconstructions.[234] Mean RCP time was 71 ± 28 minutes and flow rate 57 ± 11 mL/kg per minute (38% of normal full CPB flow). Postoperative brain MRI revealed no differences in patients undergoing RCP versus standard CPB. Twelve-month neurodevelopmental outcomes assessed with the Bayley Scales of Infant Development-III revealed Cognitive Score of 100 ± 15, Language Score of 87 ± 15, and Motor Score of 88 ± 17. Increasing duration of RCP was not associated with adverse neurodevelopmental outcomes. Neurologic monitoring, consisting of NIRS and TCD measurements, was used to adjust the flow rate during RCP.[235,236] Radial arterial pressures of 30 to 40 mm Hg were maintained during RCP.[235]

Effects of Cardiopulmonary Bypass

CARDIAC EFFECTS

In addition to myocardial ischemic injury secondary to aortic cross-clamping, several other factors can contribute to perioperative myocardial dysfunction. The first is entrainment of air into the coronary arteries, which frequently occurs during weaning from bypass.[237] Despite meticulous de-airing of the heart, air may enter the right coronary artery, producing ischemia that is heralded by a pale myocardium, poor contractility, and ST-segment elevation of the ECG. Should this occur, appropriate management involves remaining on CPB, increasing perfusion pressure, and "milking" the air through the coronary arteries, allowing time for recovery

of the ECG and ventricular function before attempting to wean from bypass. Surgical factors, such as reimplantation of coronary arteries with possible resultant ischemia or residual surgical defects, can also occasionally contribute to myocardial dysfunction.

The inflammatory response to CPB (see later discussion) has important implications for cardiac function.[238] This systemic response results in a capillary leak syndrome, which in turn leads to accumulation of edema fluid in interstitial and extravascular spaces, including the myocardium.[239] Myocardial edema can contribute to post-CPB myocardial dysfunction by impairing diastolic function and causing mechanical limitation of cardiac filling and outflow in small infants whose sternums have been closed. Additionally, myocardial edema has been implicated as a causative factor in the frequent decline in myocardial function that occurs 6 to 12 hours after conclusion of CPB. Inflammatory mediators also affect the responsiveness of the myocardium to catecholamines by interfering with their binding to the cell surface receptors,[240] rendering exogenously administered drugs, such as dopamine and epinephrine, as well as the child's endogenous catecholamines, less effective at augmenting cardiac function perioperatively.

Mechanisms for prevention and treatment of myocardial dysfunction include the use of ultrafiltration and antiinflammatory drugs, such as corticosteroids and aprotinin.[241,242] The prophylactic use of noncatecholamine inotropic agents, such as milrinone, has also been shown to prevent low cardiac output syndrome in infants, even if cardiac function is adequate in the immediate postoperative period.[243]

SYSTEMIC AND PULMONARY VASCULATURE EFFECTS

The inflammatory response to CPB often produces mediators that directly increase pulmonary and systemic vascular resistance. These include interleukins, leukotrienes, and endothelin.[244] Indeed, when pulmonary artery pressure is measured directly, it is often significantly increased immediately after bypass, even if surgical results are optimal. This increase can be extremely detrimental in children with large left-to-right shunts, those undergoing cardiac transplantation secondary to dilated cardiomyopathy, and those undergoing bidirectional cavopulmonary anastomosis, where right ventricular output depends on maintaining low PVR. Prevention and treatment of increases in PVR include maintaining an adequate depth of anesthesia, ventilating with 100% oxygen, and judicious use of hyperventilation. Milrinone will increase right-sided cardiac output via its actions as both an inotropic agent and a pulmonary vasodilator. When PVR is significantly increased, inhaled nitric oxide is often used to assist in the early postoperative period.[245] Although effective, its cost is not inconsequential, and because PVR almost always decreases with time, inhaled nitric oxide is generally reserved for selected cases of pulmonary hypertension. Other simpler, less expensive treatments include oral or IV sildenafil[246,247] and inhaled nebulized prostacyclin.[248]

PULMONARY EFFECTS

The lungs are not ventilated during CPB and are usually totally collapsed by intention, with the ventilator circuit disconnected, especially in small infants. This leads to significant atelectasis and lung function can be improved by continuation of ventilation even on bypass.[249] The lungs are also at least partially ischemic during the bypass period, resulting in decreased production and reduced alveolar levels of surfactant after CPB.[250] In addition, reperfusion injury (pulmonary edema or hemorrhage after a sudden increase in pulmonary flow) can also occur after creation of a systemic-to-pulmonary artery shunt or pulmonary artery unifocalization. Inflammatory mediators liberated by the bypass run also predispose to increases in smooth muscle tone and resistance and can result in bronchospasm.[251]

In addition to complement, endotoxins and certain cytokines can also activate neutrophils and attract them toward sites of inflammation.[252] In animal studies, endotoxin-induced lung injury can lead to rapid (within 45 minutes) accumulation of neutrophils within lung capillaries. Activation of neutrophils, with upregulation of adhesion molecules, neutrophil adhesion to the endothelium of lung vessels, and endothelial damage through proteases, appears to be the main step of the underlying pathophysiologic mechanism (Fig. 19.6). Macrophages play an important role in the evolution of the inflammatory acute lung injury through the secretion of cytokines, cytotoxic metabolites, and chemoattractants for leukocytes. At the clinical level, acute respiratory distress syndrome (ARDS) is often only one part of multiorgan failure, and lung injury should be seen as part of a more general state of systemic inflammation. The reported prevalence of ARDS after CPB in adults is 0.5% to 1.7%; the incidence in children is unknown. Interestingly, general hypothermia at 28°C failed to prevent the loss of ATP and the accumulation of lactate in lungs.[253] Other methods that aim to protect the lungs during CPB, such as continuous lung perfusion, pneumoplegia, and inhaled nitric oxide ventilation at lung reperfusion, prevent more severe hemodynamic deterioration and preserve reactivity of the pulmonary vasculature, but fail to prevent pulmonary dysfunction.

The severity of pulmonary dysfunction after CPB can be measured via changes in the alveolar-arterial oxygenation gradient, intrapulmonary shunt, degree of pulmonary edema, pulmonary compliance, and PVR. Treatment of pulmonary atelectasis includes careful reinflation of the lungs when weaning from bypass (by administering several vital capacity breaths), gentle but thorough suctioning of the tracheal tube, and prophylactic use of inhaled bronchodilators before separation from CPB. Using these measures, pulmonary function has been shown to improve immediately in most children with large left-to-right shunts, with the duration of CPB seemingly having little effect on pulmonary outcomes.[254] Thus, CPB itself has little effect on pulmonary function in most children. There is still an occasional child, however, who experiences classic "pump lung" ARDS, caused by the factors noted earlier. Treatment is supportive as for anyone with ARDS.

NEUROLOGIC MONITORING AND EFFECTS OF CARDIOPULMONARY BYPASS ON THE BRAIN

Cerebral monitoring can help to detect those children who are at risk for neurologic sequelae after bypass, promptly recognize and treat changes in cerebral blood flow/oxygenation, evaluate the effect of therapeutic interventions on cerebral physiology, optimize brain protection during the vulnerable periods of CPB, and potentially improve short- and long-term neurologic outcomes.[255] However, one must recognize that there is an increased frequency of congenital structural CNS abnormalities in association with complex CHD that appear to be present at birth in nearly half of these neonates and cannot be reversed. Further damage can be prevented using specific management strategies during the perioperative period.[255a]

The cerebral NIRS monitor measures brain tissue oxygenation (see Chapter 52). This device noninvasively measures the cerebral tissue oxygen saturation and displays a numerical value for the regional cerebral oxygen saturation (rSO_2), the ratio of oxyhemoglobin to total hemoglobin in the light path. Regional

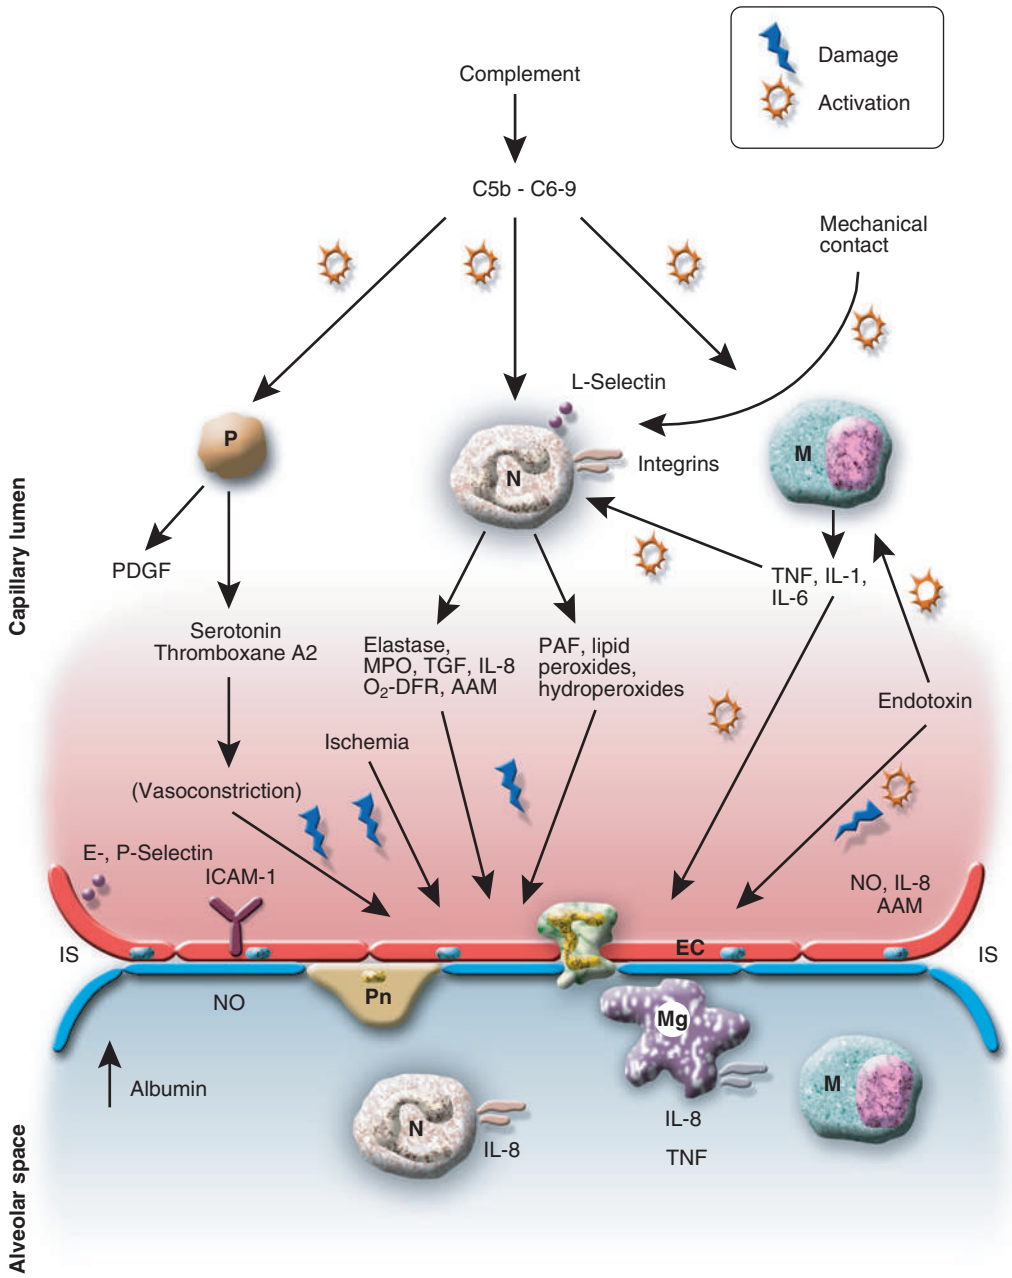

FIGURE 19.6 Leukocytes, endothelial cells (*EC*), and humoral inflammatory mediators have been shown to play an important role in the cardiopulmonary bypass-induced lung injury. Complement (*C*) activation and complement-independent mechanical injury activates leukocytes, which, in turn, secrete several inflammatory mediators, such as proteases and cytokines. Complement, cytokines, and ischemia-reperfusion also activate endothelial cells. Endotoxin, probably released from intestinal bacteria, exerts similar effects on leukocytes and endothelium. This process leads to disruption of endothelial and epithelial integrity and allows albumin, plasma, and activated leukocytes to enter the interstitial and alveolar spaces, causing tissue edema and reducing pulmonary compliance and blood oxygenation. *AAM*, arachidonic acid metabolites; *ICAM-1*, intercellular adhesion molecule 1; *IL*, interleukin; *IS*, interstitial space; *M*, monocyte; *Mg*, macrophage; *MPO*, myeloperoxidase; *N*, neutrophil; *NO*, nitric oxide; O_2*-DFR*, oxygen-derived free radicals; *P*, platelet; *PAF*, platelet-activating factor; *PDGF*, platelet-derived growth factor; *Pn*, pneumocyte; *TGF*, tumor growth factor; *TNF*, tumor necrosis factor. cerebral oxygen saturation is a measure of local microcirculatory oxygen supply-and-demand balance and is reported on a scale from 15% to 95%. It has been assumed from anatomic models that 75% of the cerebral blood volume in the light path is venous and 25% is arterial. One study verified this in children with congenital heart disease by directly measuring the jugular venous bulb and arterial oxygen saturations and comparing these with the cerebral oxygen saturation measured with NIRS.[256] The actual ratio in children varied widely, but on average the venous to arterial ratio was 85 : 15. All devices measure both the arterial and venous blood oxygen saturations. Accordingly, this device does not provide a measure of the jugular venous bulb oxygen saturation ($SjvO_2$). A corollary of this is that maneuvers that increase arterial oxygen saturation (e.g., increasing FIO_2) increase cerebral oxygenation as measured by these devices, although the $SjvO_2$ may remain unchanged. In a study of 40 infants and children with congenital heart disease who were undergoing cardiac surgery or catheterization, NIRS correlated poorly with $SjvO_2$ measurements, except in infants younger than 1 year of age.[257] In contrast, in a study of 30 children undergoing cardiac catheterization, NIRS correlated very well with $SjvO_2$ ($r = .93$).[258] These data suggest that NIRS is a useful indicator of trends in cerebral oxygenation in individual infants and children who have a stable FIO_2, hemoglobin. and carbon dioxide. NIRS values also correlate with long-term neurodevelopmental outcomes after infant heart surgery. In a prospective study of 104 two-ventricle repairs, low rSO_2 in the intraoperative period did not correlate with death or major morbidity.[259] However, when these children underwent neurodevelopmental testing at 1 year of age, lower average and minimum rSO_2 in the 60-minute period immediately after CPB correlated with worse psychomotor development index scores. Low rSO_2 also correlated with remote ischemic changes on brain MRI at 1 year of age.[260]

Neurologic Monitoring for Low-Flow Hypothermic Bypass

TCD ultrasonography has been used to determine the threshold of detectable cerebral perfusion during low-flow CPB. *TCD velocities reveal trends or changes in cerebral blood flow and not absolute values.* One report studied 28 neonates undergoing the arterial switch operation using α-stat blood gas management.[160] Their study suggested that NIRS and TCD may be useful to determine the minimum acceptable bypass flow rate for an individual neonate during low-flow hypothermic bypass. Blood flow becomes insufficient at bypass flow rates less than 30 mL/kg per minute.[160,261] Inadequate blood flow to the brain during this technique could be undetected without such monitoring, and low-flow bypass may confer no advantage to the brain over DHCA in some children. Long-term outcome studies of this monitoring strategy are not available.

Neurologic Monitoring for Deep Hypothermic Circulatory Arrest

Despite clinical and experimental evidence that periods of DHCA that exceed approximately 40 minutes are associated with an increased risk of adverse long-term neurologic and developmental outcomes, this technique is still widely used in surgery to correct congenital heart defects. Recent recommendations for improving outcomes after DHCA, based on both animal and clinical studies, were described previously. During DHCA, rSO_2 predictably decreases to a nadir 60% to 70% (relative change) below baseline values obtained before bypass. The nadir is reached at 10 to 20 minutes, after which there is no further decrease.[262] At this point, it appears that there is no additional oxygen uptake by the brain. Several studies suggest the potential for NIRS to determine the safe conduct and duration of DHCA in the individual child. In a study of infants and children undergoing surgery with bypass and DHCA, three children with low rSO_2 developed acute postoperative neurologic changes–seizures in one and prolonged coma in two.[262] In these three children, the increase in rSO_2 after the onset of CPB was much less (average 3% relative increase vs. 33% increase in children without neurologic deficit), and the duration of cooling before DHCA was less than in the remaining 23 children who did not develop neurologic changes. In a neonatal pig model, the timing of the nadir of rSO_2 values during DHCA correlated with neurologic outcome: a more prolonged period without oxygen uptake by the brain correlated with a greater incidence of adverse neurologic outcomes. The maximum safe duration at 17°C without additional brain oxygen uptake was 30 minutes.[153] Interestingly, this time period correlates with clinical and experimental studies, suggesting that 40 minutes is the safe duration for circulatory arrest (see Fig. 19.3). When circulatory arrest is initiated at warmer temperatures (e.g., 25°C), the rSO_2 decreases more rapidly, and the nadir is achieved sooner, than at cooler temperatures.[263] Reperfusion results in an increase in rSO_2 to levels observed at full bypass flow before DHCA, with a subsequent decrease during rewarming. Based on these data, our current practice is to reperfuse after the NIRS nadir has been reached for a period of 20 to 25 minutes.

Neurologic Monitoring for Regional Cerebral Perfusion

RCP (also known as selective cerebral perfusion or antegrade cerebral perfusion) uses a polytetrafluoroethylene (PTFE) graft or a small aortic cannula as arterial inflow to the right innominate artery for neonatal aortic surgery, such as the Norwood stage 1 operation or aortic arch advancement. The other brachiocephalic vessels and descending thoracic aorta are snared, resulting in a bloodless operating field. The brain is perfused through the right innominate and right vertebral arteries only. This approach significantly reduces or eliminates the use of DHCA for these operations and preserves brain perfusion, potentially improving neurologic outcome. Initial descriptions of this technique used the pressure in the radial artery or a predetermined bypass rate of 25 to 30 mL/kg per minute as an estimate for the bypass flow during RCP without neurologic monitoring. When flow rate was estimated on the basis of NIRS monitoring in individual children, it was determined that 20 to 25 mL/kg per minute was required.[229] However, NIRS was applied only to the right side of the skull (i.e., the right side of the brain), the same side as the sole arterial inflow. Using a pH-stat blood gas strategy for RCP, we noted that the majority of our children had an rSO_2 of 95% (the maximum reading on the rSO_2 scale) when we used the left radial artery pressure of 20 to 25 mm Hg as the target for bypass flow. These children were theoretically at risk for excessive cerebral perfusion. Therefore we performed a study using both NIRS and TCD of the right cerebral hemisphere to determine if TCD could be used as a guide to RCP flow rate.[235] The bypass flow rate was adjusted to achieve a cerebral blood flow volume within 10% of baseline (e.g., TCD was used to determine necessary flow). The estimated flow rate, 63 mL/kg per minute (range, 24–94 mL/kg per minute), proved to be significantly greater than that estimated in the earlier studies. This flow rate did not correlate with the pressure in the right or left radial artery. The rSO_2 was well maintained in all children, leading us to conclude that TCD was a useful monitor to ensure adequate but not excessive cerebral blood flow during

RCP. Because RCP perfuses the brain through a single arterial inflow vessel, questions have arisen about the adequacy of cerebral blood flow and oxygenation to the left cerebral hemisphere. Although the circle of Willis is expected to be intact without stenoses in neonates, 10% of healthy full-term neonates exhibit deviations from normal flow patterns. Two studies concluded that although cerebral blood flow and oxygenation were adequate to both cerebral hemispheres in neonates during RCP, bilateral monitoring, at least of NIRS, may be warranted.[235,264]

SYSTEMIC INFLAMMATORY RESPONSE SYNDROME

In cardiac surgery, SIRS is thought to result from four main sources of injury: (1) contact of the blood components with the artificial surface of the bypass circuit, (2) ischemia-reperfusion injury, (3) endotoxemia, and (4) operative trauma. Inflammatory cytokines, together with endothelial activation and endothelial-leukocyte interactions, appear to play an important role in the induction of this systemic inflammatory response.

Exposure of blood to the artificial materials in the bypass circuit–plastics, polypropylene oxygenator fibers, and metal suction devices–initiates a cascade of inflammatory responses, including activation of the complement system, the kallikrein system, and the coagulation system.[239] As a result, interleukins, TNF, endotoxin, heat shock protein, and many other inflammatory mediators are released into the circulation. Leukocyte activation also results in secretion of inflammatory mediators, such as proteases and cytokines (e.g., TNF-α and IL-1), which are secreted early in the evolution of the inflammatory process. This chemokine-mediated increased leukocyte activation constitutes an important link in the chain of the propagation of the inflammatory response (see Fig. 19.6).

This inflammatory response is counterbalanced by a complex system of inhibitors, such as IL-10 and soluble cytokine receptors.[265] Also, the inflammatory response of the neonate may be more exaggerated than that of the infant or older child,[266] justifying a more aggressive approach to its modulation in the neonate (see later discussion).

A number of novel treatments have been studied, including monoclonal antibodies for inflammatory products, such as complement, endotoxin, and TNF. Although theoretically attractive, no clinical difference has been noted with any of these treatments.

Effective treatments used every day in the operating room and ICU include:

- Use of corticosteroids[267]
- Ultrafiltration[241] (see earlier discussion)
- Aprotinin (if available)[242] (see earlier discussion)
- Leukocyte depletion[268]: leukocyte-depleted blood in prime and in-line arterial filter
- Initiate bypass using normoxic management (FIO_2 of 21%) in severely cyanotic infants.

Corticosteroids interrupt the inflammatory response at several levels by entering cell nuclei and changing the rate of transcription of inflammatory molecules. Increasing evidence suggests that glucocorticoids act by regulating transcription or translation of antiinflammatory cytokines, such as IL-10, and altering expression of other proteins, such as endothelin-1 and inhibitor NF-κβ.[269,270] Because these processes take time to develop, the effects of corticosteroids are not immediate, taking up to several hours.[271] Thus the common practice of adding corticosteroids to the CPB prime will not fully prevent the inflammatory response[272]; to be effective, corticosteroids may need to be administered 4 or more hours before the onset of CPB.[273]

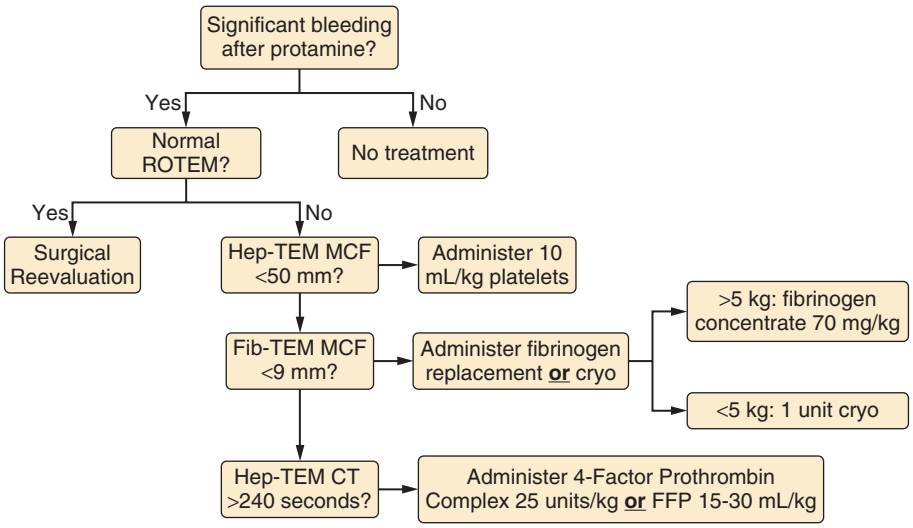
Despite these theoretical advantages of using corticosteroids to modulate the inflammatory response, the benefit is still unproven.[274] A recent large discharge database review of more than 46,000 infants and children, in which 54% received corticosteroids, demonstrated no difference in mortality. Using propensity score matching, the authors concluded that corticosteroids were associated with greater length of hospital stay, greater rate of infection, and greater use of insulin. There was no difference in duration of ventilation. Steroids conferred no significant benefit; conversely, in the simpler surgery categories, there was increased morbidity with these drugs.[275] Although inflammatory activation from CPB definitely occurs, and it would seem intuitive that this would lead to worse outcomes in those patients with excessive inflammation, in contemporary practice, the correlation of the magnitude of this response and length of ICU stay and blood product administration is statistically significant, but clinically modest, accounting for only 4% to 9% of the difference in these variables, in a large study of infants undergoing two-ventricle repairs.[276]

COAGULATION EFFECTS

Blood coagulation is frequently abnormal after CPB for several reasons. The inflammatory cascade activates the coagulation system, resulting in factor consumption and fibrinolysis, which, in turn, breaks down existing blood clots, leading to increased bleeding.[16] Treatment is adequate heparinization, reversal with protamine, and the use of an antifibrinolytic to inhibit fibrinolysis and improve platelet function.[34] In addition, the smaller the child, the greater the dilution of clotting factors by the bypass prime, and the greater the risk for low concentrations of clotting proteins and fibrinogen postoperatively. Platelets are also degranulated and consumed by the CPB circuit, leading both to low platelet counts and nonfunctioning platelets.[16] The smaller the infant, the greater the duration of bypass, and the more complicated the surgery, the greater the incidence of coagulopathy after bypass. Efforts to minimize the postbypass coagulopathy in infants include priming the CPB circuit with fresh whole blood for small infants, if available, or packed cells plus FFP if fresh whole blood cannot be obtained.[20,277] Treatment often involves administration of platelets to small infants as the first line of therapy, followed by the replacement of fibrinogen and FFP to replace clotting factors. If these factors are repleted and studies are normal, then surgical bleeding may be the cause and surgical reexploration may be warranted.[278] Coagulation can be monitored intraoperatively with thromboelastography (TEG), rotational thromboelastometry (ROTEM), or laboratory coagulation studies. TEG has been shown to be a cost-effective monitor to decrease the amount of transfusions.[279] rVIIa has also been used as a last resort in children who have significant postbypass bleeding unresponsive to standard measures.[61] Current interest exists in the use of factor concentrates such as fibrinogen concentrate and three- or four-factor prothrombin complex concentrates for correction of coagulopathy in children undergoing cardiac surgery (see also Chapter 12). Fig. 19.7 presents the intraoperative coagulation monitoring and blood product and factor transfusion algorithm used at Texas Children's Hospital.

HEPATIC, RENAL, AND GASTROINTESTINAL EFFECTS

The liver, kidneys, and gastrointestinal tract, like the brain and heart, may be rendered ischemic by prolonged CPB, DHCA, or low cardiac output syndrome. Renal function is compromised on CPB. This is manifested by the appearance of proteinuria and impaired tubular cellular function immediately after CPB. Renal



CV Operating Room Transfusion Pathway

1. Identify patients at risk for postbypass coagulopathy. If none of the following patient or procedural factors are identified, there is a low risk for post-CPB bleeding, and no ROTEM is needed.

a. Patient factors
- ☐ Young age, low weight
- ☐ Cyanosis/polycythemia
- ☐ Preoperative anticoagulant or antiplatelet therapy
- ☐ History of VAD or ECMO support

b. Procedural factors
- ☐ Multiple reoperation
- ☐ Use of deep hypothermia
- ☐ Complex surgery; extensive high-pressure suture lines

2. If patient has one or more of the above factors, confirm availability of all blood products and pharmacologic factors.
3. Send ROTEM upon rewarming to guide postbypass factor replacement.
4. Evaluate clinical bleeding and ROTEM results.

5. If clinically indicated, send second ROTEM after treatment.
6. If bleeding continues, consider use of recombinant Factor VIIa 90 μg/kg unless four-factor prothrombin complex has been given due to high risk of thrombosis.

dysfunction from ischemia is also common. Low urine output may occur secondary to secretion of antidiuretic hormone, a response to surgical stress. However, the latter appears to be transitory and usually resolves spontaneously.[280] The incidence of acute renal dysfunction after surgery with bypass to correct congenital heart defects is 17%, ranging from 0.7% for atrial septal defect closure to 59% for arterial switch operations.[281] Deep hypothermic cardiac arrest subjects the kidney to additional ischemia reperfusion injury.[282] Acute renal failure after CPB is uncommon in children, with fewer than 3% requiring dialysis perioperatively.[281,283] Infants who undergo cardiac surgery routinely receive diuretics or a peritoneal dialysis catheter, the latter prophylactically in some instances.[284,285] Although some have attributed the improved survival with early peritoneal dialysis to the prevention of fluid overload, others have attributed it to a more rapid clearance of CPB-induced proinflammatory cytokines.[286] Further study is required to clarify the mechanism of action of early peritoneal dialysis. In our center, neonates and children with a complex heart defect usually receive peritoneal dialysis immediately postoperatively to prevent fluid overload and decrease inflammatory cytokines. The use of aminophylline has been tested as an alternative but without success.

Recovery of hepatic and gastrointestinal function follows hemodynamic recovery but may require several days. Therapy is mainly supportive. Splanchnic and renal perfusion can be monitored noninvasively using somatic oximetry. Somatic oxygenation may predict renal dysfunction and predict organ failure. Interventions based on the somatic NIRS may improve outcome.[287]

IMMUNE SYSTEM EFFECTS

Leukocytes are activated by the CPB circuit, although their numbers may be depleted by leukocyte filters, which are sometimes used

to attenuate the inflammatory response. Despite the theoretical possibility that this may increase the risk of infection or neutrophil dysfunction, this has not been observed in published studies or clinical practice.[288]

ENDOCRINE SYSTEM EFFECTS

The magnitude of the inflammatory and endocrine responses after cardiac surgery depends in part on the duration of the surgical procedure and CPB.[289] In children undergoing brief operating times, postoperative blood concentrations of cortisol, adrenocorticotropic hormone, and β-endorphins are significantly greater than those in children undergoing prolonged operation times. In contrast, the serum concentrations of the proinflammatory cytokines IL-6, IL-1β, and TNF-α are similar in the two groups. Adrenocorticotropic hormone and cortisol concentrations correlated positively with the blood concentrations of IL-1β, IL-6, and TNF-α in the group of children with prolonged operation times.

The plasma concentrations of both epinephrine and cortisol increase after cardiac surgery.[290] In children, prebypass and postbypass cortisol and norepinephrine increase significantly during isoflurane anesthesia when 2 μg/kg of fentanyl is used rather than 25, 50, 100, or 150 μg/kg.[291] No significant increase in the blood concentrations of these hormones occurred with any of the fentanyl doses of 25 μg/kg or greater. In addition to cardiovascular stability, continued use of larger doses of opioids during bypass minimizes the stress responses and stabilizes hemodynamics during and after bypass, but may delay recovery.[292] Also, growth hormone, glucose and insulin, lactate, glutamate, aspartate, and free fatty acid concentrations increase after cardiac surgery, whereas total triiodothyronine concentrations decrease.[293] Limiting the amount of opioids balances the negative effects of inflammation and stress with the opportunity to fast-track children's recovery after surgery for congenital heart disease.[294,295]

Transport to the Intensive Care Unit

Extreme vigilance is required during transfer of the child from the cardiac operating room to the ICU. Monitoring of ECG, arterial, venous, and atrial pressures, and end-tidal CO_2 and pulse oximetry must be maintained continuously; the battery charge of the monitor and the infusion pumps should be checked beforehand to prevent monitor failure and interruption of the infusions of vasoactive medications. Resuscitation drugs, airway equipment, and blood products should accompany the child to the ICU. Before leaving the operating room, a report should be given to the ICU staff. Children who are transported with tracheal tubes in situ are usually ventilated manually during transport using the Jackson-Rees modification of the Ayres T-piece circuit, with either 100% oxygen or, for those who require an F_{IO_2} less than 1.0, an oxygen-air blender. For children who require nitric oxide, a respiratory therapist should assist with transport to ensure that no interruptions in therapy occur and that a smooth transfer occurs in the ICU as well. On arrival in the ICU, vital signs are confirmed, all monitoring devices are transferred sequentially to the ICU monitors and rechecked to ensure they are in working order, and a detailed report is given to the ICU staff.

Summary

CPB is a necessary technique for intracardiac and major extracardiac surgery on the great vessels. CPB induces a multitude of physiologic and inflammatory derangements, but, through extensive experience and research, these ill effects can be largely mitigated by a number of evidence-based strategies. Therefore, outcomes after CPB have improved dramatically, and CPB is no longer a barrier to accomplishing complex surgery to correct congenital heart defects, even in neonates.

ANNOTATED REFERENCES

Andropoulos DB, Easley RB, Brady K, et al. Neurodevelopmental outcomes after regional cerebral perfusion with neuromonitoring for neonatal aortic arch reconstruction. *Ann Thorac Surg.* 2013;95(2):648-654; discussion 654–655.

Fifty-seven neonates were studied using MRI and 12-month neurodevelopmental outcome after neonatal aortic arch reconstruction using regional cerebral perfusion (RCP). Pre- and postoperative MRI revealed new injuries in 40% of all patients. However, cognitive outcomes were comparable to a population norm with slightly reduced language and motor outcomes than the reference. RCP can be considered an effective and safe method to support intraoperative cerebral perfusion.

du Plessis AJ, Jonas RA, Wypij D, et al. Perioperative effects of alpha-stat versus pH-stat strategies for deep hypothermic cardiopulmonary bypass in infants. *J Thorac Cardiovasc Surg.* 1997;114:991-1000.

In this study, 182 neonates and infants were randomized to pH-stat or α-stat CPB strategy. Important trends or statistically significant improved outcomes were seen with pH-stat management for deaths, electroencephalographic (EEG) seizures, return of EEG activity, acidosis, hypotension, inotropic support, and length of mechanical ventilation. These improvements were most significant for arterial switch operation patients.

Jonas RA, Wypij D, Roth SJ, et al. The influence of hemodilution on outcome after hypothermic cardiopulmonary bypass: results of a randomized trial in infants. *J Thorac Cardiovasc Surg.* 2003;126:1765-1774.

One hundred thirteen infants randomized to a target hematocrit of 20% (actual 21.5%) versus 30% (actual 28%) on CPB had lower neurodevelopmental outcome scores on the Psychomotor Development Index of the Bayley Scales of Infant Development with 82 for the low hematocrit versus 90 for the high hematocrit group at 1 year of age. The children with lower target hematocrit also had a greater incidence of scores more than 2 SD below the mean (29% vs. 9%).

Manlhiot C, Gruenwald CE, Holtby HM, et al. Challenges with heparin-based anticoagulation during cardiopulmonary bypass in children: impact of low antithrombin activity. *J Thorac Cardiovasc Surg.* 2016;151(2):444-450.

Antithrombin III is an important co-factor for heparin to work particularly in neonates who have lower values leading to a lower heparin efficacy and less suppression of thrombin generation. Recognizing risk factors and individually treat these can improve anticoagulation during pediatric cardiac surgery.

Miller BE, Mochizuki T, Levy JH, et al. Predicting and treating coagulopathies after cardiopulmonary bypass in children. *Anesth Analg.* 1997;85:1196-1202.

This is the classic article describing the reasons for post-CPB bleeding in infants and children. Platelet defects are the most important cause and the first blood product to administer; hypofibrinogenemia is the second most important, and fibrinogen is the next most important blood product, with fresh frozen plasma ineffective or possibly worsening bleeding.

Newburger JW, Jonas RA, Soul J, et al. Randomized trial of hematocrit 25% versus 35% during hypothermic cardiopulmonary bypass in infant heart surgery. *J Thorac Cardiovasc Surg.* 2008;135:347-354.

Perioperative hemodynamics during hypothermic cardiopulmonary bypass and developmental outcome and brain magnetic resonance imaging at 1 year were evaluated. Hemodilution to hematocrit levels of 35% compared with those of 25% had no major benefits or risks overall among infants undergoing two-ventricle repair. Developmental outcomes at 1 year of age in both randomized groups were below those in the normative population.

Odegard KC, Zurakowski D, DiNardo JA, et al. Prospective longitudinal study of coagulation profiles in children with hypoplastic left heart syndrome from stage I through Fontan completion. *J Thorac Cardiovasc Surg.* 2009;137(4):934-941.

Coagulation profiles throughout staged repair of the hypoplastic left heart syndrome were studied. In general, pro- and anticoagulatory factors were lower than the norm and patients after the Fontan operation presented with significantly higher F. VIII levels. This could potentially increase the risk of thrombosis.

Wypij D, Jonas RA, Bellinger DC, et al. The effect of hematocrit during hypothermic cardiopulmonary bypass in infant heart surgery: results from the combined Boston hematocrit trials. *J Thorac Cardiovasc Surg.* 2008;135:355-360.

In this combined review of 271 infants, analysis was undertaken of the effects of hematocrit level at the onset of low-flow cardiopulmonary bypass. A hematocrit level at the onset of low-flow cardiopulmonary bypass of approximately 24% or higher was associated with higher Psychomotor Development Index scores and reduced lactate levels.

Wypij D, Newburger JW, Rappaport LA, et al. The effect of duration of deep hypothermic circulatory arrest in infant heart surgery on late neurodevelopment: the Boston Circulatory Arrest Trial. *J Thorac Cardiovasc Surg.* 2003;126:1397-1403.

Neurodevelopmental outcomes were assessed with a battery of 6 tests in 155 8-year-olds who had a neonatal arterial switch operation using α-stat bypass management, hematocrit of 20% on bypass, and varying duration of DHCA at 18°C. Neurodevelopmental outcomes were not adversely affected for the group as a whole until the DHCA time exceeded 41 minutes (95% lower confidence limit 32 minutes).

Yamamoto T, Wolf HG, Sinzobahamvya N, et al. Prolonged activated clotting time after protamine administration does not indicate residual heparinization after cardiopulmonary bypass in pediatric open heart surgery. *Thorac Cardiovasc Surg.* 2015;63(5):397-403.

A prolonged activated clotting time after pediatric cardiac surgery is a common finding. At a closer look, this does not represent residual heparin concentrations but rather low concentrations of coagulation factors.

Summary

BLEEDING IS AN INEVITABLE CONSEQUENCE of surgery and trauma. Provided the coagulation processes are normal, a meticulous hemostatic surgical technique is usually adequate to achieve hemostasis for most surgical procedures. However, if the degree of injury is more extensive, major blood loss can occur, particularly if there is a coexistent deficiency of the normal coagulation process. Since the early part of the 20th century, it has been appreciated that transfusion of fluids and human (allogeneic) blood can prevent many of the adverse effects of blood loss. Despite this, it is important to appreciate the risks and limitations of transfusion: packed red blood cells (PRBCs) will fail to correct any existing coagulopathy and immunologic and pathophysiologic adverse effects of exogenous stored blood products may occur.

This chapter examines the specific interventions to correct coagulopathy and reduce the requirement for transfusion of blood products by encouraging hemostasis. Although similar, these objectives are not synonymous. During many types of surgery, in vitro tests may demonstrate only mild coagulation defects, and yet the use of hemostatic medications may reduce blood loss and obviate the need to transfuse PRBCs.[1,2] In the absence of these medications, bleeding itself is often unlikely to be life-threatening. In comparison, severe coagulopathic bleeding is, by its nature, life-threatening. Transfusion of blood products cannot be avoided and the hemostatic medications used are often the blood products themselves. The balance of risk and benefit is very different in these two situations. In the former case, benefit will occur if the risk reduction associated with the avoidance of blood products is greater than the risk from the medication itself. In the latter case, the use of medications that carry a high risk of causing adverse effects is more acceptable if the aim is to prevent death from uncontrolled bleeding.

Avoiding the transfusion of human blood products seems to be a fundamentally good notion. However, many common ideas about the potential harm of transfusion may be mistaken. An audit of the Serious Hazards of Transfusion (SHOT) organization in the United Kingdom reported 3239 adverse events over a 10-year period; this is only 0.013% of all blood transfusions.[3] These adverse events were more common in infants but were reported in only 0.037% of infants who had transfusions. The true incidence of events is likely to be more common because of underreporting, though many of these "events" were procedural errors not associated with actual harm. It is clear that the risk of immediate harm directly attributable to transfusion is exceptionally low. The risk of direct transmission of infection (the most feared risk in the public perception) is particularly small; the risk of transmission of HIV from transfusion of blood in the United Kingdom is 1 in 5 million.[3] The greatest hazard of immediate harm is transfusion of incompatible blood.[4] However, subtle negative effects of transfusion on children's outcomes may be considerably more important.[5] Transfusion of blood may lead to deterioration in pulmonary function and immunologic effects that predispose children to infection. In addition, if the objective of transfused red cells is to boost tissue oxygenation by improving oxygen-carrying capacity, then transfused blood is less effective than the child's own blood for this purpose.[6] Additional considerations include the increasing costs of transfused blood products, the logistical difficulties of maintaining a secure blood supply (in both well-resourced and less well-developed health systems),

substantially greater risks of transfusion in poorly developed health systems, and the possibility of new, unrecognized, infective agents entering the blood supply.

There are 2.3 million transfusions each year (37 per 1000 population) in the United Kingdom; 4.2% are given to children younger than 18 years of age (7.1 per 1000) and 1.7% to infants less than one year of age (52 per 1000). An audit of pediatric blood transfusion from Australia revealed 41% of blood transfused was given perioperatively,[7] and blood was transfused during 6.3% instances of anesthesia. The majority of units were used during heart surgery (58% of perioperative use), while a very small minority, 4%, were used during major trauma surgery. Heart surgery (on and off bypass), craniosynostosis surgery, and liver transplantation were all commonly associated with blood transfusion. The epidemiology of major bleeding is less certain. Reports of blood use may be misleading (e.g., neonates undergoing cardiac surgery to correct congenital defects may receive few blood units despite significant bleeding), and blood is also used for purposes such as priming the bypass circuit. Observational studies have reported very heavy blood loss associated with heart surgery in children, with increased (per kilogram) blood loss in smaller children and more complex surgery.[8,9] Cardiac surgery can probably be considered the main cause of major blood loss in children and account for most severe bleeding events in children younger than 1 year.

Aprotinin, recombinant factor VIIa (rFVIIa), and fibrinogen concentrate have all been proposed as "magic bullets" able to restore hemostasis at some stage. However, all of these agents have proved to have limitations; each is of value when they address a specific deficit in coagulation. In many respects, the management of severe bleeding has not greatly changed in recent years. Newer approaches are now emerging, although at the time of writing, robust evidence of their risks and benefits for children is not available. Optimal management of severe bleeding requires the following:

- Good surgical hemostasis
- Adequate preparation, including availability of blood products and the means to administer them
- Targeting of coagulation defects that are either likely (given the clinical context) or have been identified by appropriate coagulation tests
- Avoidance (and recognition) of hypothermia, acidosis, and electrolyte disturbance

Physiology of Coagulation

The understanding of coagulation has shifted greatly in the past few years. The "traditional" model, which emphasizes the importance of a cascade of proteolytic enzymes, has given way to the "cell-based" model of coagulation that emphasizes the importance of cellular elements in coagulation and presents coagulation as a complex web of interactions rather than a linear process.[10,11] This complexity can be confusing and abstract compared with the decisions made in clinical care. However, there are lessons that can be drawn from this, and a basic knowledge of current models of coagulation is of value.

To achieve effective hemostasis, a platelet plug must form at the site of vessel injury. To prevent widespread thrombosis, this process needs to remain localized to the injured site. This is achieved through changes at the cell surface and localization of the procoagulant reactions on the surfaces of specific cells. Different cells possess different procoagulant and anticoagulant properties; these are incompletely understood, but platelets and cells bearing tissue factor (TF) are central to the process. Endothelium is vital to inhibition of coagulation, both by forming a physical barrier between components of the coagulation system (principally preventing activated factor VII and platelets from contacting collagen and TF bearing cells) and by playing a more active role in the expression of inhibitory proteins such as thrombomodulin (TM). The phases of coagulation are often described as initiation, amplification, and propagation,[11] though in reality there is considerable overlap.

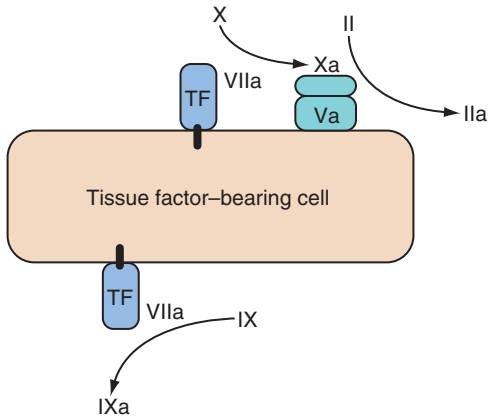

FIGURE 20.1 Initiation. The tissue factor (TF)/VIIa complex on the TF-bearing cell activates factors IX and X. The factor Xa/Va complex, known as the "prothrombinase" complex, forms small amounts of thrombin (factor IIa). (Reproduced from Hoffman M. Remodeling the blood coagulation cascade. *J Thromb Thrombolysis.* 2003;16:17–20.)

INITIATION

Coagulation is initiated by an interaction between circulating factor VIIa and TF (a membrane-bound lipoprotein expressed on subendothelial cells such as fibroblasts). A complex is formed between TF and factor VIIa (TF/VIIa), which activates factors IX and X. Factor Xa, in association with cofactor Va, also forms "prothrombinase" complexes on the surface of the TF-bearing cell, which activates a small amount of thrombin (factor IIa)[11] (Fig. 20.1), leading to activation of platelets and factors V and VIII.

This low level of thrombin production occurs constantly and is not sufficient to initiate widespread clot formation. Inhibitors, such as TF pathway inhibitor (TFPI) and antithrombin (AT), provide a localizing function on factor Xa by inhibiting any factor Xa that becomes dissociated from the TF-bearing cell.

AMPLIFICATION

More extensive damage to the vasculature allows greater interaction between TF and factor VIIa and contact between platelets and extravascular components (including collagen and von Willebrand factor [vWF]).[10] There is a strong positive interaction between these two processes that leads to recruitment of further platelets and production of thrombin in large quantities.

Small quantities of thrombin are generated on the TF-bearing cells. This sets up the subsequent propagation phase, during which thrombin is generated in larger quantities (Fig. 20.2). This thrombin has several functions:

- Activation of platelets, exposing receptors and binding sites for clotting factors
- Activation of cofactors V and VIII on the activated platelet surface, thereby releasing vWF to mediate additional adhesion and aggregation at the injury site
- Activation of factor XI to XIa[12]

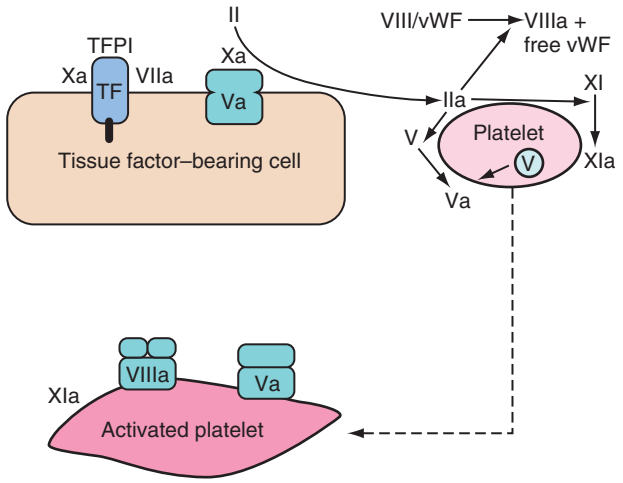

FIGURE 20.2 Amplification. Small amounts of thrombin (factor IIa) set the stage for large-scale generation of thrombin in the propagation phase. Small amounts of thrombin activate platelets, as well as other important coagulation enzymes and cofactors. *TF,* tissue factor; *TFPI,* tissue factor pathway inhibitor; *vWF,* von Willebrand factor. (Reproduced from Hoffman M. Remodeling the blood coagulation cascade. *J Thromb Thrombolysis.* 2003;16:17–20.)

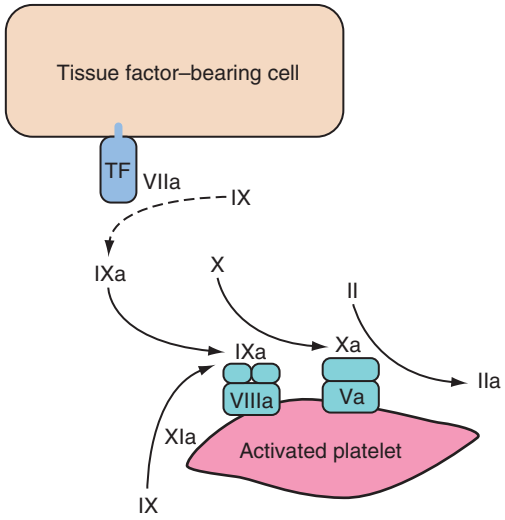

FIGURE 20.3 Propagation. Factor Xa is formed locally by the VIIIa/IXa complex on the surface of the activated platelet. The resulting Xa/Va prothrombinase complex causes a burst of thrombin (factor IIa) generation. *TF,* tissue factor. (Reproduced from Hoffman M. Remodeling the blood coagulation cascade. *J Thromb Thrombolysis.* 2003;16–20.)

- Activation of factor XIII (fibrin-stabilizing factor) and promotion of fibrin cross-linking
- Cleaving fibrinopeptides A and B from fibrinogen (forming fibrin)

The concept of platelet activation is important. Circulating platelets are discoid in shape. Upon activation, they change shape dramatically to increase their surface area, increase expression of a variety of receptors and binding proteins, and release a series of chemicals (including clotting factors and platelet activators). These complex intracellular changes are central to normal coagulation and alterations in this process are central to the coagulopathy seen during surgery and major bleeding.[13,14] Once formed into a clot, the platelets will undergo a further change spreading out to form a physical plug.

PROPAGATION

Propagation occurs on the surface of activated platelets that are recruited to the site in large numbers. Activated factor IX (from both initiation phase and provided by factor XI on the platelet) binds to factor VIIIa. The resultant IXa/VIIIa complex activates factor X on the platelet surface. This factor Xa associates with factor Va and forms the prothrombinase complex. The prothrombinase complex causes a "burst" of thrombin generation to cause clotting via fibrinogen (Fig. 20.3).[10] An inability to form the IXa/VIIIa complex and therefore produce this sustained burst in thrombin production explains the bleeding tendency of children with hemophilia A.[10]

Traditional models of coagulation have also described an alternative pathway initiated by contact factors (XII, XI, prekallikrein, and high–molecular-weight kininogen [HMWK]). This pathway is of no physiologic importance in terms of coagulation activation; however, it provides important acceleration loops through feedback activation of factors VIII, IX, and XI[15] and is important in fibrinolytic and inflammatory pathways.[16]

CLOT INHIBITION

The clot is confined to the site of injury by direct and indirect thrombin inhibitory systems. The direct system consists of AT, α_2-macroglobulin, and heparin cofactor II (HCII). AT and HCII activities are accelerated in the presence of heparin.

Several indirect systems inhibit thrombin, including the protein C-protein S-TM system and TFPI. Thrombin binds to TM on the surface of intact endothelial cells and can no longer cleave fibrinogen to form fibrin. The TM/thrombin complex is neither able to activate platelets nor activate factors V and VIII. Instead, this complex activates protein C, which binds to the cofactor protein S and inactivates factors Va (on the surface of endothelial cells and platelets) and VIIIa.[10,15]

FIBRINOLYSIS

Fibrinolysis, the breakdown of fibrin into soluble degradation products, is mediated by the proteolytic enzyme, plasmin. Plasmin is formed from an inactive zymogen, plasminogen, which is produced in the liver. This process is controlled by activators and inhibitors. The principal intravascular plasminogen activator is tissue plasminogen activator (tPA).[17] The main inhibitory proteins are plasminogen activator inhibitor-1 (PAI-1), antiplasmins (α_2-PI and α_2-macroglobulin), and thrombin-activated fibrinolysis inhibitor (TAFI) (Fig. 20.4).[18]

In addition to cleaving fibrin, plasmin metabolizes a number of other proteins, including the platelet receptor for fibrinogen (glycoprotein IIb/IIIa) and fibrinogen.[19] Furthermore, plasmin accelerates its own production by metabolizing the conversion of single-chain plasminogen activators to more active two-chain versions. The action of plasmin on fibrin produces a series of degradation products, some of which convey anticoagulant properties; this effect is achieved by preventing polymerization of fibrinogen and by inhibition of platelet function.

tPA is released by vascular endothelium of small blood vessels. Release is increased in the presence of stimuli such as trauma, endotoxins, ischemia, or normal exercise. This effect is mediated via contact activation (through the kallikrein system) and by a series of other substances, including thrombin. Once released, tPA is rapidly metabolized by the liver with a half-life of approximately 5 minutes.[20] Fibrin binds both plasminogen and tPA and

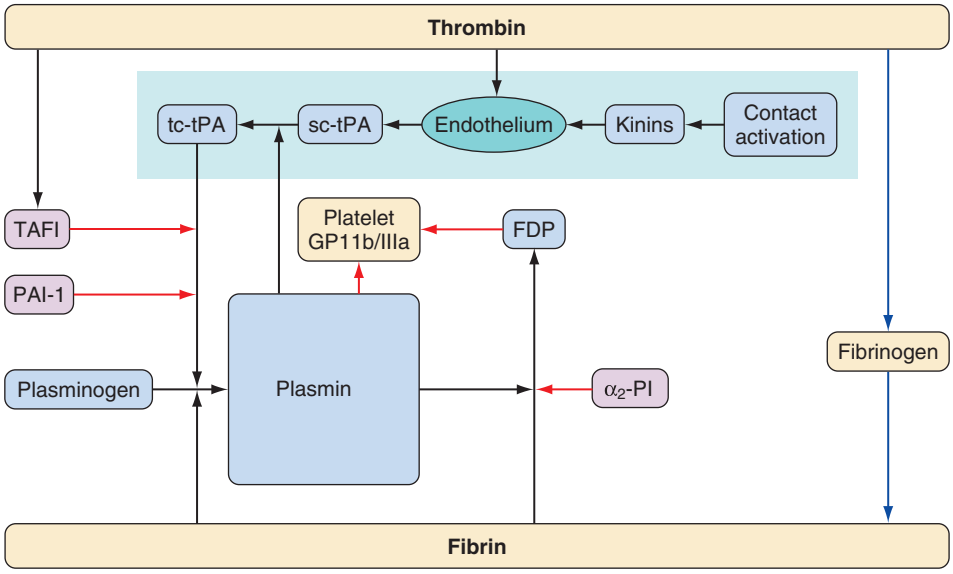

FIGURE 20.4 The main fibrinolytic pathway, leading to the breakdown of fibrin into fibrin degradation products *(FDP)*. It is initiated by release of tissue plasminogen activator *(tPA)* from endothelial cells in response to contact activation *(shaded area)*. Plasminogen needs to be bound to fibrin in order to allow conversion to plasmin. *sc-tPA* and *tc-tPA* refer to single- and (more active) two-chain tPA, respectively. Endogenous fibrinolysis inhibitors are shown in *blue boxes*. Interactions with the coagulation system are shown by *red arrows*. *TAFI,* thrombin-activated fibrinogen inhibitor; *PAI-1,* plasminogen activator inhibitor; *GP,* glycoprotein; *α_2-PI,* α_2-plasmin inhibitor.

greatly accelerates the conversion of plasminogen to plasmin (facilitating its own degradation, but also localizing the process to areas of clot). An alternative mechanism for plasminogen activation by tPA exists through binding to receptors expressed by certain cells (endothelium, white cells, and some tumor cells); the importance of this is unclear.

Excessive fibrinolysis can directly result from excess production of fibrin, as in disseminated intravascular coagulation. This is termed secondary hyperfibrinolysis and in this context, the fibrinolysis is considered beneficial because it prevents widespread vascular occlusion. Therapy is directed at replacement of consumed clotting factors, inhibition of excessive coagulation, and treatment of the underlying cause. Primary hyperfibrinolysis can occur during cardiac bypass, massive blood loss, trauma, and liver transplantation.[20] During the anhepatic stage of liver transplant surgery, there is hyperfibrinolysis because of failure to metabolize tPA. On reperfusion of the liver, a further surge of tPA occurs that can take several hours to return to normal. In coagulopathic patients, reduced thrombin formation may lead to reduced production of TAFI (important in inhibition of membrane-bound plasmin), whereas conversion of single- to two-strand tPA by plasmin may further sustain the process. Individual susceptibility is likely to be important and may have a genetic component.[21,22]

Two groups of drugs are used clinically to inhibit fibrinolysis:

1. Synthetic lysine analogs–for example, tranexamic acid (TXA) and ε-aminocaproic acid (EACA)
2. Protease inhibitors (e.g., aprotinin)

Synthetic lysine analogs are specific inhibitors of plasminogen activation, working by competitively binding to lysine-binding sites on the plasminogen molecule (see Fig. 20.5). This blocks the binding of plasminogen to fibrin, a required step for the conversion of plasminogen to plasmin by plasminogen activators.[23] At larger doses, they may have additional effects through direct inhibition of plasmin; this includes inhibition of the plasmin-mediated effects on platelets.

Aprotinin is a less specific inhibitor of proteolytic enzymes; it has actions on the kallikrein-kinin (contact) system, as well as the enzymes involved in coagulation and fibrinolysis. In addition, aprotinin may be associated with greater preservation of platelet function, as well as an antiinflammatory effect. This wider spectrum of effects from aprotinin may have additional benefits over the antifibrinolytic lysine analogs.

Developmental Coagulation

The hemostatic system in the neonate rapidly matures toward that of the adult (see also Chapter 10).[24–26] Understanding the rate at which the coagulation system matures with age in childhood is necessary to correctly interpret coagulation tests and to select appropriate interventions to manipulate hemostasis in vivo.

All fetal coagulation factors are produced independently of the mother; fibrinogen starts to be formed as early as 5.5 weeks gestation, and blood can clot at 11 weeks. The development of microassay techniques in the 1980s facilitated the determination of reference ranges for the coagulation factors beginning at 19 weeks gestational age.[15,24,25] In general, there are four fundamental differences between the coagulation systems in the infant and the adult[27]:

- Concentrations of components of the hemostatic system
- The turnover rate of coagulation proteins
- The rate of synthesis
- Differences in the overall ability to generate and regulate the key enzymes: thrombin and plasmin

The concentration of vitamin K–dependent factors II, VII, IX, and X in the neonate are only 50% those of adult values; this leads to a slightly prolonged prothrombin time (PT) or international normalized ratio (INR).[15] Similarly, the concentrations

of contact factors HMWK, prekallikrein, and factors XI and XII are approximately 50% of adult values.[15,27] The reduced contact factors account for a disproportionally prolonged activated partial thromboplastin time (aPTT). The reduced concentration of factors at birth is probably explained by the reduced synthesis by the liver; however, concentrations increase rapidly after birth, reaching approximately 80% of adult values by 6 months of age.[15,28]

In contrast, the plasma concentrations of fibrinogen and factors V and VIII at birth are similar to those in adults, although the fetal form of fibrinogen differs in structure from that in the adult; the physiologic significance of this is not clear.[29] Concentrations of vWF in the first 2 months of life are greater than those in adults.[30]

The inhibitor systems of coagulation also differ from adults. At birth, plasma proteins C and S are 35% of adult values and do not reach adult values until adolescence. Neonatal concentrations of AV and HCII are 50% of adult values; they reach adult concentrations by 6 months of age. The concentration of α_2-macroglobulin, however, is increased at birth and remains increased throughout childhood. It has been postulated that this may be one of the mechanisms that protects young children from thromboembolic complications.[31] Thrombin generation in vitro is reduced in children to approximately 75% of adult values.

Despite reduced plasma concentrations of many procoagulant and anticoagulant proteins in infants, there still appears to be an effective hemostatic balance; healthy fetuses, neonates, and children do not suffer excessive hemorrhage in the presence of minor challenges. This is consistent with the thromboelastogram (TEG) studies of healthy children younger than 2 years of age; no defects in coagulation were noted using this test compared with adults, indicating an intact hemostatic system.[32] A further study, conducted using TEG, reported that infants younger than 1 year with complex congenital heart disease have an intact and balanced coagulation-fibrinolytic system but at a "lower level" than healthy children.[33]

GENETICS OF BLEEDING

The hemophilias are a group of genetic diseases that cause excessive bleeding, often in response to minor trauma. Hemophilia A and von Willebrand disease are the most common variants (see also Chapters 10 and 12), associated with low levels of factor VIII and vWF, respectively. A wide range of single-gene defects resulting in deficiencies of single clotting proteins or regulatory proteins has now been described. A further group of single-gene disorders may result in thrombophilic disorders, associated with abnormalities of inhibitory proteins.

Unexplained variation has been observed in bleeding between apparently similar patients in the absence of specific factor deficiency. The causes of this variation are likely to be multifold, according to nuances of surgical technique and subtle difference in disease process and therapy. It might appear counterintuitive that genetic factors have a significant role in acquired bleeding resulting from surgery; however, recently there has been increased interest in the interplay of genetic and environmental factors in the progress of acquired diseases. The genetics of most clotting proteins has been described, and common variations within populations have been revealed for some. Of these, a common polymorphism of PAI-1 has been well described. PAI-1 is an important endogenous inhibitor of fibrinolysis, and deficiency is associated with increased bleeding.[34] The *G5/G5* polymorphism is common (about 20% in European populations) and is associated with reduced concentrations of PAI-1. It has been linked (though not consistently) to bleeding after heart surgery and to increased benefit from use of antifibrinolytics.[21,22] Should these findings be substantiated, then PAI-1 may still be an exceptional example. In general, the influence and consequences of genetic determinants of bleeding are likely to be more subtle. In infancy, an additional factor may be the relationship between developmental and genetic factors. Many clotting proteins are present in infants as isoforms distinct from those in adults; this implies a different gene expression in the young. It is possible that understanding genetically determined variations in bleeding will increase our understanding of bleeding and allow us to guide therapy for the individual child. The practical applications of such observations remain speculative.

Coagulopathy and Major Surgery

Bleeding is an inevitable consequence of invasive surgery. Severe bleeding can be associated with derangement of coagulation, which may increase the severity of bleeding or, alternatively, may put the child at risk for thrombosis. These two adverse events are not mutually exclusive: patients who bleed more and who demonstrate coagulopathic bleeding may also be at increased risk of thrombosis.

Coagulation changes during major surgery and bleeding are complex[35] and depend on the clinical context in which bleeding occurs. Coagulation changes that occur in surgical patients have some similarities to those who present after severe trauma. However, the balance of pathophysiologic factors is likely to be very different. The factors underlying these coagulation changes include the following:

- *Dilution.* Components of the coagulation system are lost in shed blood. The volume of blood lost is then replaced by crystalloid, colloid, or blood products that lack these components, leading to progressively smaller concentrations of these coagulation components. To some degree such changes are balanced as the concentration of coagulation inhibitors also decreases. In addition, coagulation components may be produced or released in response to trauma, which limits the reduction in concentration. To complicate this issue, a reduction in the concentration of one component of the coagulation system may not have the same clinical effect as the same reduction of another component. For example, substantial decreases in the concentration of many clotting proteins will not result in severe bleeding, whereas even modest decreases in the number of platelets or the fibrinogen concentration may cause clinically noteworthy bleeding (see also Chapters 10 and 12).
- *Effect of tissue damage.* Extensive interactions occur between inflammatory and coagulation pathways. Inflammation following trauma to tissues can be linked to excess activation of fibrinolytic pathways (resulting in excess bleeding) and to activation of procoagulant pathways (resulting in increased risk of thrombosis).
- *Physiologic derangement associated with blood loss.* Acidosis, hypothermia, and hypocalcemia are associated with excess bleeding.[36] Hypothermia slows proteolytic enzyme activity, reduces fibrin synthesis, and reduces platelet function. These effects are largely reversible on rewarming. Acidosis markedly reduces the activity of coagulation proteins.[37] These effects are not fully reversed by correcting acidosis. Dilution and the effect of citrate (contained in many blood products) cause the plasma calcium concentration to decrease. During major bleeding, the concentration of calcium ions should be monitored and replaced as needed. Cryoprecipitate and fresh frozen plasma (FFP) contains high concentrations of citrate and rapid

administration may cause a precipitous decrease in the plasma concentration of calcium (Fig. 12.9).

- *Effects of treatment.* The use of some synthetic colloids may worsen bleeding to an extent greater than might be expected by dilution. The use of hydroxyethyl starch increases the risk of coagulation abnormalities and of acute kidney injury when compared with albumin, gelatins, or crystalloids.[38] Whether differences exist in coagulation effects of different starches is controversial.[39–41] Concerns about safety of starch solutions have limited their use in adults and children.
- *Use of specific techniques during surgery.* The important effects of cardiac bypass and anticoagulation are discussed later. Liver transplant surgery (see also Chapter 31) and major trauma (see also Chapter 39) are discussed in detail elsewhere in this book.

Alterations in Hemostasis During Pediatric Cardiac Surgery

ROUTINE ANTICOAGULATION

Without anticoagulation, blood will rapidly form thrombi on the artificial surface of the cardiopulmonary bypass (CPB) circuit. The major mechanism for activation of the coagulation cascade during CPB is thought to be the "extrinsic" TF pathway, which is activated as a result of surgical trauma and inflammation.[42–45] Inflammatory mediators induce expression of TF on endothelial cells and monocytes. The "intrinsic" coagulation system is also activated when factor XII is adsorbed onto the surface of the CPB circuit, causing activation of complement, neutrophils, and the fibrinolytic system via kallikrein.[42] Although the intrinsic system has little role in initiating coagulation, activations of kinins will lead to increased fibrinolysis and inflammation.[16]

Heparin

Heparin remains the most effective anticoagulant used to facilitate CPB.[46] The binding of heparin to lysine sites on AT causes a conformational change in AT. This results in an increase in AT potency; the inhibition of thrombin and factors IXa, Xa, XIa, and XIIa is increased by a factor of 1000.[42,47] In infants, AT concentrations are low until 3 to 6 months of age and other heparin cofactors may have greater importance. However, neonates who require surgery for congenital heart disease have unusually reduced concentrations of all major heparin cofactors, and this may be one reason for the greater concentrations of thrombin produced in these patients.[48]

Heparin therapy is most frequently guided by the activated clotting time (ACT). The ACT is an inexpensive and rapid on-site test in which a small sample of blood is mixed with a coagulation activator such as celite, kaolin, or diatomaceous earth. The ACT is the time to produce a stable clot, with a normal value being between 80 and 140 seconds. A value greater than 400 seconds is required for CPB.

There are limitations to the use of the ACT. First, the ACT is altered by hypothermia, hemodilution, platelet activation, activation of the hemostatic system, and aprotinin therapy.[49,50] Accordingly, it does not accurately reflect the heparin concentrations. One study reported that the heparin concentration decreased by 50% as soon as the children went on CPB, even though the ACT doubled.[51] The decrease in the heparin concentration was attributed to hemodilution. Second, in the bleeding child, the ACT is unable to differentiate bleeding because of excess heparin from that of other acquired hemostatic defects.[51] The gold standard for measurement of heparin concentration is the antifactor Xa assay; however, this test remains too cumbersome for routine clinical use. An alternative point-of-care test is protamine titration (Medtronic Hepcon HMS Plus, Medtronic, Minneapolis, MN). In adult patients, use of this system reduces thrombin formation.[52] Reduced bleeding and reduced thrombin generation in children, as well as reduced thrombin formation in infants, have also been demonstrated with this system.[23,53] However, the accuracy of the device has been questioned[54] and a trial, in infants, was terminated early when increased bleeding and increased length of stay were demonstrated in children in whom the Hepcon device was used.[53] The device underestimated heparin concentration in this group, leading to excess dosing of heparin and inadequate reversal with protamine. After modification of their protocol, use of the device demonstrated reduced bleeding, length of stay, and reduced thrombin formation compared to standard treatment.[53] Agreement between protamine titration, measures of heparin concentration, and laboratory measures has been demonstrated.[55]

A common feature of the pediatric studies using the Hepcon device is increased heparin use compared with regimens based on units per kilogram kg dosing or ACT. This is consistent with other studies of traditional dosing regimens. Using common pediatric heparin regimens (300 units/kg before CPB, then 100 units/kg to keep the ACT above 450 seconds), 50% of children on CPB had low levels of heparin (<2 units/mL).[51] It is suggested that reduced heparin concentrations during CPB is a major factor responsible for activation of coagulation and fibrinolysis. It is likely that widely used regimens for dosing of heparin in children lead to inadequate dosing, and that units per kilogram kg dosing fails to allow for important pharmacokinetic (PK) and pharmacodynamic (PD) differences in children.

Even effective dosing of heparin does not completely abolish the production of thrombin. Low-grade ongoing thrombin production leads to ongoing activation of the coagulation cascade, platelets, fibrinolysis, and the endothelium. The continued thrombin generation and activity during CPB reflects the inability of the heparin/AT complex to inactivate fibrin-bound thrombin or to inhibit thrombin-induced platelet activation.[56] Theoretically, direct thrombin inhibition may be free of these limitations. Practically, the use of the current generation of thrombin inhibitors (such as hirudin and bivalirudin) is limited because of a lack of effective monitoring and reversal. Currently few reports exist of the use of thrombin inhibitors in children, although they would be indicated when heparin use is not possible.[57–62]

Adverse effects of heparin are uncommon; hypotension can result from a reduction in calcium ions or, rarely, anaphylaxis. A benign transient decrease in the platelet count can occur. Heparin-induced thrombocytopenia is a rare but life-threatening prothrombotic condition.[60,63–68]

Reversal of Anticoagulation With Protamine

Protamine is a positively charged polypeptide derived from salmon sperm. It neutralizes heparin by forming an ionic bond with heparin. The resultant complex is removed by the reticuloendothelial system. The most appropriate dosing regimen has yet to be determined. Current dosing used in pediatric practice fails to take into account the range of concentrations of heparin that occur in infants and children.[46,53] The administered heparin dose is often used to guide the dose of protamine; however, it is unclear how this should be modified by various factors, such as additional doses of heparin administered (to prime or during bypass), duration

of bypass, ultrafiltration, or developmental coagulation differences in children.[69]

Excessive protamine has been associated with catastrophic pulmonary hypertension and hemorrhagic pulmonary edema.[70,71] It is also known that protamine can be associated with coagulation abnormalities; an increasing ACT occurs at a protamine/heparin ratio of 2.6 : 1, and platelet aggregation occurs with a minimal excess in protamine.[72] Although some studies of regimens to titrate protamine in adults demonstrated encouraging results in terms of reduced bleeding,[73] others failed to demonstrate differences in transfusion requirements.[74]

The clearance of protamine is greater than that of heparin, and "heparin rebound" is described when tissue-bound heparin redistributes.[46] The diagnosis of residual heparin effect or heparin rebound is challenging. The ACT is not a specific measure of excessive heparin and is also poor at detecting heparin at low concentrations (<0.5 unit/mL).[75] The aPTT and PT are similarly nonspecific and may be increased after CPB in the absence of heparin.[76] An unmodified TEG does not reliably detect heparin rebound if the heparin concentration is small.[77] The sensitivity of these tests may be improved by performing similar tests in parallel and comparing the results, such as a reptilase time (unaffected by heparin), or by eliminating residual heparin in vitro with heparinase or protamine. Protamine titration can be used to guide the protamine dose in children; however, in infants, protocols will require modification (50% greater than the calculated dose).[53] In practice, most anesthesiologists continue to give protamine empirically at a protamine/heparin ratio of between 1 and 1.3 to 1. The author's current practice is to give a standard dose of protamine (4 mg/kg) regardless of heparin dose and to give a further 2 mg/kg in the presence of continued bleeding or unusually high ACT. In the presence of continued bleeding, a TEG is run both with and without heparinase to exclude residual heparin.

FAILURE OF HEMOSTASIS ASSOCIATED WITH CARDIAC SURGERY

Complex abnormalities occur in the coagulation system during cardiac surgery owing to the profound surgical insult, hypothermia, acid-base disturbance, blood transfusion, anticoagulants, and use of cardiac bypass. In addition, children and infants with congenital heart disease may have preexisting coagulation defects or be taking medications that affect coagulation before surgery (Table 20.1). The common preoperative and intraoperative risk factors for excessive bleeding are summarized in Table 20.2.

Antiplatelet drugs such as aspirin or clopidogrel may exacerbate bleeding. The clinician must balance the risk of perioperative bleeding against the risk of drug discontinuation when deciding if, and when, to withhold the drug before surgery. In most cases, aspirin can be safely discontinued 5 days before surgery. Prostaglandin E_1 can inhibit platelet aggregation at clinically relevant concentrations,[78] although this effect is too subtle to detect in vitro using the TEG.[33] For elective surgery in children receiving oral anticoagulant therapy, it is usually possible to stop the drug before surgery, but "bridging" the patient with heparin may be necessary. An INR of less than 1.5 is usually considered acceptable for surgery. If urgent correction of anticoagulants is required, prothrombin complex concentrates, together with vitamin K, are more effective than FFP.[79] FFP should be used only if prothrombin complex concentrates are not available.

In children with cyanotic congenital heart disease, hemostasis is impaired because of polycythemia, low platelet count and altered function, reduced factors V, VII, and VIII, and increased fibrinolysis.[33,80] The degree of derangement is related to the degree of cyanosis.[81] Preexisting coagulopathy may also occur in children with severe underlying illness or poor nutritional status.

Despite improvements in the design and materials of equipment, CPB and associated techniques still pose a considerable challenge

TABLE 20.1 Causes of Excessive Bleeding After Pediatric Cardiac Surgery

Preoperative Causes
Liver immaturity
Congenital coagulopathy
Poor nutrition
Cyanotic congenital heart disease
Drugs: prostaglandin E_1, aspirin, clopidogrel
Intraoperative Causes
Surgical insult
Inadequate surgical hemostasis before bypass
Inflammatory cascade, fibrinolysis, and so on
Cardiopulmonary bypass
Inflammatory cascade
Ongoing fibrinolysis
Increased vascular permeability
Capillary damage
Hemodilution
Platelet reduction
Clotting factor reduction
Fibrinogen reduction
Complement activation
Platelet abnormality
Disseminated intravascular coagulation
Postcardiopulmonary Bypass
Inadequate surgical hemostasis
Acidosis
Hypothermia
Hypocalcemia
Excessive blood transfusion and clotting factor dilution
Inadequate reversal of heparin with protamine
Excess protamine
Inadequate reversal of heparin in transfused pump blood

TABLE 20.2 Common Predictive Factors for Bleeding

Preoperative	Intraoperative
Age <1 year or weight <8 kg	Individual surgeon
High hematocrit	Complex surgery
Congestive heart failure	Low platelet count during CPB
Repeat sternotomy	Prolonged CPB
Congenital and preoperative acquired coagulopathy	Duration of hypothermia on CPB
Cyanotic congenital heart disease	Deep hypothermic cardiac arrest

CPB, cardiopulmonary bypass.
Data from Williams GD, Bratton SL, Ramamoorthy C. Factors associated with blood loss and blood product transfusions: a multivariate analysis in children after open-heart surgery. *Anesth Analg.* 1999;89:57–64.

to the coagulation system. Children are particularly vulnerable because of their small size (relative to the size of the circuit), the complexity of many surgeries, and a lack of reserve owing to developmental differences in the coagulation system.[82] As soon as CPB is established, there is a decrease in the concentration of all hemostatic protein concentrations with a commensurate decrease in platelet numbers as a result of dilution.[51,83] This effect is exacerbated owing to organ sequestration, mechanical disruption, and adhesion to the circuit.[84] Despite anticoagulation, there will be further platelet consumption resulting from activation of coagulation (and particularly platelets) on the surface of the bypass circuit and the contact of "spilt" blood with the pericardium or air (and returned via pump suction). In addition to acquired deficiencies, it is likely that substances that interfere with coagulation accumulate during bypass (e.g., degradation products of fibrin and activators of fibrinolysis). The risk of greater coagulopathy (and of severe bleeding) is increased by smaller patients, more complex surgery, longer bypass, and use of deep hypothermic circulatory arrest.[9,85,86]

A further feature of coagulopathy after heart surgery is platelet dysfunction.[13,14,51,87] As described previously, platelets exert many functions initiated by a range of different activators. Assessing this function in vitro can be difficult. Recent studies have used "multi-plate platelet aggregometry" to access platelet function.[88–90] Platelet adhesion to an electrode is detected in response to specific agonists, with different agonists chosen to detect different pathways within the platelet. When assessing the effect of drugs used to inhibit individual pathways, the application of this is logical and relatively straightforward. It is less clear how this relates to a "global" measure of platelet function during coagulopathy. In a study conducted in children after heart surgery, three of these measures do appear to alter in tandem, suggesting a global change in platelet function. Recovery is observed at 24 hours, despite persistence of thrombocytopenia, with early signs of recovery seen by the time the patient is admitted to the intensive care unit.[14] The speed at which recovery to restore adequate hemostasis occurs, or whether this recovery will occur in patients during active bleeding, is unclear. More widely available testing using TEG demonstrated an inconsistent relationship to "platelet function" measured in this way.[13] In the period soon after bypass it should be assumed that platelet function is abnormal, especially in the patient with active bleeding.

Medications Used for Hemostasis

The pathophysiology of coagulopathies and bleeding in children during surgery is complex, with a multifactorial etiology (see Table 20.1). No single blood component or drug treatment can reverse the abnormal clotting profile. Initially, an attempt should be made to identify the causes of bleeding that may be remedied by surgical interventions. The anesthesiologist should attempt to ensure adequate reversal of heparin and restore normal physiologic variables, such as body temperature, serum calcium concentrations ($[Ca^{2+}]$), and acid-base balance. In the postoperative period, platelets and other blood products, such as FFP and cryoprecipitate, remain the mainstays of treatment for excessive bleeding.[91] Blood products (see also Chapter 12) are briefly discussed here, primarily within the context of pediatric heart surgery.

BLOOD PRODUCTS

It is frequently necessary to administer blood products on a largely empirical basis; laboratory tests describe only parts of the coagulation process[33] and it often takes too long to obtain results that guide the anesthesiologist in real time as to the requirement for blood components. The TEG is a dynamic whole-blood test that is frequently used as a near-patient test to assess clot elasticity properties and more precisely delineate the bleeding and homeostasis profile. The role of TEG during pediatric heart surgery has been reviewed.[92–95] The use of treatment algorithms based on TEG can limit transfusion of blood products in adults[96–100] and children.[101] In children, it may not be appropriate to use protocols originally designed for adults; alternative approaches have been proposed.[92]

PLATELETS

Platelet dysfunction and thrombocytopenia are common after cardiac bypass in infants. Hence, in the presence of bleeding, transfusion of platelets is logical. Coagulation variables that relate to platelet number and function (such as TEG maximum amplitude) are corrected by infusion of platelets, and clinical experience indicates that platelet transfusion reduces bleeding. This has been confirmed in a small study of children after cardiac surgery.[32] A platelet count of less than 108,000/mm^3 has been identified as a predictor of bleeding, whereas clot strength measured by TEG reduces steeply at platelet counts below 120,000/mm^3. It would appear sensible to follow the common current practice by targeting a platelet count of approximately 100,000/mm^3 during bleeding after heart surgery.[102] In the absence of bleeding, platelet transfusion is generally not indicated unless thrombocytopenia is profound.[103] It would also appear reasonable to use platelets for the initial treatment of presumed coagulopathic bleeding (in the absence of specific clotting tests).

FRESH FROZEN PLASMA

The case for the use of FFP, either as empirical treatment of bleeding or guided by coagulation tests, is considerably weaker than for platelets. The use of FFP in cardiac surgery is based on the observation that the concentration of clotting factors is often reduced in bleeding patients, especially in the period after bypass. The PT (with its derived measure, INR) is the most common test used to detect the presence and gauge the severity of clotting factor deficiency. Unfortunately, observation studies have shown that (1) the PT correlates poorly with clinical bleeding and (2) transfusion of plasma often achieves neither measurable change in the INR nor provides a clinical benefit (particularly if the INR was only marginally raised to <1.7; see also reference 104 and Fig. 12.1). Despite this, FFP is frequently transfused in the absence of either bleeding or significantly increased PT.[105] Administration to patients with greater PT values is more effective in correcting clotting test results; however, large volumes may be required[104] even in the absence of ongoing loss of clotting factors. The situation is further complicated in that initially normal coagulation test results deteriorate during severe bleeding.

Systematic reviews of the use of FFP to treat or prevent bleeding resulting from acquired coagulopathy failed to demonstrate benefit, although the trials examined were small, used a wide range of outcomes, and were conducted in heterogeneous populations.[106,107] In a small observational study of children undergoing heart surgery, a number of patients had coagulopathic bleeding after transfusion of platelets; if these patients were then given FFP, the bleeding increased, whereas if cryoprecipitate was given, bleeding decreased.[32]

It is possible that the lack of efficacy may be related to the dose of FFP used. The dose of FFP most frequently recommended (10–15 mL/kg)[105,108] may be inadequate to restore

factor concentrations.[104] Modeling of FFP administration in major trauma suggests that larger doses (30–40 mL/kg) may be required to increase or maintain factor concentrations[109]; however, administration of such a large volume is often undesirable in the absence of severe ongoing bleeding. Addition of FFP to the bypass circuit or during modified ultrafiltration may allow administration of much larger doses but benefit appears to be confined to small infants.[110,111]

CRYOPRECIPITATE

Not all coagulation factors are of equal importance during bleeding. Fibrinogen is present in much greater concentrations than other clotting factors, and while other factors are mainly involved in initiating or amplifying thrombin formation, fibrinogen is the substrate for the production of fibrin. Deficiencies of fibrinogen are reflected in reduced strength of clot and increased bleeding.[112] Cryoprecipitate is the most concentrated fibrinogen replacement widely available, with a fibrinogen concentration four to eight times that of FFP. However, a unit of cryoprecipitate contains less fibrinogen than a unit of FFP, and multiple cryoprecipitate units are required in larger patients. One cryoprecipitate unit for each 10 kg should increase the fibrinogen concentration by 0.5 to 1.0 g/L. Cryoprecipitate is also a source of vWF and factors VIII and XIII, although the clinical significance of this to prevent bleeding is unclear. Cryoprecipitate has been effective in treating bleeding resistant to platelet concentrates alone during pediatric heart surgery.[32]

FRACTIONATED HUMAN BLOOD PRODUCTS

Products such as FFP or cryoprecipitate can be considered crudely purified blood products. It is possible to produce more refined products containing greater concentrations of a single clotting protein or relatively standardized concentrates of selected proteins. Examples of these are prothrombin complex concentrates and fibrinogen concentrate (e.g., RiaSTAP, Haemocomplettan P, CSL Behring GmbH, Marburg, Germany). These products are human blood products produced from pooled plasma; they are presented as a powder requiring reconstitution for use. They do not require freezing or cross-matching, which simplifies their supply, storage, and administration. Risk of viral transmission should be small[113] because of sourcing of plasma from low-risk populations, pooling of plasma from many individual donors (reducing viral load resulting from a single infected donor), and pasteurization. Although the effect of pasteurization on prion infection is less certain, the risk of transmission would be expected to be similarly low. Recombinant factor concentrates (as opposed to factor concentrates of human origin) are increasingly available and avoid cross infection. One such agent, rFVIIa, is discussed later in this chapter (see also Chapter 12). Although the agents discussed in this section are used in a manner similar to traditional factor supplementation to reestablish near-physiologic concentrations, rFVIIa is used very differently to produce factor levels greatly in excess of "normal."

Prothrombin Complex Concentrates

Prothrombin complex concentrates (PCCs) are mixtures of coagulation proteins and inhibitors whose production depends on vitamin K. Initially developed for treatment of hemophilia B (now superseded by the development of factor IX concentrates[114]), PCCs are now most commonly used for rapid reversal of oral anticoagulants,[115] although there is increasing interest in their use to treat other forms of abnormal coagulation.[116–120]

Factor concentrations in different preparations of PCC differ and the production of PCCs has also varied over time.[121] All PCCs contain large concentrations of factors II (PT), IX, and X. They differ in the degree of activation of the factors, the addition of heparin and coagulation inhibitors (such as AT, proteins C and S) and the concentration of factor VII. Those with reduced concentrations of fVII are referred to as three-factor PCCs, while those with greater concentrations as four-factor PCCs. Four-factor PCCs have only recently become available in the United States (KCentra [CSL Behring, King of Prussia, PA], essentially identical to Beriplex or Confidex marketed in other countries). These differences affect both the risks of administration (largely thrombotic risk) and efficacy. Thrombotic risk is associated with low concentrations of inhibitors, high concentration of activated factors (principally VIIa), and possibly with greater activity of prothrombin (essentially owing to accumulation when given repeatedly).[122] Three-factor PCCs are considered less effective at reversing the effects of oral anticoagulants and presumably also in the reversal of other causes of abnormal coagulation.[121,123]

PCCs should be regarded as the agent of choice when rapid reversal of warfarin is required.[79] FFP is indicated (for this indication) only when PCCs are not available. They should be used only when rapid reversal is required (because of bleeding or the need for urgent surgery). In other cases, discontinuation of the anticoagulant is preferred. Vitamin K should be given simultaneously, as the duration of effect of the anticoagulant will exceed that of the PCC (and repeat administration may lead to increased risk of thrombosis). Oral anticoagulants are given to patients at risk of serious complications of thrombosis; when PCCs are given, there should be a clear plan about the timing of surgery and the need for continuing anticoagulation. Dosing depends on the PCC used, on the patient's INR, and on the target INR. Oral anticoagulants other than warfarin are rarely used in children, although such use can be expected to increase. PCCs may be used for reversal of the effects of some of these drugs (e.g., dabigatran, apixaban[124]); however, this can be a complex problem, the management of which is uncertain and such cases should be discussed with a hematologist.

The use of PCCs in cases of severe coagulopathy (not associated with oral anticoagulants) has been described. These agents have been used for some time in some European countries. The scientific rationale is that coagulopathy can result from low concentrations of clotting proteins leading to a failure of adequate thrombin production and failure to initiate and maintain coagulation. Agents such as FFP allow the administration of these clotting proteins but only in a dilute form (reflecting normal population concentrations but no greater). As described earlier, FFP may lack efficacy in reversing established coagulation defects. PCCs may help to restore thrombin production by providing (as inactive zymogens) those clotting factors most critical to coagulation: principally in restoring prothrombin concentration. This is supported by experimental research[125] and observational studies.[116–120] One study conducted ex vivo used plasma from children after cardiac bypass, in which a three-factor PCC was more effective than rFVIIa in restoring thrombin generation.[125] European Society of Anaesthesiology (ESA) guidelines on management of massive bleeding support the use of PCCs (at a dose of 20–30 IU/kg) in adults.[126] It is acknowledged, however, that the evidence for this approach is limited and the associated risks are uncertain. It would be wise to confine use to management of life-threatening bleeding when there is evidence of slow initiation of clotting (a long PT or latent period on TEG) and only after failure of more established therapies. Risk of thrombosis

is unclear[127]; however, the risk benefit in this situation is likely to support measures that prove effective in reducing bleeding. Risk should also be compared with other therapeutic options in this situation. The dose in this situation (especially in children) is uncertain. The author has only rarely used these agents and would use a dose of 20 to 40 units/kg.

Fibrinogen Concentrate

The importance of fibrinogen depletion in coagulopathy and bleeding has been increasingly appreciated.[128,129] It has also been recognized that traditional cutoff values for supplementation of fibrinogen during bleeding (1.0 g/L) may be too low and that further advantage can be gained from greater targets, possibly as large as 2.0 g/L. This may be difficult to achieve with traditional blood products. FFP contains only physiologic concentrations of fibrinogen and only modest increases may be achieved, whereas cryoprecipitate requires administration of product from several donors to achieve significant increases in fibrinogen concentration (especially in larger patients). Human fibrinogen concentrate has been available in continental Europe for some time and has recently been licensed within the United Kingdom and the United States for treatment of congenital fibrinogen deficiency. Unlike cryoprecipitate, fibrinogen concentrates contain only fibrinogen and a direct comparison in other forms of coagulopathy has not been made.

Initial reports on the use of fibrinogen concentrate to manage bleeding were largely positive.[130,131] This was supported by two systemic reviews[132,133]; however, the variable quality of early studies was noted. Three recent larger randomized trials reported a lack of efficacy in the management of postpartum hemorrhage,[134] prevention of bleeding after heart surgery,[135] and management of bleeding after adult cardiac surgery.[136] In all three studies the fibrinogen concentration was within the "normal" range (>1.5 g/L) in the majority of patients. The later study (the REPLACE [Randomized Evaluation of fibrinogen versus PLACEbo] trial)[136] is of particular note. Patients were recruited if they demonstrated clinical evidence of significant bleeding shortly after bypass. A low fibrinogen concentration was not required for recruitment, though dosing of the drug (or placebo) was based on the FIBTEM assay (Instrumentation Laboratory, Bedford, MA). The median fibrinogen concentration at recruitment was almost 2 g/L with a narrow interquartile range. Transfusion of allogenic blood products was actually increased in the group receiving fibrinogen.

Several descriptions report individual children receiving fibrinogen concentrates with apparently good effect.[101,137,138] A small trial that compared fibrinogen concentrates with cryoprecipitate in children after heart surgery reported no difference.[139] The role of this agent, therefore, remains uncertain and initial enthusiasm should be tempered by more recent findings.[140] Further trials that may provide a clearer picture are under way in both adults[141] and children. Current use should be confined to the treatment of established bleeding in the presence of a low fibrinogen concentration. The decision to use fibrinogen concentrates in place of cryoprecipitate is likely to be dictated by their availability in different locations, cost, and logistical factors rather than presumed efficacy or safety. The optimal fibrinogen concentration in the presence of bleeding of different severities, and the means by which the fibrinogen concentration is measured, remain issues for further investigation.[142] Inadequate fibrinogen concentration is likely to be a common feature of severe bleeding in children and efforts to maintain concentrations within the normal range are required.

Factor XIII Concentrate

Deficiency of factor XIII during and after CPB has been described, although the importance of this finding is uncertain.[143–146] Supplementation with human or recombinant factor XIII has been demonstrated to reduce bleeding after adult heart surgery, although possibly only in the presence of factor deficiency.[145,147,148] A study in children after heart surgery (in which FFP had been added to the prime) did not demonstrate clinically significant deficiency or correlation between low concentrations and bleeding.[149] The action of factor XIII is to catalyze the formation of cross-bridges between fibrin molecules. High concentrations of factor XIII can be administered as cryoprecipitate, human factor XIII, and recombinant factor XIII. There is insufficient evidence to support its use in acquired bleeding.

PHARMACEUTICAL AGENTS TO REDUCE BLEEDING

Blood products (including fractionated products of human origin) are, in most cases, effective in treating coagulopathic bleeding, but they may be associated with deleterious effects on the patient. An alternative is to use pharmaceuticals to reduce bleeding and blood product requirements. The most commonly used agents are antifibrinolytic drugs are synthetic lysine analogs TXA and EACA and protease inhibitors (aprotinin). Other classes of drugs include recombinant factor VIIa (rFVIIa), used as rescue therapy for severe bleeding, and the hormone analog desmopressin.

Antifibrinolytic Drugs During Pediatric Heart Surgery

Fig. 20.5 summarizes the data currently available on the efficacy of antifibrinolytics during heart surgery in children (to reduce postoperative blood loss).[150–169] Overall almost 2000 children have been recruited into studies of these drugs. Some caution is required in the interpretation of these data. The majority of trials are small, trial methodology is of variable quality; the studies examine a diverse population, use variable dosages, and are statistically heterogeneous. Data from adult cardiac surgical patients are included in Fig. 20.6 for comparison.[169] While these adult studies are also primarily small and of variable quality, they include almost 10,000 patients (in studies reporting postoperative blood loss) and 7 trials with more than 200 participants. Given the available data on efficacy of antifibrinolytic drugs (e.g., tranexamic acid [TXA], ε-aminocaproic acid [EACA], and aprotonin) in children undergoing heart surgery and the evidence of efficacy in different but similar patient populations, it is reasonable to conclude that these drugs are effective (compared with placebo) in reducing blood loss after heart surgery in children. In addition, the three drugs (TXA, EACA, and aprotinin) can all be shown to reduce blood loss individually.

Efficacy is not the only consideration when choosing whether to use a drug. To further define the benefit, it is necessary to consider whether the reduction in blood loss is of a magnitude likely to produce a clinical benefit, whether any benefits are offset by adverse effects, how other outcomes are affected, if the drug also works in important subgroups of patients, and whether the benefits can be better realized by use of other medications. From the earlier analysis, a crude estimation of the expected reduction in bleeding (in children) can be made at 7.7 (3.9–11.6) mL/kg. while the mean blood loss across these studies is 28 mL/kg. This is a potentially useful reduction in blood loss. In a previous meta-analysis, the mean volume of red cell transfusion was also reduced, although only by relatively small volumes.[2] The use of these drugs has not affected the avoidance of transfusion, life-threatening bleeding, surgical reexploration (for bleeding), or

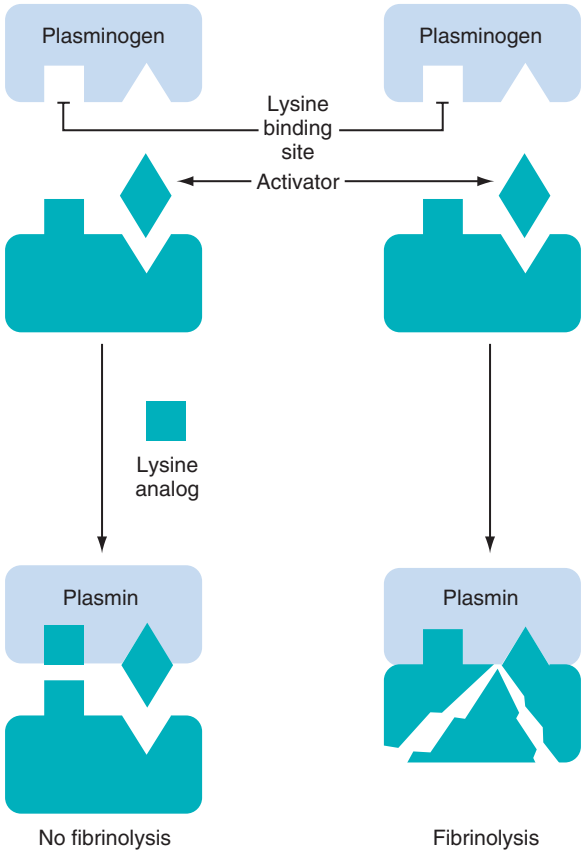

FIGURE 20.5 Diagrammatic representation of the mode of action of the synthetic lysine analogs tranexamic acid and ε-aminocaproic acid. (Reproduced from Mahdy AM, Webster NR. Perioperative systemic haemostatic agents. *Br J Anaesth.* 2004;93:842–858.)

mortality in children. In adults undergoing heart surgery, exposure to transfused blood and surgical rexploration is reduced, although the impact on mortality is unclear.

Children undergoing heart surgery represent a heterogeneous group. Efficacy may be affected by the presence (or absence) of chronic hypoxemia and polycythemia (owing to excessive fibrinolysis in cyanotic patients) or might differ in neonates as opposed to older children (owing to developmental differences in the coagulation system and its response to surgery). Studies of synthetic antifibrinolytic drugs have been undertaken mainly in children with cyanotic heart disease and most studies originate from a single institution (the All India Institute of Medical Science)[152,153,159,160,170] undertaking late correction of cyanotic heart disease. From studies of TXA, data on 6-hour blood loss were available for 144 acyanotic children. No significant reduction in bleeding (mean reduction 1. 8 mL/kg, 95% confidence interval [CI] of –0.8 to 4.5 mL/kg) was demonstrated.[150,151,155]

The fibrinolytic system of neonates differs from that of older children. Plasminogen concentrations are about 50% of adult values, and plasminogen activation occurs more slowly, while levels of inhibitor (PAI-1) are normal.[26] Reduced concentrations of TXA are required to inhibit fibrinolysis in cord blood.[171] Deficiency of substrate (fibrinogen and platelets) may be a greater risk factor for bleeding in neonatal patients than fibrinolysis and it cannot therefore be assumed that inhibition of fibrinolysis will be equally effective.[112] Among studies of synthetic antifibrinolytics, only one recruited infants younger than 2 months of age[150] and it is not possible to identify any effect specific to this group of patients. In a study of use of aprotinin in children undergoing arterial switch procedures, reduced blood loss, exposure to allogeneic blood products, and reexploration for bleeding was demonstrated.[166] A further randomized trial of aprotinin in neonates was terminated early (because of the concerns about toxicity in adults) and did not show any advantage in indexes of bleeding or postoperative recovery.[168]

Adverse Effects of Synthetic Lysine Analogs

As with any drug used to promote hemostasis, the most worrisome complication is thrombosis. This is likely to be a particular concern in cardiac surgical patients because of vascular anastomoses, conduits, and indwelling vascular lines. Thrombosis is also a potential concern for those patients receiving extracorporeal support.

After any major surgery or trauma patients can be hypercoagulable and at risk of thrombosis. The lysine analogs (TXA or EACA) have not shown an increased risk of renal, cardiac, or cerebral events in adult cardiac surgery patients.[172] Several meta-analyses in adults concluded that prophylactic lysine analogs in cardiac surgery did not increase the incidence of thromboembolic complications.[173–175] However, thrombosis has been reported in nonsurgical hypercoagulable states.[176] Despite isolated case reports, there is no clear-cut evidence that the incidence of thrombosis is increased with either of the lysine analogs. Both TXA and EACA have a very low incidence of anaphylaxis.

The most common acute adverse effect of EACA is hypotension, usually associated with rapid intravenous (IV) administration. Rash, nausea, vomiting, weakness, myopathy, and rhabdomyolysis have been less frequently reported and are associated with longer-term use.[177] EACA is teratogenic and therefore contraindicated in pregnancy. Rapid IV administration of TXA can cause hypotension. Oral administration can be associated with gastrointestinal adverse effects. In an adult study, prolonged infusion was associated with renal dysfunction.[178]

Concern has been raised that both TXA[179–182] and EACA[183] may be associated with an increased risk of seizures in a dose-dependent fashion. Possible mechanisms have been recently reviewed.[184] TXA crosses the blood-brain barrier[185] and causes seizures when applied directly to the brain of animals. The most probable mechanism is antagonism of (inhibitory) glycine receptors.[180] A similar effect can be observed with EACA at equivalent concentrations.[180] This effect is inhibited by general anesthetic agents including propofol and inhalational agents but not by sedatives commonly used during intensive care. A recent large randomized trial in adults undergoing coronary surgery demonstrated an increase in the incidence of seizures in those treated with TXA compared with placebo (0.7% vs 0.1%).[186] A meta-analysis of observational studies of TXA in adults demonstrated a 2.3% incidence of seizures with an odds ratio (compared with no exposure to TXA) of 5.4 (3.3–8.9).[182] This association has also been described in children undergoing heart surgery.[187] A strong publication bias is likely and this may be an overestimate the true size of this effect.

Adverse Effects of Aprotinin

There has been much controversy regarding the adverse effects of aprotinin, largely after the publication of an observational study in adults with acute coronary syndromes that concluded that rates of renal failure, serious intravascular thrombosis (myocardial infarction and stroke), and death at 5 years were increased if aprotinin was used.[172,188] The rate of these complications was not increased with the use of synthetic antifibrinolytics, whereas all

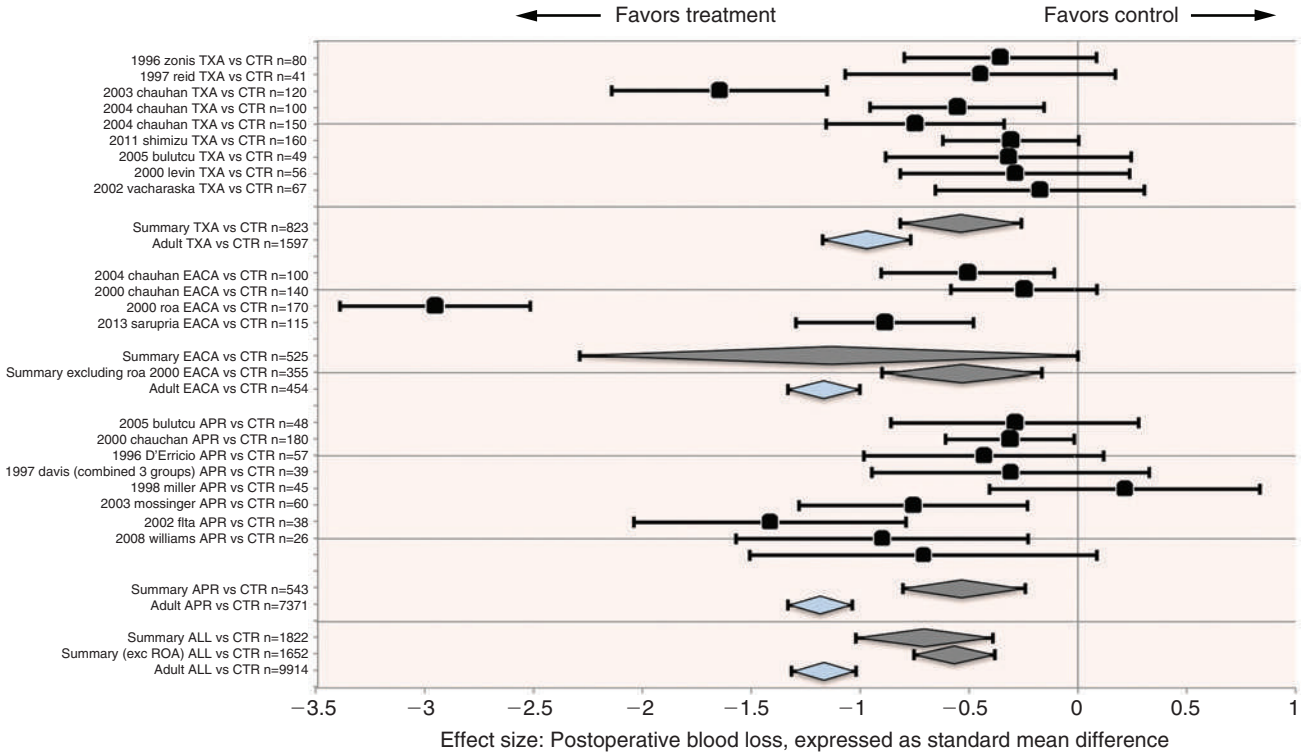

FIGURE 20.6 Efficacy of antifibrinolytic medications in reducing postoperative blood loss compared with control. Results of studies are shown as a standardized mean difference (the size of the treatment effect divided by the standard deviation of the outcome); the outcome used is expressed as milliliters per kilogram over the first 24 postoperative hours. Standardized mean difference is given to allow studies with similar but different outcome measures to be included and to allow a comparison with adult studies. The effect size expressed in this way is generally smaller than that seen in adults, indicating that other causes for variation in bleeding have a greater impact. All three drugs perform better than control. *APR*, aprotinin; *EACA*, ε-aminocaproic acid; *TXA*, tranexamic acid.

agents appeared effective for reducing bleeding. This was followed by the early termination of a large randomized trial (the Blood conservation using Antifibrinolytics: Randomized Trial [BART]) comparing synthetic antifibrinolytics and aprotinin (in "high-risk" adults undergoing heart surgery), when interim analysis showed an increased mortality in the group treated with aprotinin.[189] Excess deaths appeared to result from heart failure and myocardial infarction. Rates of renal failure were not increased in those treated with aprotinin, although an increase in plasma creatinine was common. The relative risk of death in adults treated with aprotinin compared with those treated with synthetic antifibrinolytics was 1.53 (95% CI 1.06–2.22). Data on bleeding in this study were inconclusive, although they suggested a small benefit for aprotinin in preventing severe bleeding. The conclusion of these papers was that aprotinin should not be used in the patient populations studied and led to the drug being effectively unavailable in several countries. Subsequently there has been a reevaluation of the evidence regarding adult patients, pointing at potential shortcomings in the BART study, and the availability of aprotinin has once more increased.

The implication of these studies for children and young adults with congenital heart disease is uncertain. The use of aprotinin in children has reduced dramatically within the United Kingdom.[190] The main cause of death reported in adult patients was from stroke and myocardial infarction. Although thrombotic complications do occur in children, the pathogenesis and underlying risk factors are very different from those in adults. Renal failure occurs in children after high-risk operations and may share pathogenic factors with postoperative renal failure in adults; aprotinin accumulates within renal tissue and affects local autoregulation of blood flow in response to ischemia. Whether aprotinin causes any more than temporary derangement of renal function tests in adults or children remains unclear. A number of retrospective studies have attempted to examine the link between aprotinin and renal failure in neonates and in children[191–197] with contradictory results. In a large retrospective study, the use of aprotinin was not associated with an increased risk of either renal failure or death.[198] In a further study on an overlapping data set, aprotinin was again not associated with increased risk relative to no antifibrinolytic; however, risks of dialysis or death were lower in those treated with TXA.[199]

Of greater concern is the association between aprotinin and the risk of anaphylaxis.[200,201] The risk is small in children during primary exposure, but the risk increases with repeated exposure (estimated as 2.4%).[202] Therefore, administration of a test dose before the full dose is wise.

Secondary Benefits of Aprotinin

While synthetic antifibrinolytics are selective inhibitors of fibrinolysis, aprotinin is a less specific inhibitor of proteolytic enzymes.[16] Proteolytic enzymes are important mediators of inflammation via contact activation and the complement system; it is postulated that aprotinin may exert a beneficial antiinflammatory effect. A number of studies have demonstrated a reduction in inflammatory

markers, although other studies have failed to corroborate this effect.[203–205] One trial demonstrated that inflammatory markers were reduced postoperatively in infants treated with aprotinin compared with infants treated with TXA.[206] Another small study in older children undergoing mainly low-complexity surgery failed to demonstrate any effect of aprotinin on a series of inflammatory markers compared with control.[204] At the same time, it is important to appreciate that broad inhibition of inflammation may not always be beneficial: inflammation is to some degree a part of an appropriate physiologic response to tissue injury and contact activation may provide some protection against ischemic reperfusion injury.[16] There are no convincing clinical data to show any clinical benefit from an antiinflammatory action of aprotinin.[204] A trial designed to detect a reduction in ventilation days (as a marker of organ dysfunction) in neonates was terminated before an adequate number of patients had been recruited to identify a significant effect.[168]

DOSING OF ANTIFIBRINOLYTIC MEDICATIONS

Both the beneficial and adverse effects of these drugs most likely depend on their doses. It is desirable that the dose is optimized to ensure a balance between these effects. This will require a knowledge of the pharmacokinetics of the drugs and the relationship between their plasma concentration and both effect and toxicity. Regimens based on a single dose have performed less well than those based on infusions or repeated intermittent dosing.[152,161] A reasonable approach is to aim to maintain effective concentration of the drugs throughout surgery and such regimens are best informed by pharmacokinetic studies.[207–213] Experiments conducted in vitro can identify the concentration required to produce the intended biochemical effect (inhibition of fibrinolysis); however, these may vary with the concentration required to produce the intended clinical effect in vivo. The gold standard would be properly conducted dosing studies, using a PK/PD design based on clinically relevant outcomes. As yet only limited dosing studies have been conducted in children.[152,161,214,215]

Dose of Tranexamic Acid

There is considerable uncertainty regarding the dose of TXA. A survey of pediatric cardiac anesthetists in the United Kingdom demonstrated a 50-fold variation in TXA dose used during surgery (from a single dose of 5 mg/kg to a cumulative dose of 250 mg/kg).[190] Furthermore, the doses recommended in the literature vary substantively.

Two studies have addressed the PKs of TXA in children undergoing heart surgery.[210,211] In children older than 1 year, there is good agreement between these studies and suitably scaled adult data.[208] In younger infants and neonates, the PKs could not be extrapolated from data in adults or older children, and there were significant changes in the PKs during the first year of life. Table 20.3 lists three possible dosing schedules that target low, intermediate and large plasma concentrations. Unfortunately, these studies did not address the PD effect of blood loss. In vitro, a concentration of 20 µg/mL is sufficient to inhibit fibrinolysis and effects of plasmin on platelets.[171,216] Smaller concentrations may be adequate to inhibit fibrinolysis in neonatal plasma. However, in adult cardiac patients, regimens that targeted larger concentrations may produce an improved clinical effect.[217] Factors such as bleeding and administration of large volumes of IV fluid may also affect the PKs the drug. The author's practice is to routinely administer a dose similar to the intermediate concentration described (i.e., 60 µg/mL); although more drug is given during severe bleeding.

Dosing of EACA

Two small PK studies can be used to inform the dose of EACA in children[207] and neonates.[218] A larger dose is required to maintain target concentrations assumed to be therapeutic in children older

TABLE 20.3 Three Possible Dosing Schedules Targeting Plasma Concentrations of Tranexamic Acid in Children

		TARGET TXA CONCENTRATION		
Age		**Low (20 µg/mL)**	**Intermediate (60 µg/mL)**	**High (150 µg/mL)**
0–2 months	Loading dose (mg/kg)	15	50	120
	Infusion (mg/kg per hour)	2.5	7	17
	CPB prime dose (µg/mL prime)	20	60	150
2–12 months	Loading dose (mg/kg)	9 (6–12)[a]	26 (20–30)[a]	65 (45–85)[a]
	Infusion (mg/kg per hour)	2	6	14
	CPB prime dose (µg/mL prime)	20	60	150
>12 months ≤20 kg	Loading dose (mg/kg)	4	13	31
	Infusion (mg/kg per hour)	2	5.5	14
	CPB prime dose (µg/mL prime)	20	60	150
Adults[a,b]	Loading dose (mg/kg)	8	12.5	30
	Infusion (mg/kg per hour)	4	6.5	16
	CPB prime dose (mg/kg prime)	0.6	1	2

Suggested dosing regimen for tranexamic acid during heart surgery to achieve target concentrations of 20, 60, and 150 µg/mL . A dose is added to the circuit prime to prevent dilution on initiation of bypass. This is calculated according to the size of the circuit rather than the patient.

CPB, cardiopulmonary bypass; *TXA,* tranexamic acid.

[a]The required loading dose in children aged 2 months to 1 year alters rapidly with age. The larger relative dose in the range is appropriate for infants close to 2 months while a smaller dose (relative to body size) is appropriate for children closer to 1 year.

[b]Adult low, intermediate, and high dosing would aim for target concentrations of 33 µg/mL, 52 µg/mL, and 126 µg/mL, respectively. The prime dose is in milligrams per kilogram rather than micrograms per milliliter. Pediatric dosing estimations from Wesley MC, Pereira LM, Scharp LA, et al. Pharmacokinetics of tranexamic acid in neonates, infants, and children undergoing cardiac surgery with cardiopulmonary bypass. *Anesthesiology* 2015;122(4):746–758. Adult dosing estimations from Dowd NP, Karski JM, Cheng DC, et al. Pharmacokinetics of tranexamic acid during cardiopulmonary bypass. *Anesthesiology* 2002;97(2):390–399.

than 9 months compared with adults. A dose of 75 mg/kg at induction and repeated on bypass combined with an infusion of 75 mg/kg per hour was recommended.[207] This dose was more effective than two divided doses of 100 mg/kg in a study of patients undergoing late repair of tetralogy of Fallot.[161] A dose of 40 mg/kg, followed by 30 mg/kg per hour and a prime concentration of 100 mg/mL added to the prime, should be adequate to maintain a plasma concentration of 50 µg/mL in neonates.[218] This is, however, a smaller concentration than targeted by the earlier study in children. As with TXA, the concentration required to produce an optimal clinical effect is uncertain. Generally, potency is around 10 times less than TXA and lower concentrations are effective in vitro using neonatal plasma.

Dosing of Aprotinin

Aprotinin rapidly redistributes into the extracellular space after IV administration. It is metabolized in the proximal renal tubules and eliminated in a biphasic pattern: a distribution half-life of 40 minutes and an elimination half-life of 7 hours.[219,220] A PK study of aprotinin in children undergoing CPB examined aprotinin concentrations after administration of weight-based dosing (25,000 KIU/kg bolus before CPB, 35,000 KIU/kg in CPB prime, and 12,500 KIU/kg per hour infusion).[221] There was considerable variation in plasma concentration of aprotinin, with the lowest concentration seen in the smallest patients. This study may help to explain inconsistent results from aprotinin trials in children. Using a dose-per-weight regimen, the smaller children may fail to achieve therapeutic concentrations of aprotinin, in terms of plasmin inhibition and antiinflammatory effects (a concentration of aprotinin <200 KIU/mL would be insufficient to inhibit contact activation on the CPB circuit). This is consistent with greater clearance (expressed as per kilogram) in children (see also Chapter 7, Fig. 7.5). A further PK study of aprotinin in neonates also demonstrated rapid clearance and suggested that considerably larger doses are required to maintain therapeutic concentrations: a 50,000-KIU/kg bolus, 40,000 KIU/kg for CPB priming, and continuous infusion of 54,000 KIU/kg per hour for 3.4 hours and 10,000 KIU/kg per hour for 3.4 hours. Calculation of the dose using nonlinear functions (e.g., body surface area or an allometric ¾-power model; see Chapter 7), as opposed to the linear dose per kilogram may provide more effective dosing. This would result in a 2.5 times greater doses in neonates than would otherwise be given.[54]

WHICH ANTIFIBRINOLYTIC DRUG FOR PEDIATRIC CARDIAC SURGERY?

A meta-analysis of trials in adult patients demonstrated no difference between EACA and TXA. Aprotinin was more effective than either TXA or EACA, and although that effect was marginal, only aprotinin reduced the risk of reoperation.[173] Direct comparisons between TXA and EACA demonstrated no differences in their effects in children.[170,222] Low-dose aprotinin (10,000 KIU/kg followed by 10,000 KIU/kg per hour) has been compared with EACA (100 mg/kg on induction, 100 mg/kg in the pump prime, and 100 mg/kg on weaning from CPB).[159] There was a reduction in postoperative blood loss and transfusion requirements in both groups compared with control, but no significant difference between the two drugs. More recently, TXA (100 mg/kg before, during, and after CPB) was compared with aprotinin (30,000 KIU after induction, 30,000 KIU in the pump, and 30,000 KIU after weaning off bypass). There was a reduction in the time to sternal closure, transfusion requirements, and blood loss compared with control but there was no significant difference between the two drugs. When the two drugs were combined at the same doses, they showed no additional benefit.[156] A further small trial demonstrated no difference in outcomes between aprotinin and TXA.[223]

Retrospective studies have examined a number of outcomes related to efficacy and adverse effects. Results have been contradictory; some studies reported greater benefit with aprotinin,[192,195,224] whereas others showed no significant effect.[225] One study reported reduced bleeding with aprotinin, but greater creatinine concentrations and more prolonged postoperative ventilation.[193] A large multicenter study (>22,000 patients) demonstrated a benefit with all these drugs; however, mortality and reexploration were least in those who received TXA.[198]

In the absence of convincing evidence of improved efficacy for any drug, the choice of antifibrinolytic depends on the adverse effects and cost. The incidence of important adverse effects is also uncertain. Both mechanistically and from the available data, it would appear that the recent "safety" concerns about aprotinin in adults are not applicable to children. A more certain risk of aprotinin is anaphylaxis with repeated exposure. This is a concern because many pediatric cardiac patients undergo repeat surgery. The greater cost of aprotinin is also difficult to justify in the absence of a clear advantage over lysine analogs. In the absence of further studies, it is the author's conclusion that if an antifibrinolytic is indicated, lysine analogs are preferred over aprotinin.

USE OF ANTIFIBRINOLYTIC DRUGS IN NONCARDIAC SURGERY

There is a trend toward increased use of antifibrinolytic drugs (especially TXA) during noncardiac surgery; principally major orthopedic surgery (e.g., spinal instrumentation, see also Chapter 32) and craniofacial surgery (see also Chapter 35). Aprotinin is less commonly used because of reduced availability and the safety concerns discussed previously.

A total of 27 trials have examined the use of TXA during orthopedic surgery in adults[173]; they report a 50% reduction in the relative risk of requiring a blood transfusion. In 20 of these trials. there was a reduction in the incidence of total blood loss of more than 400 mL. Almost all these studies were conducted in adults undergoing major joint replacement surgery. In one study of adults (n = 147) undergoing posterior spinal fusion, TXA reduced total blood loss by 25%; however, the reduction in blood products transfused was not statistically significant.[226] The popularity of antifibrinolytic use during scoliosis surgery in children and adolescents is reflected in two surveys, which show use in 70% to 80% of hospitals.[227,228] It is unclear whether this use is mostly confined to higher-risk cases; however, in the author's institution, TXA is currently used during all scoliosis surgery as part of a program aimed at reducing the use of blood products. Two meta-analyses and a further systematic review have examined this question (reviewing 6 and 7 studies, respectively); no single prospective study included more than 45 patients.[2,229,230] These meta-analyses concluded that antifibrinolytic drugs reduce bleeding and the volume of red cells transfused. To date there has been no single prospective trial comparing different antifibrinolytics. A retrospective comparison of TXA and EACA appeared to show a superiority of TXA but the doses used were not comparable.[231] The two meta-analyses failed to establish any difference between the drugs.[2,229] It is also not possible to determine whether reported benefits hold for all children undergoing scoliosis repair. Bleeding is

greater in children with nonidiopathic scoliosis (including patients with Duchenne muscular dystrophy),[232] those with hemostatic disorders, and in those undergoing more extensive surgery; therefore, in these groups a greater advantage in terms of bleeding reduction might be expected. At least one study examined children with idiopathic scoliosis and demonstrated a reduction in blood loss with aprotinin (see also Chapter 32).[233] As with cardiac studies there is a considerable range in the dose of drug used; in a survey of practice in the United Kingdom, the TXA dose ranged from 3-fold to 5-fold, whereas in published trials the dose varied 10-fold.[227]

Antifibrinolytics are also used widely in craniosynostosis surgery.[234–236] In a survey of North American practice, they were used in 20% of hospitals for strip craniotomy, increasing to 30% for more complex repairs.[237,238] Four small trials–three using TXA[239–241] and one using aprotinin[242]–(a total of 141 children) have addressed the use of these agents for this indication. All of these trials demonstrated reductions in blood transfused and in bleeding. A recent publication demonstrated a greater than 50% reduction in the volume of blood transfused and in the proportion of children transfused (70% vs. 37%).[239] Although all these studies were relatively small, it would appear likely that antifibrinolytics produce a useful reduction in blood loss during craniosynostosis surgery.

A further trend has been the use of antifibrinolytic drugs during surgery not commonly associated with transfusion.[243–246] The objective is to prevent uncommon, but potentially life-threatening, bleeding. Even if these drugs are beneficial in this circumstance, it is likely that very large numbers of patients would require treatment to realize this benefit. In this context, even rare adverse effects may outweigh any advantage.

ANTIFIBRINOLYTIC MEDICATION AND TRAUMA

There is no evidence in children that antifibrinolytic medications should be used to treat massive hemorrhage after trauma. The Clinical Randomization of an Antifibrinolytic in Significant Hemorrhage 2 (CRASH-2) study (a blinded randomized control trial of more than 20,000 patients) demonstrated a reduction in mortality with TXA in adult trauma patients with, or at risk for, significant hemorrhage; mortality was reduced from 16% to 14.5%.[247] Mortality related to bleeding was reduced from 5.7% to 4.9%. No difference was reported in the rates of vascular occlusive events. Despite the size and complexity of the study, it appears that it was properly randomized and blinded. One nonrandomized study of 766 children younger than 18 years of age who were victims of trauma in Afghanistan evaluated 66 children who received TXA; the study found that TXA administration was independently associated with decreased mortality.[248] In the absence of prospective well-controlled studies in children and in the absence of definite evidence of toxicity, it would seem reasonable to consider TXA as part of the treatment for *severe* bleeding from trauma or surgery. Some caution is required and its use should be reserved for severe bleeding–for example, bleeding requiring treatment with non–red cell blood products. A dose of 15 mg/kg followed by 2 mg/kg per hour has been recommended for use in trauma.[249] This represents a simple per kilogram scaling of the dose used in the CRASH-2 study. The dose in children should probably be modified in line with the previous discussion regarding cardiac surgery. A further caveat is that administration more than 3 hours after injury in adults appeared to increase mortality.[250] The significance of this is unclear; however, such late administration should be avoided.

AUTHOR'S RECOMMENDATIONS FOR USE OF ANTIFIBRINOLYTICS

Many children and adults have been recruited for studies of antifibrinolytic drugs. As a consequence, it is reasonable to use these drugs during cardiac surgery, during other surgeries likely to require blood transfusion, and in the management of trauma associated with severe bleeding. Considerable uncertainty remains, however: the dose remains uncertain, the incidence of important adverse effects is unclear, the choice of drug is open to question, and their effectiveness in different patient subgroups and clinical situations is debatable. Any further studies should be designed very carefully to address these questions. In the absence of these data, it is not possible to make solid recommendations. The author's current practice is as follows:

- Antifibrinolytics are used routinely during heart surgery in children with cyanotic heart disease, especially in the presence of polycythemia, reduced saturations for a prolonged period, or iron deficiency.
- Antifibrinolytics are used during cardiac procedures in other children as part of a strategy to reduce transfusion. Greater benefit is likely (but not proven) in children with a greater tendency to bleeding, including smaller children, when bypass times is likely to be long and during repeat surgery.[151,162]
- Antifibrinolytics are given during other major surgical procedures in children including scoliosis repair, multilevel joint surgery, and craniosynostosis repair.
- Synthetic antifibrinolytics are used in preference to aprotinin.
- TXA is used in high dose: 30 to 50 mg/kg bolus followed by 15 mg/kg per hour infusion. Additional drug is given to the CPB circuit. Infusion is continued until significant bleeding has stopped up to 4 hours postoperatively. A larger bolus dose is administered to smaller infants.
- EACA is not used by the author; however, an appropriate dose would be a 75-mg/kg bolus followed by 75 mg/kg per hour (plus, if cardiac bypass is used, an additional 75 mg/kg to the CPB circuit).
- These drugs are used together with other measures to reduce bleeding and transfusion.

DESMOPRESSIN

Desmopressin acetate (1-desamino-8-D-arginine [DDAVP]) is a synthetic analog of vasopressin. The production of desmopressin involves alteration in the chemical structure of naturally occurring vasopressin. In the process, the antidiuretic effect is enhanced and the vasopressor effect is virtually eliminated. Desmopressin is more resistant to enzymatic cleavage, and hence the duration of action is prolonged to 6 to 24 hours.[177] Desmopressin potently causes endothelial release of factor complexes VIII/protein C and VIII/vWf. It has been used in mild hemophilia, von Willebrand disease, coagulopathy of uremia, liver failure, and in adults undergoing cardiac and spinal fusion surgery (see also Chapter 12). The maximum effect of desmopressin is observed at a dose of 0.3 μg/kg. It must be given *after* cessation of the extracorporeal circuit to prevent unwanted platelet activation.[54]

Several meta-analyses of the use of DDAVP in adults have been published. The most recent showed that desmopressin was associated with a small reduction in blood loss, but had no benefit in terms of repeat sternotomy, proportion of patients requiring transfusion, or mortality.[174] It was also associated with a 2.4-fold increase in risk of myocardial infarction.

In children, desmopressin at 0.3 μg/kg failed to demonstrate any benefit for both non–high-risk[251] and high-risk cardiac surgery.[252]

Younger children are not as capable of releasing vWf from endothelial storage sites as older children, and the maximal release of vWf caused by the operative stimulus cannot be enhanced by desmopressin.[253] Potential adverse sequelae from desmopressin include fluid retention, hyponatremia, tachyphylaxis, tachycardia, and mild hypotension.[254] Desmopressin is not currently recommended in pediatric surgery,[82] although one could postulate that it could be reserved for those with ongoing bleeding with evidence of platelet function abnormalities, such as prolonged bleeding time or decreased maximum amplitude values on a TEG.[255]

RECOMBINANT FACTOR VIIA

Recombinant activated factor VII (rFVIIa) is known to be safe and effective for treatment and prevention of hemorrhage in children with hemophilia who have circulating inhibitors to replacement factors (see also Chapters 10 and 12). It is also used in patients with Glanzmann thrombasthenia refractory to platelet transfusion and in patients with factor VII deficiency. Regulatory approval has been granted in Europe and the United States for these indications.

Off-label use of this drug has grown steadily and now accounts for 97% of in-hospital use (Fig. 20.7).[256] This has encompassed a number of indications involving treatment or prevention of acquired bleeding or coagulopathy of varying severity.[257–269] The most common off-label indications are treatment of bleeding related to cardiovascular surgery, trauma, and intracranial bleeds. Off-label use in children is also widespread. One retrospective study recorded 3655 administrations (in 39 U.S. pediatric hospitals over a 7-year period); 46% of uses were in children admitted to a surgical specialty or to a pediatric intensive care unit and more than 20% to cardiac surgery or cardiology. Administration was most common in children younger than 1 year. Another report from a single U.S. hospital reported use in 148 patients over 3 years. This is approximately 7% of cardiac surgeries in children performed at that hospital.[270]

The therapeutic effects of factor rFVIIa begin at doses up to 10 times greater than physiologic concentrations of the endogenous factor. It is therefore not simply a "replacement" therapy of a deficient factor.[271] For rFVIIa to exert a beneficial action, it must generate a burst of thrombin at the site of injury. Two mechanisms likely work in synergy to produce this: first, the TF pathway described previously is stimulated to augment generation of factor Xa; second, high concentrations of rFVIIa bind directly to the surface of activated platelets, again activating factor Xa, leading to thrombin production (Figs. 20.8 and 20.9).[272] Sufficient concentrations of substrate are needed to produce a clot. Measures should be taken to ensure adequate fibrinogen concentration and platelet numbers before giving rFVIIa. In addition, factors such as acidosis and hypothermia reduce the efficiency of rFVIIa.[273] Adequate circulating concentration of prothrombin is also required and a synergy between administration of prothrombin concentrates and rFVIIa has been suggested. Given the expense of rFVIIa, in addition to doubts over its safety, it appears wise to use more established measures before administration.

Evidence that rFVIIa reduces bleeding comes mainly from case reports. Numerous anecdotes appear to demonstrate dramatic reductions in bleeding in apparently catastrophic situations. Demonstrations of even occasional success, in the face of an otherwise hopeless situation, might themselves be taken as a good reason to use the drug. However, rFVIIa is often used for patients at much lower risk of bleeding to death. Reported cases of off-label use in anesthesiology and surgical practice range from truly prophylactic use (in high-risk populations before evidence of severe bleeding), use to control prolonged or severe (but not immediately life-threatening) bleeding, to compassionate use in immediately life-threatening bleeding after exhaustion of all conventional

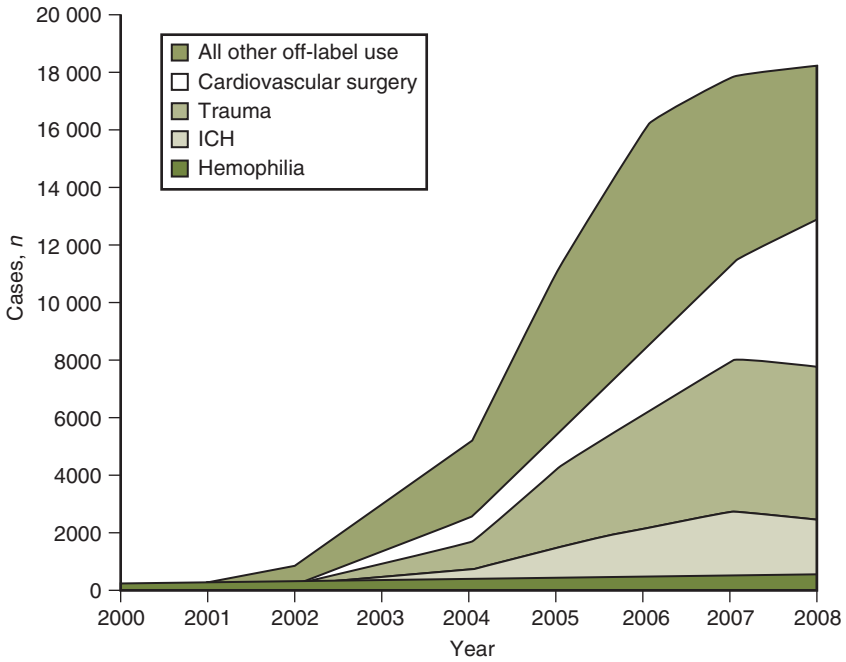

FIGURE 20.7 Use of rFVIIa during hospitalizations in a sample of U.S. hospitals. Data from 12,644 hospitalizations in children and adults. "Off-label" use has grown substantially, while use for hemophilia has remained largely constant. (From Logan AC, Yank V, Stafford RS. Off-label use of recombinant factor VIIa in U.S. hospitals: analysis of hospital records. *Ann Intern Med.* 2011;154(8):516–522.)

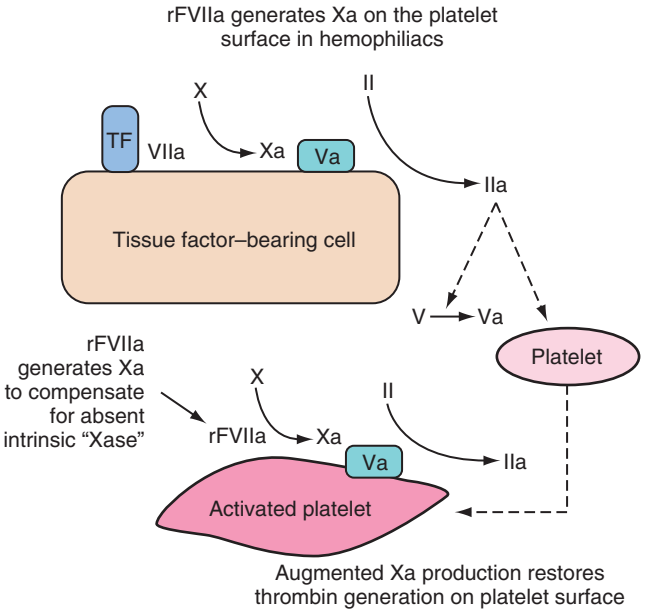

FIGURE 20.8 Schematic representation of the cell-based coagulation model and the proposed mechanism of how recombinant activated factor VII *(rFVIIa)* can potentially improve coagulation in hemophiliacs. At supraphysiologic concentrations, rFVIIa can bind to the phospholipid membranes of activated platelets, where it activates factor X independent of the tissue factor (*TF*) pathway, causing a large rise in thrombin at the platelet surface. It can therefore compensate for a lack of factor VIII or IX, a possible explanation for its effectiveness in platelet function disorders. (From Welsby IJ, Monroe DM, Lawson JH, Hoffmann M. Recombinant activated factor VIIa and the anaesthetist. *Anaesthesia* 2005;60:1203–1212.)

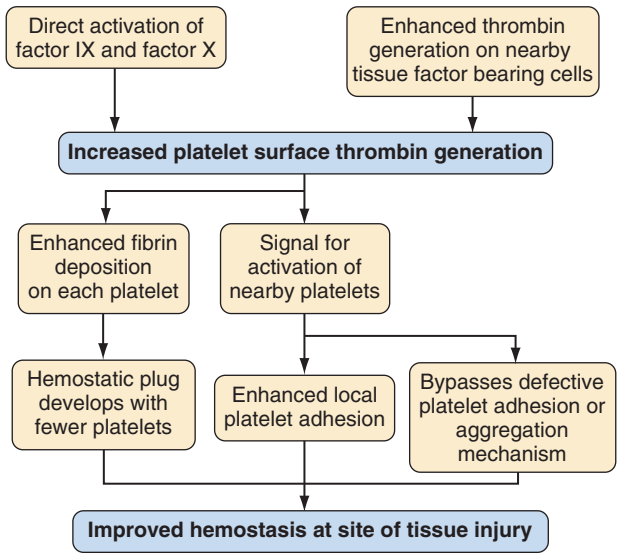

FIGURE 20.9 Theoretic mechanisms by which recombinant activated factor VII could increase thrombin generation and fibrin deposition that may lead to improved hemostasis. (From Welsby IJ, Monroe DM, Lawson JH, Hoffmann M. Recombinant activated factor VIIa and the anaesthetist. *Anaesthesia* 2005;60:1203–1212.)

treatments. The balance of risk and benefit will vary widely within these differing clinical scenarios.

Most controlled trials of rFVIIa have focused on prophylactic use or use in less severe bleeding. Twenty-six randomized controlled trials have examined off-label use of rFVIIa and five have focused on surgical use.[220,274–277] A meta-analysis of these trials demonstrated no reduction in mortality and only relatively modest reductions in bleeding and transfusion.[278] A study that examined patients with moderately severe bleeding (>200 mL/hour or >2 mL/kg for 2 consecutive hours) after heart surgery in adults demonstrated a reduction in reexploration, bleeding, and in transfusion requirements.[275] The objective of the trial was to examine the safety of using rFVIIa. Unfortunately, the trial was terminated early and although a trend to increased adverse effects was seen, the result was inconclusive. The authors of this study cautioned against wider use before further trials. A single randomized trial ($n = 76$) that examined prophylactic rFVIIa administration (40 μg/kg) in infants undergoing heart surgery[276] demonstrated neither efficacy nor toxicity in this group. A small trial of patients undergoing neurosurgical procedures appeared to demonstrate a dose-dependent reduction in bleeding.[279] The use of rFVIIa in children has been reviewed.[280]

Concerns about adverse effects of this drug have grown. Two studies have systematically reviewed the data on toxicity.[281,282] In the first study, the rate of thrombosis was greater (10.2% vs. 8.7%) in those treated with rFVIIa. In the second study, data from observational trials reported that mortality was unaffected by treatment with rFVIIa, although the risk of thrombosis increased in some groups (including adult cardiac patients). Both reviews combined data from studies on very different patient populations; thus some caution is required in their interpretation. The risk of thrombosis in children is uncertain and data are inconclusive.[280] In a large multicenter registry, thrombotic complications occurred in 10.8% of children who received off-label rFVIIa and the overall mortality rate in those receiving rFVIIa was 34%.[283] In a further series of children receiving rFVIIa for severe bleeding, the reported rate of thrombosis was low; however, only events believed by the reporter to be directly related to use of rFVIIa or events with a fatal outcome, were reported.[284] Neonates treated with either FFP or rFVIIa for similar indications had a similar incidence of thrombosis (7%),[285] and administration of very large repeated doses in preterm infants did not produce thrombosis.[286] It is clear that both thrombotic complications and mortality are common in patients with bleeding serious enough to warrant use of this drug. Use of rFVIIa is likely to increase the risk of thrombosis, although the impact of this–and the benefit of the drug–vary in different clinical situations. The risk of thrombosis may be further increased in highly proinflammatory states resulting from damage to endothelium and expression of TF on circulating monocytes and platelets. For this reason, rFVIIa should be used very cautiously in patients supported by extracorporeal membrane oxygenation[280] and avoided when there is evidence of widespread activation of coagulation (disseminated intravascular coagulation). The importance of this to patients soon after separation from bypass is unknown.

The dosing regimen for off-label use of rFVIIa is not yet firmly established. One of the difficulties is that there is no satisfactory laboratory test to monitor its effectiveness,[287,288] and factor VII activity does not always predict efficacy.[289] Although it is known that the PT, aPTT, and TEG improve after rFVIIa is given in liver surgery,[290] they cannot reliably be used to determine a dosing regimen. If the main effect of rFVIIa is at the site of injury, clinical observation still remains the best indication of effect.[287] The dose used often closely relates to the dose indicated in hemophilia patients (90 μg/kg), although in practice doses are often rounded to the nearest vial.[290] Although a lower dose of 40 to 60 μg/kg has been proposed,[280] a dose of 40 μg/kg has been shown to have

no effect.[276] Larger doses of 60 to 90 µg/kg may prove more effective. Differences in the pharmacokinetics may be a justification for use of larger does in children (clearance is 67 mL/kg per hour in children vs. 37 mL/kg per hour in adults).[291,292]

It would appear that rFVIIa can be effective for the treatment of severe bleeding refractory to other treatments, but it is not universally effective. A detailed review of the off-label use of rFVIIa concluded that evidence of efficacy across a wide range of indications was poor.[293] The risk of thromboembolic complications is substantial in those recovering from severe bleeding, and rFVIIa is likely to increase this risk.[294] There seems to be no reason to think that these considerations do not apply to children, although the balance of risk and benefit may be very different. It is the author's view that rFVIIa should be used only to treat life-threatening bleeding that has proved refractory to other treatments. Outside of properly conducted trials, it should not be used to prevent bleeding, for treatment of less severe bleeding, or as an alternative to blood products. Its use should not delay surgical reexploration if indicated. Every attempt should be made to ensure an adequate platelet count, adequate fibrinogen concentration, correction of acidosis, and near-normothermia before use.

New Drug Development

Much of the previous discussion has concerned use of drugs (and blood products) that have been available for many years. Development of medications for treatment of bleeding is largely driven by a desire to improve long-term treatment of congenital hemophilias.[295] In the past this has led to new therapies for acute bleeding and acquired coagulopathy, and this may be the case in the future. A novel area of research that may be more directly applicable to management of surgical bleeding is development of novel inhibitors of fibrinolysis.[296]

Summary

This chapter began with a review of the mechanism of coagulation and how this is altered during normal development and disease. This understanding of coagulation has led to the development of new treatments, most notably rFVIIa.[11] Complex systems such as the coagulation system behave in unanticipated ways and while mechanisms can be found to justify many interventions, not all interventions will result in a clinically useful improvement for the patient. The coagulation model becomes more complicated when the interactions between coagulation and other systems (noticeably the kinin-kallikrein system[16] and other proinflammatory cascades) are considered in addition to the effects of transfusion of allogeneic blood products. Mechanistic justifications for use of any treatment are therefore limited. Direct evidence that a specific treatment provides a benefit to the child is required. Although the evidence available is still lacking, and at times appear contradictory, I have aimed to give clear advice to the practicing anesthesiologist when possible.

The problems associated with conducting research on this subject are demonstrated by the aprotinin studies. Despite relatively large numbers of patients (including children) recruited into trials, many important questions remain incompletely resolved. Concerns over safety in adults led to the effective withdrawal of this drug. Reappraisal of this evidence (without further studies) has led to its reintroduction in many countries. Regardless of the pros and cons of using this drug in children, its use has been dictated by factors other than the interests of this population. For therapies aimed at treatment rather than prevention of bleeding, the challenges of conducting well-designed trials are even greater. Currently, several therapeutic approaches are proposed (rFVIIa, fibrinogen concentrates, transfusion protocols based on TEG) that differ from traditional treatment. The requirement for well-conducted trials, with meaningful outcome measures, remains greater than ever.

ACKNOWLEDGMENT

I thank Andrew Wolf and Adam Skinner for their prior contributions to this chapter.

Extensive and informative guidelines produced in the United Kingdom covering aspects of transfusion in the child, infant, and fetus. While written to reflect U.K. practice, the guidelines are informative for readers from other locations.

Rahe-Meyer N, Levy JH, Mazer CD, et al. Randomized evaluation of fibrinogen vs placebo in complex cardiovascular surgery (REPLACE): a double-blind phase III study of haemostatic therapy. *Br J Anaesth*. 2016;117:41-51.

The REPLACE trial is an important trial conducted in adult cardiac surgical patients. The findings cast doubt on the effectiveness of fibrinogen concentrates in the management of bleeding serving as a further warning that there is no "magic bullet" in the treatment of severe bleeding. Rather, there is a need for good surgical hemostasis and a methodical approach based on an understanding of the physiology and pathophysiology of coagulation.

The Future

THE NUMBER OF INFANTS and children who are hospitalized each year with cardiorespiratory collapse that requires artificial support is substantive. Despite maximal medical therapy, failure of the cardiac and/or respiratory systems to provide adequate end-organ perfusion and oxygenation often results in the need for mechanical support of the circulation, either as an adjunct to cardiopulmonary resuscitation (CPR) or as a bridge to recovery or transplantation. The number of pediatric patients requiring support has been increasing yearly, especially for those with primary cardiac dysfunction. Improved recognition, management, and surgical and perioperative survival of those with congenital heart disease (CHD) has significantly increased the number of children with impaired ventricular function.[1] In addition, with earlier recognition and more aggressive medical management, children with cardiomyopathies are surviving the initial phase of their illness. As a result, there are nearly 15,000 admissions for pediatric heart failure in the United States each year. These admissions carry a mortality of approximately 10%, although 10% to 15% result in the institution of mechanical circulatory support (MCS).[2,3]

The prevalence of heart failure in adults is greater than in the pediatric population, and the development of MCS for adults with end-stage heart failure has correspondingly grown and matured at a faster pace than in children. First-generation ventricular assist devices (VADs) came into routine use in adults in the 1980s.[4] The use of VADs in children began with the application of adult devices in adolescents. Expansion of their use in the children has proceeded more slowly as technologic challenges of effectively "miniaturizing" adult devices to accommodate pediatric weight ranges has resulted in fewer VAD options for children compared with the number and types of devices available for adults. Potential differences between the adult and pediatric patient population include physiologic and anatomic variations, a dissimilar immunologic response to blood transfusions, and a greater thromboembolic risk owing to an immature coagulation cascade.[5,6] Finally, regulatory constraints of device evaluation in a small and heterogeneous patient population[7] also make advances more challenging. Although the number and type of MCS devices available for children remains comparatively limited, particularly for children weighing less than 20 kg in the United States, the use of extracorporeal life support (ECLS) in this population has continued to grow. Initiatives by the National Heart, Lung, and Blood Institute (NHLBI) supporting the development of MCS devices for infants and children offer promising future alternatives.[8]

Mechanical support can be provided either in the form of extracorporeal membrane oxygenation (ECMO) for cardiopulmonary support or in the form of VADs to support cardiac function and maintain perfusion.

Indications for Mechanical Circulatory Support

It is important and often difficult to choose the appropriate time for initiation of MCS. As ECMO has become safer, it is generally agreed that MCS should be initiated early to avoid prolonged low cardiac output states and organ hypoperfusion. Early institution of support better preserves end-organ function and maximizes the opportunity for recovery or bridge to transplantation. Indications for MCS in children can be divided primarily into cardiac and noncardiac indications (Table 21.1). The following criteria for implementation of MCS have been used in one institution: (1) cardiac index less than 2 L/minute per square meter with inotropic dependence; (2) poor peripheral perfusion with metabolic acidosis and mixed venous oxygen saturation less than 40%; (3) signs of impending respiratory, renal, or hepatic failure; and (4) increased or rapidly increasing B-type natriuretic peptide (BNP) concentrations (Table 21.2).[9]

In general, with the exception of pulmonary hypertension and isolated respiratory failure, either ECMO or VAD can be used for all indications. Each device has pros and cons, with the optimal device depending on the acuity of the illness, patient comorbidities, potential for recovery, and anticipated duration of support.[10] Table 21.3 summarizes the numerous patient and device characteristics that must be considered when choosing a strategy for mechanical

TABLE 21.1 Indications for Mechanical Circulatory Support
Preoperative Stabilization
Severe cyanosis/hypercyanotic spells
Pulmonary hypertensive crises
Myocardial dysfunction/cardiac arrest
Malignant dysrhythmias
Sepsis
Postcardiotomy Patients
Heart failure Early: inability to wean from cardiopulmonary bypass
Late: prolonged low cardiac output syndrome
Procedure related Stage I palliation for hypoplastic left heart syndrome
After ALCAPA[a] repair
Persistent malignant dysrhythmias
Bridge to Myocardial Recovery
Acute myocarditis
Cardiomyopathy
Acute cardiac transplant rejection
Bridge to Transplantation
Direct bridge to transplantation
Bridge to bridge (short- to long-term support)
Noncardiac Indications
Respiratory failure of oxygenation and/or ventilation
Near-drowning
Severe hypothermia
Drug toxicity
Critical airway (tracheal stenosis)
Sepsis/shock
Extracorporeal Cardiopulmonary Resuscitation
Refractory Cardiopulmonary Arrest

[a]*ALCAPA*, anomalous origin of the left coronary artery from the pulmonary artery.

TABLE 21.2 Suggested Clinical Criteria for Mechanical Cardiac Support Implementation
Rapid Circulatory Deterioration (CI <2 L/minute per meter squared)
Inotropic dependence
High or rapidly increasing B-type natriuretic peptide
Critical Peripheral Perfusion
Development of metabolic acidosis
Mixed venous oxygen saturation <40%
Signs of Renal, Hepatic, and Respiratory Failure
Ventilatory support with increasing FIO_2

Critically Impaired Myocardial Function on Echocardiography.
CI, cardiac index; *FIO_2*, fraction of inspired oxygen.
Modified from Hetzer R, Potapov EV, Alexi-Meskishvili V, et al. Single-center experience with treatment of cardiogenic shock in children by pediatric ventricular assist devices. *J Thorac Cardiovasc Surg.* 2011;141(3):616–623; and Potapov EV, Stiller B, Hetzer R. support. In patients with cardiac failure, the primary goal is to allow the myocardium to rest and recover function (bridge to recovery). In the absence of myocardial recovery, heart transplantation is often considered. However, considering the paucity of available organs, the patient may be transitioned with long-term mechanical support while awaiting a suitable organ (bridge to transplant). Primarily in the adult patient population, a large patient subset exists who are not expected to have myocardial recovery nor are they considered transplant candidates. Use of MCS in this population is designated as destination therapy and is extremely rare in the pediatric population, with the possible exception of a small group of children with Duchenne muscular dystrophy who have undergone VAD placement.[6,11] It is expected that this population will continue to grow because of strong advocacy by these patients and their families. Other pediatric patients who may ultimately benefit from destination therapy include children with chemotherapy-induced cardiomyopathy with ongoing malignancy and unlikely long-term remission, and children with cardiac dysfunction accompanied by multiple comorbidities or impairment that might preclude transplantation.

A critical early decision point in the deployment of VAD support in children is determining whether left ventricular (LV) support alone will suffice. For a left ventricular assist device (LVAD) to provide satisfactory support, adequate right ventricular (RV) function is crucial to allow for adequate LV function and, ultimately, LVAD filling. Unlike heart failure in adults, pediatric heart failure is commonly associated with biventricular failure and/or elevated pulmonary vascular resistance (PVR), both of which may limit LV diastolic filling. Limited data suggest that biventricular VAD (BiVAD) support is more common in pediatric patients, with 29% requiring BiVAD support in a large single-center trial[12] and 35% in the Berlin Heart Investigational Device Exemption (IDE) trial.[13] This contrasts with 9% in a large analysis of the United Network for Organ Sharing (UNOS) data from adult MCS patients listed 1A for heart transplantation and 7% in data from the Interagency Registry for Mechanically Assisted Circulatory Support (INTERMACS).[14] BiVAD support has been associated with increased mortality in both adults and children, likely reflecting the severity of disease in patients requiring such intensive support.

Preoperative cardiopulmonary stabilization may be required in children with profound hypoxemia and/or cardiovascular collapse resulting from hypercyanotic spells, pulmonary hypertensive crises, obstructed total anomalous pulmonary venous return, occlusion of systemic-pulmonary shunts, or cardiogenic shock (see Table 21.1). Preoperative ECMO was used as a bridge to surgical repair or palliation in 26 children, with 62% surviving to discharge and no observed differences in outcome between single-ventricular and biventricular patients.[15] ECMO has also been successfully used to stabilize children with refractory dysrhythmias.[16–18] In a retrospective study, ECMO was used in nine infants with a variety of tachy- or bradydysrhythmias, with all nine surviving to discharge.[19] ECMO has also been used to stabilize children in the cardiac catheterization laboratory, both preemptively before high-risk interventional procedures and as a rescue technique for catheter-induced complications, persistent low cardiac output, or hypoxemia.[20,21]

Failure to wean from CPB after congenital heart surgery is the most common cardiac indication for mechanical support.[22,23] It is estimated that 2% to 5% of all children require ECMO after congenital heart surgery.[24] Postcardiotomy myocardial dysfunction can manifest as either early (inability to wean from CPB) or late

TABLE 21.3 Characteristics of Commonly Used Pediatric Support Devices

Device	Patient Size Restrictions	Duration of Support	Type of Support	Pump Type	Flow	Advantages	Disadvantages	FDA Approval
Short-Term Support Devices								
ECMO	None	<3 weeks	Cardiac/ Pulmonary	Continuous	Variable	• Central or peripheral cannulation • Extensive experience in all age groups • Rapid rescue capability • Can be placed at bedside • Less expensive • Easy decannulation	• Higher levels of anticoagulation needed • Increased neurologic complications • Increased bleeding/transfusions • No/limited patient mobility • Usually remain intubated • Need for trained personnel and continuous monitoring	Yes
BioMedicus BP-50 (Medtronic)	None	Days/ weeks	Univentricular or biventricular	Continuous centrifugal		• Simpler setup than ECMO • Requires less anticoagulation than ECMO • Better ventricular unloading than ECMO	• No respiratory support • No/limited patient mobility • Generally remain intubated • Direct cannulation of the heart via sternotomy	Yes (6 hours)
CentriMag (Thoratec)	None		Univentricular or biventricular	Continuous centrifugal				
PediMag (Thoratec)	<20 kg, BSA <1.3 m^2		Univentricular or biventricular	Continuous centrifugal	Up to 1.5 L/minute			
Jostra RotaFlow (Maquet)	None		Univentricular or biventricular	Continuous centrifugal	Up to 10 L/minute			
TandemHeart (CardiacAssist)	>40 kg, BSA >1.3 m^2	Days	Univentricular or biventricular	Continuous centrifugal	Up to 5 L/minute	• Percutaneous placement possible • Extubation possible	• Transseptal puncture necessary • Risk of thromboembolism • Risk of pump dislodgment	
Impella (AbioMed)	BSA >0.93 m^2	Days	Univentricular	Continuous axial	2.5–5 L/minute	• 3 pump sizes • Percutaneous placement possible • Improved unloading of ventricle • Extubation possible	• Pump migration may occur	
Long-Term Support Devices								
Berlin Heart Excor	>3 kg, BSA 0.2–1.3 m^2	Months-years	Univentricular or biventricular	Pneumatic, pulsatile	Varies with pump size	• Extubation, ambulation possible • Less anticoagulation than ECMO • Reduced anticoagulation requirements compared with older VADs • Discharge home possible	• Sternotomy required for implantation • Device exchange may be necessary	Yes for BTT
HeartWare HVAD	>15 kg or BSA >0.65 m^2	Years	Univentricular or biventricular	Continuous centrifugal	Up to 10 L/minute			Yes for BTT
HeartMate II	>30 kg, BSA >1.4 m^2	Years	Univentricular	Continuous axial	>2.5 L/minute			Yes for BTT and DT
SynCardia TAH	BSA >1.2 m^2 (50 mL) BSA >1.7 m^2 (70 mL)	Years	Biventricular	Pneumatic, pulsatile	Up to 9.5 L/minute			Yes for BTT

(sustained postoperative low cardiac output syndrome) failure with poor end-organ function, persistently increased plasma lactate concentrations, low mixed venous saturations (<40%), reduced cerebral saturation (>20% below baseline), and escalating inotropic support. It is essential to rule out the presence of residual surgical lesions, coronary insufficiency secondary to surgical manipulation, and mechanical problems (e.g., cardiac tamponade) before initiating MCS.[25] Again, it is crucial to reiterate that early initiation of mechanical support leads to better outcomes. In a study of 81 children, those who had ECMO initiated in the operating room (OR) had a survival rate of 64% compared with 29% in those who had initiation of ECMO in the intensive care unit (ICU).[26] Patients with single-ventricle physiology or cyanotic heart disease are more likely to require mechanical support after CPB. According to the 2015 Extracorporeal Life Support Organization (ELSO) registry,[27] hypoplastic left heart syndrome (HLHS) is the most frequent type of CHD requiring ECMO in neonates. Certain centers have advocated the routine use of MCS to optimize postoperative cardiac output following stage I Norwood procedures.[28] Both ECMO and LVADs have been used for postoperative ventricular support in infants with anomalous origin of the left coronary artery from the pulmonary artery trunk (ALPACA), either as a bridge to recovery or transplant.[29,30]

In children without CHD, viral myocarditis is the most common cause of acute heart failure and ECMO has been successfully used as a bridge to either subsequent VAD therapy or recovery in this population.[31] Other cardiac pathophysiologic processes, such as coronary ischemia, graft rejection after cardiac transplantation, or end-stage heart failure owing to chronic cardiomyopathies, dysrhythmias, or congenital heart defects, may also warrant the use of MCS. ECMO has been used for patients with early and late ventricular dysfunction after cardiac transplantation. In cardiac transplant recipients, 10% required venoarterial (VA) ECMO within the first 2 days of surgery.[32] ECMO is usually the initial modality of choice for support because of the speed of application, familiarity of use, and the ability to manage situations in which RV failure and/or high pulmonary artery vascular resistance are present.[33]

Patients with pulmonary hypertension of varying etiologies may be considered as candidates for ECMO support. Both perioperative patients with reversible pulmonary hypertension (for example, patients with total anomalous pulmonary venous drainage, whose increased PVR should improve after surgical intervention) and those experiencing pulmonary hypertensive crises may benefit from ECMO support. Patients with severe medically refractory pulmonary hypertension may also require VA-ECMO as a bridge to lung or heart-lung transplant. Novalung (Novalung GmbH, Hechingen, Germany) has recently developed a paracorporeal pumpless interventional lung assist device using a low-resistance hollow fiber oxygenator that has been used in patients with cardiogenic shock secondary to pulmonary hypertension. Cannulas are placed in the pulmonary artery and left atrium and the high pulmonary pressures drive the blood through the oxygenator, removing carbon dioxide and improving oxygenation, without the need for a mechanical pump. This allows pulmonary pressures to decrease, off-loading the failing right ventricle and thus facilitating recovery. Four infants and children, 23 days to 23 months of age, were bridged from ECMO to a pumpless paracorporeal lung assist device while awaiting lung transplantation for chronic lung disease and pulmonary hypertension. Three of the four were extubated while supported by the device. One was bridged to recovery, one to transplant, and two died supported by the device while awaiting transplant.[34] One potential advantage of the device is its small size; as it is much smaller than an ECMO circuit, it may allow for easier patient transport during device utilization.

Multiple noncardiac indications exist for the use of ECMO, most importantly respiratory failure. Data from the 2012 ELSO Registry Report show that nearly 50% of patients receiving ECMO have been neonates with respiratory failure.[23] In neonates, the most common indications for ECMO are congenital diaphragmatic hernia, meconium aspiration syndrome, and persistent pulmonary hypertension of the newborn, with an overall survival rate of more than 70%.[23,35] With the H1N1 influenza pandemic, the number of pediatric patients supported by ECMO for respiratory failure increased dramatically.[23,36–38] ECMO can also provide short-term respiratory support for tracheobronchial reconstruction in infants and children with critical airways when conventional mechanical ventilation is either not feasible or has not been successful.[39] Other noncardiac indications for MCS include hypothermia, drug toxicity, and near-drowning. Although septicemia was initially considered a contraindication to MCS, a review of 45 children who required ECMO for hemodynamic support because of septic shock found that almost half survived to discharge.[40] In fact, utilization of ECMO as a bridge to recovery in children with refractory acute respiratory distress syndrome (ARDS) or pneumonia has become widely accepted.[23] ECMO can provide a bridge to lung transplantation or retransplantation, and after transplantation it can be used in cases of severe primary graft dysfunction, although survival in these patient groups remains lower overall than for other indications.[41–43]

ECPR, or extracorporeal CPR, was suggested by the American Heart Association Pediatric Advanced Life Support (AHA PALS) 2010 guidelines for use during refractory CPR during in-hospital cardiac arrests resulting from potentially reversible causes.[44] The AHA 2015 evidence summary continues to support the use of ECPR in pediatric patients, showing improved survival compared with CPR alone. Outcomes after ECPR for children with underlying cardiac disease have been better than for children without underlying heart disease. AHA 2015 guidelines recommend that ECPR be used for children with an underlying cardiac diagnosis who suffer in-hospital cardiac arrests in centers with ECMO protocols.[45]

Contraindications

Contraindications to implementation of MCS should be considered on a case-by-case basis but may include advanced multisystem organ failure, active infection, significant neurologic damage or intracranial hemorrhage (ICH), and severe coagulopathy. Extreme prematurity, very low birth weight, certain chromosomal defects, and/or multiple congenital anomalies may also be considered contraindications.[46] Neonates with low birth weight, extreme prematurity, and pre-existing ICH pose a particular risk when considered for ECMO because of the risk of developing or worsening ICH. Most bleeds occur within the first 72 hours of birth so, in theory, the risk of hemorrhage or extension of existing hemorrhage may be less after 3 days of age. Most ECMO exclusion criteria include patients with grade 3 or 4 ICH, and many consider a birth weight of less than 1.6 kg as a reasonable contraindication to ECMO, as a regression analysis suggested that a minimum weight of 1.6 kg was necessary to achieve a 40% survival in noncardiac ECLS.[47]

For children who require MCS secondary to a cardiac etiology, due consideration should be given to the likelihood of myocardial recovery before instituting support; and if it is unlikely, whether the child is a suitable candidate for cardiac transplantation. While there are no true contraindications, there are some common anatomic

issues that should be considered before initiating MCS. These include the thickness of the ventricles, semilunar valve regurgitation, and presence of intracardiac shunts. Thick ventricles, such as in hypertrophic cardiomyopathy, can prevent proper filling of the device. In some patients with a large atrium, atrial cannulation may allow proper filling of the VAD. Significant aortic or pulmonary valve insufficiency will not permit adequate ventricular emptying. Instead, blood recirculates through the regurgitant valve, occasionally necessitating closure or repair of the valve at the time of VAD implantation.[48] Intracardiac defects will also need to be closed at the time of device placement to prevent embolization of thrombus, air, or right-to-left shunting.

The Devices

A variety of devices are available to provide mechanical support for the cardiopulmonary circulation in children. Devices are discussed sequentially based on the type and duration of support provided.

Extracorporeal Membrane Oxygenation

Whereas adults generally have isolated LV failure, children more often require cardiopulmonary support because of hypoxemia, pulmonary hypertension, or concurrent RV failure. For infants and children who require short-term or urgent cardiopulmonary support, ECMO remains the modality of choice. Initially reported for the treatment of cardiac failure in children in the 1970s, ECMO was subsequently used for mechanical support during interhospital transport.[49,50] Currently the most common cardiac indications for ECMO are failure to wean from CPB, emergent support after cardiac arrest with failure of conventional resuscitation, and early graft failure after cardiac transplantation. Since the ELSO registry began in 1989, ECMO has been the MCS modality with the most pediatric usage, with more than 7500 usages in neonates and children for cardiac indications and more than 26,000 usages in neonates for respiratory support.[23,51]

A typical ECMO circuit is composed of a pump (either a roller pump with a servoregulatory mechanism for controlling circuit flow or a centrifugal pump); a hollow fiber or membrane oxygenator; a heat exchanger; and cannulas (either venous, arterial or both) (Fig. 21.1). A modified ECMO circuit composed of a heparin-coated circuit, Bio-Medicus centrifugal pump (Medtronic, Minneapolis, MN), hollow fiber membrane oxygenator, flow probe, and hematocrit/oxygen saturation monitor, allowing the circuit to be set up and primed in 5 minutes for rapid resuscitation, has been described.[52] Most hospitals supporting such a service have readily available trained personnel to assist with implementing and

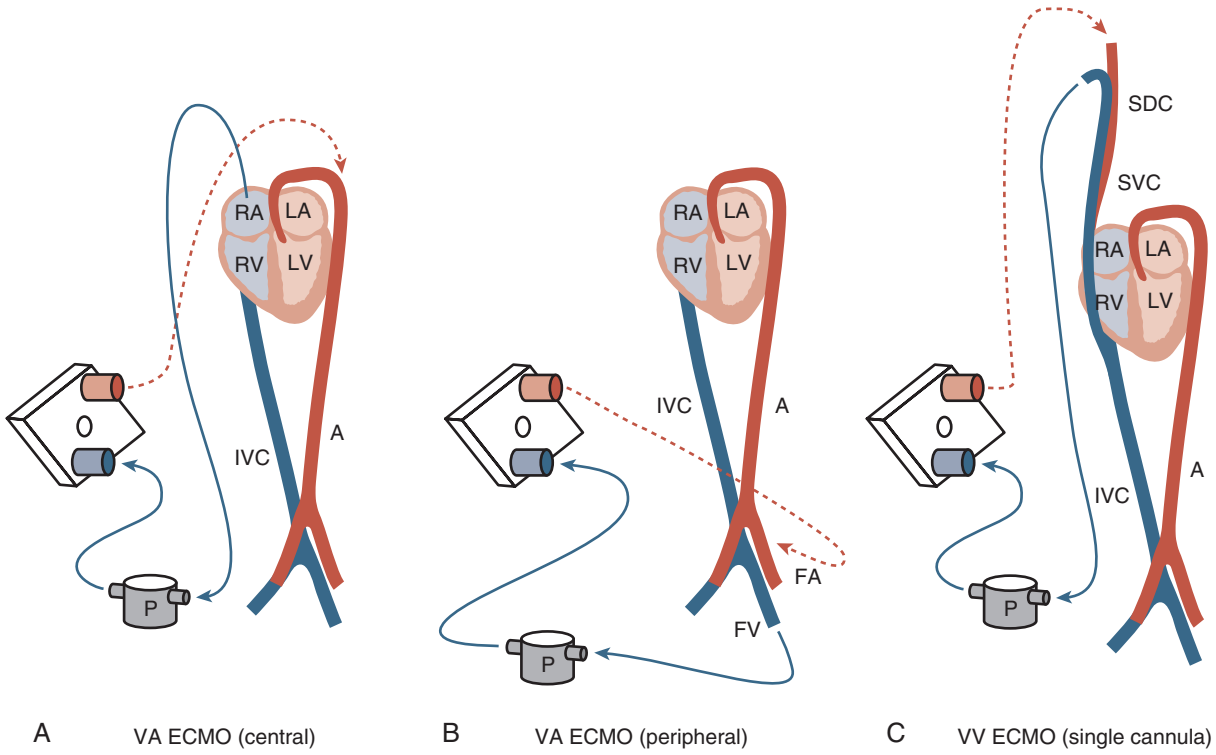

FIGURE 21.1 Schematic diagram of extracorporeal membrane oxygenation (ECMO) circuit configurations. *Dotted red arrow:* oxygenated blood. The *solid blue arrow* designates deoxygenated blood. **A,** venoarterial (*VA*) central ECMO. The dual venous cannula (right atrium *[RA]* and interior vena cava *[IVC]*) drain blood toward a pump *(P)* that pushes the blood through an oxygenator *(O)* with an integrated heat exchanger before returning via an aortic cannula placed in the ascending aorta *(A)*. **B,** VA peripheral ECMO. The venous drainage via a cannula in the femoral vein *(FV)* is pumped through the oxygenator and returned into the femoral artery *(FA)*. **C,** Veno-veno *(VV)* ECMO: single dual-chamber *(SDC)* venous cannulation strategy. One chamber has the distal orifice in the inferior vena cava *(IVC)* and the proximal orifice in the superior vena cava *(SVC)*. Together they drain blood into the pump/oxygenator; blood returns through an outflow exit orifice into the RA. *LA,* left atrium; *LV,* left ventricle; *RA,* right atrium; *RV,* right ventricle. Alternatively, this can be accomplished through cannulae in both femoral veins. (From Martinez G, Vuylsteke A. Extracorporeal membrane oxygenation in adults. *Continuing Education in Anaesthesia, Critical Care & Pain* 2012;12(2):57–61.)

maintaining ECMO therapy. Versatility and suitability for rapid implementation are advantages of ECMO; venoarterial cannulation in postcardiotomy patients may be either transthoracic via the right atrial appendage and aorta, transcervical via the right internal jugular vein and common carotid artery, or femoral via the femoral artery and vein in larger patients. Heparin-bonded circuitry is often used to minimize surface-induced complement activation, platelet dysfunction, and anticoagulation requirements.[53] A dry circuit can be kept ready for rapid deployment, with crystalloid prime used during initiation of support and addition of blood products (packed red blood cells [PRBCs] and fresh frozen plasma [FFP]) as soon as they become available. Alternatively, use of non–cross-matched blood (O negative) can be used, especially in neonates, until type-specific blood becomes available. During resuscitative efforts, before institution of mechanical support, multiple doses of vasoconstrictors should be avoided if possible, acidosis should be corrected, and the infant's head should be packed in ice to facilitate cerebral protection. Ultimately, the restoration of cardiac output, even with a low hematocrit, is the most important factor for successful resuscitation and long-term survival.[54,55]

Other advantages of ECMO include the ability to institute support in the ICU, provide ultrafiltration or hemodialysis for children during mechanical support, and provide biventricular cardiopulmonary support even in very small neonates.

ECMO CIRCUIT CONFIGURATIONS

Three common configurations exist for ECMO circuits (see Fig. 21.1). The most commonly used configuration, venoarterial ECMO (VA ECMO), is similar to cardiopulmonary bypass (CPB). A venous cannula is placed centrally via the superior or inferior vena cava and an arterial cannula is placed in either the aorta (open chest), femoral, or carotid artery. Blood is drained from the venous cannula, bypassing the heart and lungs, and replaced into the patient via the arterial cannula. VA ECMO can provide gas exchange and hemodynamic support without assistance from the native heart. VA ECMO decreases myocardial work and oxygen consumption and can be used to "rest" the native heart, especially in cases of myocarditis. If there is minimal ventricular ejection, care must be taken to avoid ventricular overdistention, which may necessitate placement of a left atrial vent.

Veno-veno ECMO (VV ECMO) can be accomplished either with a double-lumen catheter or two venous cannulas placed in large veins (femoral, internal jugular). Blood is drained from the patient, gas and/or heat exchange occurs, and the blood is returned to the patient's venous circulation. VV ECMO can provide gas and/or temperature exchange and is primarily used for primary respiratory failure in patients with preserved cardiac function, since VV ECMO requires adequate function of the native heart. Although VV cannulation is technically more difficult and may be associated with a greater frequency of flow issues and cannulation site bleeding, CNS injury is seen less frequently than with VA ECMO.[56]

In arterial-venous ECMO (AV ECMO), both arterial and venous cannulas are placed. The patient's own blood pressure and native heart function pump the blood through the ECMO circuit specifically for gas exchange.

Cannulation in infants and small children is generally performed either directly through the chest (especially postoperatively) or via the neck (carotid and jugular) vessels, as in small patients the ability to provide adequate flow is often unachievable through the femoral vessels. While they are supported by ECMO, patients generally remain continuously ventilated to allow for surfactant production and circulation and for mobilization and extrusion of secretions to avoid infection. "Lung rest" settings, with minimal inspiratory pressure and inspired oxygen and addition of positive end-expiratory pressure to prevent atelectasis, have been suggested.[35]

In a small series of 27 children who underwent VA ECMO for cardiac indications, both nonsurgical and postcardiotomy, the overall survival rate was 59%; of these, 56% required CPR at the time ECMO support was instituted. Of the latter group, 73% survived.[57] Hemodynamic benefits of ECMO include decreased RV preload and pulmonary artery pressures. Owing to reentry of blood into the aorta, an increase in afterload often occurs and may require pharmacologic afterload reduction therapy such as milrinone.

Several management options exist for children with single-ventricle physiology and shunt-dependent pulmonary circulation who require ECMO support. The survival rate of 10 children who underwent single-ventricle palliation and subsequently required ECMO support was greater in those in whom the aortopulmonary shunt was left open during ECMO.[58] Adequate alveolar ventilation must be provided, however, and greater ECMO flow rates are generally required to maintain adequate pulmonary and systemic circulations. In children with low PVR, pulmonary blood flow may prove to be excessive and limitation of shunt flow with surgical clips may become necessary. Although overall children with single-ventricle physiology have comparable survival rates after ECMO support compared with other cardiac patients,[57] in neonates who required ECMO after stage I palliation for HLHS survival to hospital discharge was only 36%, with reduced body weight, duration of support, and renal failure associated with greater mortality.[59] ECMO has been successful in treating children with single-ventricle physiology who develop acute shunt thrombosis or transient depression of ventricular function.[60] Of 44 children with single-ventricle physiology and shunts who required ECMO support, the indication for support was the strongest predictor of survival to discharge, with 81% of those cannulated for hypoxemia surviving, but only 29% of those cannulated for hypotension surviving to discharge.[61] Patients with Fontan physiology who require ECMO have a significantly greater mortality rate (65%), possibly the result of long-standing ventricular dysfunction that is not easily reversible.[62]

ECMO for primary respiratory failure in larger pediatric patients and young adults was heavily used during the H1N1 pandemic starting in 2009. The H1N1 influenza pandemic resulted in a significant number of pediatric patients with respiratory failure and ARDS that proved refractory to conventional and advanced modes of ventilation. According to the ELSO database, use of either VV ECMO or VA ECMO achieved a 60% survival rate in patients refractory to medical therapy.[23]

Disadvantages of ECMO include complex circuitry, the need for greater levels of systemic anticoagulation than required by VADs, the necessity for both blood prime and frequent transfusions, and decreased pulmonary blood flow. Compared with other support modalities, ECMO circuitry is complex and requires full-time supervision by trained personnel. Left atrial decompression may occasionally be inadequate, requiring either the placement of a left atrial vent or an atrial septostomy. Inadequate unloading of the left atrium can lead to mitral regurgitation and pulmonary edema or hemorrhage, and can also minimize the chances of myocardial recovery when the left ventricle is not sufficiently unloaded. Most often moderate levels of ventilatory support must be maintained to ensure that well-oxygenated blood is provided to the coronary arteries, requiring tracheal intubation and sedation throughout the

ECMO period.[63] However, there are recent case reports of awake or ambulatory ECMO (VV or VA) in children.[64]

Although it is effective for rapid rescue and short-term support, ECMO support is generally maintained only for 1 to 3 weeks before the risk of significant complications limits its usefulness.[65] In children who require postcardiotomy ECMO support, the need for prolonged support, renal failure, and low pH in the first 24 hours of support have been associated with a greater mortality.[66] A review of combined data between 2004 and 2009 from the ELSO registry and the Organ Procurement Transplant Network database showed that more than half the children bridged with ECMO to heart transplant failed to survive to hospital discharge, illustrating that ECMO is not able to reliably provide intermediate to long-term mechanical support to bridge children safely to transplantation.[67] Survivors of ECMO support also have greater risk of neurologic impairment than those supported with VADs, with poorer outcomes noted in younger children with more complex disease.[68]

Ventricular Assist Devices

VADs are used for cardiovascular support and are designed to reduce the work of the left ventricle, right ventricle, or both ventricles and to restore adequate cardiac output. They can be classified based on the duration of support, the mechanism by which they propel blood, and the indication for therapy (as discussed earlier). Commonly used devices in children are shown in Fig. 21.2. The length of support is generally divided into short-term use (typically <2 weeks) and long-term use (>2 weeks). Forward flow of blood can be achieved with a rotational device (e.g., centrifugal pumps), a pneumatic pusher plate (e.g. Berlin Heart [Berlin Heart GmbH, Berlin, Germany]), or axial flow (e.g., HeartMate II [Thoratec Corp., Pleasanton, CA]) (see Table 21.3).

Compared with ECMO circuits, VAD circuits have reduced priming volume owing to the lack of an oxygenator and shorter tubing and cause less trauma to blood cells. VAD circuits are composed of an inflow and outflow cannula, a pump (intracorporeal or extracorporeal), a power source with a driveline, and a system controller. Because they do not have an oxygenator and heat exchanger, they require reduced systemic anticoagulation compared with an ECMO circuit. For the LVAD, blood travels from the inflow cannula in the left atrium or the left ventricle, through the device, and into the aorta via the outflow cannula. For the right-sided VAD (RVAD), blood travels from the inflow cannula in the right atrium or the right ventricle, through the device, and into the pulmonary artery via the outflow cannula. In general, inflow cannulas in the ventricle achieve better unloading of the heart, thereby reducing wall stress and allowing for better ventricular recovery and a reduced incidence of thrombotic events.

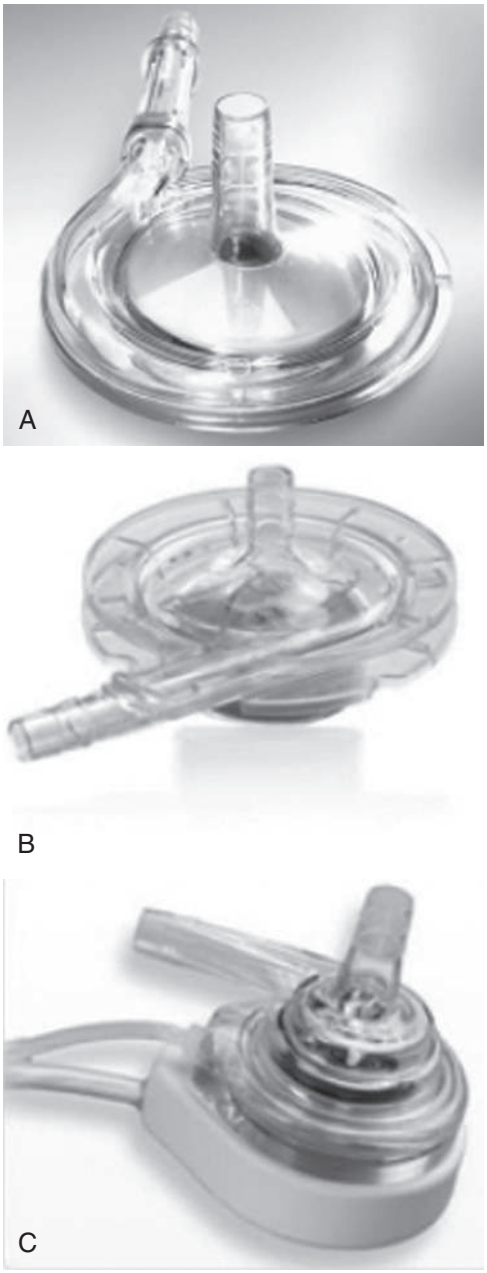

FIGURE 21.2 Ventricular assist devices. **A,** RotaFlow assist device. **B,** PediMag assist device. **C,** TandemHeart assist device. (Modified from Mascio CE. The use of ventricular assist device support in children: the state of the art. *Artif Organs.* 2015;39(1):14–20.)

SHORT-TERM DEVICES

Most commonly used short-term devices are centrifugal pumps providing continuous flow. They include the Bio-Medicus Biopump (Medtronic), CentriMag and PediMag (Thoratec), RotaFlow (Maquet Cardiovascular, Wayne, NJ), and TandemHeart (CardiacAssist, Pittsburgh, PA). The Impella (Abiomed, Danvers, MA) is a continuous-flow axial device. The term *centrifugal pump* is not always synonymous with VAD because a centrifugal pump may also be used with an oxygenator to construct an ECMO circuit. Centrifugal pumps offer the advantage of excellent ventricular unloading and decreased wall stress, optimizing the chances of myocardial remodeling and recovery. Unloading the left ventricle can also decrease LV size and improve septal configuration, resulting in improved tricuspid valve function and RV inflow.[69] Decreased trauma to red blood cells and a less pronounced systemic inflammatory response are also observed compared with roller pumps.[70] A centrifugal pump spins, creating a vortex, with negative pressure at the inlet drawing blood into the cone and positive pressure at the outlet allowing nonpulsatile ejection at the base. Cardiac output from a centrifugal pump depends on preload, afterload, and the rotational speed of the pump. A flow probe is necessary because increases or decreases in preload and afterload can affect pump flow without changes in rotational speed. Excessive negative inlet pressures (hypovolemia) must be avoided because air can be entrained into the circuit. The main limitation of centrifugal

pumps is the inability to provide long-term support related to issues with thrombosis, bleeding, and infection

The RotaFlow pump (see Fig. 21.2A) is an extracorporeal, centrifugal, continuous-flow device that has a rotating mechanism levitated in three magnetic fields with one point bearing, allowing laminar flow and reducing mechanical friction, heat production, and clotting potential compared with the Bio-Medicus pump.[71] It can be used in patients of all sizes, irrespective of body surface area (BSA), and can flow up to 10 L/minute. It has a small priming volume (32 mL), surface area, and passage time, minimizing hemodilution and blood trauma, and can be used along with a membrane oxygenator as an ECMO circuit. It is approved by the U.S. Food and Drug Administration (FDA) for up to 6 hours of use. However, one report described 2 months of support using the RotaFlow in an infant with a dilated cardiomyopathy.[72]

The PediMag (see Fig. 21.2B) is the pediatric version of the CentriMag. It is an extracorporeal, centrifugal, continuous-flow device for children who weigh less than 20 kg. The device has a bearingless, magnetically levitated technology with no points of contact. It has a priming volume of only 14 mL and can provide up to 1.5 L/minute of flow. The PediMag is approved by FDA for up to 6 hours of support and is also commonly used as part of an ECMO circuit.[73]

The TandemHeart is an extracorporeal, centrifugal, continuous-flow device with a priming volume of 10 mL and is capable of flows up to 5 L/minute, with a hydrodynamic fluid bearing supporting the spinning rotor (see Fig. 21.2C). Although size requirements (>40 kg) preclude its use in most children, it is advantageous because it can be placed percutaneously through the femoral vessels in either the OR or the cardiac catheterization laboratory, with a transseptal extended-flow cannula allowing entry from the femoral vein into the left atrium. The arterial cannula can be placed directly into the femoral artery in larger patients, and in patients who weigh less than 80 kg, a vascular graft to the femoral artery may be cannulated to avoid lower extremity vascular compromise.[74] It is FDA approved for up to 6 hours of support.

The Impella is a microaxial continuous-flow device contained in a single-pigtail catheter with three pump sizes: 2.5 L/minute (Impella 2.5 via 12F), 3.3 L/minute (Impella CP via 14F), and 5 L/minute (Impella 5.0 via 21F), respectively (Fig. 21.3). The smaller pump is designed for use in adults requiring partial LV support during high-risk cardiac catheterizations and ablation procedures.[74a] It can also provide full LV support in pediatric patients. The Impella is inserted retrograde through a femoral artery; with the device inlet zone resting in the LV cavity where blood is collected and propelled into the aorta, the deployment is performed under direct vision by fluoroscopy and transesophageal echocardiography (TEE). It has been placed into the ascending aorta in smaller patients via a sternotomy. Pediatric experience is limited to small case series, and the smallest patient reported to be supported was 10 years old, weighing 21 kg with a BSA of 0.93 m^2.[75]

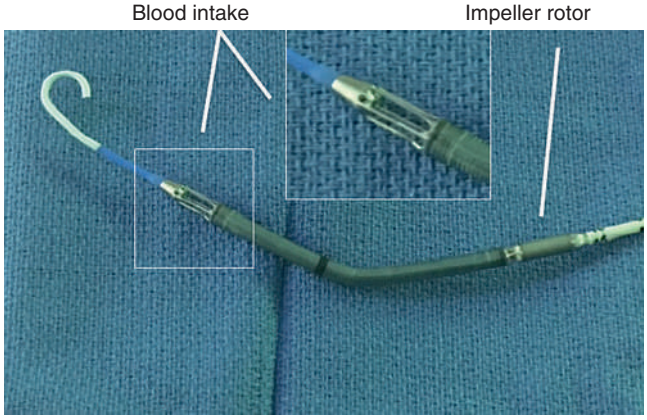

FIGURE 21.3 Impella microaxial continuous-flow device pigtail catheter. The pigtail end with the blood intake is inserted into the left ventricle. The impeller rotor is positioned in the aortic root/ascending aorta and is electromagnetically powered, generating suction and driving blood through the outflow into the aorta.

LONG-TERM DEVICES

Pulsatile Pumps

Pulsatile pumps are VADs facilitating long-term support of the circulation while also allowing tracheal extubation, enteral nutrition, and ambulation for the child. They are paracorporeal and either pneumatically or electromechanically driven. Like centrifugal pumps, pulsatile VADs enjoy several advantages over ECMO: they are simpler in design, less expensive, require lower levels of anticoagulation, and may be used for left, right, or biventricular support of the circulation. Unlike the previously discussed devices, pulsatile pumps are suitable for long-term MCS, but until the advent of the Berlin Heart Excor (BHE), their use in infants and children was severely limited by patient size constraints.

At the time this chapter was written, the BHE is the most popular pediatric long-term support device. First used in adults in 1987, the BHE is a pulsatile, paracorporeal pump currently manufactured in several different pump sizes (10, 15, 25, 30, 50, and 60 mL) (Fig. 21.4).[76] Smaller pumps are appropriate to support neonates and infants, while the 25- and 30-mL pumps will support children weighing up to 20 to 25 kg. The pediatric version was first used in 1992 and has since been successfully used in neonates and infants with a BSA as low as 0.2 m^2.[77,78] An investigational device exemption (IDE) trial was begun in the United States in 2007; before this, the BHE was used nearly 100 times in North America at 29 different institutions under compassionate use regulations. A review of 73 of these initial patients (weight 3–87.6 kg) revealed a 77% success rate in bridging to either transplant or recovery, with a median support time of 1.6 months. Younger age and the need for BiVAD support were risk factors for increased mortality.[79] The BHE received FDA approval in 2011.

The BHE consists of a pneumatically driven translucent polyurethane pump, trileaflet polyurethane inlet and outlet valves, and silicone inflow and outflow cannulas (see Fig. 21.5). The cannulas exit the skin to the paracorporeal location through the upper abdominal wall. One advantage to the external location is the ability to change the device if thrombus formation is identified.

All blood-contacting surfaces, including the polyurethane valves, are heparin-coated (Carmeda AB, Upplands Väsby, Sweden). A flexible diaphragm in three layers divides the pump chamber into an air chamber and a blood chamber (Fig. 21.6B), with the two diaphragm layers facing the air chamber serving as driving membranes and the third seamless blood membrane passively moved by the driving membranes.[80] In diastole, blood enters the pusher-plate polyurethane chamber through an inlet valve and negative pressure is generated to aid in pump filling. In systole, the blood-filled chamber is compressed from an air-filled chamber, creating pulsatile systolic flow ejected through the outlet valve into the aorta. Mechanical valves direct the flow, and there is no direct contact between the pumping mechanism and blood. The pump rate can be adjusted to between 30 and 150 beats/minute. The BHE has been successfully used to provide univentricular (left or right) or biventricular support, even in infants, and may be operated in a synchronous, asynchronous, or fill-to-empty mode. A rechargeable battery is available that can provide up to 5 hours of independent power supply for adult-sized pumps, but power requirements are greater for pediatric pump operation,

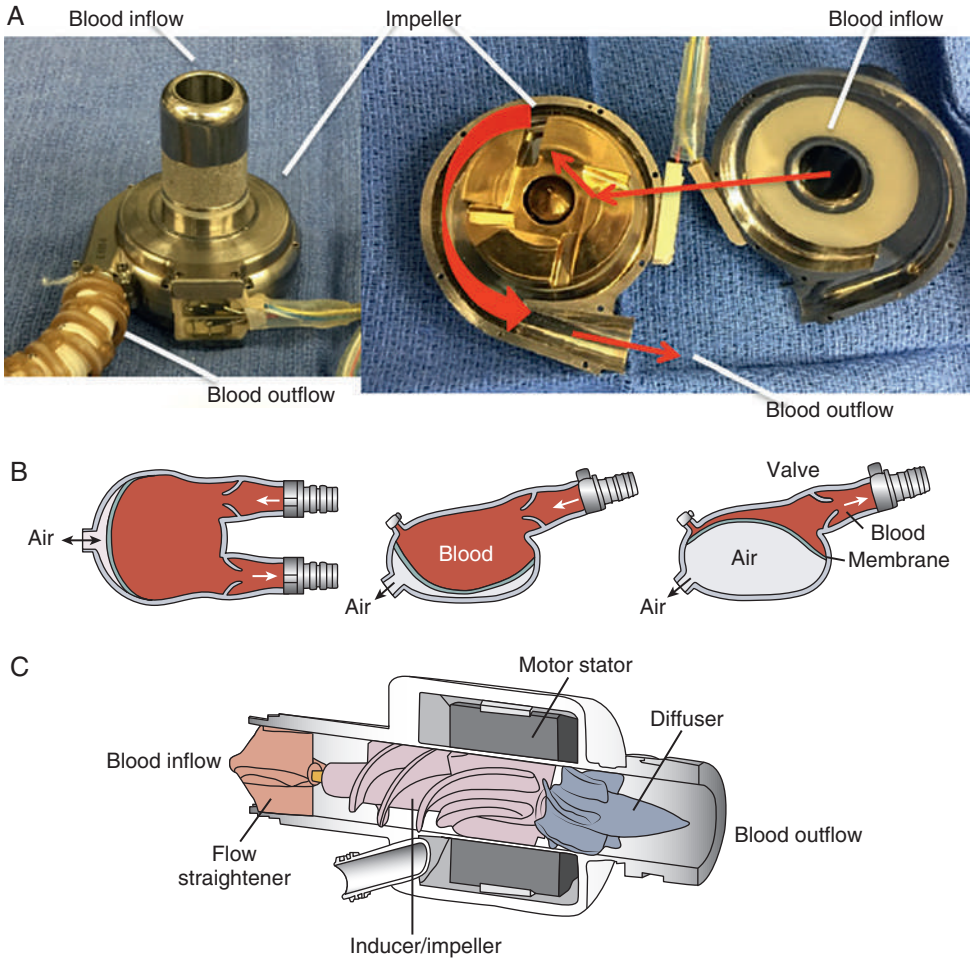

FIGURE 21.6 Illustration of ventricular assist device internal functionality. **A,** In the HeartWare device, the inflow cannula is placed in the ventricle while an internal electromagnetically driven impeller creates suction driving blood through the outflow into the aorta (blood pathway shown by *red arrows*). **B,** In the Berlin Heart Excor, a flexible diaphragm in three layers divides the pump chamber into an air chamber and a blood chamber. **C,** MicroMed DeBakey Child ventricular assist device (MicroMed Cardiovascular, Inc.; Houston, TX). (**A** and **B** from Hetzer R, Potapov E, Stiller B, et al, Improvement in survival after mechanical circulatory support with pneumatic pulsatile ventricular assist devices in pediatric patients. *Ann Thorac Surg*. 2006;82:917–925. **C** Images provided courtesy MicroMed Cardiovascular, Inc.)

owing to the greater flow resistance with small-diameter cannulas and greater pump rates.[81] A newer-generation pneumatic driver is under development that will permit discharge from the hospital for pediatric patients.[46]

Major benefits of BHE support include the ability to extubate the trachea, encourage enteral nutrition, and optimize patient mobility during long-term support. In addition, the transfusion of blood products during MCS is less in children supported with the BHE compared with those supported with ECMO. In a study comparing 30 children receiving BHE support with 34 children supported by ECMO, transfusion requirements for platelets, PRBCs, and FFP were significantly less in BHE patients. The overall mortality rate was also noted to be lower in BHE patients.[82] Anticoagulation is currently initiated with unfractionated heparin, maintaining the activated thromboplastin time (aPTT) at 60 to 80 seconds. Thromboelastography (TEG) is also used, along with platelet aggregation tests, to monitor the use of aspirin and dipyridamole. Antithrombin III (AT III) concentrations are closely monitored and substituted if the concentrations fall below 70%.[80] Low–molecular-weight heparin (LMWH), with monitoring of anti–factor Xa concentrations, has been used since 2007.[9] Pump exchange may be necessary if thrombus formation occurs in the valves, although one group reported no complications from this procedure during 15 years of adult and pediatric experience.[83]

Continuous-Flow Pumps

The increased risk of thromboembolic events with the BHE and the current absence of an option for hospital discharge prompted interest in the pediatric application of adult continuous-flow devices despite patient–device size mismatch. Continuous-flow pumps can be either axial or centrifugal, depending on the design of the impeller, and are designed to limit the interaction of moving parts. Like a centrifugal pump, axial pump function depends on the preload and afterload. Decreases in preload can cause emptying and collapse of the ventricle ("suction events"), whereas increases in afterload initially result in reductions in forward flow and ultimately can lead to regurgitant flow. Axial pumps offer several advantages over pulsatile pumps, including their small blood-to-device interface, the lack of a compliance chamber or artificial valves, and fewer moving parts. They are quieter than pulsatile pumps, which is a decided advantage for the child. Axial pumps can also allow some pulsatile flow to occur as the ventricle recovers, and cardiac output can increase in response to increased patient activity. The major disadvantages for children are the continuing size limitations for placement and the fact that the device provides only LV support.

The HeartMate II (Thoratec; Fig. 21.7) is an implantable, intracorporeal, axial flow device that is FDA approved for use as bridge-to-transplant and destination therapy and has been used in more than 10,000 adults[73]; it is an option for children with a BSA greater than 1.3 m^2. The device is placed in a pocket developed by dissecting the diaphragm away from the abdominal wall. It uses an electrical motor accelerating the blades of a rotating impeller to propel blood entering the device and has only one moving part and no unidirectional valves. The HeartMate II has a lower thromboembolic risk compared with other devices, and anticoagulation is managed using vitamin K antagonism and antiplatelet therapy (aspirin and dipyridamole). The portable system controller is also small enough to wear on a belt, allowing unencumbered movement for several hours, and even discharge home.[84,85] One group reported a bridge-to-transplant rate of more than 90% with use of the HeartMate II in their pediatric population.[86]

FIGURE 21.7 HeartMate II device. (From Adachi I, Burki S, Zafar F, et al. Pediatric ventricular assist devices. *J Thorac Dis.* 2015;7[12]:2194–2202.)

FIGURE 21.8 HeartWare Ventricular Assist System. (From Adachi I, Burki S, Zafar F, et al. Pediatric ventricular assist devices. *J Thorac Dis.* 2015;7[12]: 2194–2202.)

The HeartWare Ventricular Assist System (HVAD) (HeartWare Systems, Framingham, MA) is a continuous-flow device with a centrifugal pump directly attached to the inflow cannula (Fig. 21.8). It can provide up to 10 L/minute of flow. Although recommended for use in patients with a BSA greater than 1.5 m^2, it is clear from the literature that multiple groups are using these devices off-label in smaller children[87–89]; use has been reported in a toddler weighing 13 kg with a BSA of 0.65 m^2.[85] The HVAD is a small pump with a rotating impeller forcing blood through the device via hydrodynamic and centrifugal forces (see Fig. 21.6A) It can be placed either adjacent to the heart in the pericardial space or in a small pocket created above the left hemidiaphragm (Fig. 21.9, Video 21.1).[90] The HeartWare Left Ventricular Assist Device for the Treatment of Advanced Heart Failure (ADVANCE) trial[91] provided the data for FDA approval for bridge-to-transplant therapy, and it is anticipated that the HeartWare will be approved for destination therapy as well. In this trial, 140 patients receiving HeartWare were compared with a control group (n = 499) from the INTERMACS database, most of whom had received the HeartMate II device. Less bleeding and infection were observed

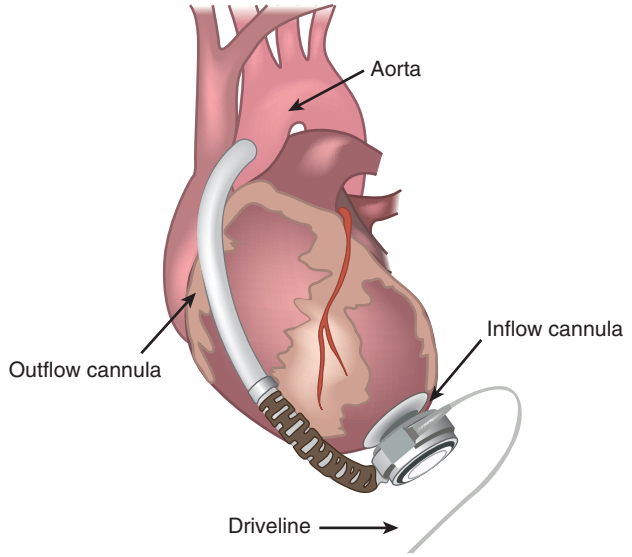

FIGURE 21.9 Illustration of a HeartWare ventricular assist device in situ. (Image provided courtesy HeartWare.)

in the HeartWare cohort with similar 180-day survival. Importantly, these children can be discharged home and often return to school and pursue normal daily activities.[85]

Total Artificial Heart

The SynCardia Total Artificial Heart (TAH) (SynCardia Systems, Tucson, AZ) is an implantable biventricular device capable of providing to 9.5 L/minute of pulsatile flow (Fig. 21.10). Currently each pump is 70 mL but a 50-mL version is in FDA trials. It is a pneumatically driven pulsatile device designed with two prosthetic polyurethane ventricles that provide biventricular support. Each ventricle has two mechanical valves providing inflow and outflow. The TAH has the largest inflow and shortest distance of blood traveled of all available VADs. The large valves and short blood path provide little resistance, thereby decreasing stasis and thrombosis.[92,93] The 50-mL version would allow application of the TAH in patients down to a BSA of 0.9 m^2 or in patients in whom virtual fit has determined that size is appropriate.[94] It is FDA approved for bridge to transplant and more than 1200 implants have occurred worldwide. Major advantages of the TAH include immediate elimination of concern regarding right heart failure, atrioventricular or aortic valve issues, dysrhythmias, LV clot, and intracardiac shunts.[46] Its use has also been described in patients with chronic graft dysfunction who are immunocompromised, as use of the TAH eliminates the need for immunosuppressive therapy.[95] A recent review of the SynCardia database showed that the TAH was used in 24 patients with CHD, or 2.2% of total implants.[96] Six of the 24 patients were adolescents (age 12–18 years) and this subgroup had 100% survival. For the entire CHD cohort, survival was 62%.

Perioperative Management of Mechanical Circulatory Support

Successful management of critically ill children receiving MCS requires multidisciplinary expertise. The Hospital for Sick Children, Toronto, Ontario, developed an Interprofessional VAD Support Team involved in clinical care, education, and family support for patients receiving Berlin Heart Excor MCS. In addition to physicians (cardiac surgeons, cardiac intensivists, heart failure and transplant cardiologists, hematologists, and psychiatrists) and nurses (cardiac and critical care), team members include pharmacists, respiratory therapists, dieticians, social workers, physiotherapists, biomedical engineers, and perfusionists.[97] Development of a team approach and use of interdisciplinary guidelines for care of these children can enhance communication, family support, and outcomes.[98]

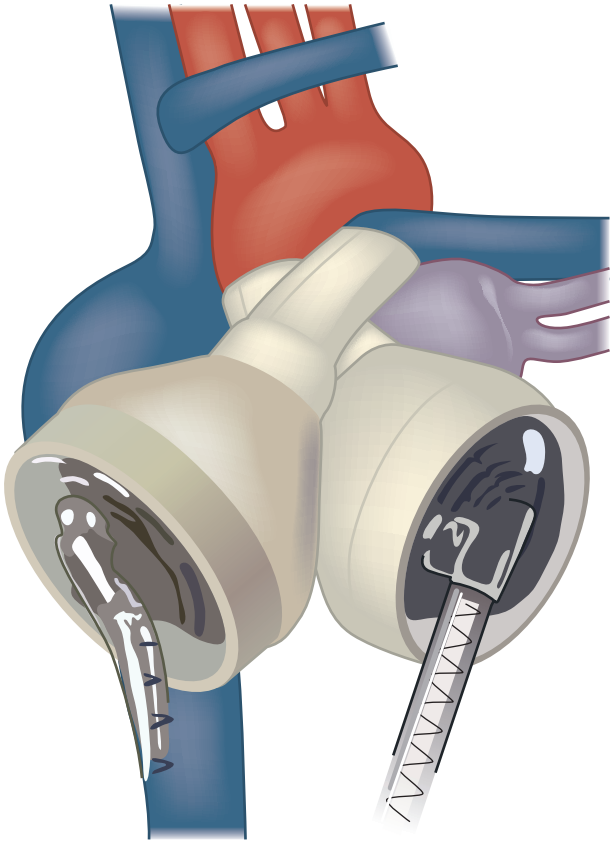

FIGURE 21.10 SynCardia Total Artificial Heart. (From Vanderpluym C, Fynn-Thompson F, Blume E. Ventricular assist devices in children: progress with an orphan device application. *Circulation* 2014;129:1530–1537.)

HEMODYNAMICS

During ECMO support, central venous pressure (CVP) should remain low to ensure adequate venous drainage. Left atrial pressure should be closely monitored using echocardiographic evaluation of atrial septal position. An increase in left atrial pressure may indicate incomplete unloading of the left atrium and ventricle, potentially requiring a blade and/or balloon atrial septostomy or surgical placement of a left atrial vent.[99] Anatomic issues, such as the presence of aortopulmonary collateral vessels, aortic insufficiency, or a patent ductus arteriosus, can also result in a persistently increased left atrial pressure.

Increased arterial pressures and systemic vascular resistance during ECMO can be due to large pump flows, but other causes, such as unrecognized seizure activity, inadequate pain or sedation management, and hypothermia, should also be considered. High systemic vascular resistance (SVR) during ECMO support can be

pharmacologically managed. In general, mean arterial pressures should be maintained at a level appropriate to the child's size and body weight.

Unlike ECMO support, LVAD support requires maintenance of effective RV output to provide adequate LV preload. RV failure, pulmonary hypertension, and arrhythmias can all limit LV filling and must, therefore, be aggressively treated.[100] Other potential causes of inadequate LV filling include cannula malposition or low intravascular volume. CVP can be used to evaluate volume status. Serial echocardiograms are useful to assess RV function and estimate RV and pulmonary artery pressures. Clinical signs of right-sided heart failure include increased central venous or right atrial pressures, hepatomegaly, peripheral edema, and decreasing hemoglobin-oxygen saturations. RV function can be augmented pharmacologically with drugs such as milrinone or isoproterenol. Increased pulmonary artery pressures are best initially treated by ensuring adequate alveolar ventilation, and subsequently by using inhaled nitric oxide if necessary. Mechanical issues, such as cardiac tamponade, can also negatively affect hemodynamics. These can be diagnosed at the bedside using echocardiography. Inadequate LV decompression can increase left atrial and pulmonary artery pressures and may be treated by augmenting LVAD flow; if necessary, biventricular or ECMO support can be initiated.[101]

Children supported by VADs often require vasodilators to maintain the low SVR necessary for optimal pump function. Frequently used vasodilators include milrinone, hydralazine, β-blockers, angiotensin-converting enzyme (ACE) inhibitors, and clonidine. Left atrial pressure is optimally maintained at 3 to 4 mm Hg, while allowing some ventricular ejection to avoid stasis. Systemic mixed venous hemoglobin-oxygen saturation, either continuously via in-line monitoring with a centrifugal VAD, or intermittently with a paracorporeal pulsatile VAD, is a useful metric to monitor the adequacy of cardiac output.

RESPIRATORY CONSIDERATIONS

Although ECMO can provide full cardiopulmonary support, tracheal intubation and mechanical ventilation help to avoid atelectasis and optimize oxygenation of blood returning to the left atrium that will provide coronary artery blood flow. Modest ventilator settings are generally recommended: (1) 6 to 8 mL/kg tidal volume, (2) 5 to 10 cm H_2O of positive end-expiratory pressure, (3) a rate of 10 to 12 breaths/minute, and (4) a fractional inspired oxygen value of 0.4 or less (to avoid oxygen toxicity). Recently "awake" VA ECMO has been reported in pediatric patients, including allowing the tracheas to be extubated during support.[102] Maintenance of adequate ventilation is particularly important in children with single-ventricle physiology with an open systemic-pulmonary shunt. Because of the complexity of the ECMO circuit, mechanical issues, such as oxygenator malfunction, must be considered when increasing hypoxemia occurs. After ruling out oxygenator failure, ECMO flow may be increased or the membrane size may be increased to improve systemic oxygenation.

Children supported by VADs receive only cardiac support. With centrifugal VAD support the trachea generally remains intubated and the lungs mechanically ventilated, while paracorporeal pulsatile VADs and implantable VADs, on the other hand, allow children to be weaned to extubation. Anatomic issues, such as an atrial septal defect, should be recognized as potential causes of hypoxemia from right-to-left shunting.[103] Children who receive LV support via either a centrifugal or pulsatile VAD may also require inhaled nitric oxide to decrease PVR and augment RV function.

HEMATOLOGIC CONSIDERATIONS

Anticoagulation management continues to be one of the most challenging clinical issues in caring for children who require MCS, in part owing to age-based differences in the coagulation cascade.[104] Patients with MCS are at substantive risk for hemorrhage and/or thromboembolic complications.[105] Ongoing hemorrhage around cannulation sites is a frequent issue, particularly with ECMO support. Of greater concern are gastrointestinal (GI), pulmonary, or, more devastatingly, ICH; infarctions or thromboembolic events may also occur. Serial ultrasonography of the head may be used to monitor for intracranial bleeding in infants and neonates, and, when possible, computed tomography may be used in older children.

Contact with the non-endothelial surfaces in an ECMO circuit can activate hemostatic agents, including platelets, factor XII, tissue factor, and von Willebrand factor (vWF). There is also a tendency toward fibrinolysis as well as release of proinflammatory cytokines. This leads to both a state of hypercoagulability and coagulopathy in ECMO patients. These effects are more pronounced in neonates and infants because of their lower blood volume relative to circuit size.[106] Destruction of platelets and coagulation factors and an increase in fibrinolysis can cause bleeding around cannula sites and, more detrimentally, in intracavitary spaces. Activation of tissue factor and the inflammatory system contribute to hypercoagulability, which can cause both internal and circuit thrombosis. It is the role of the ECMO team to balance this precarious state of coagulation.

Unfractionated heparin is the first-line drug for maintenance of anticoagulation during ECMO therapy. Heparin binds to ATIII, producing anticoagulation via inhibition of activated factors IXa, Xa, XIa, XIIa, and, to a lesser extent, IIA (thrombin). Infants tend to have reduced ATIII concentrations and can rapidly develop acquired ATIII deficiency during MCS, which is reflected by the need for increased supplementation of ATIII to provide adequate levels in this age group.[107,108] The anticoagulation effect of heparin is most commonly monitored with the activated clotting time (ACT), a real-time bedside test that measures whole blood clotting after exposing the blood to either kaolin or celite activators. Although ECMO protocols vary, ACTs are generally maintained between 180 and 220 seconds using heparin infused at 10 to 50 units/kg per hour. The use of heparin-bonded tubing can reduce the need for greater ACTs. There are numerous concerns regarding the reliability of ACT monitoring and its correlation with heparin concentration in pediatric patients on ECMO. Many factors, including hemodilution, temperature, reduction in coagulation factors, and platelet dysfunction, may alter ACT results. Some centers rely on alternative monitoring tests including aPTT, anti-Xa concentration assays, anti-Xa range, TEG, and rotational TEG.[109]

Hematocrit is generally maintained between 40% and 50%, although efforts are made to limit transfusions because most children are potential candidates for cardiac transplantation. When necessary, leukocyte-reduced, cytomegalovirus-negative, irradiated PRBCs are administered. Platelet counts greater than 100,000/mm^3 and fibrinogen concentrations greater than 100 mg/dL are maintained to minimize bleeding complications.[110] In the presence of continued bleeding, cryoprecipitate and/or FFP may be added to the circuit prime. TEG may assist in determining which blood products are appropriate. In cases of persistent hemorrhage refractory to blood component administration, recombinant activated factor VII significantly decreases bleeding and aids in normalizing

the TEG profile, although disastrous clotting of circuitry has also been reported with its use.[111–114] Hemolysis may be monitored by measuring of plasma-free hemoglobin, with increasing concentrations potentially representing the development of thrombus in the circuit. Antifibrinolytic agents have also been used in pediatric patients receiving ECMO therapy, albeit with limited available data. In one study of 298 patients, the frequency of thrombotic events or ICH was increased with the use of ε-aminocaproic acid.[115]

Without an oxygenator in the circuit, anticoagulation requirements are not as stringent for children on VADs, and ACTs may be maintained between 140 and 180 seconds. A percutaneously placed VAD, such as the TandemHeart, requires a target ACT greater than 180 seconds. Most long-term VADs, such as the BHE, are placed while the patient is supported by CPB and under full anticoagulation. Once weaned from bypass, the heparin is fully reversed with protamine. In the first 24 hours after VAD placement, there is a high incidence of reoperation to achieve hemostasis. After the immediate postoperative period, the risk of bleeding decreases while the risk of thrombosis increases. Unfractionated heparin infusions are used with a target aPTT of 1.5 times normal. The ATIII levels are also monitored and maintained in excess of 70% to avoid thrombotic complications. The use of argatroban (a small molecule direct thrombin inhibitor) has been described in children with heparin-induced thrombocytopenia type II.[116]

While a recent study examining trends in coagulation therapy in pediatric patients with assist devices revealed wide variability of in-hospital anticoagulation management,[117] currently most institutions follow the Edmonton antithrombotic protocol once the patient is discharged from the ICU. This protocol involves a three-drug regimen: aspirin, dipyridamole, and either warfarin (for patients ≥12 months of age) or enoxaparin (for patients <12 months of age). Enoxaparin is used more frequently in infants because warfarin is difficult to manage, as infants are more likely to use vitamin K–containing formulas and have significant changes in diet during their growth. There is also a lack of robust data on which to base the dose of warfarin in infants and no appropriate formulations (i.e., suspensions) are available. The use of LMWH requires the use of anti–factor Xa activity monitoring.[118,119] After normalizing the platelet count and function, aspirin and dipyridamole are started, using TEG and platelet aggregation tests to monitor clotting tendency, with a target activation of 30%. Once an appropriately aged child is tolerating enteral feedings, a transition to warfarin may commence. Although embolic and bleeding complications remain problematic, with this management strategy a marked increase in survival has been noted in children undergoing BHE support compared with earlier regimens.[120]

Although hemolysis and thrombosis may be less frequent with continuous-flow devices, acquired von Willebrand syndrome has been frequently described in adult patients, most likely secondary to the shear stress of the pump, with unfolding and cleavage of the high–molecular-weight multimers of vWF. This is also thought to account for the increased incidence of GI bleeding noted in these patients, though not all patients with documented acquired von Willebrand syndrome display increased bleeding tendencies.[121,122]

PREVENTION OF INFECTION

Infection is a constant concern, particularly in children requiring intermediate- to long-term ECMO and VAD support. Devices with larger surface area and areas of turbulent flow are associated with greater infection rates owing to increased adherence of blood-borne pathogens. As a result, smaller, fully implantable devices and devices with improved flow dynamics may decrease the incidence of infection.[123,124] Devices such as the BHE allow for removal of tracheal tubes, indwelling catheters, and intravenous lines; minimize the need for blood transfusions; and offer a reduced risk of device-related infections.[82,125] Deep wound complications of inflow and outflow cannulas have been successfully treated with vacuum-assisted wound closure systems.[126] The fact that children with the HeartMate II and HeartWare devices can be discharged home may also decrease the incidence of infection.

The use of MCS can result in immunologic dysfunction, further increasing infection risk.[127] Signs and symptoms of infection can be subtle, and a need for increasing inotropic support to maintain mean arterial pressure can often be a harbinger of infection. Endogenous reactions to infection can also result in activation of the coagulation cascade, increasing the difficulty of anticoagulation management.[128] Many children prophylactically receive antibiotics with gram-positive coverage, as well as oral nystatin for fungal prophylaxis.

ANESTHETIC CONSIDERATIONS

In preparing for the anesthetic care of infants and children, either when ECMO or VAD support is being used or when implementation of MCS is imminent, initial planning centers on two main areas of concern: the child's current status and the location of the proposed procedure (Table 21.4). The need for emergency surgery, the child's condition at the time of surgery, the presence of preoperative multiorgan failure, and the need for CPB with cross-clamping of the aorta have all been shown to increase perioperative risk.[129]

A comprehensive preoperative evaluation is essential, with knowledge of the underlying pathology necessitating MCS and the length of the child's illness, along with evaluation of other potential multiorgan dysfunction, including neurologic, hematologic, renal, hepatic, and pulmonary issues. Review of current drug therapy, particularly the duration and degree of current inotropic support, anticoagulation protocols, sedation regimens, cardiac function, intravascular volume status, and the presence and degree of preoperative hemorrhage, is also necessary. Physical examination should encompass the airway and both current vascular access and the availability of sites for potential vascular access. In infants, ultrasonography of the head is useful before considering institution of MCS, as significant intraventricular hemorrhage is a relative contraindication to MCS. Similarly, infants on ECMO, especially those younger than 35 weeks gestation, are at high risk for intraventricular hemorrhage and are often monitored by daily head ultrasound.[130]

Preoperative laboratory evaluation should include a complete blood cell count (CBC) with platelet count, electrolytes, blood urea nitrogen and creatinine concentrations, prothrombin time and partial thromboplastin time, and liver function tests. Concentrations of BNP, produced in the myocardium, serve as a marker of ventricular overloading and have been shown in adult and children with CHD to correlate with the degree of ventricular dysfunction.[131,132] Serial BNP concentrations in children supported with ECMO have also been used to predict clinical outcomes, with greater BNP concentrations noted after termination of ECMO support in nonsurvivors than in children who ultimately survived.[133]

Useful preoperative coagulation data includes recent TEG results, fibrinogen concentrations, and platelet function tests, if available. The most recent echocardiography data and chest radiograph should be reviewed. Blood products, including PRBCs, platelets, cryoprecipitate, and FFP, should be available at the bedside or in the OR, with provision for a continuing supply of

TABLE 21.4 Anesthetic Considerations

Preoperative Assessment	**Intraoperative Management**
History	*Availability of blood products*
Etiology and duration of cardiac failure	*Monitoring*
Review of system/end-organ dysfunction	Standard ASA monitors
Pulmonary	Electrocardiogram
Renal	Noninvasive blood pressure
Hepatic	End-tidal CO_2
Neurologic	Ttemperature
Medications	Peripheral oxygen saturation
Inotropic/vasoactive support	Assess need for invasive arterial or central venous monitoring
Angiotensin-converting enzyme inhibitors	Urine output
Antiarrhythmic therapy	
Anticoagulation protocols	*Transesophageal echocardiography*
Analgesic/sedative drugs	Presence of septal defects
Antibiotics	Aortic insufficiency
Planned surgical procedure	Mitral stenosis
Timing of procedure: elective/urgent/emergent	Cardiac de-airing
	Ventricular function
Laboratory	
Hematology	*Management principles*
Complete blood cell count	Maintain adequate intravascular volume/preload for ventricular assist device
Platelet count	Avoid abrupt decreases in preload
Serum chemistries	Support right ventricular function, reduce pulmonary vascular resistance
Electrolytes	Nitric oxide availability
Liver function studies	Maintain adequate ventilation
Blood urea nitrogen, creatinine	Inotropic support: milrinone, prostaglandin E_1
B-type naturietic peptide concentration	Hypotension can be treated with volume or α-adrenergic agonists

Airway	
Vascular access, both existing and available	
Neurologic status	
Evidence of ongoing hemorrhage	
Assessment of intravascular volume status	

products as needed. PRBCs should preferably be cytomegalovirus-negative, leukocyte-reduced, and irradiated, because all of these children should be considered potential transplant candidates (note that the potassium concentration of irradiated PRBCs may be greatly increased, resulting in acute hyperkalemia if administered rapidly). Appropriate antibiotic prophylaxis should be discussed with the surgeon.

Standard American Society of Anesthesiologists monitoring should be used before induction of anesthesia. Depending on the child's condition and the type of surgery planned, the use of arterial and central venous lines should be considered. In children who have been in the ICU for a prolonged time or those undergoing current resuscitation, securing additional vascular access lines can be quite challenging and may occasionally require surgical assistance. For children already supported by mechanical support device, it is important to know that VAD ejection is usually asynchronous with the child's underlying heart rate, yielding a discrepancy between the observed electrocardiographic and the arterial line waveform. Multiple peripheral intravenous lines are useful for the administration of volume and blood products. If RVAD support is being used, special care must be taken not to entrain air if the great veins are accessed.

For patients undergoing VAD placement, etomidate is generally an advantageous drug for induction of anesthesia because it does not depress myocardial contractility at clinically relevant concentrations, even in children with severely compromised ventricular function.[134] Judicious doses of opioids and benzodiazepines may be used. The choice of a neuromuscular blocking agent is usually based on the presence of hepatic or renal dysfunction. Adequate depth of anesthesia should be ensured before tracheal intubation to avoid abrupt increases in PVR, particularly in children with marginal RV function. In children undergoing device placement, induction drugs should be given incrementally as the onset time may be abnormally slow owing to depressed ventricular function. Children may be less responsive to β-adrenergic agonists owing to depletion of myocardial catecholamines.[135] Hypotension on induction of anesthesia and decreased responsiveness to catecholamines may also be observed in children receiving long-term ACE inhibitors for

afterload reduction preoperatively.[136–138] Opioids, benzodiazepines, and neuromuscular blocking agents are generally used to maintain anesthesia before ECMO cannulation or initiation of CPB for VAD implementation, with the express goal of maintaining adequate cardiac output and resultant systemic perfusion to end organs. Serial serum lactate concentrations, mixed venous hemoglobin-oxygen saturations, and the presence or absence of metabolic acidosis are useful indexes to evaluate the adequacy of cardiac output.

Unless contraindicated, a TEE probe should be placed after the induction of anesthesia for use throughout the procedure. Initial TEE examination is important for determining the presence of any intracardiac shunts that would require closing before initiation of MCS. Aortic valve competence should also be evaluated, because greater than trivial insufficiency can recirculate blood through an LVAD. The mitral valve should also be examined for significant stenosis that could limit LV inflow. After device placement, TEE ensures that adequate cardiac de-airing has occurred, evaluates ventricular function, monitors the orientation of intracardiac cannulas, and evaluates whether the left atrium and ventricle have been decompressed after pump activation.

For children undergoing LVAD placement, as the venous line from the CPB circuit is occluded, the pump speed is gradually increased. If LVAD flow (and rate when fill-to-empty mode is used) is less than desired, the major areas of concern center on hypovolemia or poor RV function. The RV should be monitored closely for signs of dysfunction or failure. In children with preexisting RV dysfunction, pulmonary vasodilatory agents, such as milrinone, prostaglandin E_1, or nitric oxide, should be aggressively used to optimize right-sided heart function. Children with low pressures and signs of vasodilatory shock may require infusions of vasopressin, epinephrine, or norepinephrine to support the circulation. In addition, adequate volume loading and VAD output should be ensured.

Tracheal extubation is not generally an option for those undergoing ECMO or centrifugal VAD support, but children receiving pulsatile VADs or axial pumps may be considered candidates for extubation. Timing of the extubation depends on the child's preoperative condition, degree of preexisting pulmonary dysfunction, duration of the surgical procedure, extent of postoperative bleeding, and maintenance of appropriate hemodynamic parameters.

Poorly predictable drug pharmacokinetics is another important consideration in patients undergoing VAD or ECMO placement. These patients often have altered hepatorenal perfusion and function, drug interactions, reduced protein binding, and may additionally be receiving renal replacement therapy. ECMO in particular complicates drug pharmacokinetics related to the volume of the circuit, the polymer components, and altered perfusion and drug eliminations. At the time of commencing ECMO, the volume of fluid within the membrane oxygenator and tubing increases the circulating blood volume by 200 to 300 mL depending on the circuit. This has little effect on drugs with large volumes of distribution, such as fentanyl, which show little change in plasma concentration. However, drugs with smaller volumes of distribution, such as nondepolarizing neuromuscular blocking agents and the antibiotics gentamycin and vancomycin, have larger changes in plasma concentration and may therefore have a prolonged elimination half-life. Hemodilution with ECMO may also be associated with reduced concentrations of plasma proteins, which in turn would increase the free fraction of highly protein-bound drugs. Significant drug absorption can occur on the large surface area of the tubing or the membrane oxygenator of the circuit, further increasing the volume of distribution of drugs. The opposite may occur when a drug is discontinued; it is then released back into the circulation, adding further unpredictability to its disposition and potential prolongation of its effect.[139] The degree of this sequestration depends on both the materials used in the circuit and the nature of the drugs. In general, drugs that are lipophilic, such as opioids, propofol, and benzodiazepines, are more likely to adhere to the tubing. Drug clearance may improve in children supported by ECMO, coincident with better organ function as oxygenated blood flow to those organs improves.[140] Multiple factors in this patient population make accurate prediction of drug doses extremely challenging and understanding of the issues involved is essential.

Anesthesia for the VAD Patient for Noncardiac Surgery

With the steadily increasing use of VAD support in infants and children, a growing demand for anesthesia for noncardiac surgeries during the period of support has occurred. While these patients should generally be cared for in centers with personnel and resources accustomed to caring for children with VADs, the increasing number of children discharged to home while receiving MCS raises the possibility that these patients require emergent care at other institutions. As these patients require significant care coordination, it is prudent to conduct a preoperative discussion with all perioperative team members to discuss the specifics and concerns related to caring for a patient with a VAD. The patient's baseline VAD flow parameters should be identified to readily identify any deviations from the new physiologic "normal." When possible, assistance from the perfusion or VAD management team should be sought. Temporary conversion from warfarin or LMWH to an unfractionated heparin infusion should be discussed with the team caring for the patient, including the hematologist, prior to surgery, and appropriate blood products should be ordered. As previously discussed, VADs depend on adequate preload for filling and an afterload that is not excessive so as to impede forward flow. For children with VAD support, appropriate pump function continues independently of the induction drugs used, provided adequate preload is maintained and no acute changes occur in SVR. When preload may be inadequate, it may be prudent to administer blood or fluids before induction of anesthesia. In a series of children with in situ BHE support undergoing noncardiac surgeries, anesthesia induced with ketamine was less likely to induce hypotension that required treatment with a fluid bolus or α-adrenergic agonists.[141] As continuing function of an LVAD relies on adequate right heart function, measures to maintain or increase right heart output may be required. Care should be taken to avoid increases in PVR, as RV failure is the likeliest cause of decompensation in such patients. Nitric oxide and appropriate vasoactive drugs should be readily available for use. When possible, the use of spontaneous ventilation is thought to enhance venous return and hemodynamic stability.[74,142] Before induction of anesthesia, defibrillation pads should be applied as rhythms other than sinus may reduce VAD inflow. The VAD should be connected to wall power whenever possible.

Noninvasive blood pressure monitoring can be challenging in patients with VADs, particularly in those with continuous-flow devices. Blood pressure may be difficult to measure noninvasively. Sampling errors and the ability to obtain reliable cuff pressures should be established before induction. Placing an arterial line is often warranted to continuously measure mean arterial blood pressure. Intraoperative use of transthoracic or transesophageal echocardiography may be helpful to continuously assess volume status, monitor inflow cannula patency, and to help diagnose any

disruptions in VAD output. The use of minimal insufflation pressures should be discussed with the surgical team in cases involving laparoscopic surgery as excessive pressures can adversely affect VAD filling conditions. Additionally, extreme positioning maneuvers such as steep reverse Trendelenburg may affect VAD preload, resulting in hemodynamic changes. Whenever possible, consultation with an anesthesia provider experienced in caring for these patients should be sought.

Outcomes and Complications

OUTCOMES

Regardless of the type of MCS chosen, it has become increasingly apparent that the indication for and timing of initiation of support are major factors in determining outcome. Although the majority of pediatric patients with cardiac disease have structural CHD, only 20% of children undergoing VAD implantation have structural disease.[143] Universally, survival has been greater in children who required support secondary to acute myocarditis or dilated cardiomyopathy compared with children who received support because of congenital heart defects or postcardiotomy failure.[144–146] Patients presenting with long-standing cardiomyopathy who require VAD support as a result of gradual or acute decompensation represent a much different cohort than those who have CHD and require salvage VAD support postoperatively. The latter group has a significantly greater mortality rate, particularly if they also require ECMO to bridge them to VAD support.

When feasible, VAD support offers several major advantages over ECMO. First, the lack of an oxygenator simplifies the circuit, lessening anticoagulation requirements and trauma to blood elements. Second, ECMO-supported patients suffer greater rates of neurologic deficits than those supported with VADs, particularly in younger children with more complex heart disease,[68] although the frequency of neurologic complications with VV ECMO is less than with VA ECMO.[147,148] Additionally, evidence suggests that VAD support provides superior ventricular decompression and physiologic rest, promoting myocardial recovery in children with acute myocarditis or dilated cardiomyopathy by normalizing the ventricular geometry and reverse remodeling.[149–151] Children with chronic heart failure who are waiting for transplantation and who experience progressive multiorgan dysfunction benefit from the use of pulsatile VADs with recovery of pulmonary, renal, and hepatic function.[152]

In some children, transition to VAD support may follow initial ECMO support.[79,145] Patients supported with ECMO may require transition to a VAD if they do not achieve adequate myocardial recovery and cannot be weaned from ECMO. Most often these patients are supported with ECMO after congenital heart surgery or cardiopulmonary support. Rarely, children previously listed for transplantation deteriorate rapidly requiring emergent institution of MCS and thus are initially supported by ECMO. In evaluating VAD usage and outcomes, one review reported that 21% of 187 children with VADs had prior ECMO support.[145] Regardless of diagnosis, the use of ECMO to bridge patients to VAD is associated with significantly decreased survival; children in whom ECMO was initiated for cardiac failure after cardiac surgery and who required VAD support for continued cardiac dysfunction had particularly poor survival rates.

A review of 55 pediatric patients revealed significantly increased survival rates in children who received BHE support compared with those who received ECMO, despite a mean duration of support that was nearly three times as great in the BHE group.[153] The first multiinstitutional study reviewing the outcomes of 99 children bridged to cardiac transplantation with MCS compared them with 2276 children listed for transplantation during the same era (1993–2003) who did not require MCS. Significant findings included a lack of difference in survival rates between VAD-supported and non–VAD-supported children, along with similar survival rates for children who required BiVAD support versus LVAD support. An increasing trend in the number of children undergoing transplantation who required pretransplantation VAD support was also observed, with an increase in the use of long-term MCS devices in the most recent era. Children with long-term devices were more likely to survive to transplantation than those with short-term devices. Ten children were "double bridged" from ECMO to VAD support before transplantation, with nine then undergoing successful transplantation. Not surprisingly, smaller, younger patients and those with CHD had poorer outcomes.[154]

Single-center reports of the use of BHE in children in the United States increased in the early 2000s, with markedly improved transplant wait-list survival.[79,153] This resulted in the NHLBI-sponsored randomized, controlled trial of the BHE VAD in 2006, with results published in 2012.[13] This study, notable for being the first controlled trial of a VAD in children, led the FDA to issue IDE approval for the Berlin Heart Excor. Using strict inclusion criteria, 48 patients were enrolled, 24 with BSA less than 0.7 m^2 and 24 with BSA 0.7 to 1.5 m^2. The prospectively enrolled patients were compared with a historical control group of patients who received ECMO support. Survival to transplantation occurred in a substantially greater proportion of patients supported with the BHE VAD compared with patients receiving ECMO, while the time receiving support without catastrophic neurologic events was significantly greater in the BHE VAD group.

Outcomes of all children with an implanted BHE VAD between May 2007 and December 2010 (n = 204) showed a 12-month survival of 75%, including 6% who underwent device explantation after recovery and 5% who continued with the device in place at the end of the study.[155] In multivariate analysis, smaller patient size, renal impairment, greater total bilirubin, and the use of biventricular support were associated with a greater mortality rate. Patients weighing less than 5 kg experienced particularly high mortality (64%). The incidence of stroke, 29%, was identical to the incidence in the IDE study and notable as the largest cause of death.

In a multicenter analysis of the BHE in children weighing less than 10 kg, major risk factors for mortality during support included a diagnosis of CHD and increased bilirubin, likely reflecting more severe right heart failure.[156] Outcomes were especially poor in infants with CHD, in whom mortality exceeded 90%. ECMO was identified as a univariate predictor of mortality in patients weighing less than 10 kg. No children who weighed less than 5 kg with CHD supported by ECMO survived after transplant. The challenges involved in improving survival in the smallest patients with CHD are especially daunting because of their complex physiology and hemodynamics, immature coagulation systems, infection risk, and previous surgical correction. Pump size in relation to BSA has been shown to have a major impact on the rate of thromboembolic events. Children supported with large pumps (>50 mL/m^2) had significantly more thromboembolic events compared with those supported with small- or normal-for-BSA–sized pumps.[157] This was initially observed when adult VADs were implanted in older children who subsequently developed complications such as arterial hypertension and cerebral vascular

accidents,[158] possibly owing to pumping large stroke volumes into anatomically small aortas.[159] In 2013 a new 15-mL BHE designed especially for children with a BSA of 0.3 to 0.5 m^2 was introduced. This 15-mL pump has the potential to substantially reduce the risk of thromboembolic events in the subset of pediatric patients for whom the 10-mL device was too small and the 25-mL device was too large.[157]

INTERMACS, an NHLBI-sponsored registry for FDA-approved durable MCS devices in the United States, began data entry on adult and pediatric durable device implants in June 2006. As part of this project, a dedicated pediatric component was developed to collect data on MCS devices and outcomes in the pediatric population. This database, the Pediatric Interagency Registry for Mechanical Circulatory Support (PediMACS) national registry, began registering patients on September 19, 2012. Through April 2015, 36 institutions had enrolled 251 devices in 216 patients receiving temporary or long-term MCS devices. This registry focuses on capturing data elements unique to pediatric patients, evaluating special issues in pediatric MCS, chronicling the variety of devices applied in the pediatric population, and identifying the particular cohort in whom therapy is most effective. Goals of this registry are to delineate the best support strategies for VAD therapies, refine patient selection of VAD therapies, develop "best practices" by analyzing outcomes, and facilitate and guide the development and clinical evaluation of pediatric devices. Between September 19, 2012, and December 31, 2014, nearly 50% of implants in children younger than 5 years of age were pulsatile LVADs. Fifty-six percent of implants in children 6 to 10 years of age and nearly 90% of those 11 to 18 years of age were continuous-flow LVADs. Among patients with continuous-flow devices, the overall actuarial 6-month survival has approached 90%, with 66% of children undergoing transplantation by 12 months.[160]

The Effect of MCS on Wait-List Survival

Of all patients wait-listed for organ transplantation in the United States, children listed for heart transplantation face one of the largest mortality rates on a waiting list, regardless of age.[161] Every year, approximately 500 additional pediatric candidates are added to the transplant waiting list, with approximately 17% dying each year while awaiting a donor heart.[162] The impact of MCS on cardiac transplantation is evident when considering the evolution of the proportion of patients supported by MCS devices at transplant. In 2000, fewer than 5% of patients were supported by durable devices at transplant, but by 2013 the frequency had increased to greater than 20%.[163] For critically ill children, the presence of a pediatric VAD program decreases the wait-list mortality by as much as 50%, despite the increased waiting time.[164] Importantly, the increased proportion of pediatric patients supported by MCS devices at the time of transplant has not adversely affected posttransplant survival.[165] Not only has the wait-list mortality decreased, many patients are actually stabilizing and rehabilitating, making the posttransplant period easier.

The UNOS database from 1999 to 2012 identified 5532 pediatric candidates (age ≤18 years) actively listed for pediatric heart transplant; 2191 were listed between 1999 and 2004 (Era 1) and 3341 were listed between 2005 and 2012 (Era 2). Wait-list mortality rates were less in Era 2 (8%) versus Era 1 (16%). VAD therapy was used more frequently in Era 2 (16%) than in Era 1 (6%) and was associated with improved wait-list survival (P <.001). Independent predictors of wait-list mortality included weight less than 10 kg, congenital heart diagnosis, ECMO, mechanical ventilation, and renal dysfunction. Independent predictors of survival on the wait-list included VAD therapy, cardiomyopathy diagnosis, blood type A, and being listed in Era B. Despite an increase in the number of children listed as status 1A, wait-list mortality decreased more than 50% during Era B. Irrespective of other factors, those supported with a VAD were four times more likely to survive to transplant.[164]

The first multi-institution study to evaluate outcomes of VAD support in pediatric patients revealed that 77% of children bridged to transplant survived.[166] Risk factors for mortality in the VAD cohort in this study included earlier era and CHD. There was no difference in 5-year survival after transplantation for patients with VADs at the time of transplant compared with those not requiring VAD support.[154] In addition, a study that evaluated posttransplant outcomes after VAD support in children using the UNOS database found that posttransplant survival was improved in VAD patients compared with patients supported with ECMO or those without mechanical support. VAD support is likely superior to ECMO for several reasons: increased need for sedation and mechanical ventilation with ECMO, the need for greater levels of anticoagulation, the persistent inflammatory response, and the possibly deleterious effects of nonpulsatile flow on renal perfusion in small children.[5,13,146] Although the use of ECMO as a bridge to transplant continues to be necessary in selected cases, especially for those whose congenital anatomy is not amenable to VAD support, every effort should be made to avoid its use when other methods of mechanical support are possible. Less favorable outcomes with the use of extracorporeal VADs were also observed, suggesting that conversion to other modes of support may improve posttransplant outcomes. Consistent with adult data,[167] the researchers found that the poor survival with extracorporeal VADs extended to the posttransplant period. They acknowledge that although the use of extracorporeal devices to stabilize children may be necessary in some situations, there should be a timely conversion to an implantable device to improve outcomes. A retrospective study comparing children who received multimodality MCS before transplant with those who received single-modality MCS showed similar survival to transplant and discharge between groups, despite the greater duration of support required in patients with multimodality MCS.[168]

Of 259 children who were listed for isolated heart transplantation at Texas Children's Hospital between 1995 and 2013, the proportion of patients who received MCS while on the wait-list increased significantly from 13% before 2005 (i.e., before BHE when only ECMO and centrifugal pumps were available for those <20 kg) to 37% after 2005 (P = .0001). Among the 70 patients who received MCS, a temporary device was used as an initial therapy in 27 (ECMO = 14 and short-term VAD = 13), whereas long-term VAD was the first device in 43 patients. Wait-list mortality before 2005, 25%, decreased significantly after 2005, 11% (P = .0006). Median MCS duration before 2005, 12 days, also increased compared with after 2005, 78 days (P = .004). Kaplan-Meier estimates showed weak evidence (P = .08) for improved survival after bridge-to-transplant both at 1 year (70% before 2005 and 88% after 2005) and at 5 years (60% and 78%, respectively).[169] This reduction in wait-list mortality is likely attributable to both the increased use of MCS as well as improvements in medical management and the maturation and experience of their program.

Mechanical Circulatory Support and Single-Ventricle Physiology

Not surprisingly, children with CHD who require VAD support are often anatomically more challenging to support and have a

greater mortality rate compared with children with cardiomyopathy.[155,170,171] In multiple studies, CHD has been identified as a risk factor, with those with single-ventricle physiology at greatest risk.[172] Based on data from the Pediatric Heart Transplant Study (PHTS) and Cardiac Transplant Research Database, single-ventricle anatomy is the most common cardiac lesion necessitating heart transplantation from age 6 months to adulthood. Unfortunately, outcomes after VAD support have been disappointing in the growing population of patients with failed single-ventricle palliations, with only 50% survival compared with overall pediatric VAD survival rates of 70% to 86%.[79,154,171] Because most patients who have undergone palliative cavopulmonary connections ultimately develop heart failure, the Mechanical Support as Failure Intervention in Patients with Cavopulmonary Shunts (MFICS) registry has been developed to improve the quality of care in this population.[170]

Infants who require ECMO support after stage I palliation for HLHS experience significant mortality. In a recent review of the ELSO database from 1998 to 2013, only 36% of children survive to hospital discharge for this population.[59] An analysis of ELSO data from 1999 to 2012 reported a 41% survival to hospital discharge in those who had undergone superior cavopulmonary anastomosis.[173] Of patients with single-ventricle physiology who required VV ECMO for oxygenation/ventilation, the majority of whom had stage I physiology, 48% survived.[174]

Although MCS has been used after all stages of single-ventricle palliation, a multiinstitutional analysis of BHE use in patients with functional single-ventricle physiology reported particularly poor outcomes in neonates who required support after stage I palliation for HLHS and successful bridge to transplant in only 40% of patients overall.[172] Only 11% of those who received an implant after stage I palliation survived, whereas 58% to 60% of patients after stage II or III palliation survived. Difficulty in selecting the correct pump size for patients with parallel circulations, extra sources of collateral pulmonary blood flow, and difficulty in balancing systemic and pulmonary circulations may all contribute to the high mortality after stage I palliation.

Supporting the patient with failing Fontan circulation presents unique barriers for MCS. Two basic physiologic subsets exist, which importantly affect support options. When heart failure symptoms develop because of a failing systemic ventricle (primary ventricular dysfunction), either pulsatile or continuous mechanical support is quite feasible, typically including inflow from the systemic ventricle and pump outflow to the ascending aorta. If right-sided pressures have been markedly increased, fenestration can be added at the time of implant.[175] When increased PVR or increased cavopulmonary resistance exists (failing Fontan physiology), successful support is more difficult to achieve and may require the addition of a pump from the systemic venous to the pulmonary circulation, requiring revision of the Fontan pathway to separate systemic venous and pulmonary circulations. When ventricular function is preserved and PVR is the predominant issue, pump outflow can be directed toward the pulmonary artery, providing isolated right-sided MCS. In circumstances in which a patient has significant diastolic dysfunction or residual structural lesions, a SynCardia TAH may be the most viable option for support[176]; successful use has been described in a teenager with failing Fontan circulation.[177]

VAD implantation is also technically difficult after previous sternotomies. Cannulation of the systemic right ventricle can be complicated secondary to dense trabeculations and septal positioning, predisposing to "suction" events in which the cannula is too closely opposed to the septum. After device implantation, Fontan patients generally have more bleeding and thrombotic complications related to inherent protein C and S deficiencies, resulting in coagulopathy.

Predicting the Need for BiVAD Support

The pathology leading to left heart failure in the pediatric population is also more likely to lead to RV failure than the typical adult ischemic cardiomyopathy.[178] As a consequence, BiVAD support is more often necessary in pediatric patients, with reports of BiVAD use in 25% to 45% of patients.[79,179,180] Multiple studies have shown that patients who receive BiVAD support have reduced rates of survival.[155,180–182] This may be related to the pathophysiology necessitating BiVAD support, or the fact that use of multiple devices can lead to an increased risk of adverse events including infection, bleeding, and clot formation. Outcomes are also worse in patients who have delayed RVAD placement.[183] RV dysfunction was assessed in 57 patients who underwent BHE implantation for bridge-to-transplant; 25% required BiVAD support and an additional 17% had RV dysfunction (defined as CVP >16 mm Hg with inotropic therapy and/or inhaled nitric oxide for >96 hours). Preoperative variables such as younger age; use of ECMO; and increased urea, creatinine, and bilirubin were associated with RV dysfunction and increased urea and need for ECMO were risk factors for BiVAD placement. Patients who developed RV dysfunction with LVAD support had complicated postoperative courses but excellent survival (100%) comparable with those with preserved RV function (91%). Survival of those patients who required BiVAD support was only 71%.[180] Another study demonstrated that patients who required biventricular support had a significantly greater postoperative mortality and that preoperative milrinone therapy decreased the risk of severe RV failure necessitating RVAD insertion and improved postimplantation survival.[12]

ECMO for Cardiac Arrest

Emergent use of ECMO for children during in-hospital cardiac arrest with failure of conventional resuscitation methods has become increasingly common. An analysis of data from the National Registry of CardioPulmonary Resuscitation (NRCPR) database of outcomes from children younger than 18 years of age who received ECPR for cardiac arrest refractory to conventional CPR demonstrated a 43.7% survival to discharge. Preexisting septicemia, pneumonia, and/or renal insufficiency correlated with an increased risk of mortality. Children with a cardiac-related diagnosis exhibited slightly improved odds of survival to discharge when compared with children without cardiac disease.[184] In a review of pediatric cardiac patients from the ELSO registry who received ECPR, single-ventricle physiology and a history of more complex cardiac surgery were negative predictors of survival.[185] Renal dysfunction, pulmonary hemorrhage, neurologic injury, and the need for additional CPR during ECMO have also been associated with increased mortality.[186]

Acceptable neurologic outcomes have been described in children after CPR of up to 3 hours in duration before institution of ECMO.[187] The duration of CPR before ECMO cannulation was similar in survivors and nonsurvivors.[188] Of the children in the ELSO registry who received ECPR, 22% of the 682 developed an acute neurologic injury, with an in-hospital mortality rate of 89%. The risk of neurologic injury in children with cardiac disease in this cohort was reduced.[189]

COMPLICATIONS

VAD use is associated with neurologic, hematologic, GI, and immunologic complications, with the frequency and severity of many of these complications being device specific. The profiles of adverse events differ between pulsatile devices and currently used continuous-flow pumps.

Stroke is the most feared complication related to MCS, occurring more commonly with pulsatile-flow than continuous-flow devices.[190] Strokes may be hemorrhagic in nature or ischemic owing to embolism from ventricular clot or device thrombus, the latter being more common. Of 3517 cardiac surgical patients who received ECMO support between the years 2002 and 2013, neonatal status, smaller weight for age, and greater duration of ECMO were associated with a greater risk of stroke risk.[191] In the BHE trial, stroke occurred in 29% of supported patients, with thromboembolic strokes occurring eight times more often than hemorrhagic strokes.[13] Temporally, neurologic events were more common during the first month of support and, overall, was the leading cause of death after pump implantation. Mortality was 42% among patients with at least one neurologic event versus 18% in the absence of this event (P = .0006). Patients weighing less than 10 kg have the greatest incidence of stroke.[166,192] Increased institutional experience and appointment of a single physician to manage a patient's anticoagulation therapy can decrease the risk of stroke.[193]

Bleeding is quite common after ECMO and VAD device placement and is usually most severe in the early postoperative period. One-third of patients in the Pediatric Heart Study assist device multiinstitutional study and up to 50% of those in the Berlin Heart Trial had bleeding requiring reoperation.[154] Major bleeding was also the most commonly encountered complication in patients enrolled in the randomized Berlin Heart Pediatric VAD study, occurring in 42% of the low-BSA and 50% of the high-BSA cohorts.[13]

Infection is a relatively common complication and occurs in 50% to 69% of patients,[13,194] with infection attributable to the prolonged hospitalizations and exposure to multiple invasive therapies. The potential also exists for VAD-specific (driveline, hardware, or pump pocket) or VAD-related (mediastinitis, endocarditic, or bloodstream) infections. Commonly implicated organisms include *Staphylococcus aureus*, coagulase-negative staphylococci, *Pseudomonas aeruginosa*, and *Candida* spp.[194] Aggressive antibiotic and/or antifungal therapy, in addition to source control, is crucial, particularly in the setting of antirejection medications at the time of transplantation. Patients with driveline infections are often maintained with suppressive oral antibiotic therapy until 2 weeks after cardiac transplantation.

Immunologic complications related to VAD support involve the formation of antibodies against human leukocyte antigens (anti-HLA antibodies), a process that has been consistently observed. The mechanism of antibody formation is complex and likely involves factors specific to the device itself as well as clinical events occurring during VAD support, particularly blood product transfusion.[195] After taking into account the blood product usage, some studies still reported an increase in panel reactive antibodies.[196] The presence of HLA antibodies is of significant concern as their presence in significant numbers may limit the suitability of a donor organ should the donor have preformed anti-HLA antibodies against specific HLA antigens. Although the adult sensitization rates of patients supported with a VAD have been reported to be as great as 60% on modern devices,[197] the true incidence of anti-HLA antibody formation in children supported with VADs is difficult to ascertain. In one study, there was a decrease in survival approximately 5 years after transplantation for patients who received VAD support[166]; the authors postulated that this could be related to increased risk of graft failure, secondary to increased allosensitization in VAD patients. The smaller surface area and materials used to make the newer continuous-flow devices appear to decrease the incidence of anti-HLA antibody formation.

Increased rates of both aortic insufficiency and aortic valve leaflet fusion exist with continuous-flow devices, thought to be due to an increased gradient across the aortic valve and increased strain on valve leaflets.[198] An increased rate of pulmonary hypertension and GI bleeding in the adult population has also been reported with continuous-flow devices.[199] GI bleeding occurs from a combination of factors, including anticoagulation, acquired vWF deficiency and decreased pulsatility, leading to the formation of arteriovenous malformations.[121] Although this has not been described in the pediatric population, acquired vWF deficiency has been described and is attributed to the destruction of the large vWF multimers by the rotor.[88] The risk of GI bleeding may become an issue in pediatric VAD patients as more of them receive continuous-flow devices for longer durations.

VAD therapy is also associated with other GI complications, including the need for peritoneal disruption as part of implantation. It is estimated that 55% of adult patients experience abdominal complications with VAD support, with problems such as wound/pocket infection, *Clostridium difficile* infection, hepatic dysfunction, and pancreatitis.[200] The incidence of such complications in the pediatric population is unknown.

The Future

In the face of an increasing need for advanced circulatory support in the pediatric patient population, the NHLBI developed a Pediatric Circulatory Support Program in 2004 that matured into the Pumps for Kids, Infants, and Neonates Program (PumpKIN) in 2010. Although a prospective, randomized trial of two implantable pumps was designed (PumpKIN trial) for 22 centers, the FDA suspended the study before it started after in vitro studies revealed an excessive degree of hemolysis with the Jarvik 2000 device (Jarvik Heart, Inc., New York, NY).[201] Additional in vitro studies failed to reveal the source of hemolysis. Since then a slightly larger version of this pump, the Jarvik 2015 (with 40% larger inflow cannula) was designed and in vitro studies reported an acceptable level of hemolysis. Further in vitro studies are planned before proceeding with the clinical trial.[163]

Both Thoratec (HeartMate III device) and HeartWare (MVAD device) have new, smaller continuous-flow devices entering U.S. clinical trials. These devices, especially the MVAD, will be rapidly applied to the pediatric population as an off-label indication as soon as FDA approval occurs.[163]

Minimally invasive pulmonary replacement devices are also now in development; devices such as the Biolung[202] and others are being developed as an alternative to ECMO for gas exchange and may become available in the near future.

Mascio CE. The use of ventricular assist device support in children: the state of the art. *Artif Organs*. 2015;39(1):14-20.

The author provides an excellent overview of the commonly used ventricular assist devices in children.

Maslach-Hubbard A, Bratton SL. Extracorporeal membrane oxygenation for pediatric respiratory failure: history, development and current status. *World J Crit Care Med*. 2013;2:29-39.

The authors provide a comprehensive review of the use of extracorporeal membrane oxygenation for respiratory failure in children.

Mossad E, Motta P, Rossano J, et al. Perioperative management of pediatric patients on mechanical cardiac support. *Paediatr Anaesth*. 2011;21:585-593.

The authors review the demographics of children requiring MCS and perioperative management concepts for their care.

Rais-Bahrami K, Van Meurs KP. Venoarterial versus venovenous ECMO for neonatal respiratory failure. *Semin Perinatol*. 2014;38(2):71-77.

The authors provide a good brief review of ECMO in neonates complete with cannulation pictorial.

Sani A, Spinella PC. Management of anticoagulation and hemostasis for pediatric extracorporeal membrane oxygenation. *Clin Lab Med*. 2014;34:655-673.

The authors provide a thorough review of various methods for anticoagulation and monitoring for patients on ECMO support.

Future of Anesthesia in Interventional Cardiology

THE USE OF CATHETERIZATION in the care of children with congenital heart disease (CHD) was first described by Dexter and colleagues in 1947[1] with the first interventional procedure, balloon atrial septostomy, subsequently described by Rashkind and Miller in 1966.[2] Over the intervening decades the discipline of pediatric interventional cardiology has vastly expanded within the field of pediatric cardiovascular medicine.

Technologic advances have increased the scope of pediatric cardiac catheterization procedures. As echocardiography, computed tomography (CT), and magnetic resonance imaging (MRI) diagnostic capabilities have increased, the need for purely diagnostic cardiac catheterization has waned.[3] There has been a transition from diagnostics toward more therapeutic interventions, with interventional procedures now accounting for more than two-thirds of all pediatric cardiac catheterizations.[4] Interventional cardiology has afforded patients a wider range of nonsurgical options for the management of CHD, postponing or replacing the requirement for surgery. Hybrid procedures, combining interventional cardiology with cardiac surgery, have enabled the management of more complex cardiac lesions.[5] As more children with CHD survive into adulthood, there has been a shift in patient demographics. Children presenting for interventional cardiology represent a diverse group from premature neonates to older adolescents, with simple to complex pathophysiology, requiring procedures of varying complexity. Catheterization laboratories are often remote sites and can be challenging environments. Anesthesiologists providing care to children undergoing cardiac catheterizations must have a good understanding of the patient's pathophysiology and tailor anesthesia to the patient- and procedure-specific requirements. Adverse events are common during catheterization procedures. The anesthesiologist must be able to anticipate, prevent, and treat complications that may arise in this high-risk population.

In this chapter, we outline the main procedures performed in interventional cardiology, describe the challenges and complications faced by anesthesiologists, and address the principles and details of anesthetic techniques.

Types of Procedures Performed

DIAGNOSTIC CATHETERIZATION

Diagnostic catheterization allows accurate documentation of pressure and oxygen content from different regions of the circulation. Interpretation of these hemodynamic data allows quantification of the degree of intracardiac shunting and calculation of vascular resistances. This information is necessary to guide critical decisions, such as the suitability of a child to undergo palliative or reparative surgery for congenital heart lesions, and to direct medical therapy. Consistent and reproducible physiologic conditions are required during the procedure to allow correct interpretation and comparison of results. Expected values for hemodynamic variables are listed in Table 22.1. There are no absolute values for these variables, which vary with the age of the child. The use of angiocardiography during catheterization to define complex cardiac anatomy is waning because of the increased use and capabilities of noninvasive imaging modalities such as echocardiography, CT, and MRI.[6]

INTERVENTIONAL CATHETERIZATION

Interventional procedures now account for approximately two-thirds of all cardiac catheterization cases in children of all ages.[7]

Atrial Septostomy

Atrial septostomy involves passing a balloon-tipped catheter across the atrial septum, typically through the membranous foramen

ovale. The balloon is inflated and pulled back through the septum creating a larger intraatrial communication that improves mixing of oxygenated and deoxygenated blood at the atrial level. The procedure is most commonly performed in neonates with D-transposition of the great vessels (D-TGA) as an emergency procedure. Children with D-TGA have systemic and pulmonary circulations in parallel rather than in series; the right ventricle pumps deoxygenated blood to the aorta, and the left ventricle pumps oxygenated blood to the main pulmonary artery. Atrial septostomy allows critical mixing of oxygenated and deoxygenated blood, thereby increasing systemic oxygen saturation. The procedure can be performed in the catheterization laboratory under fluoroscopic guidance or undertaken at the bedside in the intensive care unit using echocardiographic guidance.[8] Other indications for atrial septostomy include tricuspid atresia, mitral atresia, and pulmonary atresia with intact ventricular septum. The major risks associated with the procedure are vessel injury, paradoxical embolism, arrhythmia, and cardiac perforation. More recent concerns of an association with increased brain injury do not seem to have been evidence-founded.[9]

Atrial Septal Defect Closure

With the development of specifically designed closure devices, atrial septal defect (ASD) closure has become one of the most commonly performed endovascular procedures. The technique is intended for closing secundum ASDs, which are defects located in the region of the fossa ovalis. Defects falling outside this area, such as sinus venosus and primum ASDs, are generally not suitable for percutaneous closure.

To warrant closure, children need to demonstrate clear evidence of volume loading of the right heart structures and a defect that is unlikely to close spontaneously in the short to medium term. Devices have evolved from the early bulky meshes and a wide variety of sizes and designs are now available. The choice of closure device depends on the size and margins of the defect, but brand selection depends more on the clinician's preference than objective performance (Fig. 22.1).[10] Daily aspirin in a dose of 3 to 5 mg/kg is recommended for a minimum of 6 months after the procedure. The main perioperative complications associated with ASD device closure include vessel injury, cardiac arrhythmia, cardiac perforation, and device embolization. In the long term, devices are well tolerated with atrial arrhythmias the most common problem, although life-threatening complications such as cardiac erosion have been reported.[11] ASD closure devices can also be used to close surgically created fenestrations when they are no longer required, such as between the atrium and venous conduits after a Fontan operation.

TABLE 22.1 Normal Values in Diagnostic Cardiac Catheterization

Structure	Value (mm Hg)
Right atrium	3–5 (mean)
Right ventricle	20–25/3–5 (systolic/end-diastolic)
Pulmonary artery	12–15 (mean)
Left atrium	7–10 (mean)
Left ventricle	65–110/3–5 (systolic/end-diastolic)
Aorta	65–110/35–65 (systolic/diastolic)

Ventricular Septal Defect Closure

Ventricular septal defect (VSD) closure presents a technically greater challenge than ASD closure and is associated with a greater incidence of complications. Defects of the midmuscular septum or apex are most suitable for device closure, although perimembranous VSDs may also be closed percutaneously.[12,13] A combined surgical and interventional approach may be appropriate for certain cases, such as the small infant with an anterior apical VSD that is difficult to reach surgically.[14]

When using a device to close a VSD, a snare is placed in the right side of the heart to capture a guidewire that has been passed across the VSD from the left ventricle. The guidewire is brought outside the body via the venous access to form an arteriovenous rail. The delivery sheath for the VSD device is then advanced over the wire to approach the VSD from the right side of the heart. For anterior and high muscular defects, the wire is best snared and exteriorized through a femoral vein approach, whereas for defects in the middle to low muscular septum, the wire is best snared and exteriorized through a jugular venous approach (Fig. 22.2).

Complications include dysrhythmias, blood loss, valve dysfunction, low cardiac output state, and device embolization.[15,16] Device closure of perimembranous VSDs in particular has been associated with an increased incidence of complete heart block and aortic valve disruption owing to the close proximity of conduction pathways and the aortic valve apparatus. This has led to some controversy in their use, with many centers considering the risk unacceptable, given the good outcomes following surgical VSD closure.

Patent Ductus Arteriosus Closure

Transcatheter closure of patent ductus arteriosus (PDA) was the second specific intervention developed for children with CHD, and

FIGURE 22.3 The coil is used for closure of a patent ductus arteriosus.

the procedure continues to be performed using techniques similar to the original methods pioneered by Rashkind and associates.[17] The procedure has a high occlusion rate with the smallest incidence of adverse events of all interventional procedures and is indicated in any child with evidence of left ventricular overload. PDA morphology varies from short and broad to narrow and tortuous, so the customary approach is to perform an aortogram to define the size and geometry. For closure of small and moderate PDAs, stainless steel coils (e.g., Gianturco, Cook Medical, Bloomington, IN) are most commonly used, whereas for larger PDAs, occluder devices (e.g., Amplatzer, St. Jude Medical, St. Paul, MN) are more appropriate.[18,19] Devices can be deployed with a retrograde or anterograde approach. Embolization of the device at the point of deployment is a risk but there are several techniques that can help control device release. Embolization may also be delayed, so proper follow-up is required; the other major risk associated with this procedure is vessel injury. Despite impressive technical evolution over the years, PDA device closure in premature or low body weight infants remains prohibitively challenging and further catheter design is required in this area.[20] These techniques can also be used to close other unwarranted vascular connections such as major aortopulmonary collateral arteries (MAPCAs) and Blalock-Taussig (BT) shunts that are no longer required (Figs. 22.3 and 22.4).

Balloon Dilation and Stent Implantation

Balloon angioplasty techniques are used to dilate stenotic valves, most commonly pulmonary and aortic, as well as stenotic segments of the aorta or pulmonary arteries and surgically placed shunts or pulmonary artery bands. Neonatal membranous pulmonary atresia can be treated using this technique, crossing the pulmonary valve membrane with the stiff end of a guidewire or with radiofrequency catheters[21] before subsequent dilatation of the valve annulus. Balloon valvuloplasty of isolated pulmonary stenosis in older infants and children is often a curative procedure, whereas neonates with critical pulmonary stenosis or atresia often require further interventions to supplement pulmonary blood flow such as ductal stenting or a BT shunt.[22] Inflation of the balloon temporarily arrests right ventricular output and is often accompanied by transient hypotension but is generally well tolerated.[23] Paradoxically, those with tighter stenosis and little antegrade flow may maintain

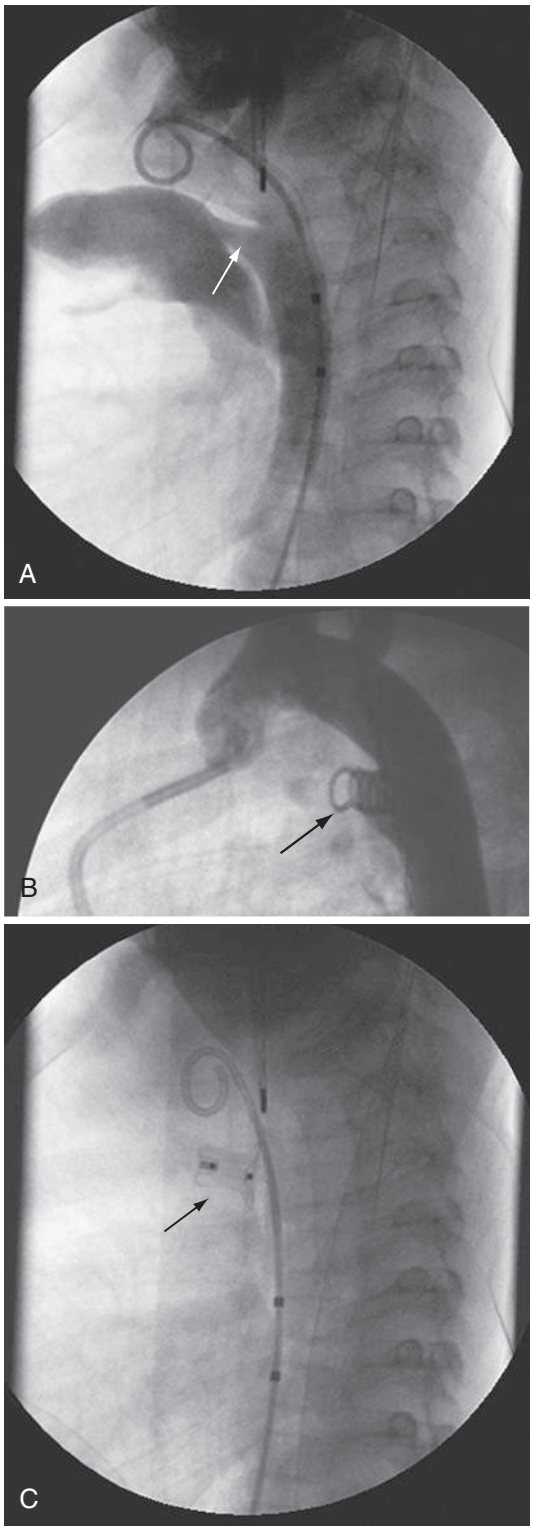

FIGURE 22.4 **A,** Lateral angiography demonstrates a patent ductus arteriosus (PDA) (*arrow*). The PDA lies between aorta and pulmonary artery (*arrow*). The device (*arrow*) is in the PDA.

hemodynamic stability better, particularly if the duct is still open, as cardiac output is less disrupted.

The role of balloon valvuloplasty for critical aortic stenosis remains controversial; in some centers, it remains the treatment of choice, whereas others prefer a primary surgical approach. Concerns relate to longer-term outcomes and the rate of surgical intervention required in those treated initially with valvuloplasty.[24,25] When performed, balloon dilation of aortic stenosis in the neonate is a particularly high-risk procedure. These infants often present in a low–cardiac output state requiring ventilation, inotropic support, and prostaglandin E_1 (PGE_1) infusion to maintain ductal patency. Catheterization can be complicated by arrhythmias (including asystole), the development of significant aortic regurgitation (which may require surgical intervention), and sudden death resulting from acute coronary ischemia.[26] The complication rate in older children is less than in younger children, yet transient hypotension, bradycardia, and left bundle branch block are commonly reported.

Stents are sometimes implanted across focal areas of persistent stenosis in the systemic and pulmonary circulations or within surgically placed shunts.[27] The technique of implantation requires great precision for correct positioning of the stent, and the cardiac interventionalist needs to take into account the inevitable shortening that occurs with stent implantation when selecting a device for a particular lesion. There is also a risk of stent malposition with the potential for dislodgment. Although rare, late aneurysm formation has been reported after stenting the aorta for coarctation.[28]

Nonsurgical Pulmonary Valve Replacement

Bonhoeffer and colleagues[29] first described the technique of replacing a dysfunctional valve in a right ventricle to pulmonary artery (RV-PA) conduit with a catheter-implanted valve in 2000. The Melody valve (Medtronic Inc., Minneapolis, MN) is one such device that has been approved for use in surgically placed RV-PA conduits meeting specific requirements.[30] Studies have confirmed a high procedural success rate and satisfactory short-term and medium-term valve function after implantation of the Melody valve.[31] The need for careful patient selection and for adequate relief of right ventricular outflow tract (RVOT) obstruction at the time of valve implantation are paramount in achieving results comparable to those of surgical replacement of dysfunctional conduits. Off-label use has additionally demonstrated promising results with implantation of Melody valves in children with native RVOTs.[30] Unfortunately, most children who are managed with transannular patch repair of tetralogy of Fallot are currently unsuitable for transcatheter valve replacement because of an aneurysmal RVOT. New hybrid procedures are, however, emerging to circumvent this, allowing more options for patients with tetralogy of Fallot, many of whom are likely to require recurrent interventions over their lifetime.[32] Alternative devices are also being developed to reduce the size of the delivery systems to enable use of these technologies in younger and smaller children. As with surgical valve replacements, thrombus formation and infective endocarditis are concerns after transcatheter valve implantation.[31]

ELECTROPHYSIOLOGIC CATHETERIZATION

Endocardial catheters that record an electrocardiogram first became available in the early 1960s. Intracardiac electrograms, supplemented by external electrocardiogram leads, record electrical activity in the heart, and programmable stimulators aim to induce and terminate tachyarrhythmias. This allows arrhythmia mechanisms to be defined and arrhythmogenic foci to be mapped. Ablation

catheters can then be guided to deliver local energy to the endocardium to destroy the source of the arrhythmia or interrupt aberrant conduction pathways. Ablation can be delivered as radiofrequency, cryoablation, laser therapy, or direct currents. Ablative procedures are indicated for the treatment of cardiac arrhythmias, particularly atrial tachyarrhythmias.

The procedures are complex, requiring specialized equipment, specially trained staff, and use of multiple catheters to measure electrical signals. These procedures are often of greater duration than other catheterization procedures. Ablation of ectopic foci has a good success rate and small complication rate.[33,34] The main risks with this procedure are heart block, cardiac perforation, vessel injury, and stroke.

Choice of Vessel Access

The most common approach for cardiac catheterization is the femoral route. Femoral venous catheterization avoids the risk of pneumothorax and the vessel is often easier to access than the internal jugular vein in the unanesthetized child. In children who are likely to have a cavopulmonary shunt placed surgically for palliation, avoiding routine cannulation of the internal jugular vein may decrease the risk of compromising the superior vena cava. Internal jugular vein access, however, is sometimes required, such as during some VSD closures, investigation of cavopulmonary connections in children, and when the cardiac interventionalist is unable to obtain femoral access. In neonates, the umbilical vein may be used, although difficulty can be encountered attempting to cross the ductus venosus to access the inferior vena cava. Patency of the ductus venosus can be assessed by ultrasound before the procedure to avoid unnecessary manipulation of the umbilical vein. An alternative route is transhepatic puncture. This route has been used for temporary access during catheterization and for long-term vascular access.[35]

Complications and Limitations of Procedures

The pediatric cardiac catheterization laboratory is a high-risk environment associated with significant morbidity and mortality. Of the 373 anesthesia-related cardiac arrests reported in the Pediatric Perioperative Cardiac Registry, 34% occurred in children with cardiac disease and 17% of these occurred in the catheterization laboratory.[36] Additionally, there are complications directly attributable to the procedures. Successful practice in this setting requires a thorough understanding of pathology, vigilance, excellent communication between team members, and appropriate backup from surgeons and other specialties. Standard procedures for predictable emergencies should be in place. An intensive care bed should be available for high risk procedures. The facility for cardiopulmonary bypass or extracorporeal membrane oxygenation (ECMO) for high-risk patient groups or procedures may be beneficial,[16] although this type of therapy may not be available everywhere. Local policies on appropriate case mix should be based on experience and infrastructure and clear referral pathways for high-risk cases should be established.

OVERALL MORTALITY AND MORBIDITY

Recent studies of pediatric catheterization have reported mortality rates in the immediate perioperative period (in theatre or recovery) of between 0.05 and 0.28%.[18,30] However, the **IM**proving **P**ediatric and **A**dult **C**ongenital **T**reatment (IMPACT) database of more than 16,000 pediatric catheterizations reports all-cause mortality for children undergoing catheterization during their admission as 2.1%, with the majority of deaths occurring within 14 days of the procedure.[4] Despite the increasing complexity of both patients and procedures being undertaken, the mortality rate is decreasing.

Adverse events occur in 8.8% to 10.6% of catheterization procedures overall.[4,37] Morbidity may be classified as either major or minor. Major complications are life-threatening events requiring immediate medical or surgical intervention (e.g., cardiac arrest, removal of an embolized device) or which result in a significant permanent lesion (e.g., embolic stroke, vessel aneurysm). These types of adverse events occur during 1% to 2% of procedures. Minor complications are transient and resolve with specific treatment (e.g., tolerated dysrhythmias, transient arterial thrombosis). Complication rates have remained largely constant despite technologic advances, reflecting the changing nature of the patient population and interventions.

Certain patient and procedural characteristics confer increased risk of complications. Neonates are particularly vulnerable, with a reported rate of major complications of 4.7% for interventional catheterization, which may be explained by reduced physiologic reserve, presence of uncorrected or partially palliated congenital heart defects, and an increased risk of obstruction to great vessels and cardiac chambers by wires and devices.[23] Age younger than 1 year and low body weight have been identified as independent risk factors for complications.[38] Specific cardiac lesions are also associated with greater risks of both morbidity and mortality, notably single ventricle physiology, whether unrepaired or palliated, and significant left ventricular outflow tract obstruction (e.g., Williams-Beuren syndrome and hypertrophic cardiomyopathy).[39] The presence of pulmonary hypertension, particularly with an idiopathic etiology and suprasystemic pulmonary artery pressures, increases perioperative risk substantially.[40] With respect to procedural risk, interventional procedures have greater complication rates than diagnostic procedures for all age groups except neonates, in whom the complication rates are similar.[4,23] Specifically, high-risk procedures include VSD device closure; atrial septostomy where the septum is restrictive; balloon interventions for the mitral valve, pulmonary vein, pulmonary artery, and neonatal aortic valve; and stent placement in surgical shunts.[41,42] At the other end of the spectrum, PDA and ASD device closures have the least risks of complications.[23]

VASCULAR COMPLICATIONS

Vascular complications are the most common complication of pediatric catheterizations, accounting for almost a third of the total.[43] They may be acute, leading to unexpected hemodynamic instability, or delayed, leading to longer-term morbidity. Many factors may contribute to unexpected hemodynamic instability, including blood loss, balloon- or catheter-induced interruptions in blood flow or coronary perfusion, arrhythmias, tamponade, vessel rupture, acute valve dysfunction, and device malposition.

Arterial Thrombosis and Occlusion

Arterial thrombosis is common after pediatric cardiac catheterization, with a reported incidence in two large studies of 4.3% and 11.4%.[44,45] However, diagnosis based on clinical assessment of pulses is likely to lead to underestimation; when measured by Doppler ultrasound, 32% of infants had compromised arterial blood flow to the leg.[46] Young age, small size, larger sheath size, and repeated arterial catheter exchanges are independent risk factors

for thrombosis; polycythemia and dehydration may increase risk further.

Prophylactic heparin reduces but does not remove the risk of arterial thrombosis[47]; and despite widespread use, there is no consensus on the appropriate dose. Common schedules prescribe 50 to 100 IU/kg; larger doses do not appear to add additional benefit. Most cases of reduced or absent pulse will resolve either spontaneously or with additional heparin anticoagulation. Thrombolysis is a viable next step, but surgical intervention will be needed for thrombosis resistant to medical therapy, arterial tears or avulsion, and pseudoaneurysms. Percutaneous thrombectomy may be suitable in older children.[48,49] Occasionally, a pulse may be persistently reduced in a clinically well-perfused limb despite intervention. The long-term concern is delayed limb growth; cases have been reported but one small study failed to demonstrate limb-length discrepancy after median follow up of 3½ years. Currently there is no means to identify those at risk.[48,50]

Venous Thrombosis and Occlusion

Isolated cases of femoral or iliofemoral venous occlusions with limb edema have been published as part of large series,[37] but two small prospective observational studies found an incidence of 0% and 1.6%, respectively.[51,52] All affected children responded to heparin therapy without the need for further intervention. Using the smallest catheter necessary and heparin prophylaxis should assist in limiting the incidence.

Vessel Rupture, Perforation, and Dissection

Vessel rupture can occur at the site of vessel entry or at the site of intervention. It is a rare but potentially catastrophic event. One death caused by intraabdominal hemorrhage after rupture of a femoral vein in a neonate was reported in a series of 4454 catheterizations.[23] Arterial or venous perforations were responsible for four major complications and six minor complications in a series of 4952 procedures, and significant groin hematoma occurred in 25 cases.[37]

Vessel rupture appears most common during balloon dilation of branch pulmonary arteries and during RVOT valve implantation procedures, but it has also been reported along the ascending aorta and arch after dilation on the aortic valve.[53] Occasionally, arterial dissection, aneurysm, and pseudoaneurysm formation may occur. Rupture may cause hemopericardium or hemothorax, or both; pulmonary artery disruption after balloon dilation may manifest as hemoptysis.[48] If rupture and hemorrhage occur, hypertension should be avoided, the trachea should be intubated (if the airway is not already secured), and any circulating heparin should be reversed. In extremis, blood from pericardial or pleural drains may be returned directly to the patient via femoral cannulae until surgical intervention can be achieved.

Cardiac Perforation and Tamponade

Perforation of the myocardium during catheterization procedures is relatively common, with the atrial appendage and RVOT the most common sites. Procedures associated with a greater risk include atrial septostomy, balloon dilation of the mitral valve, and attempted radiofrequency perforation of membranous pulmonary atresia.[48] Signs that suggest a perforation include wires appearing in unexpected places, atypical contrast appearance, lack of a return to baseline blood pressure after catheter-induced tachycardia, narrow pulse pressure, and hemodynamic instability. Echocardiography should always be immediately available to confirm a suspected perforation or tamponade. Perforation is often well tolerated and frequently can be managed conservatively, but the **C**ongenital **C**ardiac **C**atheterization **P**roject on **O**utcomes (C3PO) database of nearly 9000 cases recorded 5 neonatal deaths resulting from cardiac perforation during atrial septostomy.[54]

Cardiac tamponade is an uncommon complication of cardiac catheterization with an incidence reported at 0.1% to 0.2%.[4] In one series of 4952 patients, tamponade was responsible for 2 deaths: one neonate after a balloon atrial septostomy and one 4-year-old child after a recent Fontan procedure for stent insertion in a branch pulmonary artery.[37] Tamponade may be treated by needle pericardiocentesis, insertion of a pericardial drain, or occasionally, by the formation of a pericardial window by cardiac surgeons.

DAMAGE OR DYSFUNCTION OF A VALVE

Damage to a valve is uncommon but most commonly occurs with balloon valvuloplasty rather than with other procedures. The primary complication is creation of excessive regurgitation. The hemodynamic consequences of such a defect are more significant on the systemic side of the circulation than on the pulmonary side.[48] The mechanism of injury is most commonly leaflet avulsion during dilation, although the leaflet can be inadvertently perforated by the guidewire and then further damaged as the catheter wire is manipulated. Emergency repair is occasionally required.[48] Direct injuries to atrioventricular valves are rare, but placement of wires and large sheaths across atrioventricular valves and septal defects can cause severe, albeit temporary, hemodynamic disturbance. This is particularly true during implantation of VSD occlusion devices.[15] ASD and PDA occlusions are less likely to produce significant hemodynamic disturbance.[26]

BLOOD LOSS

Blood loss may be sudden with rupture of vessels, but more often, it is slow and insidious owing to multiple blood samples and blood loss associated with catheter exchanges, exacerbated by systemic heparinization. Noteworthy blood loss is more likely to occur during device placement procedures because of the necessity of larger catheters and multiple catheter exchanges. Preoperative blood measurements of hematocrit and a current blood type and screen are advisable. For procedures with a greater risk of blood loss, a crossmatch should also be requested. Access to emergency blood and blood administration equipment should be readily available for unexpected bleeding.

DYSRHYTHMIAS AND THE CATHETERIZATION LABORATORY

Cardiac dysrhythmias are common during cardiac catheterization. Most are mechanically induced and repositioning the wire or catheter usually results in rapid resolution. Other causes of rhythm abnormality include coronary air embolism, electrolyte imbalance, and hypercarbia. Although most are minor and self-limiting, dysrhythmias can cause significant hemodynamic instability and are a common cause of major complications.[23,43] Young age and a prolonged duration of the procedure are both risk factors for developing dysrhythmias. Treatment may include defibrillation, pacing, or medical therapy and should be managed in collaboration with the cardiologist. The relevant equipment should always be available in the catheterization suite.

Types of Dysrhythmias

Dysrhythmias may originate from the atria, ventricle, or involve the conduction system with varying degrees of block. Atrial

tachyarrhythmias are generally considered the most common but frequently resolve with adjustments to the catheterization technique or spontaneously. However, they may be poorly tolerated by children with single ventricle physiology, mitral stenosis, or poor myocardial function and these children may need intervention earlier than others. Catheter-induced complete heart block (CIHB) has been reported between 0.3% and 2.2% of cases; the latter study retrospectively searched specifically for CIHB from a database of more than 6000 pediatric catheter cases.[43,55] In this series, 96% of CIHB resolved spontaneously shortly after the procedure, but six children required pacemaker insertion. First- or second-degree atrioventricular block is well tolerated at all ages. Device closure for VSD may cause severe junctional bradycardia or complete heart block in up to 10% of cases, and almost half of these children require pacing or isoproterenol.[15]

The overall incidence of ventricular tachycardiac or fibrillation is around 0.3% but these are the most common rhythms causing major complications.[43] Children undergoing VSD device placement had ventricular arrhythmias that required lidocaine or cardioversion in 8.5% of cases.[15]

Children with obstructions to systemic flow (e.g., hypertrophic obstructive cardiomyopathy or aortic stenosis) are at a greater risk of developing ventricular fibrillation secondary to myocardial ischemia.

CARDIOVERSION

Histologic injury to the myocardium is rare when the starting power for cardioversion is set at 0.5 J/kg.[26] Systemic and pulmonary emboli are rare in children compared with adults, for whom the incidence is 1% to 2%. All forms of dysrhythmia may occur after cardioversion; factors that influence the incidence include the underlying pathology, electrolyte disturbance, residual drugs, and the strength of shock. Children with implantable pacemaker devices requiring cardioversion require special consideration. Electrode pads should be placed a distance from the generator and the pacemaker circuits, and pacemaker programming mode should be checked after the procedure.

DESATURATION

Arterial desaturation or cyanosis in the pediatric patient undergoing cardiac catheterization may be respiratory or circulatory in origin. A systematic approach is required to diagnose and treat the underlying cause. A transesophageal echocardiographic (TEE) probe can cause desaturation by compressing the bronchi or vessels, compressing on the trachea, or precipitating bronchospasm. These events are more common in children weighing less than 10 kg.[26] Pneumothorax is rare but possible during cardiac catheterization. Hypercarbia, acidosis, excessive positive-pressure ventilation, contrast media, and hypoxia can increase pulmonary vascular resistance, which may lead to increased shunting and cyanosis. Hypercyanotic episodes are frequently observed,[37] particularly in infants with uncorrected tetralogy of Fallot. In one study, 12% of children with tetralogy of Fallot exhibited a hypercyanotic episode within 12 hours of catheterization despite adequate hydration, sedation, and the use of nonionic contrast media.

EMBOLIZATION

Introduced devices, native tissues, and air can all result in embolization. Children with aberrant connections between the right and left circulations are at risk of embolization to the systemic circulation, with cerebral and coronary vessels at particular risk.

Device, Balloon, Thrombus, or Dislodged Material

Embolization of devices including coils, duct umbrellas, occlusion devices, and endovascular stents have all been reported, although improvements in device design (particularly in retrieval techniques) have reduced these risks.[4,37] Similarly, the incidence of balloon rupture has decreased with technical improvements in materials and design. Use of an inflation device with an attached manometer is recommended to ensure that the inflation pressure does not exceed the burst pressure of the balloon. Thrombus may be dislodged from devices or catheters, and balloon dilation may dislodge calcium, intimal lining from conduits, and thrombus from surgical systemic-pulmonary shunts.

Air Embolism

Gas emboli may originate from sheaths, catheters, burst balloons, or anesthetic infusion lines. The many wire and catheter exchanges required during interventional procedures make air embolism an ever-present risk.[26] Balloons are dilated with a weak contrast mixture and, in view of the occasional balloon rupture, it is important to ensure all gas bubbles are eliminated from the contrast mix syringe and catheter before dilation is undertaken. All intravenous (IV) lines, i njections, and infusions should also be free of air bubbles. Balloons used for flotation tip catheters should ideally be filled with carbon dioxide rather than air to minimize the potential embolic effect if the balloon bursts. Nitrous oxide should be avoided because it may expand air bubbles.

CONTRAST TOXICITY

Adverse reactions to intravascular media are relatively uncommon, but accurate recognition and management by the anesthesiologist is critical. Idiosyncratic reactions may be acute or delayed, but the pathophysiologic mechanisms underlying these responses are complex, varied, and remain to be fully elucidated. Unless formal allergy testing has been undertaken, hypersensitivity is an appropriate term that does not misattribute a mechanism.[56] Both acute and delayed reactions can occur with first exposure to contrast media, and all grades of severity including anaphylaxis are possible.[57]

Acute Reactions

Acute reactions to contrast agents can range from mild to severe; symptoms include tachycardia, bronchospasm, flushing, urticaria, laryngeal edema, and cardiovascular collapse. Replacing high-osmolar (ionic) contrast solutions with isomolar or low-osmolar (nonionic) solutions has reduced the incidence substantively. In one series of more than 11,000 administrations of nonionic iodinated contrast media to children, acute reactions were noted in 20 (0.18%) cases; 16 were mild, 1 moderate, and 3 severe.[58] Reactions appear to be more common when contrast medium is given through an arterial access compared with venous access. Acute reactions should be managed in accordance with standard anaphylaxis protocols (i.e., oxygen, IV fluid, epinephrine, corticosteroids, and histamine 1- and histamine 2-antagonist therapy). If there is a history of an acute reaction to contrast agents, then prophylaxis with corticosteroids and antihistamines can be considered if further exposure is proposed. However, breakthrough reactions of all severity grades have been observed in up to 40% of all pretreated patients, so alternative agents or imaging modalities should be strongly considered.[56]

Delayed Reactions

Delayed reactions have a much broader spectrum of clinical symptoms including: headache, heat feeling, skin redness, fixed

drug eruptions, drug reaction with eosinophilia and systemic symptoms (DRESS) and Stevens-Johnson syndrome. With the increasing trend to day-case treatment, many such reactions occur once the child has left hospital. It is therefore important that a specific history is taken from children presenting for catheterization of any previous exposure and reactions to contrast media.

Renal Adverse Reactions and Prevention

The term contrast media nephrotoxicity (CMN) refers to an increase in serum creatinine concentration by more than 25% or 0.5 mg/dL within 3 days of receiving IV contrast media in the absence of another cause.[59] The underlying mechanism of injury is unclear, although it is thought that contrast can reduce renal perfusion and is toxic to tubular cells. CMN occurs more frequently but not exclusively in children with preexisting renal damage; additional risk factors include dehydration, cardiac failure, and the subclinical renal insufficiency seen in cyanotic children. It has been suggested that infants and children who receive more than 5 mL/kg of nonionic contrast agent are at increased risk for CMN.[60] Contrast for angiography does not increase the risk of postbypass acute kidney injury[61] and most CMN appears to resolve without intervention. However, a recent study of 233 heterogeneous children receiving contrast for CT scanning found an association between CMN and unfavorable outcome, suggesting the process may not be as benign as previously hoped.[62] Many interventions have been given prophylactically to prevent CMN; preliminary studies with *N*-acetylcysteine (NAC) have been promising but no interventions have been more effective than normal saline hydration.[63] Currently, the only modifiable risk factors are hydration status and dose of contrast used. When possible, potentially nephrotoxic drugs should be stopped at least 24 hours before the procedure. Gadolinium-based contrast materials are considered nonnephrotoxic in the normal MRI dose of up to 0.3 mmol/kg. However, there is some evidence that the increased doses required for cardiac angiography may confer adverse renal effects.[64] Most radiologic contrast media have significant osmotic diuretic effects. During procedures requiring large volumes and/or repeated doses of contrast media, a significant diuresis may occur, causing concealed fluid losses and potential hypovolemia. Additional IV fluid may be required to avoid dehydration. Occasionally, bladder distention and retention can also occur, which should be considered in a child with unexplained postoperative distress.

NEUROLOGIC EVENTS

Central and peripheral neurologic damage can occur as a complication of the catheterization procedure. In one prospective study, 0.38% of children suffered a neurologic complication, and the incidence was significantly greater after interventional than diagnostic procedures.[65]

Central Nervous System

Ischemic cerebrovascular events may occur because of embolization, damage to the carotid artery, or acute low–cardiac output states causing hypoxic-ischemic encephalopathy. Thrombotic emboli may originate from any site in which there is endovascular or endocardial damage from the inner surface of the catheter or an implanted device. Factors that increase the risk during interventional procedures include large catheter size, more numerous vascular punctures, and procedures of increased duration. The most common complications after an embolic stroke are convulsions and hemiplegia, but children with this type of stroke often make a good recovery. The outcome is more guarded after hypoxic-ischemic encephalopathy occurring after a period of reduced cardiac output.[65]

Peripheral Nervous System

During catheterization procedures, the arms are frequently extended above the head to improve the lateral radiologic views of the heart; in these circumstances the brachial plexus may be injured.[66] Reduced cardiac output states associated with cardiac catheterization can augment this risk. To reduce the risk of injury, the elbows should be flexed with the hands up and the elbows then adducted a minimum of 15 cm above the table (many adduct the elbows until they are positioned directly above the shoulders and taped in position), while maintaining the head/neck in a neutral position.[66] At-risk positions should be adopted only when necessary, for the briefest time possible, and all precautions documented.[67]

RADIATION

Cardiac catheterization procedures deliver some of the largest radiation doses owing to the requirement for rapid-sequence screening and/or prolonged screening.[68] Complex interventional procedures require long fluoroscopy times with multiple angiographic or fluoroscopic acquisitions. This poses a risk to both the patient and staff. Radiation overexposure can lead to scarring and skin injury, cellular injury, gene mutation, cell death, radiation-induced cancers, and birth defects. The acronym ALARA (or ALARP), which means "as low as reasonably achievable (or practical)," is a principle for radiation exposure that should be applied in the context of obtaining adequate diagnostic images.[69]

Radiation Exposure of Patients

Children are especially vulnerable to the oncogenic effects of radiation; their actively growing tissue and organs are more sensitive to radiation, a greater proportion of their bodies are irradiated during procedures, and procedures are often longer because of smaller vessel size and difficulty cannulating target vessels. Many children with CHD will require more than one catheterization procedure and, with improvements in long-term outcomes, a longer life span to develop radiation-related problems.[70]

Oncogenic effects of radiation require a long latent time, often decades. When estimating the lifetime risk of cancer from radiation exposure, the child's age and weight need to be considered along with the duration and effective dose of radiation exposure. The risk for adult coronary angiography is 6% per sievert (Sv), and the average dose is about 10 mSv, which gives an increased risk of 0.06%. In contrast, infants require smaller exposures because of their reduced body weights, but they have an increased sensitivity. An infant has a lifetime cancer risk of 11% to 15% per sievert. If an infant is exposed to approximately 20 mSv (e.g., 1 hour of fluoroscopy and 7 digital acquisition runs), the lifetime cancer risk is estimated as 0.03%.[71,72]

Radiation Exposure of Staff

Most radiation exposure to staff comes from scatter from the beam entry point on the patient. Lesser amounts come from the x-ray tube and intensifier. The need for staff protection is well established and is accomplished by wearing lead aprons, thyroid shields, goggles, and suspended mobile glass lead screens for the head and neck. In addition, staff should aim to keep a maximal possible distance from the radiation source and minimize exposure time. All personnel working regularly in the catheterization suites should wear dosimeters to monitor cumulative radiation exposure.

HYPOTHERMIA AND HYPERTHERMIA

Catheterization procedures are often prolonged, increasing the need for close temperature monitoring. Hypothermia can exacerbate blood loss or dysrhythmias and hyperthermia may exacerbate any neurologic injury. External body and fluid warming devices should be used for all but the briefest procedures and central temperature should be measured.

ENDOCARDITIS

Under current recommendations, routine endocarditis prophylaxis is not indicated for cardiac catheterization procedures; however, the CHD patient population undergoing the procedures may warrant prophylaxis because of their increased risk of endocarditis.[73] Children with acquired valvular disease, hypertrophic cardiomyopathy, and previous infective endocarditis are at increased risk. Clinical practice varies between centers. Prophylactic antibiotics should be administered before any devices are implanted, and some centers continue to recommend endocarditis prophylaxis for a minimum of 6 months after implantation. Diagnostic or routine angioplasty procedures do not usually warrant antibiotic prophylaxis, but there is usually a residual flow disturbance after angioplasty procedures that some consider warrants preventive therapy.

OVERCOMING LIMITATIONS

The main limitation in the use of catheterization techniques in younger or smaller children has been the delay in development of equipment of appropriate size. To overcome this difficulty, clinicians have developed hybrid procedures to permit current catheter-based techniques to be used in infants and small children. Examples of this collaborative approach between surgeon and interventional cardiologist include periventricular closure of muscular ventricular septal defects[74] and hybrid stage 1 palliation for hypoplastic left heart syndrome (i.e., off-pump placement of a PDA stent and creation of an unrestricted ASD).[75]

The next great challenge is to develop equipment and techniques that can be used in conjunction with MRI.[76] This would minimize radiation exposure to children and staff. However, there are significant technical obstacles that need to be overcome before this approach can fully replace catheterization laboratories using ionizing radiation.

Anesthesia

WHO AND HOW?

The aims of anesthesia care for pediatric interventional cardiology are to ensure the child is not distressed, to provide optimal conditions for accurate diagnostic measurements and successful interventions, and to manage any complications or alterations in the child's cardiovascular physiology during the procedure. These aims often require general anesthesia but occasionally may be met with deep sedation.

The choice of sedation or general anesthesia and the seniority of the anesthetic provider should match the complexity of the procedure and the child's cardiac pathology. Deep sedation can easily merge into general anesthesia; therefore children undergoing sedation should be cared for by someone skilled at providing both and who possesses the ability to manage and resuscitate children with CHD.[77] This person must not be the proceduralist. Full standard patient monitoring should be available for all cases, and there must be adequate facilities for postprocedural recovery and emergency resuscitation.

Increasingly, there are fewer diagnostic procedures and more interventional procedures. This change is reflected in a shift from sedation to general anesthesia and the expanding role of specialized pediatric cardiac anesthesiologists.[78] Anesthesia providers for these children must have a high level of experience in pediatric anesthesia and a thorough understanding of pediatric cardiology and CHD. They must understand the physiology, the procedure, and the potential complications and have the ability to anticipate, diagnose, and respond to any hemodynamic changes or deteriorations.

PREPROCEDURAL ASSESSMENT AND MANAGEMENT

Children scheduled for elective interventional cardiology are often admitted to the hospital on the day of the procedure. Ideally, all children should have an anesthesia assessment at the same time as their preprocedural cardiologic workup. An efficient and complete anesthesia assessment requires good coordination and communication between cardiology and anesthesia units. The anesthesia preoperative assessment should establish the cardiac anatomy and details of any previous surgery, interventions, and investigations. Current functional status should be elicited, as should any signs of worsening function, cyanosis, or heart failure. Baseline observations for heart rate, blood pressure, and oxygen saturation should be recorded.

Up to 25% of children with CHD have syndromes or other anomalies that may affect their anesthesia care. Children with CHD are likely to have undergone previous procedures and anesthetics, and the family may be well informed about the child's condition, hospital process, and anesthesia. It is important that discussions include sedative premedication, parental presence, and the mode of induction of anesthesia (see Chapters 1 and 4). Sedative premedication may be particularly beneficial in children where anxiety and associated sympathetic activation and tachycardia are best avoided, such as those with left ventricular outflow tract obstruction or with sympathetically induced arrhythmias.

Interventional cardiology procedures may involve considerable physiologic trespass, and some children may have limited cardiac reserve. They should be in optimal health whenever possible. Intercurrent illness or infection may bias cardiorespiratory diagnostic values, increase the risk of endocarditis, and increase the risk of anesthesia-related complications. Respiratory illness in particular may lead to detrimental increases in pulmonary vascular resistance. The urgency and extent of the procedure must be carefully balanced against the cardiovascular status of the child before proceeding in a child with intercurrent illness.

ANATOMY AND FUNCTION

When assessing the anatomy and function, answers to four primary questions may affect anesthesia management:

- Where does the blood go?
- What is the ventricular function?
- How reactive is the pulmonary circulation?
- Is there a fixed or dynamic stenosis?

Answers to these and other questions can help the anesthesiologist determine the optimal approach to management:

- How well will hyperoxia or hypoxia be tolerated?
- What is the likely effect of increased sympathetic stimulation, vasodilation, or a reduction in myocardial contractility?
- What are the likely causes of cardiovascular collapse, and how should they be managed?

Most primary questions can be answered from the record, details of previous surgery, and recent echocardiographic results. However, an index of suspicion is always required: while very

poor function may be readily detected, moderate levels of dysfunction may not be acknowledged or as easily detected clinically.

Preoperative blood tests may include hematocrit and a type and hold or crossmatch. Sedative premedication may consist of oral midazolam (0.5 mg/kg) or ketamine (up to 5 mg/kg). Larger doses of sedative premedications may be used to provide more reliable or greater sedation if required, but they may cause delayed recovery or considerable sedation after the procedure. Topical anesthesia creams facilitate venous cannulation if IV induction is planned. Care should be taken that these children do not become excessively dehydrated. In selected children, preprocedure IV fluids should be considered (e.g., BT shunts).

THE ENVIRONMENT

The cardiac catheterization suite can be a challenging environment for the anesthesiologist. Ideally, catheterization suites should be located near cardiac operating rooms to facilitate rapid availability of ECMO support for high-risk cases. In practice, laboratories are often remotely located from the main operating room complex, limiting availability of immediate assistance and additional resources. Limited functional space may hinder access to the child during procedures and during emergency resuscitation. Blood gas analyzers should be readily available, and blood should be immediately accessible for urgent transfusion for interventional procedures such as balloon dilation and device insertion.

Lateral and anterior-posterior cameras used for imaging are in close proximity to the patient during procedures and, in combination with sterile drapes, limit access to the patient and his or her airway during procedures. Blind manipulation under the drapes can dislodge monitoring or the tracheal tube. X-ray cameras are liable to move during procedures to acquire different fields and magnifications, which risk dislodging airway devices, breathing circuits, and IV fluid lines. Meticulous care must be taken to ensure all monitoring, airway devices and IV lines are well secured prior to draping and positioning of cameras. IV line extensions are required to enable easy drug administration during the procedure. The catheterization laboratories are often cooled and temperature should be monitored in all patients. Small children will likely require active warming to maintain normothermia. Lighting is often subdued to enhance viewing of the radiographs (Fig. 22.5).

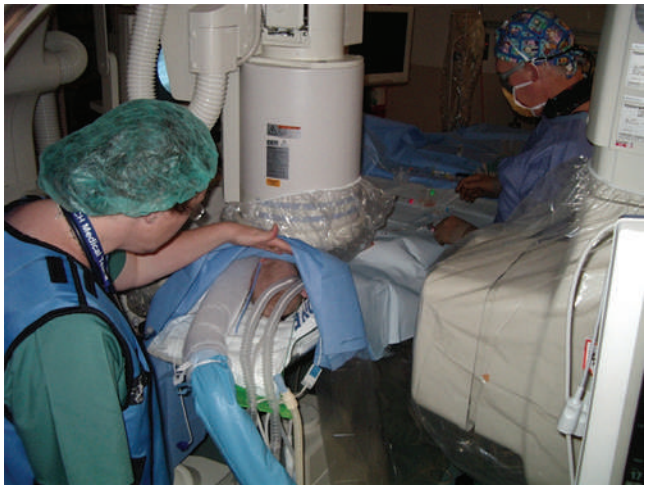

FIGURE 22.5 Typical setup of a catheterization laboratory showing limited access to a child.

THE CARDIAC PATIENT

The management of anesthesia for children with CHD is discussed further in Chapters 16 to 18. Important considerations include the potential for myocardial dysfunction and identifying limited functional reserve. This may be a particular problem in children with hypertrophied right ventricles operating at near-systemic pressures or with volume-loaded dilated ventricles. Another important consideration is the status and reactivity of the pulmonary vasculature. Difficulties may be anticipated in the following circumstances:

- Increased reactivity of the pulmonary vasculature, such as neonates, or children with primary pulmonary hypertension
- Established pulmonary hypertension with irreversible, chronically increased pulmonary artery pressures and consequent right heart dysfunction
- Circulations that require balancing (e.g., BT shunts or duct-dependent situations), in which increases or decreases in pulmonary vascular resistance may lead to spiraling hypoxia or systemic ischemia and acidosis
- Circulations that rely on low pulmonary vascular resistance to function correctly (e.g., cavopulmonary shunts or after Fontan surgery)

CHOICE OF ANESTHESIA

Many anesthetic agents and techniques have been used safely in pediatric interventional cardiology; thus the choice of technique should be guided by the patient's pathophysiology and procedural requirements. There is no specific anesthetic method that is appropriate for all children undergoing cardiac catheterization; what is important is that the operator understands the benefits and limitations of the choices he or she makes.[39]

Sedation

The difference between deep sedation and general anesthesia is imprecise and controversial, especially for small children in whom consciousness and memory are harder to measure (see Chapters 46 and 48). When considering the suitability of sedation or general anesthesia, several issues are important:

- Does immobility need to be guaranteed?
- What level of stimulation is expected?
- Do oxygen and carbon dioxide tensions need to be controlled?
- What are the cardiovascular effects of the anesthetic agents?
- How likely is significant physiologic trespass?
- What is the anticipated duration of the procedure?

Sedation is often advocated to avoid the potential effects of general anesthesia on diagnostic measurements; spontaneous ventilation may maintain a more natural intrathoracic physiology promoting the acquisition of more accurate hemodynamic data. However, sedation can be associated with substantial respiratory changes and hypoxia and can have as much effect on the circulation as general anesthesia, altering hemodynamics and intracardiac shunts and thus limiting the theoretical advantages.[79–81] Diagnostic studies require controllable, reproducible physiologic conditions, such as consistent arterial carbon dioxide tension with manipulation of inspired oxygen concentrations. Such conditions may be difficult to achieve and/or reproduce in the sedated child. Many modern diagnostic and interventional techniques require the patient to be absolutely still for prolonged periods of time and may require breath-holds. Sedation can be associated with a degree of patient movement that makes procedures such as device placement or balloon dilation potentially difficult or dangerous. However, despite these concerns, sedation remains the technique of choice in some

institutions, with evidence of a comparable safety record compared to general anesthesia. Reports from the C3PO database including more than 13,000 pediatric catheterizations reported 31% were performed with a spontaneous ventilation technique with a safety profile comparable to those managed with an artificial airway. In this series, 2% required conversion to general anesthesia with younger age and higher-risk procedures and pressor/inotrope requirements predictive of sedation failure. The eight institutions participating in C3PO had clearly established practice preferences, with two centers undertaking most cases under sedation and the remaining six using general anesthesia as their primary strategy.[82] If sedation is used, full standard monitoring should be undertaken, including monitoring of their airway and end-tidal carbon dioxide ($ETCO_2$), and provisions must be in place for rapid and expert transition to general anesthesia.

Sedation techniques have evolved over the past few decades, resulting in much more effective and titratable strategies today. In the past, the classic lytic cocktail of intramuscular meperidine, promethazine, and chlorpromazine was the standard for sedation. Rectal formulations that included thiopentone or methohexitone were also popular. However, these cocktails had a high incidence of failure and oversedation, and intramuscular routes were associated with sterile abscess formation. Oral ketamine and midazolam provide more reliable sedation, but occasionally respiratory support is required.[79] In theory, IV ketamine is an excellent choice for sedation because it provides a stable or increased heart rate and blood pressure and has little or no effect on pulmonary vascular resistance. However, prolonged recovery, vomiting, and dysphoric reactions may be problematic. The performance of IV ketamine has been improved by combination with midazolam or propofol, allowing lower doses of each agent and mitigating some of the unwanted side effects.[83] Propofol is also widely used for sedation, but compared with ketamine, it causes a greater reduction in systemic blood pressure and systemic vascular resistance, with no effect on pulmonary vascular resistance. This may increase a right-to-left shunt, or in diagnostic procedures, it may attenuate the gradient across a stenosis, making the decision to dilate the stenosis more difficult.[84] Compared with propofol sedation, a combination of ketamine with propofol produces similar sedation with less cardiovascular depression.[85] Relative combinations can be tailored to the degree of stimulus anticipated.[86] Dexmedetomidine has been proffered for sedation of children undergoing cardiac catheterization, although it may not provide sufficient sedation by itself.[87] Dexmedetomidine combined with ketamine was inferior to propofol and ketamine.[88]

Local anesthetic infiltration at cannulation sites at the start of the procedure will help reduce painful stimulation for the sedated patient, such as during catheter insertions and exchanges. Spinal anesthesia has been described as an alternative to sedation or general anesthesia in high-risk infants younger than 6 months of age when the procedure is expected to take less than 90 minutes.[89]

General Anesthesia

In the pediatric population, more than 80% of catheterization procedures are performed with patients under general anesthesia.[4] General anesthesia with controlled ventilation has several advantages, including establishing a secure airway without the risk of obstruction and hypoventilation, the ability to control arterial carbon dioxide and inspired oxygen accurately, and ensuring immobility. In addition, many patients prefer general anesthesia for fear of being awake; as many children require repeat procedures, patient satisfaction with the whole process is important. However, there are also disadvantages. The increased intrathoracic pressure associated with positive-pressure ventilation may decrease preload to the pulmonary and systemic atria, increase afterload on the right ventricle, and decrease afterload on the left ventricle. These effects may be particularly pronounced in patients with right ventricular failure or those dependent on passive pulmonary blood flow (Fontan physiology). Spontaneous ventilation through a supraglottic airway device facilitates venous return and pulmonary blood flow, although the degree of hypoventilation often seen in this situation can result in respiratory acidosis and altered pulmonary vascular resistance. This may be particularly troublesome in patients with pulmonary hypertension. The choice of tracheal intubation or supraglottic airway depends on patient factors, the length of procedure, the requirement for TEE, and whether the neck vessels will need to be accessed by the cardiology team.

A variety of general anesthetic agents have been used successfully for interventional cardiology, with no ideal agent identified. There are arguments for and against inhalational and IV anesthesia, but no outcome studies have provided strong evidence to recommend one technique over another. Great care should be taken to avoid myocardial depression or systemic vasodilation associated with excessive doses of either inhalational or IV anesthetic agents. Due to the low patient stimulation during most catheterization procedures, sufficient depth of anesthesia can often be maintained at low minimum alveolar concentration (MAC) values or plasma concentrations, particularly when supplemented with opioids and paralyzing agents, thereby mitigating some of the negative depressant effects of general anesthesia.

Inhalational agents can be used safely for both induction and maintenance of anesthesia for cardiac catheterization. Sevoflurane has a safe hemodynamic profile and isoflurane maintains cardiac output; both reduce hypoxic pulmonary vasoconstriction and increase ventilation-perfusion ($\dot{V}/\dot{Q}$) mismatch.[90] These changes may affect cardiac output calculations using the Fick principle (equations shown in Table 22.2).

While nitrous oxide does not appear to affect the pulmonary vasculature in children (in contrast to its effects in adults), it can cause expansion of gas bubbles, which is an important consideration in children at risk of paradoxical air embolus. Its use is therefore usually limited to facilitation of inhalation induction rather than routine use in the maintenance of anesthesia.[91]

Propofol has been safely and extensively used for maintenance of anesthesia in pediatric cardiac catheterization procedures. It has no effect on pulmonary vascular resistance, but dose-dependent reductions in cardiac contractility and systemic vascular resistance are well recognized. Care must be taken in patients with limited myocardial reserve, aortic stenosis, systemic-to-pulmonary shunts or pulmonary hypertension. However, there was no change in shunt fraction or pulmonary-systemic flow (Qp/Qs) ratio with doses of 100 μg/kg per minute.[92] Propofol causes loss of airway reflexes and causes respiratory depression but has the advantage of reduced postoperative delirium and postoperative nausea and vomiting compared with volatile agents.

Ketamine produces dissociative anesthesia while preserving airway reflexes and ventilation. It produces stable hemodynamics and, provided carbon dioxide is controlled, has no significant effect on pulmonary vascular resistance or pulmonary artery pressure in patients with pulmonary hypertension.[93] Disadvantages include dysphoria, nausea, prolonged recovery, and salivation. Furthermore, ketamine maintains cardiac output through stimulation of the sympathetic nervous system. A direct myocardial depressant

TABLE 22.2 Hemodynamic Calculations Using Cardiac Catheterization Data

Hemodynamic Variable	Equation	Normal Values
Oxygen consumption	$\dot{V}O_2 = (CO \times CaO_2) - (CO \times CvO_2)$	Age-, heart rate–, gender-dependent[a]
Flow		
Pulmonary	$Q_P = \frac{\dot{V}O_2}{(S_{PV}O_2 - S_{PA}O_2) \times Hgb \times 1.36 \times 10}$	L/minute per m^2: 3.5–5
Systemic	$Q_S = \frac{\dot{V}O_2}{(S_{AO}O_2 - S_{MV}O_2) \times Hgb \times 1.36 \times 10}$	3.5–5
Shunt flow ratio	$\frac{Q_P}{Q_S} = \frac{S_{AO}O_2 - S_{MV}O_2}{S_{PV}O_2 - S_{PA}O_2}$	1:1
Resistance		Wood units:
Pulmonary	$PVR = \frac{PAP - LAP}{Q_P}$	Newborns: 8–10 Older children: 1–3
Systemic	$SVR = \frac{AoP - RAP}{Q_S}$	Newborns: 10–15 Older children: 15–30

[a]LaFarge equation for $\dot{V}O_2$:
Boys $\dot{V}O_2 = 138.1 - [11.49 \times \log_e (\text{age in years})] + 0.378 (\text{heart rate})$
Girls $\dot{V}O_2 = 138.1 - [17.04 \times \log_e (\text{age in years})] + 0.378 (\text{heart rate})$
AO, aorta; *AoP*, aortic pressure; CaO_2, arterial oxygen content; *CO*, cardiac output; CvO_2, venous oxygen content; *Hgb*, hemoglobin; *LAP*, left atrial pressure; *MV*, mixed venous; O_2, pulmonary flow; Q_S, systemic flow; *PA*, pulmonary artery; *PAP*, pulmonary artery pressure; *PV*, pulmonary vein; *PVR*, pulmonary vascular resistance; *QP*, pulmonary blood flow; *QS*, systemic blood flow; *RAP*, right atrial pressure; $S_{AO}O_2$, aortic oxygen saturation; $S_{MV}O_2$, mixed venous oxygen saturation; SO_2, oxygen saturation; $S_{PV}O_2$, pulmonary venous saturation; *SVR*, systemic vascular resistance; $\dot{V}O_2$, oxygen consumption.

effect may be seen when it is administered to children whose sympathomimetic responses are already maximally stimulated.[94]

Opioids are a useful anesthetic adjunct that reduces both the required dose of other anesthetic agents and the pulmonary vascular response to noxious stimuli. Appropriate dosing should avoid the side effects of respiratory depression and hypercarbia. In general, these are not painful procedures; longer-acting opioids, however, may confer postprocedure sedation in addition to analgesia, as the children must remain recumbent for several hours to preclude bleeding from the femoral access sites. Remifentanil may offer an advantage in long catheterization procedures compared with other opioids as the short, context-sensitive half-time allows for rapid clearance and awakening. Bradycardia may be prevented by prophylactic administration of glycopyrrolate.[95] Local anesthetic infiltration around vessel cannulation sites can significantly limit the degree of procedural stimulus and further reduce anesthetic requirements. Maximum safe doses should be calculated according to the child's weight and communicated to the interventionalist to reduce the risk of local anesthetic toxicity (see Table 22.2).

Radiofrequency ablation procedures may be protracted, require immobility, and precipitate arrhythmias requiring defibrillation. For these reasons, general anesthesia is usually preferred, but many anesthetic agents affect cardiac conduction and may prevent the generation of preexcitation and automatic tachycardia. Dexmedetomidine has useful sedative, anxiolytic, and analgesic properties without effects on respiratory drive. It depresses sinus and atrioventricular nodal function, and avoiding its use in electrophysiology settings has been recommended.[96] However, a study using the different techniques of anesthetists at one institution has recently challenged this. Induction and ablation of arrhythmias was not inhibited using dexmedetomidine, although slightly higher doses of isoproterenol were required in the higher-dose group.[97] Controversy has surrounded the use of inhalational agents for the maintenance of anesthesia during ablation procedures but sound clinical data are scant. It appears that for preexcitation, isoflurane and sevoflurane have little effect at less than 1 MAC, whereas propofol and opioids have no demonstrable effects at any dose. In contrast, automatic tachycardia may be suppressed by large doses of propofol and opioids. In a prospective, randomized trial, isoflurane- and propofol-based anesthesia resulted in a similar duration of anesthesia and effectiveness of ablation.[98] Reducing the dose of anesthesia may limit some of the unwanted effects on conduction.

Principles of Technique

The most important principle of anesthesia in this setting is that the anesthetic practitioner has a sound knowledge and experience of CHD physiology and procedures and that the techniques used are reliable and are ones with which he or she is familiar. Attention to detail is critical for the provision of safe anesthesia. Consideration of preprocedural anxiolysis, fluid management, full monitoring, expert assistance, and choice of anesthetic technique is critical, in addition to generating a functional interaction with the rest of the catheterization team.

Careful attention to volume status is very important. Prolonged preoperative fasting can cause significant dehydration, particularly in small infants, and should be actively avoided. Hypovolemia is poorly tolerated in most children with CHD, particularly those with shunt-dependent circulations and those who are preload dependent such as children with single ventricle physiology. Prolonged procedures can be associated with gradual hypovolemia secondary to blood sampling, bleeding, and diuretic effects of contrast media. Volume overload is also a risk with liberal fluids and high-dose contrast, which may be poorly tolerated in children with congestive heart failure. Cyanotic patients or those with single ventricles are usually accustomed or benefit from a higher hematocrit, which needs to be taken into consideration when replacing fluid losses. Significant fluid replacement during diagnostic catheterization may affect filling pressures, gradient, and flow and should be communicated to the cardiologist.

Difficult IV access is prevalent in this patient population but reliable IV access is essential in case rapid resuscitation is required. Availability of ultrasound may facilitate access and intraosseous access should be available for emergency access (see Chapter 49). IV lines should ideally be placed in the upper extremities, as the femoral vessels are most commonly accessed for procedures in young children, and the presence of catheters may prevent reliable IV drug and fluid administration. Similarly, pulse oximetry and noninvasive blood pressure cuffs may be less reliable if placed on a limb used for cardiology access. Invasive central or arterial monitoring may be indicated for high-risk cases to monitor and treat any perioperative instability. During procedures to dilate the aortic arch or aortic valve, it may be prudent to have an arterial line (preferably a right radial line) to allow continuous blood pressure monitoring during the dilatation. If continuous arterial monitoring is not required from induction, arterial access obtained by the cardiologist for the procedure can sometimes be transduced for anesthetic monitoring using either a second stopcock or a slave monitor.

Problems associated with anesthesia-induced myocardial depression and hypotension are well recognized but inadequate anesthesia can create its own problems. Hemodynamic consequences of light anesthesia, such as hypoxia owing to laryngospasm, are poorly tolerated in children with pulmonary hypertension. Hypoxia or hypercapnia may lead to increasing pulmonary vascular resistance, which may increase cardiac shunts and further worsening hypoxia. Increased pulmonary hypertension may also lead to significant decreases in pulmonary compliance, further increasing hypoxia and precipitating a downward spiral.

Catheterization procedures often involve long periods of very little painful stimulation with discrete periods of increased painful stimuli, such as during dilation of arterial and venous vessels, sheath changes, or balloon dilation. By maintaining good communication between the cardiologist and anesthesiologist, these periods can be anticipated and the depth of anesthesia or sedation analgesia adjusted accordingly.

TEE is increasingly being used during diagnostic procedures and to guide intracardiac catheter placement. TEE insertion can be very stimulating and often requires a deeper plane of anesthesia with the addition of opioids, neuromuscular blockade, or both. A tracheal tube is required to ensure a patent airway during TEE, and care must be taken to avoid dislodging the tracheal tube during manipulations of the TEE probe.

Procedures in the catheterization laboratory can often be lengthy with limited access to the patient. Extra care should be taken to ensure careful positioning of the patient to avoid pressure areas and potential nerve injury. Patients' arms are frequently placed above the head to reduce image interference, and care must be taken to avoid excessive stretching, which can lead to brachial plexus injury.

Coughing and straining on extubation may increase the risk of hematoma formation. For this reason, deep extubation may be preferred. The advantages of deep extubation must be balanced against the risks of hypoxia, hypercapnia, and loss of airway control or laryngospasm that may ensue if the tracheal tube is removed before the child is fully awake.

Catheterization procedures are usually minimally invasive and are not associated with high levels of postprocedural pain. Simple analgesics, such as paracetamol, combined with local anesthetic infiltration are usually adequate. Opioids are rarely required for postoperative analgesia and may contribute to postoperative nausea and vomiting. Emergence delirium and postoperative restlessness may increase the risk of bleeding at catheter puncture sites. Additional analgesia or sedatives may occasionally need to be administered by the anesthesiologist in recovery to gain control of an agitated patient and prevent such complications.

Effective teamwork is critical to the safe and effective pediatric cardiac catheterization procedure. This is particularly important for high-risk children and complex procedures that may involve many multidisciplinary professionals. Good communication between the interventional cardiologist (and surgeon in hybrid procedures) and anesthesiologist should be maintained before and throughout the procedure to (1) plan and modify anesthesia and (2) anticipate any hemodynamic changes or adverse events. Often treatment of complications, such as bleeding or dysrhythmias, involves interventions using both cardiology and anesthesiology techniques. A good team approach is key to achieving the best possible patient outcomes.

FUTURE OF ANESTHESIA IN INTERVENTIONAL CARDIOLOGY

Anesthesia for interventional cardiac catheterizations will become more challenging as new interventions are developed for sicker children and more procedures are performed in combination with open surgery or MRI. As is often the case in pediatric practice, technologic advancements in cardiac catheterization have lagged behind those for the adult population. Focused development of smaller pediatric-appropriate devices will continue to expand the scope of pediatric interventional cardiology; promising potential for wider applications of transcatheter valve replacements is already on the horizon. More children are likely to require general anesthesia, and specialist pediatric cardiac anesthesiologists will be spending an increasing proportion of their time in interventional cardiology suites.

The ability to risk stratify children and procedures prospectively to accurately predict and potentially prevent adverse events is key to improving patient safety in the catheterization laboratory.[39] Significant progress has been made in this area with the development of the **C**atheterization **RIS**k **S**core for **P**ediatrics (CRISP) score (available online at http://www.pmidcalc.org/?sid=26527119&newtest=Y), which uses patient demographics, current physiologic status and procedural risk to predict the risk of adverse events for an individual child.[99] This ability is potentially invaluable both for assessing the level of resources and expertise required and informing anesthetic strategies to minimize risk of harm to the children we seek to care for.

ACKNOWLEDGMENT

We thank Drs. Geoffrey K. Lane and Adam Skinner for their previous contributions to this chapter.

Summary

THE NATURAL HISTORY OF CONGENITAL HEART DISEASE (CHD) has been favorably altered over the past several decades by remarkable advances in medical and surgical care. These refinements have resulted in decreased morbidity and improvement in long-term outcomes in affected children. As survival rates further improve and life expectancy continues to increase, an escalating number of children with CHD will present for noncardiac surgery or other procedures unrelated to their heart disease. The care of these children is becoming more common in all diagnostic and surgical settings.[1] As the trend for earlier palliation and corrective surgery for congenital cardiovascular malformations continues, children who have undergone these interventions represent the main patient group that an anesthesiologist is likely to encounter during elective, urgent, and emergent noncardiac surgery. In some cases, children may require noncardiac surgery before undergoing procedures to address their cardiovascular disease. In others, the cardiac condition may not require or be amenable to surgical intervention.

A variety of extracardiac anomalies have been described in children with CHD[2–6] and the reported prevalence of associated malformations ranges between 10% and 33%.[7–9] The organ systems most often affected include musculoskeletal, central nervous, renal-urinary, gastrointestinal, and respiratory. Although many extracardiac malformations are relatively minor and have limited or no clinical implications, a considerable number of children with CHD have significant noncardiac comorbidities.[10] These pathologic and disease processes may necessitate surgical intervention. Other routine ailments may affect these children, requiring diagnostic procedures and/or surgical care. In addition, chromosomal syndromes and genetic disorders, well known to be associated with CHD, may lead to conditions that necessitate anesthesia care.

The challenges of caring for children with CHD for noncardiac surgery are magnified by the wide range of structural malformations, each with specific physiologic perturbations, hemodynamic

consequences, and severity. This is further complicated by the variety of medical and surgical strategies available for management of these conditions. Many children, but particularly those with more than mild disease, require an individualized approach to anesthesia care.[11,12]

Clinical outcomes for CHD depend on the nature of the structural abnormalities and the possibility of successful palliation or correction.[13] The primary goal of palliative surgery is to favorably influence the natural history of the defect and decrease the likelihood of the severe consequences of the disease. However, these children continue to have abnormal cardiovascular anatomy and physiology, and their abnormal circulation is associated with an increased risk of perioperative adverse events.[14–17] Reparative, corrective, or definitive procedures are expected to improve hemodynamics and cardiac function while minimizing long-term ill effects of an abnormal circulation, improving the overall clinical outcome. Although the pathology might have been surgically treated, the cardiovascular system should not be considered normal. Therefore, repair of a congenital cardiac lesion should not be equated with a cure for many children.

Despite these considerations, for children with good hemodynamic results, the risks associated with noncardiac surgery may not be significantly different from those of others without CHD. These children are considered to be doing well clinically, have a good functional status, require few or no medications, have no exercise restrictions, and undergo routine surveillance. They require minimal or no adjustment in perioperative care compared with that provided to children without CHD. In others, however, residual abnormalities exist. In some who are less fortunate, a pathologic process may remain or develop after cardiac surgery that is related to the primary disease or therapy. This may lead to severe cardiovascular or pulmonary impairment. These residua and sequelae may necessitate further medical or surgical interventions and can increase perioperative morbidity during noncardiac surgery.[18] Management of these children is guided by several factors but to a significant extent by the residual problems of the disease and treatment and associated hemodynamic perturbations.[19]

Many publications have examined the implications of anesthesia for patients with CHD undergoing noncardiac surgery[11,19–37]; however, only a limited number provide data on perioperative outcomes.[38–45] In contrast to the extensive literature regarding perioperative cardiac assessment and risk stratification during noncardiac surgery in adults with heart disease, the availability of guidelines aimed at improving clinical outcomes, and the data regarding cardiac complications and cardiac risks of noncardiac surgery,[46–48] the lack of rigorous scientific data on this subject for the pediatric age group or the patient with CHD has made an equivalent effort challenging.[49]

Optimal anesthesia care for children with CHD requires a thorough understanding of the underlying cardiovascular anatomic abnormalities, pathophysiologic consequences of the defect, functional status, residua, sequelae, and expected long-term outcome, in addition to the planned procedure and potential complications. In this chapter, general principles of anesthesia practice are reviewed as they pertain to the care of children with CHD during noncardiac surgery. Unique perioperative considerations and issues applicable to high-risk patient groups are also addressed.

Preoperative Assessment

A detailed preoperative evaluation is indispensable for identifying and anticipating factors that may place a child with CHD at increased risk during anesthesia care (Table 23.1).[50,51] An important goal of this assessment is to gather information regarding the specifics of the cardiovascular disease and prior therapeutic interventions. A determination of functional status is based primarily on clinical data. The history and physical examination, in addition to the laboratory data and ancillary tests, provide complementary information about the structural cardiovascular malformations and hemodynamic status, enabling an overall risk assessment. Based on this clinical evaluation and consideration of the major pathophysiologic consequences of a particular condition, a systematic, detailed, organized plan is formulated for anesthesia and perioperative management. In some cases, the preoperative evaluation may establish the need to delay or defer elective noncardiac surgery, other interventions, or diagnostic procedures.

TABLE 23.1 Factors That Place Children With Congenital Heart Disease at Increased Risk During Anesthesia for Noncardiac Surgery

Anticoagulation therapy
Arrhythmias
Congestive heart failure
Emergent surgery
History of implanted device (pacemaker or defibrillator)
Hypoxemia
Long-standing cyanosis
Major noncardiac surgery
Older age at the time of cardiac intervention
Older type of cardiac surgical procedure
Pulmonary hypertension/pulmonary vascular disease
Significant outflow tract obstruction
Significant sequelae or residua
Single-ventricle physiology or complex defects
Syncope
Unrepaired pathology
Ventricular dysfunction
Young age (infancy)

An additional important aspect of the preoperative visit is that it provides an opportunity to initiate psychological preparation of parents and children before the planned intervention. Issues regarding expectations on the day of surgery in terms of premedication, the potential need for intravenous access, plans for induction of anesthesia, the estimated duration of the procedure, and postoperative recovery can be addressed at that time. In addition to the surgeon and anesthesia providers, other teams that may be part of this preoperative assessment may include the child's cardiologist, nursing, social work, child-life specialists, and other support services.

HISTORY AND PHYSICAL EXAMINATION

As for all children undergoing anesthesia, the history and physical examination are essential components of a thorough preoperative evaluation. In addition to the details regarding the present illness and planned procedure, the history should focus on the status of the cardiovascular system. Relevant information includes the type of cardiovascular disease and comorbid conditions, medications, allergies, prior hospitalizations, surgical procedures or other interventions, anesthesia experiences, and complications. Symptoms, including tachypnea, dyspnea, tachycardia, fatigue, and those

related to rhythm problems, should be sought. Feeding difficulties and diaphoresis can represent significant symptoms in infants, whereas decreased activity level or exercise intolerance may be a concern for older children. Palpitations, chest pain, and syncope should be characterized. The history should include an assessment of growth and development because these may be affected in children with CHD. Failure to thrive suggests ongoing cardiorespiratory compromise. Those with decompensated disease, complex pathologies, associated genetic defects, or other syndromes may be particularly vulnerable. Recent illnesses such as intercurrent respiratory infections or pulmonary disease may increase the potential for perioperative complications and require careful appraisal of the risk/benefit ratio in elective cases.[52,53]

The physical examination should include the child's weight and height. Vital signs, including heart rate, respiratory rate, and blood pressure, should be documented. If the child is known or suspected to have or has been treated for any form of aortic arch obstruction or has had any systemic-to-pulmonary artery shunt, upper and lower extremity and the right and left upper extremity blood pressure recordings and palpation of the quality of pulses should be documented. This assessment provides information about the patency of arterial beds and helps in the selection of blood pressure monitoring sites. The examination should explore suitable sites for vascular access (venous and arterial) and identify potential difficulties. Emphasis should be given to the airway and cardiovascular system, with particular attention to any changes from previous examination findings.

General assessment includes the child's level of activity, breathing pattern, level of distress (if any), and presence/degree of cyanosis. Respiratory evaluation focuses on the quality of the breath sounds and should indicate the presence or absence of labored breathing, intercostal retractions, wheezing, rales, or rhonchi. Abnormalities may suggest congestive symptoms or a pneumonic process. Cardiac auscultation should include assessment of heart sounds, pathologic murmurs, and gallop rhythms. The presence of a thrill, representing a palpable murmur, should be documented. The abdomen should be examined for the presence of hepatosplenomegaly. Assessment of the extremities should include examination of pulses, overall perfusion, capillary refill, cyanosis, clubbing, and edema. Noncardiac anomalies or pathology that may affect anesthesia care (e.g., specific syndrome complex, potentially difficult airway, gastroesophageal reflux) should be recorded.

An important objective of the preoperative evaluation is to identify children with functional cardiopulmonary limitations imposed by their cardiovascular disease. Symptoms and signs consistent with congestive heart failure, cyanosis, hypercyanotic episodes, and compromised functional status (i.e., significant exercise intolerance or syncopal episodes) should raise concerns about potential perioperative problems. The pediatric cardiologist should facilitate information about the nature and severity of the cardiovascular pathology, describe the child's overall clinical status, and assess prior complications. The cardiologist should identify those children who may be at increased risk and optimize their preoperative clinical condition. The perioperative care teams should be alerted to any concern that may affect the care of the child. The anesthesiologist should have a detailed understanding of the child's cardiac defect, pathophysiologic consequences, nature of the medical and surgical therapies applied, functional status, and implications for perioperative management. In patients at increased risk, pediatric anesthesia consultation is recommended before the procedure. In some cases, based on this assessment, an inpatient setting may be favored over an outpatient surgical facility. Although the surgical team may not have an in-depth understanding of the child's cardiovascular disease, by discussing the details of the surgical plan and potential issues with the perioperative care providers, problems can be anticipated and proactively addressed.

ANCILLARY STUDIES AND LABORATORY DATA

The baseline systemic arterial saturation value should be determined by pulse oximetry (SpO_2) when the child is calm and, in most cases, while breathing room air. Acceptable values depend on many factors, including the specific cardiovascular defect(s), whether the child has a two- or a one-ventricle circulation, the preoperative versus postoperative status with respect to the cardiac pathology, and the stage in the palliative pathway for those undergoing such a strategy. Children who have undergone definitive (corrective) procedures should be expected to have normal to a near-normal SpO_2 value (at least 95%). After palliative interventions, SpO_2 values typically range between 75% and 85%.

The extent of preoperative laboratory testing largely depends on the status of the patient and the type, anticipated duration, and complexity of surgery. Studies most commonly obtained include hematocrit, hemoglobin, electrolytes, and coagulation tests. In cyanotic children, a complete blood cell count allows determination of polycythemia, anemia, and thrombocytopenia. Prothrombin time, partial thromboplastin times, and international normalized ratio (INR) provide an indication of clotting ability. Cyanotic children usually have increased red blood cell mass and relatively small plasma volumes. The collection of specimens for coagulation tests requires sampling tubes that adjust the amount or concentration of citrate to prevent artifactually prolonged values. For those receiving diuretic therapy, digoxin, or angiotensin-converting enzyme inhibitors (ACEIs), the determination of a basic metabolic panel can be useful. A comprehensive metabolic panel that assesses electrolyte and acid-base balance, the health of the kidneys and liver, as well as concentrations of blood glucose and blood proteins may be more appropriate in some cases. Blood typing and cross-matching should be performed depending on the anticipated need for blood administration.

A recent electrocardiogram (ECG) should be reviewed for any changes from prior studies (particularly regarding criteria consistent with chamber dilation or ventricular hypertrophy), the presence of rhythm abnormalities, and findings suggesting myocardial ischemia. If an arrhythmia is identified on the preoperative assessment, further evaluation is warranted because it may reflect an underlying hemodynamic abnormality that may affect the perioperative course. A continuous ECG recording (i.e., Holter monitor) and further evaluation may be indicated in the child with a history of rhythm disturbance, palpitations, or syncope or with an ECG suggesting significant ectopy or arrhythmia. An exercise tolerance test or treadmill study is warranted if there is concern about myocardial ischemia, as may be the case for the child with aortic stenosis, coronary artery anomalies, or exercise-induced arrhythmias.

Review of a recent chest radiograph, including a lateral view, provides information regarding cardiac size, chamber enlargement, and pulmonary vascularity. Prior studies such as echocardiograms, cardiac catheterizations, electrophysiologic procedures, magnetic resonance imaging, and computed tomography should be reviewed. In some cases, it may be necessary to obtain further diagnostic information before proceeding with the planned procedure if there are symptoms that merit additional investigations or issues of concern. These evaluations should be coordinated with the

child's cardiologist. It is also important to consider whether the child would benefit from cardiac catheterization to undertake interventions addressing significant structural, functional, or hemodynamic abnormalities before the anticipated noncardiac procedure. In addition to providing potentially helpful information, the clinical status of the child can be substantially improved in many cases by catheter-based interventions. This may be of significant benefit when the planned procedure is of an elective nature and considered to be major.

One of the goals of the preoperative evaluation is to obtain the most diagnostic information with the fewest tests and the least risk, discomfort for the child, and expense. The anesthesiologist is particularly suited to determine which tests are appropriate for optimal perioperative planning and whether additional data are needed.

INFORMED CONSENT

The physicians involved in the care of the child should meet with the patient and family to discuss the anesthetic plan and answer any questions. The preoperative consultation provides the opportunity to alleviate patient and parental anxiety. At the same time, the possible benefits and risks involved should be discussed. Although anesthesia and surgery in children with CHD, particularly in those with uncorrected defects, may carry an increased risk, it may not be possible to define the specific contribution of each factor to the overall risk.

FASTING GUIDELINES

The optimal period of fasting for children before surgery has been the subject of debate.[54–59] However, most centers follow guidelines established by their national societies to reduce the risk of aspiration. The same principles are applicable to children with CHD with a few additional considerations. Intake of clear fluids or the intravenous (IV) administration of maintenance fluids should be considered in some children to ensure adequate hydration if the fasting period is anticipated to be prolonged. This is particularly important in small infants and in children with obstructive pathology, cyanotic disease, or single-ventricle physiology. Maintenance of adequate hydration and ventricular preload may minimize potential detrimental hemodynamic changes associated with anesthesia and surgery.

MEDICATIONS

Children with CHD may be taking medications on a regular basis. Although there may be an occasional exception, such as diuretic, vasodilator (e.g., ACEI), or anticoagulation therapy, there is usually no need to discontinue long-term medications before surgery. It is often important to continue these drugs until the time of surgery, and in most centers, children are allowed to take scheduled oral medications with small sips of water preoperatively.

Intraoperative Management

Anesthesia and surgery impose additional stresses on the cardiovascular system and provoke compensatory mechanisms to maintain homeostasis. It is important to assess the child's physiology and cardiovascular reserve to anticipate his or her ability to increase cardiac output to meet metabolic demands and procure optimal oxygen delivery. This information, along with the nature and complexity of the surgery, affects the extent of monitoring required and the selection of anesthetic agents and techniques. Prompt intervention is imperative if decompensation occurs. Good communication among the surgeon, cardiologist/intensivist, anesthesiologist, and nursing teams during the entire perioperative period is essential in treating children with complex disease.

GENERAL CONSIDERATIONS

Anesthesia Care Provider and Health Care Facility

Anesthesia care should be provided by individuals who are familiar with children with CHD, the planned operative procedure, and the surgeon's usual approach. Although many specialized centers that care for children have dedicated pediatric cardiac anesthesiologists, they may not be available at all facilities. Even if these providers are available, the number might be limited and they may not be able to support all noncardiac cases; in some instances, this type of advanced expertise may not be required. The most important factor that an anesthesiologist can offer a child with CHD is a comprehensive understanding of the anatomic abnormalities, pathophysiology of the cardiac malformation, and how this may be affected by the anesthetic and surgical procedure. Familiarity with the most likely residua and sequelae is essential.[18] Adequate communication among all physicians involved enhances the likelihood of the best possible outcome.

Recent publications have addressed one of the ongoing controversies in CHD—namely, which medical facility should provide care for these patients during noncardiac surgery.[36,60,61] Data regarding this specific issue and support for a strong recommendation are otherwise extremely limited. It has been suggested that high-risk children should be cared for at specialized centers.[36,60] A recent outcome review concluded that procedures requiring general anesthesia could be performed safely in children from any of the three risk groups in a noncardiac center with the caveat that this requires close communication and careful planning among the various specialties.[61] Further data in this regard are necessary.

Premedication

The use of premedication provides sedation and anxiolysis before most surgical procedures because some degree of fear or anxiety is expected. This facilitates parental separation, entry into the operating room, placement of monitors, and induction of anesthesia.

Commonly used premedications include oral or IV benzodiazepines, opioids, and small amounts of hypnotic agents. Drugs such as barbiturates and ketamine are occasionally used. Alternative routes for premedication include intramuscular, intranasal, and rectal. The cardiorespiratory effects of premedication in children can be influenced by the underlying systemic disease.[62–66] Children with marginal clinical status or hemodynamic decompensation may require little or no premedication. Caution should also be exercised in children with a history of cardiovascular pathology associated with pulmonary hypertension because hypoventilation and hypoxemia can be detrimental. Conversely, children susceptible to hypercyanotic episodes or those with catecholamine-induced arrhythmias can benefit from heavy premedication. In selected children, for example those affected by cyanotic heart disease, oxygen saturation monitoring after premedication should be considered with the administration of supplemental oxygen as needed.[63]

Intravenous Access

Secure IV access is mandatory for administration of fluids and medications during anesthesia care in children with CHD. In most, IV access is established after an inhalational induction. In those considered at great risk, such as children with severe ventricular

outflow tract obstruction, moderate to severe cardiac dysfunction, pulmonary hypertension, or potential for hemodynamic compromise, consideration should be given for placement of IV access before induction of anesthesia or very early in the process. The size of the IV catheter should be determined by the anticipated fluid/transfusion requirements. If peripheral access is poor, central venous access may be necessary, particularly if there is potential for large intravascular volume shifts and to allow monitoring of central venous pressure. Placement of a central venous catheter is assisted by two-dimensional ultrasound imaging or audio Doppler (see Chapter 49). In the small infant with single-ventricle physiology, central venous cannulation with catheter placement in the superior vena cava may be undesirable in view of concerns about potential vascular complications that may affect pulmonary blood flow or subsequent surgical palliation. In these children, a small catheter or alternative approach (e.g., femoral venous access) should be considered. In children with an existent or potential right-to-left shunt, all air must be removed from IV infusion tubing. Air filters can be difficult to use in the operating room because they potentially restrict the rate at which IV fluids or blood may be administered in emergency situations. They can be more useful in the preoperative and postoperative periods.

Emergency Drugs

Hemodynamic instability can occur in children with CHD under any circumstance and at any time. Therefore drugs for emergency situations should be prepared in advanced or be immediately available to the anesthesiologist providing care.

MONITORING

A fundamental principle of intraoperative monitoring is to use techniques or devices that provide useful information to facilitate clinical decision making and to avoid monitors that are distracting or redundant. Basic monitoring involves observation of the child, including skin color, capillary refill, respiration, pulse palpation, events on the surgical field, and color of shed blood. Standard noninvasive monitors used during most surgical interventions include oscillometric blood pressure assessment, electrocardiography, pulse oximetry, capnography, and temperature recordings. A precordial stethoscope can be extremely helpful for monitoring changes in heart tones that may suggest early hemodynamic compromise. In the child with CHD, relatively sophisticated and invasive monitoring may be needed.

Arterial Blood Pressure Assessment

Blood pressure monitoring begins with pulse palpation. An automated blood pressure measurement is used in most children. The selection of monitoring site is influenced by vascular anomalies (e.g., aortic arch pathology, aberrant origin and course of aortic arch vessels) or prior surgical interventions (e.g., Blalock-Taussig shunt, arterial cutdown). Direct blood pressure monitoring by an indwelling arterial catheter may be necessary for beat-to-beat assessment and for blood gas analysis. In most children, this is accomplished after induction of anesthesia. Percutaneous arterial cannulation can be achieved in most cases with a low risk of complications (see Chapter 49). The radial artery usually is preferred over the ulnar artery because avoiding the ulnar artery allows preservation of a larger contributor of blood supply to the hand. The ulnar artery often is the larger vessel and it can be cannulated if required. However, some centers have a policy that the ulnar artery should never be cannulated. This policy ensures that there is always at least one vessel (ulnar artery) available to perfuse the hand should the radial vessel be compromised. Ultrasound guidance with two-dimensional imaging or audio Doppler can facilitate cannulation. The need for invasive monitoring is largely based on the child's clinical condition and nature of the surgical procedure.

Electrocardiography

The ECG provides a surface recording of the electrical myocardial activity and is used to monitor heart rate, cardiac rhythm, and ST-segment analysis. One or multiple leads typically are displayed. Arrhythmias can occur because of hypoxia, electrolyte imbalances, acid-base abnormalities, intravascular or intracardiac catheters, and surgical manipulations near or around the thorax. Ischemia may be evident on direct examination of the ECG or ST-segment analysis.[67,68] Although in adults this is associated with worsened outcome, the implication for the pediatric population is unknown.[67,69]

Pulse Oximetry

Placement of an oximeter probe is well tolerated, even by uncooperative children, and it is usually one of the earliest monitors applied during induction of anesthesia. Monitoring arterial oxygen saturation by pulse oximetry is particularly useful in infants, cyanotic children, and those with complex anatomy or significant hemodynamic compromise. In addition to providing continuous assessment of oxygen-hemoglobin saturation and heart rate, the pulse oximeter waveform can indicate the adequacy of peripheral perfusion and cardiac output.[70,71] Other parameters that can be reflected by the Sp_{O_2} include intracardiac or great artery–level shunting and pulmonary blood flow.

Capnography

Capnography confirms proper tracheal tube placement, helps to assess the adequacy of ventilation, and aids in the recognition of pathologic conditions such as bronchospasm, airway obstruction, and malignant hyperthermia. Capnography is also useful in spontaneously breathing, sedated children receiving supplemental oxygen through a nasal cannula; a prospective, observational study in children undergoing cardiac catheterization with sedation administered by nonanesthesiologists found that exhaled carbon dioxide values (P_{ETCO_2}) provided a reasonable estimate of arterial blood CO_2 values.[72] Although the absolute value for P_{ETCO_2} may not be as reliable as in the presence of a tracheal tube, the capnograph waveform confirms the presence or absence of respirations and air exchange. End-tidal CO_2 monitoring also provides a gross index of pulmonary blood flow. In children with cyanotic heart disease, P_{ETCO_2} values can underestimate arterial carbon dioxide tension (Pa_{CO_2}) measurements owing to altered pulmonary blood flow and ventilation-perfusion mismatch.[73,74]

Temperature Monitoring

Temperature should be routinely monitored during most procedures. Although temperature swings are usually not profound, some children, particularly small neonates, may become hypothermic because of the large body surface area/body weight ratio and decreased amount of subcutaneous tissue. This can influence oxygen delivery (i.e., increased oxygen consumption) and emergence from anesthesia, cause detrimental changes in hemodynamics, and affect hemostasis. The neonate or small infant with CHD can be particularly vulnerable to the effects of hypothermia.

Urinary Output Measurements

The production of urine is a useful index of the adequacy of renal perfusion and cardiac output. Urine output is usually monitored during cases involving major fluid shifts or blood loss or when the surgical procedure is expected to be prolonged. No specific value for intraoperative urine output is predictive of good renal function in the postoperative period.

Echocardiography

Numerous publications have documented the utility of transesophageal echocardiography in general anesthesia practice[75] and as a monitoring device in high-risk adults undergoing noncardiac procedures.[76–88] Sporadic reports have demonstrated the utility of this imaging approach in children undergoing noncardiac surgery.[89–92] However, the application of this imaging modality in the pediatric age group or contributions in this particular setting has not been well defined and deserves further investigation.

Newer Technologies

Of significant interest over the past several years has been the use of point-of-care ultrasonography in various settings, including the perioperative period.[93,94] This is an evolving field that is receiving increasing attention during noncardiac surgery.[95] Continuous noninvasive cardiac output assessment represents an area of ongoing investigation in children using a variety of techniques.[96–98] These monitoring modalities are likely to further enhance the practice of pediatric anesthesia in the future.

SELECTION OF TECHNIQUES AND AGENTS

Several anesthetic regimens have been used in children with CHD undergoing noncardiac surgery and studies or procedures that require deep sedation or immobility. Although no single formula or protocol is recommended, the anesthetic techniques and agents used for a particular situation should be selected in consideration of the procedure, the child's disease process and functional status, and the impact of the hemodynamic effects of the anesthetic and procedure on the pathophysiologic process. Factors such as age, physical characteristics, and preferences of the anesthesiologist must be considered. The primary goals of anesthesia management with respect to the cardiovascular system are to optimize systemic oxygen delivery, maintain myocardial performance within expected parameters for the patient, and ensure the adequacy of cardiac output. A potentially limited cardiovascular reserve, reduced tolerance for perioperative stress, and detrimental alterations of the balance between pulmonary and systemic blood flow during anesthesia and surgery should be considered. A carefully titrated anesthetic, regardless of the specific agent or drug, should be the goal.

Anesthesia Technique

General anesthesia has the advantages of wide acceptance, ease of application, and certainty of effect. It is the appropriate choice for most children undergoing noncardiac surgery. Disadvantages include a greater potential for wide fluctuations in the hemodynamics and a prolonged recovery period. The IV route allows for rapid induction of anesthesia. If IV access is not available, inhalational induction can be performed. Inhalational anesthetics dilate vascular beds and reduce sympathetic responsiveness. These are desirable goals for most children, even those with heart disease, because adequate myocardial function and a reactive sympathetic nervous system are usual. However, sick children, and in particular those with ventricular dysfunction, may require an increased resting sympathetic tone to maintain systemic perfusion. Potent inhalational agents in this setting can further impair myocardial function, decrease sympathetic tone, and potentially lead to cardiovascular decompensation. These children and others with a relatively fixed cardiac output frequently require a technique that combines several medications (i.e., balanced technique) to achieve anesthesia while minimizing the risk of hemodynamic compromise. A combined opioid, amnestic agent, and muscle relaxant technique minimizes myocardial depression and tends to leave sympathetic responsiveness intact while providing analgesia, amnesia, and immobility.

Regional anesthesia has been used safely and shown to be effective in children with CHD (see Chapters 42 and 43).[99–102] Advantages of regional anesthesia, such as epidural and spinal techniques, include an effect largely limited to the surgical site, decreased number of systemic medications, a potentially brief recovery period, and usually a more pleasant experience for the child. Use of these techniques, however, may not always be effective. Regional anesthesia retains the potential for hemodynamic alterations, particularly in hypovolemic children or those with a fixed cardiac output. It is also contraindicated in those with coagulation defects. The administration of agents such as local anesthetics, opioids, or other adjuvants (e.g., clonidine) into the caudal space can attenuate the sympathetic outflow associated with surgical manipulation and noxious stimuli and facilitate postoperative pain management.

The choice of technique affects the termination of anesthesia and emergence. Anesthesia performed with fewer agents is inherently simpler, usually easier, and more predictable to terminate. The availability of ultra-short-acting opioids (e.g., remifentanil) and other agents (e.g., dexmedetomidine) has avoided the need for postoperative ventilation solely related to residual effects of depressant drugs. Ventricular function and the presence of intracardiac shunts can significantly affect uptake and distribution of inhalational anesthetics and the kinetics of IV medications (see Chapter 7).

Inhalational Agents

Inhalational anesthesia has been at the forefront of pediatric anesthesia practice for many years.[103,104] Sevoflurane was introduced in the mid-1990s, replacing halothane for inhaled induction in many centers. A study on the safety and efficacy of inhaled agents in infants and children with CHD during cardiac surgery demonstrated twice as many episodes of hypotension, moderate bradycardia, and emergent drug use in those who received halothane compared with those given sevoflurane.[105] These data, combined with those from other studies that demonstrated the potential benefits of sevoflurane on hemodynamic stability and minimal impact on myocardial performance, led to sevoflurane becoming the preferred anesthetic agent for children, particularly those with heart disease.[106–110] Nonetheless, in some jurisdictions and under some conditions, halothane may remain the primary anesthetic for children. After an inhalational induction with sevoflurane, agents such as isoflurane or desflurane might be used to maintain anesthesia.

Intravenous Agents

Propofol is one of the most frequently used medications for IV sedation and general anesthesia. It has been used in children with CHD in numerous settings.[111–114] The hemodynamic effects of propofol have been investigated in children with normal hearts and in those with cardiovascular disease. An echocardiographic

study in infants with normal hearts undergoing elective surgery demonstrated that propofol did not alter heart rate, shortening fraction, rate-corrected velocity of circumferential fiber shortening, or cardiac index after IV induction.[115] However, propofol decreased arterial blood pressure to a greater extent than thiopental, an effect attributed to a reduction in afterload. A comparison of propofol and ketamine during cardiac catheterization found that propofol caused a transient decrease in mean arterial pressure and mild arterial oxygen desaturation in some children.[116] In view of the significantly faster recovery, propofol was identified as a practical alternative to ketamine for elective cardiac catheterization in children.

Another investigation in 30 children with CHD undergoing cardiac catheterization demonstrated significant decreases in mean arterial blood pressure and systemic vascular resistance during propofol administration.[111] No changes in heart rate, mean pulmonary artery pressure, or pulmonary vascular resistance were observed. In children with intracardiac shunts, the net result of propofol was a significant increase in the right-to-left shunt, a decrease in the left-to-right shunt, and a decreased pulmonary/systemic blood flow ratio, resulting in a statistically significant decrease in the PaO_2 and arterial oxygen saturation (SaO_2), as well as reversal of the shunt direction from left-to-right to right-to-left in two patients. It was also shown that propofol could lead to further arterial desaturation in children with cyanotic heart disease. A recent study examined the effects of propofol on cerebral oxygenation in children with CHD.[117] Propofol sedation was associated with increased cerebral tissue oxygenation despite a significant decrease in mean arterial pressure, stroke volume, cardiac output, and cardiac index. The authors reported that the hemodynamic changes were not considered clinically relevant and none required intervention.

The effects of propofol have been examined in children undergoing electrophysiologic testing and radiofrequency catheter ablation for tachyarrhythmias. The drug has no significant effect on sinoatrial or atrioventricular (AV) node function or accessory pathway conduction in Wolff-Parkinson-White syndrome.[118,119] However, another study documented that ectopic atrial tachycardia can be suppressed during propofol administration in children.[120]

Collectively, these data support the judicious use of propofol in children with adequate cardiovascular reserve who can tolerate mild decreases in myocardial contractility and heart rate and mild to moderate decreases in systemic vascular resistance. Given the effects of propofol on the direction and magnitude of intracardiac shunts, this might be an important consideration in children with cyanotic heart disease and can influence the hemodynamic assessment of those undergoing evaluation of pulmonary/systemic blood flow ratios in the cardiac catheterization laboratory.

Sodium thiopental, a rapid-onset short-acting barbiturate, was used for many years for induction of anesthesia. The last company to market sodium thiopental in the United States stopped production of the drug in early 2011. Several investigations documented the cardiovascular responses to this agent; in children with normal hearts, the cardiac index remained unchanged, although the shortening fraction decreased along with alterations in load-independent parameters of contractility. The data regarding myocardial depressant properties of barbiturates and its effects on venodilation and peripheral blood pooling suggested that the administration of thiopental in a subset of children could cause hemodynamic instability. Thus it was recommended that thiopental should be used with caution, particularly in those with limited reserve or increased sympathetic tone.

Etomidate, a carboxylated imidazole derivative, has anesthetic and amnestic properties but is devoid of analgesic effects. This agent demonstrates favorable qualities over other IV drugs because of its lack of effect on hemodynamics.[121,122] This, combined with laboratory and clinical data that support minimal effects on myocardial contractility, makes this drug a particularly desirable agent in critically ill individuals and in those with limited cardiovascular reserve.[123] Despite these benefits, several undesirable adverse effects are associated with etomidate, including pain on IV administration, myoclonic movements that may mimic seizure activity, and inhibition of adrenal steroid synthesis perioperatively.[124,125] Although used primarily as an induction agent, etomidate has been administered for sedation of children during cardiac catheterization and in other settings.[126–128]

Ketamine is a dissociative anesthetic agent administered by the IV, intramuscular, nasal, rectal, and oral routes. Because its sympathomimetic effects result in an increased heart rate, blood pressure, and cardiac output, this drug has been widely used in children with heart disease, particularly in young infants. The effects of this agent on systemic vascular resistance make it a suitable choice in children with right-to-left shunts because pulmonary blood flow is enhanced. This contrasts with inhalational agents, which by causing systemic vasodilation can decrease pulmonary blood flow in the presence of an intracardiac communication and potentially worsen the degree of cyanosis. In clinical use, however, arterial oxygen saturation typically increases with both agents. Additional favorable properties include intense analgesia at subanesthetic doses and a lack of respiratory depressant effects.

Several investigations have addressed the concern of potential detrimental changes in pulmonary vascular tone resulting from ketamine, although no significant effects have been reported on pulmonary arterial pressures and pulmonary vascular resistance at the usual clinical doses.[129–132] Regarding its effect on myocardial performance, in vitro investigations have shown a direct myocardial depressant effect in animal species and the failing adult human heart. This is considered to be the result of inhibition of L-type voltage-dependent calcium channels in the sarcolemmal membrane and may be a consideration in the critically ill infant with a severely impaired cardiac reserve. Additional undesirable effects of ketamine include emergence reactions, excessive salivation, vomiting, and increased intracranial pressure.

Dexmedetomidine is a selective α_2-adrenergic agonist agent being increasingly used in the pediatric age group. Compared with clonidine, the drug exhibits greater specificity for the α_2-adrenergic receptor over the α_1-adrenergic receptor. Favorable effects of the drug include sedation, anxiolysis, and analgesia. This medication provides hemodynamic stability, although adverse effects have been reported, including bradycardia, hypertension, and hypotension. A study of the hemodynamic effects in children undergoing dexmedetomidine sedation for radiologic imaging demonstrated modest decreases in heart rate and blood pressure. These changes in response to moderate doses were independent of age, required no pharmacologic interventions, and did not result in any adverse events; however, high-dose dexmedetomidine can be associated with significant bradycardia.[133,134] In addition, treatment of dexmedetomidine-induced bradycardia with glycopyrrolate (5 μg/kg) has been associated with severe persistent hypertension.[135]

Dexmedetomidine is used as a premedication agent during diagnostic studies and procedural sedation, to reduce emergence delirium, in the treatment of symptoms associated with opioid withdrawal, and as an adjuvant agent in the operating room and

postoperative settings.[136] In children with CHD, its benefits have been reported during monitored anesthesia care, diagnostic and interventional cardiac catheterization, intraoperative sedation, after cardiac and thoracic surgery, as a primary agent during invasive procedures, and in the treatment of perioperative atrial and junctional tachyarrhythmias.[137–145] The drug has also been used in children with pulmonary hypertension with good results.[146,147]

Known electrophysiologic effects of dexmedetomidine in children include significant depression of sinus and AV nodal function.[148] Other findings include a reduction in the heart rate and increases in arterial blood pressure. Although dexmedetomidine has been described as an undesirable agent for electrophysiologic studies because it could be associated with adverse effects in patients at risk for bradycardia or AV block,[148] another study reported that dexmedetomidine was not associated with any significant or atypical ECG interval abnormalities, except for a trend toward a decrease in heart rate in children with CHD.[149] Until additional data are available, it may be prudent to exercise caution when considering the use of dexmedetomidine in children with conduction abnormalities. Although experience suggests an overall safety profile in children with CHD, fragile patients may not tolerate the heart rate and blood pressure fluctuations associated with dexmedetomidine; significant adverse effects include severe bradycardia progressing to asystole.[150]

Opioids and *benzodiazepines* are widely used medications in pediatric anesthesia practice. Opioids attenuate the neuroendocrine stress response associated with anesthesia and surgery.[151,152] After repair of CHD, these medications blunt the stress response in the pulmonary circulation elicited by airway manipulations.[153] Morphine administration can cause histamine release and vasodilation. The synthetic opioids are devoid of these effects and provide excellent hemodynamic stability with minimal changes in heart rate and blood pressure in children with CHD.[154] The primary concern about opioid administration is their central respiratory depressant effects because their primary cardiovascular manifestations are minimal. Benzodiazepines provide sedation and amnesia during the perioperative period. Midazolam may allow a reduction in the inspired concentration of inhalational anesthetic agents, which is a desirable feature in children with labile hemodynamics or in those considered at great risk for the myocardial depressant properties of inhalational anesthetics. Studies of the effects of benzodiazepines in children with CHD are limited.[155]

Neuromuscular blocking drugs facilitate tracheal intubation and prevent reflex movement during surgery if the anesthetics alone are insufficient. All inhalational anesthetics potentiate the effects of nondepolarizing muscle relaxants. These medications have various onsets and durations of action and diverse hemodynamic effects. The cardiovascular and autonomic effects of muscle relaxants have been characterized mainly in adults with acquired cardiovascular disease (see also Chapter 7).[156–159] Drug selection is based on the need to facilitate tracheal intubation and surgical relaxation, hemodynamic side effects, and the anticipated duration of surgery.

INDUCTION OF ANESTHESIA

Induction of anesthesia in children with CHD most commonly can be accomplished using the inhaled or IV route. The intramuscular route (i.e., ketamine administration) may be preferable in some cases, particularly in an uncooperative, developmentally delayed, or combative child. Less common induction techniques include subcutaneous, intranasal, and rectal administration of induction or sedative agents. These various approaches may also be used in combination (see Chapter 4).

An IV induction is preferable in some children in view of its potentially greater safety margin. In addition to the ability to titrate medications and rapidly correct hemodynamic alterations, other benefits include the speed of effect, although this may be slowed in children with large left-to-right shunts owing to recirculation of the drug in the lungs. Left-to-right shunting decreases the concentration of anesthetic agents reaching the brain and delays its onset of action. In contrast, right-to-left shunts speed IV inductions because a significant portion of the medication bypasses the lungs (where it is degraded) and directly enters the systemic circulation, reaching the brain more rapidly than with an intact circulation.

If IV access is not available, an inhalational induction is performed in most cases. A carefully titrated inhalational induction and early placement of an IV catheter usually is safe, even in children with moderate hemodynamic disturbances, particularly after premedication has been given. This produces loss of consciousness, with acceptable conditions for establishing IV access. Inhalational induction can be delayed in cyanotic children and those with right-to-left shunts, particularly for anesthetics with reduced blood solubility, because the decreased pulmonary blood flow limits the rate of increase in the concentration of the anesthetic in the systemic arterial blood. The rapidity of an inhalational induction is increased in the presence of a reduced cardiac output because the anesthetic partial pressure in the alveoli increases more rapidly as less anesthetic is removed by the smaller pulmonary blood flow (see Chapter 7). Left-to-right intracardiac shunts have limited effects on the speed of induction of inhaled anesthetics.

MAINTENANCE OF ANESTHESIA

After induction, anesthesia can be maintained using an inhalational, IV, or combined inhalational and IV technique. In children with CHD, anesthesia can result in hemodynamic changes regardless of the technique, agents, or experience of the anesthesiologist. Some children may not tolerate even minor alterations in hemodynamics. Factors that may lead to cardiovascular collapse in the marginally compensated child include hypovolemia, relative anesthetic overdose, increased vagal tone, positive-pressure ventilation, hypoxemia, airway obstruction, alterations in $PaCO_2$ or other factors that influence the balance between systemic and pulmonary blood flow, myocardial ischemia, arrhythmias, and anaphylaxis. The anesthesiologist should be prepared to manage these rare but occasionally unavoidable occurrences at any time.

EMERGENCE FROM ANESTHESIA

Most children undergoing noncardiac surgical interventions are expected to awaken immediately at the completion of the procedure or shortly thereafter. This usually involves reducing and then discontinuing IV or inhalational anesthetics, antagonizing neuromuscular blockade, and extubating the trachea. Ensuring the return of protective reflexes and monitoring the adequacy of the airway and respirations are important considerations.

Postoperative Care

The postoperative management of the child with CHD involves many of the same physiologic principles applicable to intraoperative care. The extent of the postoperative care, optimal place for recovery, and need for monitoring and hospitalization depend in large part on the child's clinical condition and type and extent

of the procedure. Immediately after surgery, most children awaken from anesthesia and recover from neuromuscular blockade, which may impose various stresses and hemodynamic changes. Adequate oxygenation and ventilation along with airway protection must be ensured and may need to be provided if the child cannot manage these functions on his or her own. Significant hypoventilation must be avoided during this time because it may negatively affect pulmonary vascular tone and overall hemodynamics in vulnerable children with CHD. Adequate pain control and, sometimes, sedation are important postoperatively. This may be a challenging issue for the child who requires noncardiac surgery soon after a prolonged hospitalization in view of the increased likelihood for tolerance to analgesic and sedative drugs.

Observation and physical examination provide much information about the child's respiratory status, cardiac function, and systemic perfusion during the postoperative period. Adequacy of oxygenation and ventilation can also be assessed with noninvasive monitoring and blood gas analysis. Monitoring urine output can be helpful.

Hemoglobin or hematocrit values are monitored as a measure of oxygen-carrying capability in cases in which significant blood loss or the administration of fluids might have occurred. Serum electrolytes are screened if fluid shifts have taken place during the surgical and/or postoperative periods. Although digoxin is now used less frequently, attention should be given to the avoidance of hypokalemia in children receiving this drug. Serum glucose concentrations should be followed in neonates and small infants and dextrose-containing IV solutions administered as appropriate. Determination of ionized calcium (iCa^{++}) levels is indicated for patients with a history of DiGeorge syndrome because of a propensity toward hypocalcemia. Fluid replacement is dictated by the child's heart defect, type of surgery performed, and volume losses (see Chapters 9 and 12).

Perioperative Problems and Special Considerations

Several potential problems may be encountered during the perioperative period in children with CHD undergoing noncardiac interventions. This section highlights some of these issues to serve as a framework and outlines selected considerations in these children.

HYPOTENSION

Hypotension can be related to hypovolemia owing to prolonged fasting, volume loss, arrhythmia, anesthetic agents, myocardial dysfunction, or mechanical influences associated with the operative procedure. A practical diagnostic approach to the hypotensive patient is to consider factors that may affect ventricular preload, contractility, afterload, and the assessment of cardiac rhythm. Although the management of hypotension should be guided primarily by the causative factor, acutely increasing blood pressure by the administration of volume and an appropriate vasopressor, if indicated, often restores adequate perfusion while definitive therapy is instituted. Ensuring adequate intravascular volume with a fluid challenge often helps to restore perfusion and blood pressure, especially in hypovolemic patients. A pure α-adrenergic agent such as phenylephrine increases systolic blood pressure without further increases in heart rate. Some children are unable to tolerate any degree of myocardial depression or reduction in sympathetic outflow and require continuous inotropic support or vasopressor infusions throughout and after the operative procedure.

CYANOSIS

Cyanosis is a common finding in children with defects characterized by reduced pulmonary blood flow or intracardiac mixing. As surgical management strategies evolve to target the youngest of infants, the chronic effects of cyanosis may be limited in these children. However, in those requiring delayed surgery, palliation, or staged correction of their defects, the effects of cyanosis can be long lasting. Chronic hypoxemia affects all major organ systems. Compensatory mechanisms that attempt to provide adequate systemic oxygen delivery in the presence of chronic hypoxemia include polycythemia (related to secondary erythrocytosis), increases in blood volume, alterations in oxygen uptake and delivery, and neovascularization. Despite the favorable effects of the adaptive responses, these alterations can be detrimental. Polycythemia, the most significant compensatory response, is associated with increases in blood viscosity and red cell sludging. The common occurrence of iron-deficiency anemia in cyanotic children further enhances hyperviscosity and the unfavorable consequences of this condition. Several hemostatic abnormalities (e.g., thrombocytopenia, altered platelet function, and clotting factor abnormalities) have been described as a result of hypoxemia and erythrocytosis that may affect the coagulation system and increase perioperative risks.[160–165] This is compounded by increased tissue vascularity, with a larger number of blood vessels per unit of tissue.

The increased blood viscosity in children with cyanosis is associated with stasis and a risk for thrombotic events.[165a] If the hematocrit exceeds 65% preoperatively, some clinicians advocate phlebotomy to reduce the hematocrit to 60% to 65%. This limits sludging of red blood cells and increases oxygen delivery to tissues. If blood is removed by preoperative phlebotomy, it may be saved for autologous transfusion in the perioperative period.

During the perioperative period, adequate hydration should be maintained in children with cyanotic CHD, and care should be taken to avoid prolonged venous stasis. Cyanotic children are at risk for paradoxical embolic events, mandating meticulous attention to IV lines during fluid or drug administration. This is a reasonable routine approach for all children with CHD, regardless of the nature of the structural abnormalities. The use of air filters to IV tubing should not replace vigilance.

TETRALOGY SPELLS

Hypercyanotic episodes in children with tetralogy of Fallot (i.e., tet spells) may be the result of significant dynamic right ventricular outflow tract (RVOT) obstruction leading to acute reductions in pulmonary blood flow. Tet spells are rare during noncardiac surgery, probably because general anesthesia attenuates the triggers. Occasionally, however, increased cyanosis may occur without warning in response to obscure stimuli. Whatever the cause, worsening cyanosis implies increases in dynamic obstruction and exacerbation of ventricular-level right-to-left shunting. Factors that decrease systemic blood pressure and systemic vascular resistance, such as hypovolemia and extreme vasodilation, should be avoided. Therapy consists of increasing blood volume and systemic vascular tone, the latter using either a phenylephrine bolus of 5 μg/kg IV initially and if needed, 0.1 to 2 μg/kg per minute by continuous infusion, norepinephrine 0.5 μg/kg IV initially, and then 0.05 to 2 μg/kg per minute by continuous infusion or metaraminol 0.01 mg/kg IV initially and then 0.05 to 0.5 μg/kg per minute by continuous infusion. Vasopressin infusion (0.02–0.04 units/kg per hour) may be an alternative agent. Increasing the inspired oxygen concentration and reducing inspiratory ventilatory pressures

may also produce clinical improvement. Additional therapies include increasing the level of sedation or anesthetic depth and β-adrenergic blockade (esmolol [starting dose 50 μg/kg per minute] has largely replaced propranolol in this setting) (see also Chapters 16 and 17). Pulmonary vascular tone does not play a major role in the physiology of hypercyanotic episodes in tetralogy of Fallot; however, it is reasonable to limit additional afterload stresses to the right ventricle.

HEART FAILURE

In infants, congestive heart failure is most often due to ventricular volume overload resulting from ventricular or great artery–level communications. Heart failure can also result from severe valvar regurgitation, obstructive disease, or intrinsic myocardial disease (e.g., cardiomyopathy). Structural defects can lead to heart failure as a result of poor myocardial contractility, compromising cardiac output and the ability of the cardiovascular system to meet systemic demands.

In children with significant pulmonary vascular congestion, positive-pressure mechanical ventilation may be necessary before and after surgery. In cases of elective noncardiac surgery, it can be of significant benefit to optimize medical therapy or address the cardiovascular defect(s) before the planned procedure.

In a retrospective review of 21 children with severe heart failure who underwent 28 general anesthetics, 10% had a cardiac arrest requiring unplanned postoperative admission to the intensive care unit, and 96% required perioperative inotropic support. The investigators concluded that general anesthesia for children with severe heart failure is associated with a significant complication rate.[166]

VENTRICULAR DYSFUNCTION

Children with CHD can have ventricular dysfunction involving the right heart, left heart, both sides of the heart, regional myocardium, or global cardiac tissue. The impairment can be of a temporary or permanent nature. In systolic dysfunction, contractile function is primarily impaired. Diastolic dysfunction is associated with abnormal cardiac relaxation or impaired ventricular compliance. Some children have both, systolic and diastolic dysfunction. Ventricular dysfunction can result from factors such as age at the time of the operation and chronicity of the cardiac workload (pressure or volume); it can also be caused by the primary disease, myocardial hypertrophy, ischemia, or cyanosis or can occur as a direct effect of surgery (e.g., ventriculotomy, cardiopulmonary bypass, ischemic time, circulatory arrest). Diseases that affect cardiac muscle (e.g., myocarditis, dilated cardiomyopathy) can be associated with congestive symptoms, whereas others (e.g., restrictive cardiomyopathy) can lead to diastolic heart failure.

In children with cardiomyopathy that was accompanied by severe ventricular dysfunction, general anesthesia for noncardiac procedures was associated with an increased frequency of complications.[167] The children often required hospital support before and after the procedure that in many cases included intensive care management. Hospital stay was prolonged for children with severe ventricular dysfunction compared with those with a lesser degree of impairment. Based on these findings, early consideration of perioperative intensive care support was recommended for monitoring and optimization of cardiovascular therapy.

VENTRICULAR VOLUME OVERLOAD

Ventricular volume overload, which manifests as increased left atrial pressure, left ventricular (LV) end-diastolic pressure, and stroke volume, is a common feature in many children with unoperated CHD. Long-standing volume overload results in atrial enlargement, ventricular dilation, and cardiomegaly. In the postoperative child, residual valvar regurgitation can be associated with altered loading conditions that, if significant, can result in congestive symptoms and ventricular dysfunction. Patients with a palliated single ventricle can be particularly vulnerable to conditions associated with ventricular volume overload (e.g., systemic-to-pulmonary artery shunts).

VENTRICULAR PRESSURE OVERLOAD

Pressure overload in the postoperative patient typically results from residual or recurrent muscular, valvar, or distal outflow obstruction or from increased pulmonary artery pressure or vascular resistance. In children with abnormal distal pulmonary arterial beds, for example, the hypoplastic vessels may not be amenable to surgical repair or other intervention, although associated defects may be satisfactorily addressed. This results in increased proximal pulmonary artery and RV pressures and compensatory myocardial hypertrophy. RV pressure can exceed systemic values and compromise LV function because septal shift can impair LV filling or result in obstruction to systemic outflow (ventricular interdependence). Abnormal pressure loads to the right ventricle can also result from progressive obstruction after procedures that involve outflow tract reconstructions. In children who have undergone outflow conduit placements, surgical interventions for successive conduit replacements are delayed as much as possible. This translates into long-standing pressure loads on the myocardium with associated wall hypertrophy and potentially some element of ischemia until the criteria for surgical intervention have been met.

Whether the altered loading conditions affect the right or left ventricle primarily, the result is an increased myocardial demand because of the increased wall tension. This implies a susceptibility of the ventricular myocardium to the supply-and-demand relationship, a reduced tolerance for factors that may alter this fine balance, and an increased risk of ischemia.

MYOCARDIAL ISCHEMIA

Several factors can cause myocardial ischemia in children with CHD. They include chronic hypoxemia, increased systolic and diastolic wall stress, and decreased coronary perfusion owing to reduced diastolic pressures in the presence of large systemic-to-pulmonary shunts. The effects of cardiopulmonary bypass, aortic cross-clamping, and surgery itself cannot be ignored. Other conditions with a propensity for myocardial ischemia include congenital coronary artery lesions, aortic stenosis, and the increased blood viscosity associated with cyanosis. The deprivation of myocardial perfusion can lead to ventricular dysfunction and eventual development of myocardial fibrosis.

ALTERED RESPIRATORY MECHANICS

Chronically increased pulmonary blood flow and pulmonary artery pressures can result in progressive pulmonary vascular changes, elevated pulmonary vascular resistance, and alterations in lung mechanics. The primary effects on respiratory mechanics are related to increased airway resistance and decreased lung compliance. These alterations can have detrimental respiratory consequences in children with inadequate palliation or residual shunts. In some children, left atrial dilation can lead to respiratory compromise (e.g., air trapping, atelectasis) caused by bronchial compression.

PULMONARY HYPERTENSION

Pulmonary hypertension is defined as a mean pulmonary artery pressure in the resting state that exceeds 25 mm Hg or more. Several factors can lead to increased pulmonary artery pressures. These include increased pulmonary blood flow, pulmonary venous pressure, and pulmonary vascular resistance, among many others.[168] Unoperated CHD represents a major cause in children. It usually is the consequence of an unrestricted pulmonary blood flow owing to a communication between intracardiac structures or at the level of the great arteries. One of the benefits of early correction is a reduction in pulmonary artery pressures and less potential for pulmonary vascular reactivity after cardiac surgery. However, in some cases, pulmonary hypertension can persist or develop after a corrective intervention.

A less common entity is that of increased pulmonary vascular resistance, which can be reactive or fixed. Pulmonary hypertension and increased pulmonary vascular resistance pose significant risks for perioperative complications in children, regardless of cause.[43,132,169,170]

An acute increase in pulmonary vascular tone, also known as pulmonary hypertensive crisis, can result in cardiac arrest. In the presence of an intracardiac communication that allows for shunting, acute increases in pulmonary artery pressure can manifest as arterial desaturation, bradycardia, and systemic hypotension. In the absence of an intracardiac communication, the acute increase in RV afterload can lead to encroachment of the left ventricle caused by unfavorable leftward shifting of the interventricular septum, compromising LV filling and decreasing cardiac output. These events can be catastrophic.

Several factors can acutely affect pulmonary vascular tone (Table 23.2). Treatment should be aggressive in the acute setting, aimed at reducing pulmonary artery pressures with interventions such as sedation, oxygen administration, hyperventilation to produce hypocarbia, and treatment of acidosis.[170–173] The use of selective pulmonary vasodilators (e.g., inhaled nitric oxide) and inotropic support of the right ventricle may be indicated. Manipulation of pulmonary hemodynamics is challenged by the difficulty of directly measuring these parameters in children. Management of critical situations requires a thorough understanding of the pathophysiologic process and experienced clinical judgment. Because of the significant morbidity and potential periprocedural mortality for children with a history of severe pulmonary hypertension, an in-depth evaluation of the risk/benefit ratio of the planned procedure and its impact on the overall quality of life is essential.

Children with pulmonary hypertensive vascular disease (PHVD) in many cases undergo initial cardiac catheterization to confirm diagnosis, assess disease severity, for vasoreactivity testing, and to gather data with prognostic implications. Subsequent studies may be performed to determine response to drug therapy. Although a setting that may mimic an awake state might be desirable, it is well recognized that spontaneous ventilation under conditions of sedation implies potential risk of respiratory depression and hypercapnia, which may influence pulmonary artery pressures and resistances. Thus most children require general anesthesia for these procedures. The consensus statement of the Pulmonary Vascular Research Institute, Pediatric and Congenital Heart Disease Task Forces indicates the following: "*we recommend the presence of an anesthesiologist familiar with the management of neonatal and childhood PHVD when either sedation or general anesthesia is used*."[174] It is noted that general anesthesia and mechanical ventilation provide stable conditions for the procedure but require the availability of a trained pediatric anesthesiologist with experience in the management of children with cardiopulmonary disease.

TABLE 23.2 Factors Associated With Increased Pulmonary Vascular Tone

Transmitted positive airway pressure

ENDOCARDITIS PROPHYLAXIS

The current guidelines of the American Heart Association for infective endocarditis (IE) prevention published in 2007 recommends prophylaxis only for patients with cardiac conditions associated with the highest risk of adverse outcome from IE. These recommendations represented a major change from prior guidelines significantly narrowing the indications for antibiotic prophylaxis (see Chapter 16). In accordance with the revised guidelines, only a subset of children with CHD should be offered subacute bacterial endocarditis prophylaxis for specific surgical/procedural indications (see Table 16.2).[175] The writing group considered the following cardiac conditions appropriate for IE prophylaxis:

- Prosthetic cardiac valve
- History of infective endocarditis
- Unrepaired cyanotic CHD, including palliative shunts and conduits
- Completely repaired congenital heart defect with prosthetic material or a prosthetic device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
- Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
- Cardiac transplant recipients who develop cardiac valvulopathy

For patients with these underlying conditions prophylaxis is recommended during (1) all dental procedures that involve manipulation of gingival tissues or periapical region of teeth or perforation of oral mucosa and (2) procedures on respiratory tract or infected skin, skin structures, or musculoskeletal tissue (Table 16.3). Antibiotic prophylaxis solely for the prevention of IE is not recommended for genitourinary or gastrointestinal tract procedures, although we advise verifying the institutional practice with local surgeons and cardiologists.

SYSTEMIC AIR EMBOLIZATION

Intracardiac communications in children with CHD have the potential for right-to-left shunting and paradoxical systemic air embolization. The increased right-heart pressures associated with many cardiovascular malformations further increase this risk. It is well recognized that arterial gas embolism can lead to catastrophic consequences; thus it is imperative to ascertain the presence of or likelihood for intracardiac or vascular shunting or to assume that this may potentially be the case in most children with CHD and consider appropriate precautions.

ANTICOAGULATION

Anticoagulants, antiplatelet drugs, and thrombolytic agents are increasingly being used in children, particularly in those with CHD.[176–180] Decisions regarding perioperative management of anticoagulation are primarily influenced by the nature of the procedure, urgency of the intervention, specific drug therapy, and expected effects or laboratory data. The main concern relates to the potential for significant bleeding.

Low-dose aspirin does not represent a contraindication for most simple, superficial procedures, but if major surgery is planned, a discussion should take place and consideration given to discontinuing the drug for 7 to 10 days preoperatively, if appropriate. Recommendations for the management of children receiving warfarin (Coumadin) therapy vary widely.[181–183] The proposed strategies are quite heterogeneous, and the lack of consensus reflects the paucity of studies addressing this issue in a large cohort of children. The problem is further complicated by the lack of guidelines specific to pediatric practice.[184]

If the indications for anticoagulation are for native valve disease or atrial arrhythmias, the risk of a major thromboembolic event is considered relatively small, and warfarin may be discontinued 1 to 2 weeks before the day of surgery. In those with mechanical prosthetic valves, the risk of thromboembolic events is greater. Many recommend discontinuing the oral anticoagulant a few days before surgery and allowing the prothrombin time to return to within 20% of normal.[181] Administration of parenteral vitamin K, factor concentrates, or fresh frozen plasma, may be required to restore the prothrombin time within an acceptable range, especially in those with liver disease and in emergency cases. Some experts advise elective preoperative hospitalization, particularly in high-risk individuals, such as those with mitral or combined valve prostheses, to discontinue warfarin therapy and to initiate a heparin infusion, which is continued up until a few hours before surgery. Others suggest that low–molecular-weight heparin may be the better option instead of unfractionated heparin because the perioperative conversion from warfarin therapy to heparin can be accomplished without the need for hospitalization.[182]

Anticoagulation is usually reinitiated after 24 hours in children with valvular prostheses, and this may be achieved with a continuous heparin infusion or intermittent subcutaneous injections. The advantage of heparin is the ability to rapidly reverse the drug effect with protamine sulfate if bleeding complications occur. Oral anticoagulants are reinitiated 2 to 3 days after surgery if there are no bleeding concerns and the child is able to take oral medications. Although it has been suggested that there is no need to discontinue anticoagulation therapy for minor procedures, such as dental or ophthalmologic surgery in adults, guidelines for children are less clear.

The risk of bleeding from the surgical intervention versus the risk of a thromboembolism from a reduced anticoagulant dose determines to what extent and for what duration the anticoagulant therapy should be modified. In some cases, the cardiologist and surgeon may decide to temporarily use aspirin therapy before and after surgery. There is disagreement regarding whether antiplatelet therapy is preferable to anticoagulation in children with prosthetic aortic valves or after certain surgical interventions.[185–188]

CONDUCTION DISTURBANCES AND ARRHYTHMIAS

Acute rhythm disturbances can occur with the use of any anesthetic agent or technique and can be related to several factors. The administration of drugs with vagolytic or sympathomimetic properties requires consideration in patients with a prior history of or pathology associated with arrhythmias. Bradycardia can occur during induction of anesthesia, laryngoscopy, and tracheal intubation, particularly in infants and in children with Down syndrome.[189–191] In most cases, bradycardia is self-limited and requires no therapy, although if hypoxemia is the cause, it must be treated immediately.

Certain lesions can be associated with rhythm abnormalities and the potential for acute hemodynamic deterioration, increasing perioperative risks. Conduction system disorders and rhythm disturbances can occur after cardiac surgery as a direct result of the procedure or can develop owing to the inadequacy of the palliation or repair. Because cardiac arrhythmias are more prevalent among specific surgical subgroups, anticipation of their occurrence and planning for management are advocated. These cases may require prior consultation with a pediatric cardiologist or electrophysiologist, availability of specific medications, and the ability to electrically manage an acute rhythm disorder.

PACEMAKERS AND IMPLANTABLE CARDIOVERTER-DEFIBRILLATORS

An in-depth discussion of perioperative considerations related to implanted pacemakers or defibrillators can be found in Chapter 16. Consultation with a cardiologist or electrophysiologist is essential when caring for children with implanted units. Device interrogation and programming are required in most cases. The main goal is to avoid problems with hardware malfunction related to electromagnetic interference (i.e., electrocautery). Chronotropic agents and backup pacing modalities (e.g., transvenous, epicardial, transcutaneous) should be readily available and carefully considered in the event of pacemaker malfunction associated with an inadequate underlying heart rate. A magnet should be accessible to enable asynchronous pacing if required but should not be considered a substitute for preoperative device interrogation and reprogramming to the appropriate mode. Perioperative ECG monitoring is essential, as is the use of monitoring modalities that can confirm pulse generation during pacing. Implanted devices should be interrogated and reprogrammed after the procedure.

NERVE PALSIES

Surgery for CHD can be associated with transient or permanent injury to the recurrent laryngeal and phrenic nerves. Recurrent laryngeal nerve injuries can result in abnormal phonation or airway difficulties and lead to aspiration, particularly in small infants. These injuries usually occur during or in association with aortic arch surgery (e.g., patent ductus arteriosus [PDA] ligation or aortic arch reconstruction) with two-thirds resolving within 2 years. Diaphragmatic palsies resulting from phrenic nerve injuries are associated with abnormal lung mechanics and limited pulmonary reserve, both of which may account for perioperative morbidity. These injuries occur in association with bidirectional Glenn shunts, Blalock-Taussig shunts, and others.

EISENMENGER SYNDROME

Eisenmenger syndrome, rarely seen in the current era, is characterized by progressive, irreversible pulmonary vascular disease in the patient with CHD owing to pathology associated with significant left-to-right shunting. The pulmonary artery pressure in such patients reaches systemic/suprasystemic pressures from increased pulmonary vascular resistance (usually exceeding 10 Wood units). Cyanosis is the result of reversal in the direction of an intracardiac or arterial level shunt.[192,193] When seen, Eisenmenger syndrome

is most likely to occur in older children, adolescents, or adults with CHD. Morbidity relates to problems associated with chronic cyanosis and erythrocytosis. Other medical issues include hemoptysis, gout, cholelithiasis, hypertrophic osteoarthropathy, and decreased renal function. These comorbidities in most cases mandate extensive preoperative preparation and testing. Laboratory studies of relevance include a hematologic profile, as well as assessment of renal and liver function. Other considerations include preoperative therapeutic phlebotomy in selected patients. The blood removed should be saved for potential subsequent autologous transfusion. It should be recognized that samples sent to the blood bank might require additional time for processing owing to the presence of antibodies from blood product exposure during prior surgical interventions.

Variables associated with poor outcome in Eisenmenger syndrome include syncope, increased RV end-diastolic pressure, and significant hypoxemia (i.e., $SaO_2 < 85\%$). Life expectancy is significantly reduced in affected individuals.[194] Most succumb suddenly, probably from ventricular tachyarrhythmias. Surgical modalities that have been advocated in selected patients include combined heart and lung transplantation[195] and lung transplantation alone.[196]

The considerable morbidity and mortality in patients with Eisenmenger syndrome during noncardiac surgery require not only expertise from the providers but also care at facilities capable of managing problems that may arise perioperatively. Despite the overall poor prognosis and the extremely high risk of untoward events, several reports have documented good outcomes with a variety of anesthetic techniques and agents.[39,197–200] In a retrospective study of institutional outcomes in patients with Eisenmenger syndrome, significant arterial hypotension was reported in 26% and arterial desaturation in 17%.[201] This finding led to the recommendation for blood pressure support with a vasopressor before or during the induction period to maintain systemic vascular tone and prevent worsening of the shunt flow. It is vital that the family and patient, if of appropriate age, understand these risks before undertaking any procedure requiring anesthesia or deep sedation.

CARDIAC TRANSPLANTATION

In some cases of end-stage cardiac pathology as a result of congenital or acquired disease, cardiac transplantation may represent the best or only option for survival.[202,203] The preoperative assessment should note indications for transplant and specifically assess transplant organ function.

An important consideration is the lack of external nerve supply of the transplanted heart (i.e., no sensory, sympathetic, or parasympathetic innervations). The physiology of the denervated heart implies that the usual autonomic regulatory mechanisms are not operational, increasing the vulnerability of children receiving heart transplants to hemodynamic alterations.[204] Compensatory responses may be delayed, further increasing the potential for compromise.

In the child with a transplanted heart, the resting heart rate is greater than normal because of the loss of parasympathetic inhibition. Critical determinants of cardiac output are the systemic venous return (preload dependence) and maintenance of an adequate heart rate. During the early posttransplantation period, the heart rate may be supported by exogenous chronotropes or pacing. Subsequently, circulating catecholamines drive the heart rate. Regardless of the time interval from transplantation, while caring for these children the following are recommended: (1) availability of medications with chronotropic properties and drugs with direct action on the myocardium and vasculature, and (2) access to emergent cardiac pacing modalities (see also Chapter 18).

Long-term immunosuppression in children who have undergone cardiac transplantation presents several issues during noncardiac surgery. First, administration of multiple medications, particularly immunosuppressant agents, throughout the perioperative period is a concern. In most cases, immunosuppressant medications are continued, if feasible, to maintain adequate blood concentrations and limit the potential for rejection of the transplanted organ. Children receiving long-term corticosteroid therapy can be at risk for adrenal crisis during an acute illness or other stress, such as may be encountered during surgery or other minor procedures. The perioperative administration of corticosteroids ("stress-dose") should be considered based on the procedure and severity of the illness (anticipated stress). Second, immunosuppressive therapy is associated with adverse effects that may impact various organ systems. Cyclosporine administration, for example, increases systemic arterial blood pressure, potentially influencing hemodynamics. The drug is also responsible for renal dysfunction. Anesthesia management must consider potential alterations in hepatic and renal function. Third, strict aseptic technique is needed in managing a child with a compromised immune system in view of the infectious risk.

An additional concern is the potential for cardiac allograft vasculopathy (i.e., small-vessel coronary artery disease). Because older children or adolescents with ongoing myocardial ischemia may not experience angina symptoms, it is reasonable to assume that most of these children are at risk for ischemic events, particularly those who are several years after transplantation.

MECHANICAL CIRCULATORY SUPPORT DEVICES

In recent years, an increasing number of mechanical circulatory support devices have been implanted in children, in most cases, as a bridge to cardiac transplantation. These children may require sedation/general anesthesia for noncardiac procedures of a diagnostic or therapeutic nature, for placement of indwelling catheters used for long-term vascular access, and for other procedures. As the hardware is typically implanted at specialized cardiac centers, these children are usually well known to the anesthesia teams who are involved in multiple patient encounters during a usually relatively long hospital stay.

Several publications have highlighted the unique perioperative considerations in this patient group.[205–207] Key issues include familiarity with the various devices, their operation, control features, waveforms, and alarms.[208] In addition, it is important to understand factors that influence device output such as fluid status and systemic vascular tone. The functional status of the right heart influences device preload; thus it is important to minimize any increases in RV afterload that can compromise device filling and stroke volume. Hypotension has been described as a common occurrence during anesthesia, necessitating the administration of IV fluid and α-adrenergic agents. This may be the result of vasodilation and a decrease in systemic afterload under conditions of a fixed cardiac output delivered by the device. Preparation and immediate access to drugs with vasoactive properties is key. Although in adult patients a trend toward perioperative care by educated noncardiac anesthesiologists has been reported, the anesthesia care of these children is primarily the responsibility of specialty providers.[209]

PERIOPERATIVE STRESS RESPONSE

The typical physiologic response to painful stimuli in normal children consists of an increase in heart rate and blood pressure

and a transient decrease in PaO_2. These normal patterns, however, may be detrimental to children with CHD. Tachycardia may shorten diastolic filling time and diminish cardiac output, and hypertension increases ventricular afterload. The reduced ability of the postoperative child with CHD to increase cardiac output in response to stimulation and their limited maximal exercise capacity have been well described.

Outcomes of Noncardiac Surgery

Limited data regarding the risks of noncardiac surgery and anesthesia in children with CHD raise concerns. A review of 110 children with CHD over a 1-year period undergoing noncardiac outpatient surgery found a 47% incidence of adverse events and more than one adverse event in a significant number of children.[210] In addition, the study reported an increased incidence for unplanned intensive care admission. Continuous monitoring of perioperative rhythm abnormalities in 70 children with CHD and a history of ventricular arrhythmias documented a 35% and 87% incidence of intraoperative and postoperative ventricular arrhythmias, respectively.[211] Other studies have reported cyanosis, treatment for congestive heart failure, poor health, and young age as risk factors.[40] A retrospective review of a large number of children reported that these risks involved major and minor interventions.[42]

Data from the Pediatric Perioperative Cardiac Arrest (POCA) registry shed further insight into this subject. Causes of cardiac arrest were primarily cardiovascular in nature, occurring more frequently in those with heart disease than those without. Events occurred more frequently in the general operating room, usually during the maintenance period. Two cardiac malformations stood out: children with single-ventricle physiology (particularly those managed early with palliation) and children with aortic stenosis. The overall mortality rate for children with heart disease was greater than for those without heart disease. Children with aortic stenosis (i.e., Williams syndrome) and cardiomyopathy had the greatest mortality rate.[212]

A study in children undergoing cardiac catheterization found an increased frequency of cardiac arrests in children undergoing cardiac catheterization[213]; the frequency of these events was greater compared with the incidence during pediatric noncardiac and cardiac surgery. A retrospective review of children with complex CHD identified children before stage II single-ventricle palliation, those undergoing more invasive procedures, and receiving inotropes, ACEIs, or digoxin to be at risk for intraoperative hemodynamic instability during noncardiac operations.[214] Another large database review noted that children with major and severe CHD undergoing noncardiac surgery have an increased risk of mortality and a greater incidence of life-threatening postoperative outcomes compared with matched controls of children without CHD undergoing comparable procedures.[45]

The overall data suggest that younger age, higher ASA status, severe heart disease, and emergency procedures represent risk factors for poor outcomes during noncardiac surgery in patients with CHD.

Specific Congenital Heart Defects

The provision of anesthesia care to children with CHD undergoing noncardiac surgery is strongly influenced by the specific nature of the cardiovascular anomalies, pathophysiology of the lesions, operative state (e.g., unoperated, prior palliative or definitive procedure), complications associated with the primary pathology or treatment, and other comorbidities.[35]

This section reviews selected cardiac defects with an emphasis on anatomic features, hemodynamic consequences, and treatment strategies. Potential residua, sequelae (Table 23.3), and long-term outcomes of these lesions are discussed, focusing on their implications for anesthesia care.

ATRIAL SEPTAL DEFECTS

Anatomy and Pathophysiology

Defects in the interatrial septum, or atrial septal defects (ASDs) (see Fig. 17.1), are among the most common congenital cardiac anomalies (30%–40% of CHD) in childhood. ASDs occur in 1 of 1500 live births. Based on their location, several types of defects are identified:

- *Ostium secundum or fossa ovalis defect* (75% of ASDs) results from a deficiency in the region of the fossa ovalis, representing a true defect in the atrial septum (see Fig. 17.1B). These defects can be associated with mitral valve prolapse and/or mitral regurgitation.[215–217]
- *Ostium primum defect* (15%–20% of ASDs) represents a form of AV septal (canal or endocardial cushion) defect (see Fig. 17.1A).[218] The malformation is characterized by a deficiency in the inferior portion of the interatrial septum and is frequently associated with a commissure or cleft in the anterior leaflet of the mitral valve and various degrees of mitral regurgitation.
- *Sinus venosus defect* (5%–10% of ASDs) typically is located at the superior aspect of the interatrial septum, at the junction of the superior vena cava and the right atrium (i.e., superior vena cava type) (see Fig. 17.1C).[219] An inferior-type defect (at the inferior vena cava) is less common. These defects are frequently associated with partial anomalous pulmonary venous drainage.[220]
- *Coronary sinus defect* (uncommon) consists of a communication between the atria through the mouth of the coronary sinus. Left-to-right shunting occurs across an "unroofed" coronary sinus. It is often associated with a persistent left superior vena cava that drains directly into the left atrium, resulting in a right-to-left shunt.[221]
- *Other entities* that may allow for interatrial shunting include a *patent foramen ovale* (PFO) at one end of the spectrum and a *common atrium* at the other. A PFO is a flap-like opening or channel between the two septa (septum primum and septum secundum) that divides the primordial single atrium into right and left atrial chambers. This structure can be identified in approximately 25% of individuals. The communication may have implications for perioperative care because of the potential for right-to-left shunting and paradoxical emboli under certain circumstances.[222,223] In a common atrium, there is complete or near-total absence of the interatrial septum. This can be seen in complex congenital cardiac pathologies.

An atrial communication allows mixing of the pulmonary and systemic venous returns. A left-to-right shunt permits pulmonary venous blood to enter the right atrium. The magnitude of shunting correlates with the size of the defect, relative ventricular compliances, and pulmonary artery pressures. A clinically significant defect results in right-sided volume overload. A pulmonary-to-systemic blood flow ratio ($\dot{Q}_{pulm}/\dot{Q}_{sys}$) that exceeds 2:1 and the potential detrimental effects of chronic right-sided volume overload are indications for intervention.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Surgical closure of secundum ASDs in childhood provides excellent results, almost normal long-term survival, and negligible

TABLE 23.3 Potential Issues After Interventions for Selected Congenital Heart Defects

Atrial Septal Defects
Residual intracardiac shunt
Persistent right ventricular dilation and abnormal motion of interventricular septum
Atrial arrhythmias, ventricular dysfunction if late repair
Pulmonary venous obstruction (sinus venosus defect associated with anomalous pulmonary venous return)
Mitral valve problems, left ventricular outflow tract obstruction (ostium primum defect with cleft mitral valve)
Development of pulmonary vascular disease (rare)
Atrioventricular Septal Defects
Mitral valve problems (regurgitation, stenosis)
Left ventricular outflow tract obstruction
Residual intracardiac shunts
Atrioventricular block, conduction abnormalities
Prior palliation with pulmonary artery banding might have resulted in inadequate protection of pulmonary vasculature or distortion of pulmonary artery anatomy
Pulmonary hypertension may persist
Coarctation of the Aorta
Systemic hypertension
Residual or recurrent obstruction
Death from untreated pathology related to heart failure, aortic rupture or dissection, infective endarteritis or endocarditis, premature coronary artery disease, or cerebral hemorrhage
Endocarditis risk with concomitant aortic valve disease
Congenitally Corrected Transposition of the Great Arteries
Residual defects (e.g., shunts, outflow tract obstruction)
Systemic (right) ventricular dilation, dysfunction, failure
Left-sided (tricuspid) valve regurgitation
Atrioventricular block or arrhythmias
Coronary artery anomalies
May go unsuspected for some time
Myocardial ischemia
Ventricular dysfunction
May present as syncope, or lead to sudden death
D-Transposition of the Great Arteries
Residual pathology (e.g., intracardiac shunts, outflow tract obstruction)
After atrial baffle procedure: baffle leak, obstruction of systemic or pulmonary venous pathways, progressive right ventricular dilation or failure, tricuspid regurgitation, sinus node dysfunction, or atrial arrhythmias
After arterial switch operation: aortic root dilation, aortic regurgitation, supravalvar stenosis (pulmonary or aortic), or coronary insufficiency
Ebstein Anomaly
Progressive tricuspid regurgitation and right-sided volume overload
Right ventricular dysfunction
Atrial tachyarrhythmias (particularly if Wolff-Parkinson-White syndrome)
Potential for paradoxical right-to-left shunting in the presence of an interatrial communication
Valve repair or replacement may be necessary
Interrupted Aortic Arch
Residual intracardiac defects
Subaortic obstruction
Residual or recurrent aortic arch obstruction
Left Ventricular Outflow Tract Obstructions
Residual or recurrent obstruction
Aortic regurgitation, aortic root dilation
Risk of endocarditis
Ventricular dysfunction
Potential subendocardial ischemia if ongoing ventricular pressure overload
Coronary ostial stenosis, diffuse arteriopathy (supravalvar aortic stenosis)
Need for reoperation in those with bioprosthetic or mechanical valves or conduits
After Ross procedure: autograft or right ventricular homograft failure, progressive aortic root dilation, or aortic regurgitation
Patent Ductus Arteriosus
Residual or recurrent shunting
Increased pulmonary vascular resistance (now rare)
Right Ventricular Outflow Tract Obstructions
Residual or recurrent obstruction resulting in ventricular pressure overload
Pulmonary regurgitation may require intervention
After right ventricle–to–pulmonary artery conduit: need for intervention or reoperation related to conduit failure
Single Ventricle
After aortopulmonary shunt: shunt stenosis with associated hypoxemia, ventricular volume overload, systemic ventricular dilation, distortion of pulmonary artery anatomy, or pulmonary hypertension
After bidirectional Glenn connection or hemi-Fontan procedure: progressive cyanosis owing to venous collaterals or other vascular communications, allowing venous pathways to bypass the pulmonary circuit or owing to development of pulmonary arteriovenous malformations (more likely with classic Glenn anastomosis)
After Fontan procedure: increased systemic venous pressures, right atrial hypertension (with atriopulmonary connection), sinus node dysfunction, atrial rhythm disturbances, atrioventricular valve regurgitation, hepatic dysfunction, thrombotic complications, coagulation defects, protein losing enteropathy, or progressive systemic ventricular dilation or dysfunction
Tetralogy of Fallot
Residual or recurrent pathology (e.g., intracardiac shunts, right ventricular outflow tract obstruction, distal pulmonary artery bed abnormalities)
Progressive pulmonary regurgitation with need for repeat intervention (e.g., right-sided heart dilation, dysfunction)
Arrhythmias associated with poor hemodynamics
Syncope or sudden death (arrhythmogenic cause)
Restrictive right ventricular physiology
Truncus Arteriosus
Residual intracardiac shunting
Revision of right ventricle–to–pulmonary artery reconstruction (for stenosis or regurgitation)
Truncal (aortic) valve stenosis or regurgitation
Ventricular Septal Defect
Potential residual defects
Risk of endocarditis (diminishes with time after repair)
Aortic regurgitation
Rarely, increased pulmonary vascular resistance may not improve postoperatively

mortality.[224–227] Normal ventricular function should be anticipated after repair of these defects. Rarely, children can demonstrate persistent RV dilation and abnormal ventricular septal motion, but this may not result in a functional deficit.[228] Atrial arrhythmias and ventricular dysfunction can occur after late repairs owing to chronic volume overload. Delayed defect closure can be a risk factor for the rare development of pulmonary hypertension later in life as the result the chronic abnormally increased pulmonary blood flow.[229]

Transcatheter device occlusion is an alternative approach to surgery for closure of secundum ASDs in selected children, with excellent success rates (see Chapter 22).[230–232] Complications are rare and may be associated with the catheter-based procedure or occur at a later time.[233]

After surgical closure of ostium primum defects, morbidity manifests primarily as mitral valve dysfunction (e.g., mitral regurgitation or stenosis) and LVOT obstruction.[234–238] In most children, outcomes are favorable after repair at an early age. After closure of sinus venosus defects, potential problems include pulmonary venous obstruction and loss of sinus node function.[239–241] Repair of coronary sinus defects depends on the specific nature of the defect and associated anomalies. The intervention consists of redirection of the coronary sinus blood and possibly the associated abnormal systemic venous return to the right atrium. Patch closure of the atrial communication at the mouth of the coronary sinus may be all that is required in some cases, leaving a small right-to-left shunt as deoxygenated blood from the coronary sinus continues to drain directly into the left atrium.[242] For most children with atrial communications, significant postoperative sequelae are unlikely to occur, and outcomes are generally good.

An important consideration in the child with an interatrial communication is the avoidance of IV air in view of the potential for gas embolism. In most cases, no major repercussion from a repaired defect should be expected for future anesthesia care.

VENTRICULAR SEPTAL DEFECTS

Anatomy and Pathophysiology

Ventricular septal defects (VSDs) are the most common of all congenital cardiac anomalies, occurring in 30% to 60% of CHD (excluding a bicuspid aortic valve) with an incidence of 2 to 6 cases per 1000 live births (see Fig. 17.2A).[243] VSDs can be found in isolation or within the context of other structural malformations. Large defects require early attention for symptoms related to congestive heart failure or pulmonary hypertension. VSDs have a greater rate of spontaneous closure in childhood–about 75% closure by 6 months to 1 year.[244,245]

Various classification schemes have been proposed for VSDs based on their anatomic location, size, restrictive versus nonrestrictive nature, and hemodynamic significance.[246,247] The following scheme categorizes defects as four major morphologic types based on their anatomic location. In some cases, the boundaries of a defect extend beyond the margin of a particular region of the ventricular septum into another and these are qualified as such.

- *Perimembranous defects* (most common type) are located in the membranous region, under the septal leaflet of the tricuspid valve and just below the level of the aortic valve. They are frequently associated with redundant septal tricuspid valve tissue (e.g., aneurysmal tissue) that may limit shunting or eventually result in complete defect closure.
- *Muscular defects* are located anywhere within the trabecular (muscle-bound) component of the ventricular septum. Multiple defects give the appearance of a "Swiss cheese" septum, which complicates surgical closure.
- *Doubly committed, subarterial, conal, or supracristal defects* are found within the region of the subpulmonary infundibulum. They can be associated with aortic valve herniation or prolapse into the defect and aortic regurgitation.[248]
- *Inlet defects* are located in the posterior aspect of the ventricular septum near the AV valves. Associated anomalies of the AV valves frequently coexist.

The characterization of VSDs based on their size and likely hemodynamic importance is extremely useful when caring for unoperated children:

- *Small defect:* The pulmonary-to-systemic systolic pressure ratio is less than 0.3 and the $\dot{Q}_{pulm}/\dot{Q}_{sys}$ is less than 1.4. The defect causes negligible to minimal hemodynamic effects. Normal RV systolic pressure, pulmonary vascular resistance, and LV size are typically found.
- *Moderate defect:* The systolic pressure ratio is greater than 0.3 and the $\dot{Q}_{pulm}/\dot{Q}_{sys}$ is 1.4 to 2.2. The defect can be associated with volume overload and congestive symptoms. Some degree of left atrial and LV dilation exists, as well as elevated pulmonary artery pressures.
- *Large defect:* The systolic pressure ratio is greater than 0.3 and the $\dot{Q}_{pulm}/\dot{Q}_{sys}$ exceeds 2.2. The defect is associated with significant symptoms (e.g., failure to thrive, congestive heart failure). Cardiomegaly and increased pulmonary vascularity are usual findings.

The physiologic effects of the communications that allow for ventricular-level shunting are determined by factors such as the size of the defect, amount of shunting, and relative pulmonary and systemic vascular resistances. Physiologically, isolated defects can be classified as pressure restrictive (i.e., RV pressure < LV pressure) or nonrestrictive defects (i.e., equal or near-equal ventricular pressures). Restrictive defects often imply limited flow through the communication. This is usually the case with small VSDs in which the pressure gradient determines the magnitude of shunting. If the defect is large and nonrestrictive, the amount of shunting depends on the ratio between the pulmonary and systemic vascular resistances. A low pulmonary vascular resistance in the context of a nonrestrictive VSD leads to a large left-to-right shunt, increased pulmonary blood flow, pulmonary hypertension, and increased myocardial work, as evidenced by a volume load to the left heart. Nonrestrictive left-to-right shunts result in pulmonary congestion and abnormal respiratory mechanics characterized by decreased lung compliance, increased airway resistance, and increased work of breathing. Increases in alveolar dead space and alveolar to arterial oxygen gradients are to be expected, as well as increases in minute ventilation and potential oxygen requirements.

An important perioperative consideration for children with defects associated with increased pulmonary blood flow is the pulmonary steal phenomenon, which may result from decreases in pulmonary vascular resistance as left-to-right shunting increases at the expense of systemic blood flow. This requires an appraisal of the factors that may influence pulmonary vascular tone to prevent compromises in systemic output.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Surgical closure of VSDs early in childhood results in excellent outcomes, usually without sequelae.[249–251] Surgical intervention in older children may lead to reduced LV function and increased LV mass.[252]

Small communications, although regarded as hemodynamically insignificant, may not be benign. This has led to ongoing controversy regarding the need for definitive intervention. Occasionally a young child with a defect of moderate size remains relatively asymptomatic until later life, when gradual decompensation may ensue related to increased end-diastolic volume and ventricular dilation. Defect closure in this setting is indicated if the magnitude of the increase in pulmonary vascular resistance is not prohibitive, which would be extremely rare. Severely increased pulmonary vascular resistance (more than 7 Wood units/m^2) increases the perioperative risks, and it may not return to normal levels after the surgical intervention.[253] If postoperative pulmonary hypertension persists, the prognosis is unfavorable, with the potential for eventual RV failure.[254] Development of Eisenmenger syndrome (i.e., pulmonary vascular obstructive disease and reversal in the direction of the ventricular level shunt) has become rare owing to early recognition and management of children with these defects.

Postoperative sequelae after VSD closure include residual or, less commonly, recurrent defects, arrhythmias or other conduction system disturbances, subaortic obstruction, and valvar regurgitation.[255] Although surgical closure is considered the gold standard, transcatheter closure by device placement is feasible for selected defects, typically muscular and postoperative residual defects.[256,257] Results to date demonstrate excellent closure rates with reduced rates of complications[258] (see also Chapter 22). Limited experience and follow-up are available with catheter-based interventions for closure of membranous communications.[259–262] In view of associated substantial risk of complete AV block with the initial occluder device, a newer-generation device (Amplatzer membranous VSD occluder, St. Jude Medical, Inc., St. Paul, MN) is favored.[263,264]

Children with a small defect or without residual pathology after undergoing VSD closure often have normal ventricular systolic function and should be expected to do well during future noncardiac procedures.

ATRIOVENTRICULAR SEPTAL DEFECTS

Anatomy and Pathophysiology

Atrioventricular septal defects (AVSDs), also referred to as AV canal defects or endocardial cushion defects, are characterized by deficiency of the AV septum and abnormal formation of the AV valves (see Fig. 17.2B).[265] These defects represent only 4% of CHD cases, although they have a high prevalence among patients with Down syndrome (25%). Although the nomenclature of AVSDs has been the subject of confusion and even controversy, in general the lesions that represent the spectrum of pathologies can be classified as follows:

1. The *complete form* (i.e., common AV canal defect) consists of an ostium primum defect and an interventricular communication at the superior aspect of the inlet or posterior muscular septum (contiguous defects), and a large common AV valve. They are frequently associated with various degrees of AV valve regurgitation.
2. The *partial form* (i.e., incomplete form) is usually characterized by an ostium primum ASD accompanied by a cleft or commissure in the left-sided AV valve. Two functionally distinct AV valvar orifices are usually identified (see "Atrial Septal Defects").
3. The *transitional or intermediate forms* represent variants of AVSDs. When considered as separate entities, a transitional defect is regarded as a partial form of the defect characterized by a primum ASD, a small inlet VSD (usually restrictive), and two distinct AV valve components. An intermediate defect refers to a variant of the complete form of the defect characterized by a primum ASD and a nonrestrictive VSD in the setting of a common AV valve annulus and two distinct AV valvar orifices separated by a tongue of tissue.

Complete defects are associated with nonrestrictive intracardiac shunting, excessive pulmonary blood flow, congestive heart failure, and systemic RV and pulmonary artery systolic pressures. Without intervention, they can lead to early pulmonary vascular changes. The severity of AV valve regurgitation also influences the clinical presentation. Partial AVSDs are less likely to be associated with pulmonary overcirculation of sufficient severity to cause significant heart failure.

Perioperative concerns like those previously described in children with nonrestrictive ventricular communications are applicable, but they also are magnified in those with unrepaired complete defects. In children with unrepaired defects with increased pulmonary vascular resistance and a reactive pulmonary bed, issues such as airway manipulation, light anesthesia, hypoxemia, or hypercarbia can lead to acute increases in pulmonary artery pressures to suprasystemic levels and detrimental hemodynamic consequences.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

The surgical approach for complete defects has evolved from a two-stage intervention (i.e., initial pulmonary artery banding aimed at limiting pulmonary blood flow and subsequent complete repair) to a single strategy of primary repair in infancy. In the case of a complete defect, the intervention consists of patch closure of the intracardiac communications, partition of the common AV valve, and closure of the left-sided valvar cleft (otherwise known as the zone of apposition). The long-term outlook after repair is generally good, with a small likelihood of residual dysfunction.[266-268]

Postoperative problems include left AV valve regurgitation or stenosis, residual intracardiac shunting, AV block, and subaortic obstruction.[237,238] Occasionally, pulmonary hypertension persists or develops postoperatively; it is more likely in children with Down syndrome. In the remote past, uncorrected defects associated with high pressure and high flow resulted in muscular development of the pulmonary vasculature and Eisenmenger physiology, accounting for significant late morbidity and early death.[269] As mentioned, these patients are at high risk for anesthesia for any procedure.

RIGHT VENTRICULAR OUTFLOW TRACT OBSTRUCTIONS

Anatomy and Pathophysiology

Pulmonary valve stenosis is the most common pathology among children with RVOT obstruction.[270] Other lesions that result in obstruction to pulmonary blood flow include infundibular (subpulmonary) stenosis, anomalous muscle bundles within the body of the right ventricle, and structural alterations in the pulmonary arterial bed. These pathologies may be found in isolation or occur as part of more complex malformations. Such is the case in tetralogy of Fallot (discussed later), in which multiple anatomic levels of RVOT obstruction are typically encountered (see Fig. 17.5).

Although isolated valvar pulmonary stenosis is congenital in most cases, the disease can be progressive. In the uncomplicated or pure variant, an interatrial communication in the form of a PFO or secundum ASD may be identified, and the ventricular septum is intact.

The magnitude of RVOT obstruction is directly related to the degree of valvar narrowing. This imposes an afterload burden on

the right ventricle, resulting in RV hypertrophy and decreased ventricular diastolic compliance. Tricuspid regurgitation may be an associated finding. In severe cases, the RV systolic pressure may exceed that of the left ventricle. Cyanosis in children with pulmonary stenosis usually reflects right-to-left interatrial shunting and reduced pulmonary blood flow. It can be associated with severe RV hypertrophy, myocardial fibrosis, or ventricular dysfunction.

Most children with mild to moderate valvar stenosis remain asymptomatic, and the pathology is relatively well tolerated chronically. Severe obstruction in older children is frequently associated with limited exercise tolerance. Subendocardial ischemia is a potential risk in children with a hypertensive, hypertrophied right ventricle. Management is directed at maintaining coronary perfusion and the inotropic state of the myocardium.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Percutaneous balloon valvuloplasty is very effective and currently is considered the treatment of choice for isolated valvar pulmonary stenosis, replacing surgical valvotomy in most cases. Outcomes are excellent, and long-term issues are rare.[271–273] Dysplastic valves have a less favorable response to catheter-based interventions, and affected children are more likely to require surgery. Indications for repeat intervention include residual outflow tract obstruction and progressive pulmonary regurgitation.[274]

In children with significant RV hypertrophy undergoing noncardiac surgery, adequate ventricular preload and optimization of volume status are recommended. Further increases in RV afterload should be avoided in those with residual or recurrent outflow tract obstruction.

LEFT VENTRICULAR OUTFLOW TRACT OBSTRUCTIONS

Anatomy and Pathophysiology

LV outflow tract (LVOT) obstruction may occur at the level of the aortic valve, supravalvar region, or subvalvar region. It may take place in isolation or as part of complex cardiovascular disease. A *bicuspid aortic valve* is the most common of all congenital cardiac anomalies, occurring in approximately 2% of the general population.[275] Although it may not necessarily imply valvar stenosis, this abnormality can be associated with progressive obstruction or regurgitation as well as aortic root dilation. A bicuspid valve can be found in asymptomatic individuals or within the context of severe left heart obstruction. The prevalence of coexistent defects is relatively high and frequently includes PDA, VSD, aortic coarctation, and other abnormalities of the aorta and its branches.

Infants with critical aortic stenosis and those with severe obstruction require early intervention based on ductal dependency for systemic blood flow, heart failure symptoms, and the degree of ventricular dysfunction. Older children with moderate to severe obstruction can present with decreased exercise tolerance, syncopal episodes, or myocardial ischemia. Impedance to LV ejection in aortic stenosis results in elevation of LV systolic pressure and increased myocardial work. Ventricular hypertrophy is the compensatory response to the increased afterload. Contractile function is normal to increased, but diastolic impairment can occur.

In *supravalvar aortic stenosis*, the narrowing usually occurs at the sinotubular junction. The coronary arteries arise proximal to the area of obstruction and are subjected to increased systolic pressures equal to that of the left ventricle. This pathology is seen most commonly in children with Williams syndrome (also known as Williams-Beuren syndrome). Elfin facies, developmental delay, idiopathic hypercalcemia, and other features characterize the disorder. The associated arteriopathy can involve the origin of the coronary arteries and/or other systemic and pulmonary vessels.[276] Several reports have described unexpected complications in these children, including cardiac arrest during anesthesia care.[277–281] In view of the increased risk for cardiovascular decompensation and frequently unsuccessful resuscitative efforts, careful perioperative/procedural planning is highly advised in children with Williams syndrome.[282] Care should ideally be provided by pediatric anesthesiologists familiar with the syndrome and at facilities with the infrastructure capable of providing the necessary support for these children during an acute event. Affected children should be considered at increased risk for any procedure.

Subvalvar aortic stenosis may take a variety of forms, including a discrete fibromuscular ridge or membrane, complex tunnel-like obstruction, or hypertrophy of the interventricular septum (i.e., hypertrophic cardiomyopathy). The association of LV pathology of an obstructive nature such as a bicuspid aortic valve, subaortic stenosis, aortic coarctation, and mitral valve inflow obstruction (e.g., parachute mitral valve, supravalvar mitral ring) is referred to as the *Shone complex*.

Hypoplastic left heart syndrome (HLHS) represents an extreme form of LVOT obstruction (see Fig. 17.10). It encompasses a constellation of malformations, affecting left-sided cardiac structures (e.g., mitral and aortic valves, aorta, aortic arch) (see "Single Ventricle").

Common features of the anomalies that result in obstruction to LV output include a pressure gradient across the involved region, increased LV systolic pressure, altered myocardial force, and LV wall stress. With chronic obstruction, the hypertrophied myocardium is at risk for subendocardial ischemia because of an imbalance in the ratio between myocardial oxygen supply and demand. Factors such as increases in LV afterload, inadequate hypertrophic remodeling, and decreases in myocardial systolic or diastolic performance can compromise stroke volume and contribute to cardiac dysfunction and heart failure.[283] These issues are relevant for children with more than mild obstruction, and they influence anesthesia care during noncardiac surgery or other interventions.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Individuals with a bicuspid aortic valve can remain asymptomatic for many years but are at risk for developing aortic stenosis or regurgitation and concomitant hemodynamic alterations. Some of those requiring surgical intervention during childhood undergo reoperation for recurrent stenosis or progressive regurgitation in the next 25 years.[284] Percutaneous balloon valvuloplasty may be a treatment option for critical or severe aortic valve disease.[285] Surgical alternatives include valvotomy, mechanical or bioprosthetic valve placement, and root replacement with homograft or autograft material. In the Ross operation, the native, diseased root is replaced by a pulmonary autograft, and an extracardiac conduit establishes continuity between the right ventricle and main pulmonary artery.[286] Repeat intervention for eventual failure of the RV conduit is anticipated in these children.[287] In addition to surveillance of the RVOT, monitoring for aortic root dilation and concomitant regurgitation is an important component of follow-up.[288,289] Ascending aorta aneurysm formation, dissection, and rupture also represent long-term concerns.

Management of discrete subaortic stenosis and the timing of surgery are controversial.[290] Postoperative issues include residual or recurrent obstruction and progressive aortic regurgitation. For severe

supravalvar obstruction, surgical intervention is recommended, resulting in adequate relief of the obstruction in most cases.[291]

Myocardial fibrosis and ventricular dysfunction can be a feature of severe aortic outflow obstruction in infancy. Although adequate relief of the obstruction results in significant clinical improvement, abolition of congestive heart failure symptoms, and myocardial remodeling in most children, ventricular hypertrophy or dilation persists along with various degrees of systolic or diastolic impairment in many. Other problems include myocardial ischemia, ventricular failure, and risk of sudden death.[292,293] Important concerns related to anesthesia and surgery are the potentially limited LV functional reserve and alterations of the fine balance between myocardial oxygen supply and demand. Maintenance of coronary perfusion and ventricular contractile function is key in the care of these children. Pharmacologic agents with vasoactive and inotropic properties should be readily available during anesthesia care.

PATENT DUCTUS ARTERIOSUS

Anatomy and Pathophysiology

The ductus arteriosus is an essential vascular structure in fetal life that connects the pulmonary trunk and thoracic aorta (see Figs. 17.4 and 18.1). It enables RV output into the descending aorta in the fetus, within the context of normally increased pulmonary vascular resistance. Persistent PDA can be an isolated finding or can be associated with other forms of heart disease. Prematurity is an important risk factor.

The magnitude and direction of great artery shunting depends on the size of the communication and the pulmonary vascular resistance. In children with moderate or large left-to-right shunts, the physiologic effects are those of increased pulmonary blood flow and LV volume overload.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Children with a tiny or small PDA have a normal life expectancy.[294] Those with hemodynamically significant communications eventually develop symptoms related to LV volume overload. In some cases, this predisposes them to pulmonary hypertension. Although unlikely in the current era, in the past, the long-standing high-pressure and high-flow states associated with a moderate or large patent ductus resulted in Eisenmenger syndrome in some children.

Ductal closure can be performed by surgical ligation or division. Surgery is the favored approach in preterm infants and those with large communications.[295] Percutaneous catheter occlusion can also be accomplished with a good success rate in infants and children[296] (see also Chapter 22). Ductal ligation can also be performed using video-assisted thoracoscopic surgery.[297,298] Regardless of the approach, interruption of this vascular structure is rarely associated with long-term issues. Children can expect a normal cardiovascular reserve and should be managed accordingly during future anesthesia care.

COARCTATION OF THE AORTA

Anatomy and Pathophysiology

Coarctation of the aorta is characterized by narrowing of the aortic lumen in the thoracic region. The constriction can be discrete or diffuse. In infants, a long, narrowed aortic segment often is associated with hypoplasia of the transverse arch and aortic isthmus, in which case other structural cardiac malformations may also be present.[299] Associated defects include a bicuspid aortic valve, VSD, mitral valve abnormalities, and other types of left-sided obstructive lesions. In the neonate, if the aortic arch pathology is severe, it can represent a ductal-dependent lesion for systemic blood flow. Hemodynamic consequences result from obstruction to systemic blood flow and increased LV afterload. During infancy, ventricular dilation and heart failure predominate.

In older children, the presentation is usually that of arterial hypertension, with a gradient between the upper and lower extremities. There is usually an element of LV hypertrophy although ventricular function is well preserved. Collateral circulation develops when the pathology is long-standing.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Symptoms associated with severe aortic arch obstruction or concomitant cardiovascular pathology lead to early intervention.[300] In the neonate, alterations in ventricular systolic function usually resolve after relief of the obstruction. Systemic hypertension and a residual gradient that exceeds 25 to 30 mm Hg are regarded as indications for reintervention. Various catheter-based and surgical approaches have been applied to the management of this lesion; each has advantages and disadvantages[301] (see also Chapter 22).

Repair at an early age is advocated in consideration of the reduced surgical risks for the younger age group and minimization of late morbidity with an early repair.[302] Long-term issues include systemic hypertension (independent of the hemodynamic result) and residual or recurrent aortic arch obstruction.[303] LV hypertrophy may persist in some children after repair, particularly in those undergoing interventions later in childhood. Abnormalities in diastolic ventricular function have been reported after successful repair.[304] Catheter techniques (i.e., balloon angioplasty with and without stent implantation) have been effective in relieving the obstruction and normalizing blood pressure.[305] This approach may be used either as primary therapy or to address residual or recurrent disease.[306] Aortic aneurysms can occur around the area of coarctation or elsewhere in the aorta after surgical intervention or balloon angioplasty. Additional long-term problems result from coexistent defects, such as bicuspid aortic valve and premature development of coronary artery disease. Aortic coarctation has been associated with cerebral aneurysms. Most children whose arch defects have been repaired, however, have essentially normal cardiac function when presenting for noncardiac procedures.

TETRALOGY OF FALLOT

Anatomy and Pathophysiology

Tetralogy of Fallot (TOF) is the most common cyanotic cardiac lesion (see Fig. 17.5).[307] This malformation is characterized by RVOT obstruction/pulmonary stenosis, an interventricular communication, RV hypertrophy, and aortic override. There is considerable variation in the severity of the disease, accounting for the wide clinical spectrum. The subpulmonary obstruction is due to anterior deviation of the infundibular septum and typically has both dynamic and fixed components.[308] Pulmonary valve stenosis almost invariably exists, and the main pulmonary artery and distal branches often demonstrate various degrees of hypoplasia. The limitation of pulmonary blood flow and magnitude of ventricular level right-to-left shunting account for the degree of cyanosis.

Pressure overload results in hypertrophy of the RV myocardium. The large, nonrestrictive VSD and the outflow obstruction account for a RV pressure at systemic levels while the pulmonary artery systolic pressure in the classic form of TOF remains normal. Increases in the severity of the RVOT obstruction (infundibular spasm) or decreases in systemic vascular resistance exacerbate right-to-left intracardiac shunting and systemic arterial desaturation, increasing the level of cyanosis. These features characterize

hypercyanotic episodes or tet spells in unoperated children. These spells are triggered by catecholamine release owing to pain, stress, and light anesthesia. In infants, the spells may be due to emotional upset. Treatment involves volume administration to augment RV preload and stroke volume, increasing the level of sedation or anesthesia, avoidance of exogenous catecholamines, and increasing systemic vascular resistance to enhance left-to-right shunting or minimize the amount of blood shunted in the right-to-left direction. Although the pulmonary vascular tone does not play a major role in this physiology, it is prudent to administer oxygen or increase the inspired oxygen concentration and limit factors that may increase pulmonary vascular tone and further impede pulmonary blood flow.

Several TOF variants are recognized, including the "pink" or mild forms at one end of the spectrum, and complex defects, such as pulmonary atresia with diminutive or discontinuous distal pulmonary artery branches, at the other. Associated cardiovascular anomalies in children with TOF include an atrial communication, right aortic arch, multiple VSDs, persistent left superior vena cava to the coronary sinus, complete AVSD, and abnormal origin or course of the coronary arteries.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

The surgical management of TOF has evolved from a strategy of a staged approach with initial palliation using a systemic-to-pulmonary shunt to a single-stage, definitive repair in infants. Ongoing controversy exists about the favored approach in the neonate or very young infant in need of an intervention.[309,310] In selected cases, percutaneous balloon pulmonary valvuloplasty has been performed as a palliative, temporizing measure.[311] The definitive repair of TOF, although a successful operation enabling most children to be free of symptoms, can be associated with significant postoperative residua.[312,313] Volume loads arise from pulmonary regurgitation, residual shunts, and the presence of aortopulmonary collaterals. Ventricular pressure loads can result from residual or recurrent obstruction of the RVOT or the pulmonary arteries. This pathology is associated with RV hypertension, myocardial hypertrophy, and reduced ventricular compliance.

Conditions that can require repeat intervention in TOF include pulmonary regurgitation, residual or recurrent pulmonary outflow tract obstruction, and hemodynamically significant residual intracardiac shunts. Catheter-based procedures can be effective in the management of obstruction of the pulmonary vasculature and have been applied to rehabilitate the vascular tree in cases of significant underdevelopment. Children who have undergone right ventricle–to–pulmonary artery reconstruction by means of placement of an extracardiac conduit eventually develop conduit failure (i.e., stenosis or regurgitation) requiring catheter interventions or reoperation.[314] Percutaneous valves that can be implanted in pulmonary position are now available, precluding the need for surgical valve replacement in some patients. Aortic root dilation can lead to increasing degrees of regurgitation and the need for surgery.

In the past, most children underwent definitive repair at an older age, consisting of an extensive right ventriculotomy to facilitate resection of the infundibular obstruction and closure of the VSD. Many were also subjected to procedures that included placement of a large patch that encompassed the subpulmonic region, valve annulus, and supravalvar region (i.e., transannular patch). Although effective in relieving the obstruction, this approach invariably resulted in pulmonary regurgitation, which was reasonably well tolerated but progressed over time.

On late follow-up, pulmonary regurgitation has been identified as a major cause of morbidity, and it may result in progressive RV dysfunction owing to volume overload, ventricular arrhythmias with their associated disabilities, and even sudden death. In recognition of the long-term morbidity linked to severe pulmonary regurgitation, the surgical strategy for this defect has undergone reappraisal and modification over the years.[315] A current method uses a transatrial approach for closure of the VSD, minimizing the size of an infundibular incision (if one is required), and avoiding or limiting the size of the transannular patch.[316,317]

Although surgical refinements have led to overall improvements in postoperative outcomes, the preoperative evaluation of these children for noncardiac surgery should include inquiries regarding exercise tolerance as an indicator of functional status and an appraisal of RV function, residual pathology, potential rhythm abnormalities, and conduction disturbances. Review of data obtained by surveillance echocardiography is important in planning an anesthetic. Magnetic resonance imaging is extremely useful in the evaluation of RV systolic function, quantitation of the severity of pulmonary regurgitation, and evaluation of the distal pulmonary vascular bed. If available, the results of these studies should also be reviewed. Electrophysiologic testing and programmed ventricular stimulation may be indicated to refine antiarrhythmic drug therapy, for ablation of arrhythmia foci, or for implantation of a cardioverter-defibrillator system.

After corrective surgery, a subset of children develops a pattern that is characterized by RV diastolic noncompliance, which is known as *restrictive RV physiology*. This may have acute and chronic consequences. In the late postoperative follow-up, it is associated with a reduced likelihood of progressive pulmonary regurgitation and RV dilation. The right ventricle operates at a greater end-diastolic pressure in this setting, and affected individuals demonstrate superior exercise performance in addition to a reduced likelihood of developing ventricular rhythm abnormalities.[318]

Perioperative goals for the child with pulmonary regurgitation and RV dysfunction include optimizing RV filling, maintaining or supporting RV function, and minimizing factors that may further increase RV work (e.g., increased pulmonary vascular resistance, increased peak inspiratory pressures). Any detrimental factor that may affect the right ventricle can also negatively affect the left ventricle owing to the phenomenon of ventricular interdependence.

D-TRANSPOSITION OF THE GREAT ARTERIES

Anatomy and Pathophysiology

In D-transposition of the great arteries (D-TGA), the aorta arises from the anatomic right ventricle, and the pulmonary artery arises from the left ventricle (see Fig. 17.6). This anomaly accounts for the most common cause of cyanotic heart disease in the neonatal period. Associated defects include VSDs, LVOT obstruction, and coronary artery anomalies.

In D-TGA, the systemic and pulmonary circulations operate in parallel rather than in series, resulting in cyanosis. Mixing at the atrial, ventricular, or ductal level is essential for survival. Initial management in most infants includes prostaglandin E_1 therapy to maintain ductal patency and to enhance intercirculatory mixing. If restrictive, the interatrial communication may require enlargement by balloon atrial septostomy.

Because most neonates with D-TGA are otherwise healthy, the concerns before surgical correction primarily are those associated with diagnostic procedures or interventions in the cardiac catheterization laboratory. Considerations for anesthetic management primarily are related to cyanosis. An inadequate communication for

intercirculatory mixing results in significant hypoxemia, potentially progressing to metabolic acidosis caused by compromised tissue oxygenation. Less commonly, increased pulmonary vascular resistance may account for severe cyanosis despite prostaglandin E_1 therapy and an adequate anatomic communication.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

The approach to D-TGA many decades ago consisted of an atrial baffle (i.e., atrial switch) or redirection procedure (i.e., Mustard or Senning operations). Physiologic correction was accomplished by allowing systemic venous blood to enter the left ventricle and pulmonary artery while pulmonary venous blood was rerouted through the tricuspid valve into the right ventricle and aorta. The right ventricle remained as the chamber ejecting against systemic afterload. These procedures, while relieving cyanosis and allowing reasonably good survival,[319] led to long-term complications such as sinus node dysfunction and atrial rhythm disturbances.[320] Progressive RV dilation, tricuspid (i.e., systemic AV valve) annular dilation, associated regurgitation, and eventual RV dysfunction or failure were causes of major morbidity.[321–323] In addition to the rhythm abnormalities and conduction defects, this problem was thought to account for sudden death in some individuals later in life. Other problems included progressive obstruction of venous pathways and atrial baffle leaks with associated intracardiac shunting. Abnormal RV and LV responses to exercise have also been reported in these patients.[324]

The arterial switch operation (i.e., Jatene procedure) is considered the standard surgical approach in neonates with D-TGA. The repair establishes a normal, concordant relationship between the ventricles and their respective great arteries, achieving anatomic correction. The procedure involves transection of the arterial trunks above the level of the semilunar valves, anastomotic connections to their appropriate outflows, translocation of the coronary arteries to the neoaortic root, and closure of existing intracardiac communications (see Fig. 17.7A–E). Normal physiology is restored, enabling the left ventricle to function as the systemic chamber. This surgical procedure can be performed with excellent results, and long-term outcomes are very favorable.[325–328] Potential postoperative problems include supravalvar pulmonary or aortic obstruction. Neoaortic root dilation and aortic regurgitation can be identified on follow-up in some children. Ventricular function is normal in most cases.[329]

Anesthetic management of children after the arterial switch operation in general should be the same as in those without structural or functional cardiovascular abnormalities. However, there is some degree of concern related to late coronary artery problems that may not be evident clinically or identified by routine surveillance methods. Investigations have demonstrated postoperative regional LV wall motion abnormalities, evidence of myocardial perfusion defects, and pathologic changes in the coronary vasculature, suggesting a risk for coronary insufficiency.[330–334] Thus, cognizance of these issues in this patient group is prudent.

CONGENITALLY CORRECTED TRANSPOSITION OF THE GREAT ARTERIES

Anatomy and Pathophysiology

Congenitally corrected transposition is characterized by AV and ventriculoarterial discordance (double discordance). There is ventricular inversion and malposition of the great vessels. In this anomaly, the morphologic right atrium empties into an anatomic left ventricle, which then contracts into the pulmonary trunk. The morphologic left atrium opens into an anatomic right ventricle, which ejects into the aorta. The aorta is usually oriented in a leftward and anterior position with respect to the pulmonary artery, thus accounting for nomenclature of L-transposition of the great arteries (L-TGA) in this lesion.

Cyanosis is absent because the circulations are physiologically corrected. The anatomic right ventricle functions as the systemic pump in this lesion. Associated defects are frequently present and include pulmonary outflow tract obstruction, an interventricular communication, and tricuspid valve (left-sided) abnormalities. This pathology can remain undetected until the onset of arrhythmias or syncope owing to complete AV block or the effects of concomitant defects later in life.[335]

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Without associated defects, children with corrected transposition may do well for many years. Development of complete AV block is common with increasing age.[336] Young children with coexistent defects that maintain LV pressure at systemic levels might be suitable candidates for a surgical intervention that restores the left ventricle as the systemic chamber.[337] This complex repair, known as the double-switch operation or a variation thereof, combines redirection of the systemic and pulmonary venous flows in an atrial baffle procedure with the arterial switch operation. This strategy, however, may not affect mortality compared with conservative management.[338]

Issues that require long-term surveillance in children with congenitally corrected transposition include RV performance and tricuspid valve competency.[339] The overall long-term survival of individuals with this condition is substantially reduced compared with age-matched controls.[340,341]

TRUNCUS ARTERIOSUS

Anatomy and Pathophysiology

Truncus arteriosus is characterized by a single arterial trunk that gives rise to the aorta, pulmonary root, and coronary arteries (see Fig. 17.8). A ventricular communication is located underneath the single arterial root or truncal valve. Various anatomic types are identified based on the origin of the pulmonary arteries from the arterial trunk.[342,343] Associated findings may include a right aortic arch, aortic arch interruption, abnormalities of the truncal valve (e.g., abnormal number of cusps, stenosis, regurgitation), and coronary artery anomalies. Approximately one-third of children with truncus arteriosus have DiGeorge syndrome (see Chapter 16).

Clinical features of the neonate with this defect largely depend on the status of the pulmonary vasculature. If the resistance is increased, the infant is well compensated. The normal decrease in pulmonary vascular resistance leads to symptoms related to pulmonary overcirculation and congestive heart failure, accounting for the need for surgical intervention early in life. Truncus arteriosus is one of the structural malformations associated with a significant risk for adverse events before repair, because balancing the pulmonary and vascular resistances can be quite challenging.[344] The physiology that characterizes a reduced pulmonary vascular resistance and a significant runoff setting is that of an increased arterial oxygen saturation, reduced diastolic arterial pressures (potentially leading to myocardial ischemia), systemic hypotension, impaired cardiac output, and hypoperfusion of distal beds.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Surgery for truncus arteriosus consists of detaching the main pulmonary artery from the truncal root, repairing the ensuing aortic wall defect, closing the VSD to allow LV output through the arterial root, and placing an extracardiac right ventricle–to–pulmonary artery conduit. Alternative approaches to establishing RV outflow continuity have been performed without the use of conduits.[345]

Neonates undergoing truncus arteriosus repair have excellent survival rates.[346–349] Late complications include conduit failure, residual or recurrent pulmonary artery obstruction, and truncal valve problems. Truncal valve dysfunction may require repair or replacement. The main issues of concern are the status of the right ventricle–to–pulmonary artery conduit and truncal root, consequences related to semilunar valve problems, and biventricular function.

EBSTEIN ANOMALY

Anatomy and Pathophysiology

The classic findings in Ebstein anomaly of the tricuspid valve include a large, sail-like anterior leaflet and apically displaced septal and posterior leaflets.[350,351] This configuration commonly results in an atrialized portion of the right ventricle and tricuspid regurgitation. Some degree of RV dysplasia is common. An interatrial communication is a frequent finding, and it can produce right-to-left shunting and clinical cyanosis. The spectrum of disease ranges from minimal or no symptoms to intractable congestive heart failure.[352] A neonatal presentation implies a major clinical problem and usually portends a poor prognosis. Symptoms in older children include cyanosis, palpitations, dyspnea, and exercise intolerance. The association of Wolf-Parkinson-White syndrome with Ebstein anomaly is well recognized. Initial presentation can be related to the development of supraventricular tachycardia (reported ~20%–25% incidence of accessory pathways).

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Children with Ebstein anomaly can be asymptomatic, requiring only conservative management and follow-up. Surgery is indicated for significant tricuspid regurgitation, closure of interatrial communications, or other associated problems. Procedures to ablate arrhythmias may be performed. In contrast to adults, children are less likely to require valve replacement.[353] A cavopulmonary or Glenn connection is performed in some cases as part of a so-called one-and-a-half ventricle approach to limit the right-sided volume load associated with severe tricuspid valve regurgitation.[354,355] Good functional outcomes and long-term survival have been reported after surgery for Ebstein anomaly.[356] Atrial arrhythmias in affected individuals are common before and after surgery.

INTERRUPTED AORTIC ARCH

Anatomy and Pathophysiology

Interrupted aortic arch is an uncommon malformation characterized by discontinuity between the ascending and descending thoracic aorta (see Fig. 17.14). Ductal patency is essential for systemic perfusion beyond the area of interruption. This anomaly is classified in terms of the site of interruption. Type A occurs distal to the left subclavian artery, type B between the left carotid and left subclavian arteries, and type C between the carotid arteries. Type B interruption is the most common variant, followed in frequency by types A and C.

Interrupted aortic arch is typically associated with a posteriorly malaligned VSD, resulting in subaortic obstruction. Associated defects include a right aortic arch, aberrant origin of a subclavian artery, and truncus arteriosus. Many children with this anomaly have DiGeorge syndrome.

Neonatal presentation of interrupted aortic arch is related to ductal closure in the setting of aortic arch obstruction (e.g., congestive heart failure, poor perfusion, cardiovascular collapse, shock) and occasionally to differential cyanosis (i.e., oxygen saturation in right hand is less than that in the foot). Stabilization of the infant and initiation of prostaglandin E_1 therapy is critical. The site of interruption and presence of coexistent anomalies can influence the selection of sites for blood pressure monitoring and pulse oximetry. An adequate response to prostaglandin E_1 therapy implies no significant gradient between the areas proximal and distal to the obstruction and an oxygen saturation differential (i.e., increased values in beds supplied proximal to the interruption, reduced values distally).

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Surgical intervention is necessary for interrupted aortic arch during the first few days of life. The goal is to establish aortic arch continuity and to address coexistent defects. The current approach favors a one-stage repair.[357–359] Survival in uncomplicated cases is excellent.[360] Problems after repair mainly involve the LVOT.[361] Reoperation may be required and in some cases consist of LVOT enlargement (i.e., Konno procedure). Eventual aortic root or valve replacement or a Ross-Konno procedure may be necessary. Aortic arch obstruction can occur in the long-term. Given that the site of obstruction has implications for monitoring, the anesthesia provider should be aware of the anatomic details and the severity of the pathology.

CONGENITAL ANOMALIES OF THE CORONARY ARTERIES

Anatomy and Pathophysiology

Congenital anomalies of the coronary arteries include an abnormal origin of one of the main branches, aberrant vascular course, or pathologic communications that involve the coronary circulation.[362,363] The most common anomalies detected during childhood include anomalous origin of the left main coronary artery from the pulmonary artery (ALCAPA), coronary artery–to–pulmonary artery fistulas, and coronary cameral fistulas (i.e., connection between a coronary artery and cardiac chamber). Although rare, anomalous origin of a coronary artery from the incorrect (contralateral) sinus of Valsalva can occur in asymptomatic children and adolescents.[364] In some instances, a major coronary artery courses between the great arteries. This situation can be associated with compromised coronary blood flow and myocardial ischemia during exercise, presumably related to dilation of the arterial roots to accommodate the increased stroke volume.

The clinical presentation varies depending on the nature of the anomaly. Infants and young children with ALCAPA typically exhibit severe ventricular dysfunction and mitral valve regurgitation, which are largely ischemic in nature. Children with fistulous coronary artery connections can present with a heart murmur or evidence of ventricular volume overload. Significant symptoms indicate congestive heart failure. Other coronary artery anomalies can manifest as myocardial ischemia, causing exertional syncope or chest pain, and in some cases, arrhythmias may lead to a near-death event.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

After surgical intervention for ALCAPA, most children demonstrate reasonable recovery of myocardial function. Others continue to exhibit alterations in myocardial performance and can develop dilated cardiomyopathy; if it is severe, they may require cardiac transplantation. A few children reach adulthood without symptoms or any intervention. Coronary artery fistulas resulting in congestive symptoms are referred for catheter-based or surgical interventions. Angina complaints, myocardial infarction, and sudden death are risks when an aberrant coronary artery courses between the arterial trunks. The risk is greater when the left coronary artery originates from the right sinus of Valsalva and courses between the aorta and the RVOT. Sudden death is most likely to occur during or immediately after strenuous exercise. The implications of anesthesia for coronary artery anomalies primarily are related to the underlying potential for myocardial ischemia, effects of ventricular volume overload, and ventricular dysfunction.

SINGLE VENTRICLE

Anatomy and Pathophysiology

The single-ventricle (i.e., univentricular heart) spectrum encompasses several congenital cardiac defects. They are characterized by abnormalities such as ventricular hypoplasia (i.e., HLHS), AV valve atresia (i.e., tricuspid atresia), or abnormal AV connections (i.e., double-inlet left ventricle). Pathologies with two distinct ventricles may also be considered in the functional single-ventricle category because of associated defects that may preclude a biventricular circulation (i.e., unbalanced AVSD).

Single-ventricle physiology is characterized by complete mixing of the systemic and pulmonary venous circulations at the atrial or ventricular levels. Aortic or pulmonary outflow tract obstruction is a common feature of these pathologies. An important management strategy early in the palliation pathway involves optimizing the balance between the pulmonary and systemic circulations.

Treatment Options, Residua, Sequelae, and Long-Term Outcomes

Surgical interventions available for children with functional single-ventricle physiology include the following procedures.

Systemic to Pulmonary Artery Shunt

Infants with limited or ductal-dependent pulmonary blood flow require the creation of a connection between the systemic and pulmonary circulations. This most commonly takes the form of a Gore-Tex graft between the right subclavian and right pulmonary arteries (i.e., modified right Blalock-Taussig shunt). The goal of the procedure is to augment or allow for pulmonary blood flow. Potential problems include shunt malfunction associated with reductions in pulmonary blood flow and congestive heart failure related to excessive pulmonary blood flow. Several factors determine blood flow across an aortopulmonary shunt, with systemic arterial pressure playing a major role.

Pulmonary Artery Band

Pulmonary artery banding results in limitation of pulmonary blood flow in children with minimal or no restriction. The intervention aims to protect the pulmonary vascular bed from increased flow and excessive pressure, an essential requirement for subsequent strategies in the child with a functional single ventricle.

Distortion of the proximal branch pulmonary arteries can result from pulmonary artery band placement. The main considerations in these children are the presence of an intracardiac communication, associated shunting, ventricular volume load, the consequences of ventricular hypertrophy developed as a response to the mechanical limitation of pulmonary blood flow, and issues associated with coexistent defects. In a few children, pulmonary artery banding can lead to ventricular dysfunction and the development of or an increase in the severity of AV valve regurgitation.

Norwood Procedure

In infants with HLHS, its variants, and other lesions with similar hemodynamic consequences, systemic blood flow largely depends on patency of the ductus arteriosus. Cerebral and coronary blood flow is usually provided in retrograde fashion across a typically hypoplastic transverse aortic arch. A key strategy in the management of these neonates before cardiac surgery is to optimize systemic perfusion and the balance between the pulmonary and systemic circulations.[365] Alteration of this balance manifests with signs of inadequate systemic output (e.g., hypotension, lactic acidosis, decreased urine output) within the context of high systemic arterial oxygen saturation, reflecting the relatively excessive pulmonary blood flow.

In this setting, maneuvers that increase pulmonary vascular resistance are indicated to improve hemodynamics, including limiting inspired oxygen concentrations, the administration of subambient gas mixtures, and increasing the partial pressure of carbon dioxide (P_{CO_2}) by hypoventilation or the administration of inspired carbon dioxide. A comparison of hypoxia versus hypercarbia in infants with HLHS under conditions of anesthesia and paralysis demonstrated that although decreases in both conditions, inspired CO_2 was more effective than hypoxic gas mixtures at increasing parameters associated with improved systemic output.[366] The administration of inspired carbon dioxide may be favored over hypoventilation as a means of increasing pulmonary vascular resistance and improving the overall clinical condition.

The Norwood procedure is considered the first step along the three palliative stages for infants with HLHS or similar cardiac malformations.[367] The intervention, also referred to as stage I single-ventricle palliation or reconstruction, is typically performed within the first few days of life. Surgery consists of aortic reconstruction or creation of a neoaorta, establishing continuity between the native main pulmonary artery and aortic arch to provide for unobstructed systemic outflow from the right ventricle; the creation of an unrestricted atrial communication by means of an atrial septectomy; and establishing a source of pulmonary blood flow (see Fig. 17.11). Pulmonary blood flow is allowed by the creation of a modified Blalock-Taussig shunt or placement of a right ventricle–to–pulmonary artery conduit (i.e., Sano modification and variations). Although the potential benefits of one approach over the other have been debated, additional studies, with long-term follow-up, are required to provide further information in this regard.[368-373] It should be emphasized that the functional single ventricle following stage I palliation handles both the systemic and pulmonary circulations and consequently it is a volume loaded ventricle. This leads to changes in ventricular geometry that include progressive chamber dilatation and may be associated with problems such as the development of tricuspid regurgitation, systolic and/or diastolic functional impairment.

A hybrid stage I strategy has been used as an alternate approach to the Norwood procedure in the neonate. The combined effort of an interventional cardiologist and surgeon aims at delivering a stent across the ductus arteriosus under fluoroscopic guidance and banding the branched pulmonary arteries via a median

sternotomy.[374–377] The interatrial communication is enlarged as needed at the same time or soon thereafter.

Outcomes after the Norwood procedure vary; good results imply operative survival for 85% to 90% of infants. Immediate postoperative problems include inadequate or excessive pulmonary blood flow and decreased myocardial performance. Monitoring of mixed venous oxygen saturation and cerebral near-infrared spectroscopy are helpful in balancing the pulmonary and systemic circulations in this setting. Occasionally, aortic arch obstruction develops, and less commonly, the atrial septum becomes restrictive. Interstage mortality accounts for attrition among Norwood survivors.[378] Among infants who have undergone placement of a right ventricle–to–pulmonary artery conduit, stenosis of the conduit associated with progressive cyanosis may account for significant interstage morbidity and often requires intervention or early second-stage palliation.[379,380]

The anticipated arterial oxygen saturation after stage I surgery is expected to be in the range of 75% to 85%. During perioperative care and in the selection of monitoring sites it should be considered that the presence of a Blalock-Taussig shunt can compromise ipsilateral subclavian artery flow and may not allow for accurate blood pressure assessment. In these infants, the right ventricle ejects into the pulmonary and systemic circulations. Although this is a more stable arrangement compared with the preoperative physiology, it remains a relatively fragile parallel circulation. These infants display little tolerance to even the most common childhood conditions, and ailments such as dehydration, febrile illnesses, or other stresses that can have catastrophic consequences. Despite these challenges, successful outcomes have been reported during noncardiac surgery for a variety of procedures, including those that may be associated with significant hemodynamic perturbations.[381]

Glenn Anastomosis or Hemi-Fontan Procedure

A cavopulmonary connection or Glenn procedure (i.e., stage II palliation) consists of the creation of a direct anastomosis between the superior vena cava and a branch pulmonary artery (see Fig. 17.12). This is considered an intermediary step in the sequential diversion of the systemic venous blood into the pulmonary vasculature in children with single-ventricle physiology. The original or classic Glenn operation consisted of an end-to-end anastomosis of the transected superior vena cava onto a disconnected right pulmonary artery. Long-term issues included decreasing arterial saturation, attributed in many cases to the development of pulmonary arteriovenous fistulae.[382] The current approach is to anastomose the superior vena cava to the right pulmonary artery in end-to-side fashion, preserving pulmonary artery continuity (i.e., bidirectional cavopulmonary anastomosis [BCPA] or bidirectional Glenn connection). Depending on the specific anatomic abnormalities, right, left, or bilateral BCPAs may be indicated.

An alternative approach in the second-stage of single ventricle palliation is the hemi-Fontan procedure. It directs superior vena cava blood to the pulmonary circulation while excluding entry of superior vena cava blood into the right atrium by placement of a patch (dam). This approach provides a step closer to lateral tunnel Fontan completion (described later). When present, a systemic-to-pulmonary artery connection (shunt or conduit) is ligated and divided as part of stage II palliation, regardless of whether a BCPA or hemi-Fontan procedure is undertaken.

The second-stage intervention requires a low pulmonary vascular resistance because of the passive nature of the pulmonary blood flow. This approach provides adequate palliation to a significant number of infants at an early age while conferring favorable hemodynamic benefits.[383] Diverting a portion of the systemic venous return directly into the pulmonary bed reduces the output requirements of the single ventricle while decreasing the ventricular volume load and myocardial work.

One study demonstrated a 12% rate of interstage attrition between BCPA and the Fontan procedure in children with HLHS palliation.[384] Risk factors included tricuspid valve regurgitation and low body weight at the time of the BCPA. These factors can affect the anesthesia-related risks for noncardiac procedures required between these two stages of palliation.

Considerations in children who have undergone palliation include the passive nature of the pulmonary blood flow, the importance of maintaining adequate intravascular volume (i.e., minimal fasting) to enhance pulmonary blood flow, and limiting significant increases in pulmonary vascular tone. It should be noted that high peak inflation pressures or positive-end expiratory pressure (PEEP) can reduce pulmonary blood flow. Pulmonary blood flow and systemic arterial oxygenation are significantly influenced by the interplay between pulmonary artery pressure (i.e., equal to the pressure in the superior vena cava), pulmonary venous pressure, and pulmonary vascular resistance. The expected systemic arterial oxygen saturation ranges between 75% and 85%. Although factors that increase pulmonary vascular resistance can negatively influence pulmonary blood flow, the observation has been made that early after BCPA, moderate hypercapnia with respiratory acidosis improves arterial oxygenation and reduces oxygen consumption, enhancing overall oxygen transport in these children.[385] Hyperventilation can decrease cerebral oxygenation and should be avoided.[386] Postoperative issues include hypoxemia related to the development of collateral vessels that bypass the pulmonary circulation, AV valve regurgitation, and impaired ventricular function.

Fontan Procedure

The Fontan procedure is the final step (i.e., stage III reconstruction) in the separation of the pulmonary and systemic circulations in children with a functional single ventricle. This intervention allows passive blood flow from the inferior vena cava into the pulmonary vascular bed while bypassing the heart and achieves a circulation in series (see Fig. 17.13). The creation of a fenestration, or communication, between the systemic venous pathway and physiologic common atrium is favored in some cases as it allows right-to-left shunting (pop off), providing cardiac output that is not solely dependent on pulmonary blood flow. It also alleviates potential problems associated with chronically increased systemic venous pressures. Common features of the various Fontan modifications are separation of the pulmonary and systemic circulations and relief of hypoxemia.[387] Pulmonary blood flow occurs without an intervening ventricular chamber. It depends critically on the transpulmonary pressure gradient (or driving pressure across the pulmonary bed) and is influenced by pulmonary vascular resistance. This blood flow determines cardiac output, emphasizing the importance of adequate hydration and maintenance of central venous pressure.

Several anatomic and hemodynamic variables influence Fontan physiology.[388] Critical factors include unobstructed systemic venous return, status of the pulmonary vasculature, reduced intrathoracic pressures, systemic AV valve competency, systemic ventricular function, unobstructed systemic outflow, and atrial contribution to ventricular filling.[389] Long-term problems are related to sinus node dysfunction, loss of AV synchrony, atrial arrhythmias, AV valve regurgitation, ventricular dysfunction, venous pathway

obstruction or thrombotic complications, and symptoms resulting from a chronic reduced cardiac output state.[390] Long-standing increases in systemic venous pressures in children after the Fontan procedure can produce hepatic dysfunction, coagulation defects, protein-losing enteropathy, rhythm disturbances, and plastic bronchitis. The quality of life after the Fontan operation can be compromised by a late decline in functional status, reoperations, arrhythmias, and thromboembolic events.[391–396] Decreased exercise tolerance in most children represents limited cardiopulmonary reserve, which manifests as an inability to increase cardiac output to meet the metabolic demands associated with increased work. In some cases, surgical revision to a more hemodynamically favorable Fontan modification is indicated.[397,398]

Several considerations are important in the perioperative care of children with Fontan circulation.[399,400] Even mild alterations in factors that influence cardiac output, such as ventricular preload, AV synchrony, contractile function, afterload, and stress response, can adversely affect hemodynamics. Ensuring the adequacy of hydration, preserving sinus rhythm, and limiting the stress response are key goals. Maintenance of adequate ventricular function may require the administration of inotropic or vasoactive agents perioperatively. Because systemic venous pressures are typically increased, the potential for bleeding and its effects on ventricular filling should be considered. The likelihood of blood loss with ensuing hemodynamic instability is exacerbated by the coagulation defects in these children.[401] The potential for end-organ dysfunction related to chronically decreased organ perfusion, particularly in the renal and hepatic systems, should be considered, and problems may require interventions to minimize perioperative morbidity. Drugs or devices appropriate for cardiac rhythm or arrhythmia management should be readily accessible.

Important principles apply to airway and ventilatory management after the Fontan operation. Although spontaneous ventilation favors phasic pulmonary flow patterns in these children, controlled ventilation is preferable in most cases. This approach minimizes the detrimental effects of factors, such as hypoventilation, atelectasis, hypoxemia, hypercarbia, and respiratory acidosis on pulmonary vascular resistance during spontaneous ventilation, limiting passive drainage of systemic venous blood into the pulmonary circulation. The pH and P_{CO_2} should be maintained within the normal range, and arterial oxygen saturation should remain close to baseline. The saturation level may depend on the presence or absence of a fenestration in the Fontan pathway and the degree of right-to-left shunting. Mechanical ventilation with large lung volumes can impair pulmonary blood flow because high mean intrathoracic pressures transmitted to the pulmonary vascular bed increase pulmonary artery pressures and decrease systemic venous return. Judicious use of mechanical ventilatory support is therefore warranted. Suggested parameters include smaller than usual tidal volumes and reduced PEEP times, allowing delivery of the smallest mean airway pressure possible and normal to relatively small inspiratory times (i.e., normal to slightly prolonged inspiratory/expiratory ratios). Although adequate minute ventilation may require increases in the respiratory rate, the potential detrimental effects of very fast rates should also be considered. The goals are to maintain adequate lung volumes, functional residual capacity, and optimal gas exchange. Modern modes of assisted mechanical ventilation–for example, pressure support ventilation with the ability to accurately control preset indexes–may also be suitable in this patient population.

It should be emphasized that patients with single-ventricle physiology are at high risk for complications during noncardiac surgery regardless of their stage of palliation.[44] A retrospective chart review of 70 patients with single-ventricle physiology who underwent 102 anesthetics for a variety of procedures revealed 100% 48-hour survival, although almost 12% of cases involved an adverse event associated with their anesthetic.

Several reports have documented the use of laparoscopic surgery in the patient with single-ventricle circulation.[381,402–404] Despite its benefits, a significant concern in this setting is the potential for cardiorespiratory compromise owing to the physiologic effects of the pneumoperitoneum, patient positioning (Trendelenburg or reverse Trendelenburg), and increased carbon dioxide tensions. A study assessing cardiac function by transesophageal echocardiography in single-ventricle patients reported a reversible decrease in shortening fraction during laparoscopic gastrostomy tube placement.[405] It is well recognized that in the single-ventricle patient group there is also less tolerance for complications that might be associated with the procedure (e.g., gas embolism, pneumothorax, and pneumomediastinum), resulting in increased vulnerability for untoward events. During these procedures communication between the anesthesia and surgical teams is imperative. Early consideration should be given to reducing the intraabdominal pressure by deflation of the pneumoperitoneum and possible conversion to an open procedure if hemodynamic, oxygenation, or ventilation difficulties are encountered.

Summary

Noncardiac surgery in children with CHD can usually be accomplished in a safe and effective manner. A comprehensive understanding of the child's cardiovascular anatomy, physiology, and potential hemodynamic alternations is essential to guide appropriate perioperative management and to achieve the best possible outcomes. Many children with CHD have undergone complete repair in infancy, with resultant normal or near-normal hemodynamics at the time of noncardiac surgery. Routine care is likely to be well tolerated by these children. However, special attention should be given to identify children at increased risk, particularly those with unrepaired defects or those who have undergone palliative interventions. Factors such as congestive heart failure, cyanosis, pulmonary hypertension, young age, or significant residua or sequelae increase the potential for perioperative problems.

An important objective in caring for children with a history of CHD is to diminish cardiac-related morbidity and minimize the likelihood of an adverse outcome. An interdisciplinary approach is much preferred to accomplish this goal. Application of perioperative strategies that can limit the risks of anesthesia and surgery should be a combined effort by all health care providers involved. Anticipation of these risks can decrease the potential for complications and facilitate prompt and appropriate treatment when difficulties are encountered. Good communication among the perioperative team members is essential.

ANNOTATED REFERENCES

Brown ML, DiNardo JA, Odegard KC. Patients with single ventricle physiology undergoing noncardiac surgery are at high risk for adverse events. *Paediatr Anaesth.* 2015;25(8):846-851.

This is a retrospective review of all patients who underwent single-ventricle palliation at a single institution with the goal to assess outcomes related to noncardiac surgery. The study identified 417 patients with single-ventricle physiology who underwent a palliative procedure. Of these, 70 patients (16.7%) underwent 102 anesthetics for 121 noncardiac procedures. The study observed no mortality during

or after noncardiac surgery; however, a high rate (11.8%) of intraoperative and early postoperative adverse events was identified in this patient population.

Chau DF, Gangadharan M, Hartke LP, et al. The post-anesthetic care of pediatric patients with pulmonary hypertension. *Semin Cardiothorac Vasc Anesth*. 2016;20(1):63-73.

This work presents an excellent review regarding the perioperative care of pediatric patients with pulmonary hypertension. The paper addresses topics such as current concepts related to the condition, preanesthetic preparation, risks factors for adverse events during postanesthesia care, and postanesthetic disposition.

Faraoni D, Zurakowski D, Vo D, et al. Post-operative outcomes in children with and without congenital heart disease undergoing noncardiac surgery. *J Am Coll Cardiol*. 2016;67(7):793-801.

This study compared the incidence of mortality and major adverse postoperative outcomes following noncardiac surgery in children with and without CHD using a pediatric database of the American College of Surgeons National Surgical Quality Improvement Program. The review identified 4520 children with CHD who underwent noncardiac surgery. Children in each of three subgroups consisting of minor, major, and severe CHD were matched and compared with controls without CHD who underwent noncardiac surgery of comparable complexity. It was found that children with major or severe CHD who undergo noncardiac surgery have an increased risk of mortality with a higher incidence of life-threatening postoperative outcomes compared with children without CHD.

Matisoff AJ, Olivieri L, Schwartz JM, et al. Risk assessment and anesthetic management of patients with Williams syndrome: a comprehensive review. *Paediatr Anaesth*. 2015;25(12):1207-1215.

The article is a comprehensive review addressing the clinical manifestations of Williams syndrome and proposing a protocol for risk assessment based on current literature. The paper also provides recommendations for preoperative evaluation and management of anesthesia in affected low-, moderate-, and high-risk patients.

Ramamoorthy C, Haberkern CM, Bhananker SM, et al. Anesthesia-related cardiac arrest in children with heart disease: data from the Pediatric Perioperative Cardiac Arrest (POCA) registry. *Anesth Analg*. 2010;110:1376-1382.

This is a report from the Pediatric Perioperative Cardiac Arrest (POCA) registry on anesthesia-related cardiac arrests, with a focus on children with heart disease. The data were provided by many North American institutions. Children with heart disease who suffered a cardiac arrest were sicker that those without heart disease and more likely to suffer arrest from cardiovascular causes. Mortality rates were greater for those with heart disease. The events were more likely to occur in the general operating room compared with the cardiac setting. The subset of children with a single ventricle was the most common category of heart disease to suffer cardiac arrest. Children with aortic stenosis (e.g., Williams Syndrome) and cardiomyopathy had the greatest cardiac arrest–related mortality rates.

Williams GD, Maan H, Ramamoorthy C, et al. Perioperative complications in children with pulmonary hypertension undergoing general anesthesia with ketamine. *Paediatr Anaesth*. 2010;20(1):28-37.

This is a retrospective study in children with pulmonary arterial hypertension to determine the nature and frequency of periprocedural complications and to assess whether ketamine administration was associated with complications. In this cohort (68 children), the incidence of cardiac arrest was 10% for major surgery, 0.78% for cardiac catheterization, and 1.6% for all procedures. There was no procedure-related mortality. Ketamine administration was not associated with an increased rate of complications.

Summary

DISORDERS OF THE NERVOUS SYSTEM are common in childhood, and their diverse manifestations and complications may lead to diagnostic and surgical interventions that require anesthesia. Children with these disorders are subject to the same acute illnesses, such as acute appendicitis, as other children. Many neurologic disorders exert profound effects on other body systems that function under complex autonomic control. For example, dysfunction of bulbar musculature may predispose to regurgitation and aspiration in the perioperative period because protective reflexes may be impaired. Medications taken for chronic conditions may interact with anesthetic agents, which may have an impact on an underlying disorder in specific ways. The mechanisms of these interactions are becoming better understood with advances in molecular genetics. Anesthesiologists must have an understanding of the patient's underlying neurologic or neuromuscular condition and its influence on anesthesia management to optimize perioperative outcomes.

General Considerations

The term *neurologic disorder* encompasses a wide variety of conditions that may have extremely mild or very serious effects (Table 24.1).[1–5] These disorders are likely to be associated with a degree of physical, cognitive, or combined disabilities. Many children with severe physical disabilities have normal intelligence and are competent to make decisions about treatment options. Those with mild cognitive impairment may wish to be consulted about treatment choices; adolescents in particular must be involved in decision making.[6] This approach is especially important for managing individuals with chronic disorders who are accustomed to thinking about health issues and who often have strong and well-defined opinions about how they wish to be treated.[7]

When planning anesthesia for these individuals, physicians must become knowledgeable about them and their conditions. Assumptions should not be made about their level of comprehension or about how they and their parents' view the choices available.[8] It was formerly acceptable practice for children with chronic neurologic disorders to be excluded from the full range of therapeutic options, but it is now essential that all options are included.[9]

Parents of children with chronic disorders of all types are usually accustomed to dealing with health care situations and often have thought carefully about the implications of various treatments. They know the child best and are usually most qualified to make decisions by proxy. Widespread use of the Internet has assisted many parents in becoming knowledgeable about their child's condition and about potential interventions.[10] Their aims are usually entirely appropriate, and this knowledge may assist physicians in their collaboration with children and parents in determining optimal management. Occasionally, the information has been obtained from an unreliable source and may be inaccurate or inappropriate for a particular child.[11] Misinformation can precipitate difficult situations for professionals, especially when there is a perceived disparity between the desires of the parents and those of the child and what the clinician considers to be in the child's best interest. The surgical team members usually are most involved in the process of obtaining informed consent, but the anesthesiologist must participate in the dialogue because anesthesia may be the part of treatment that carries the greatest risk.

TABLE 24.1 Neurologic Disorders

Condition	Prevalence
Cerebral palsy: all types	2.2 per 1000 live births
Epilepsy	5–10 per 1000 all ages
Central nervous system tumors	1–5 per 1000 all ages
Neuromuscular disorders (all ages)	1 per 2900 total population
Congenital myopathy	1 per 28,600
Duchenne muscular dystrophy	1 per 3500
Myotonic dystrophy	1 per 12,000
Limb girdle dystrophy	1 per 90,000
Spinal muscular atrophy	1 per 74,000
Mitochondrial disorders	11.5 per 100,000 all ages

Children with neurologic disorders usually have a regular physician overseeing their care, and this person should participate in the decision-making process. For elective procedures, the surgeon should establish contact with the child's regular pediatric specialist and anesthesiologist as soon as surgery is contemplated, inform them about the proposed operation, and seek their opinions to optimize perioperative management. Cognitive, communication, and behavioral problems; coexisting diseases; and drug therapy that may influence management of the anesthesia for these patients should be evaluated at an early stage.[12] Some children may be receiving long-term respiratory support, including cough assist devices and home ventilation; all current therapies should be considered.

Oral communication may be difficult for some children with neurologic disorders. Use of age-appropriate assisted communication devices may help to ensure open communication between physician and patient.[12] Parents' opinions and attempts to protect their children should be respected and understood as a consequence of previous experiences, stress, frustration, anger, and probably guilt.[13] Each procedure has to be assessed in terms of morbidity, mortality, and probability of improving quality of life. All aspects must be clearly and objectively discussed with parents or guardians and informed consent forms signed.

Clinicians who are responsible for providing emergency care to children must have the knowledge and skills required to manage children with neurologic disorders. A preoperative assessment may be required on an urgent basis; a parent-held record of previous diagnoses and treatment is extremely helpful. Concurrent medications, previous reactions, and a history of complications such as respiratory insufficiency, electrolyte disturbance, or cardiac, renal, or hepatic dysfunction should be elicited before induction of anesthesia. A specific management plan for seizure medications is important for children who are likely to develop ileus postoperatively and thereby require a change from oral to intravenous (IV) medications.

Static Neurologic Disorders

CEREBRAL PALSIES

Cerebral palsies are a group of disorders of movement, muscle, or posture that are caused by injury or abnormal development of the immature brain attributed to nonprogressive causes. The prevalence of cerebral palsy is 1 case per 500 live births.[14] About 40% of these children are born premature. Eighty percent of cases are acquired prenatally and have no obvious cause, although they are associated with prematurity, low birth weight, placental insufficiency, maternal infection and pyrexia, intrauterine infections, intrauterine growth retardation, intracranial hemorrhage, and trauma. Birth complications, including asphyxia, are estimated to account for another 6% of cases. Postnatal causes of cerebral palsy (10%) usually arise from infectious causes (e.g., bacterial meningitis, viral encephalitis), trauma (e.g., motor vehicle collisions, falls, child abuse), or metabolic disturbance (e.g., hyperbilirubinemia).[15,16]

Classification depends on the severity, distribution, and the nature of the motor deficit. With the advent of modern imaging techniques, including magnetic resonance imaging (MRI), understanding the pathogenesis of cerebral palsies has advanced dramatically.[17–19] Clinical features are classified most commonly according to the type of motor deficit, its distribution, and the severity of the deficit (Table 24.2). Involvement of a single limb is referred to as *monoparesis*, of both limbs on one side of the body as *hemiparesis*, of both lower limbs as *paraparesis* or *diparesis*, of three limbs as *triparesis*, and of all four limbs as *tetraparesis* or *quadriparesis*. The motor deficit may manifest as hypotonia, spasticity, or extrapyramidal features such as choreoathetoid/dystonic movements, dyskinesia, or ataxia. A descriptive classification includes neurologic deficit, severity, and distribution (e.g., spastic paraparesis or paraplegia dystonic hemiparesis). Paresis or palsies are terms used to denote differing severities.

Children with cerebral palsies require neuroimaging to confirm the diagnosis and underlying cause of the condition. Although some centers use oral sedation (i.e., midazolam or chloral hydrate) for neuroimaging, many children require general anesthesia. They may require multiple anesthetics throughout their lifetimes because of the associated comorbidities (i.e., respiratory, gastrointestinal, neuromuscular, and orthopedic), common surgical conditions, and problems unique to cerebral palsies that require treatment.[20–22]

Many of the comorbid conditions can affect anesthesia management. Understanding the pathophysiology and comorbidities of cerebral palsies allows anesthesiologists to anticipate and prevent perioperative complications.

Multisystem Comorbidities

Most children with cerebral palsies have clinically significant oromotor dysfunction, and when associated with gastroesophageal reflux, it may lead to recurrent aspiration, decreased respiratory reserve, esophageal stenosis, and malnutrition.[23] Frequently used procedures include fundoplication, gastrostomy, and esophageal dilatation.[12] Immobility, underhydration, and poor diet predispose patients to bowel stasis and constipation and, if severe, may result in fecal impaction. Malnutrition may depress immune responses, and electrolyte imbalance and anemia are common. Preoperative assessment of these parameters is essential.

Pulmonary complications are common causes of death in cerebral palsies. Aspiration associated with gastroesophageal reflux is the leading cause, and it may be exacerbated by excessive oral secretions, bulbar dysfunction, recurrent respiratory infection, and chronic lung disease.[24,25] Scoliosis may also restrict pulmonary function, with cardiopulmonary involvement depending on the curve pattern and the severity of the curve (see Chapter 32).[12]

Orthopedic operations are the most frequently performed procedures in children with moderate to severe cerebral palsies.[12] Procedures include tendon releases to ease contractures, femoral osteotomy, and hip adductor and iliopsoas releases.[26] The trend in orthopedic surgery is to perform multiple procedures involving

TABLE 24.2 Cerebral Palsy

Type and Cause	Motor Deficits	Distribution	Complications
Hypotonic • Syndromic • Dysgenesis • Hypoxia-ischemia	Low axial tone Variable limb tone Deep tendon reflexes usually increased	Diffuse	Learning disability Epilepsy Feeding dysfunction Hearing or vision impairment Respiratory infections
Spastic (pyramidal) • Hypoxia-ischemia • Vascular	Increased tone: pyramidal type Increased deep tendon reflexes	Monoplegia Diplegia Hemiplegia Triplegia Quadriplegia	 Epilepsy Contractures Feeding difficulties Learning difficulties
Dyskinetic (extrapyrimidal) • Hypoxia-ischemia • Neonatal hyperbilirubinemia • Metabolic	Involuntary movement: often a mixture of choreoathetosis, dystonia and dyskinesia	May be diffuse involving all four limbs or confined to one or more limbs Often coexists with spasticity	Hearing impairment Contractures Intellect can be maintained
Ataxic • Cerebral dysgenesis • Rare syndromes	Usually generalized truncal and limb ataxia May coexist with spasticity	May be diffuse but often associated with diparesis	Poor balance, speech difficulties, poor fine motor skills
Mixed	Can be a combination of all above	Often diffuse	Mixture of all above

tenotomies or osteotomies at different levels of all extremities during a single general anesthesic, rather than staging them during multiple operations.[12,20] Scoliosis often requires surgery to prevent further deterioration in lung function and to stabilize the spine to facilitate ambulation and sitting. Spinal fusion is considered in all children with progressive curves greater than 40 to 50 degrees.[27]

Botulinum toxin is commonly used to reduce muscle spasticity in affected children, and it may be injected with or without sedation or, more commonly, in children under general anesthesia. The need for repeated treatments (every 3-6 months) and the use of a nerve stimulator to confirm correct placement of the needle should be taken into consideration when assessing the child's need for sedation or anesthesia.

Approximately 30% of children with cerebral palsies have epilepsy. It is more common in spastic hemiplegia and quadriplegia, especially with a history of neonatal encephalopathy (53% vs. 29%) and less common in the ataxic and choreoathetotic forms. Secondary generalized and focal seizures frequently occur. Anticonvulsants should be maintained until the surgery date (given the morning of surgery) and restarted as soon as possible in the postoperative period.[12,28]

Anesthesia Considerations for Cerebral Palsies

The many multisystem comorbidities and therapies specific to children with cerebral palsies must be understood to minimize perioperative complications. Risk factors include an inability to walk, severe neurologic deficit, major cognitive dysfunction, severe scoliosis, malnutrition, and the presence of a gastrostomy or tracheostomy.[20] Severely compromised children can be optimally managed postoperatively with admission to the pediatric intensive care unit to provide analgesia with comprehensive monitoring, maximum support, and aggressive respiratory care; after their conditions are stabilized, they can be transferred to a setting with less intense monitoring.

All medications that the child is receiving should be reviewed; they may include anticonvulsant, antireflux, and antispasticity agents. Baclofen should not be discontinued abruptly because it can produce acute withdrawal symptoms. Oral dantrolene has also been used to reduce spasticity. Baclofen and dantrolene cause weakness; therefore the dose of neuromuscular blocking drugs may need to be reduced as these antispasticity drugs can delay the return of adequate respiratory effort during emergence from anesthesia.

Most of these children have above-average intelligence. They have the same emotional and cognitive concerns as others about undergoing anesthesia, including preoperative anxiety that may require premedication. Children with contractures, especially in the upper extremities, may present a challenge for establishing IV access. If gastroesophageal reflux is not controlled, consideration should be given to rapid-sequence induction. Although these children have a peripheral motor disorder, IV succinylcholine yields only a normal release of potassium,[29] despite evidence of proliferation of extrajunctional acetylcholine receptors.[30] Maintenance of and emergence from anesthesia requires special considerations, including the possibility of a reduced minimal alveolar concentration (MAC),[31] resistance to neuromuscular blocking agents,[32] and reduced bispectral index (BIS) measurements.[33] If vomiting is likely to occur, the airway must be protected.

These children have normal responses to pain, which should be managed as if they were unaffected by cerebral palsy. Caudal or epidural analgesia may be a reasonable approach for perioperative pain management if the child does not have a ventriculoperitoneal shunt.[34] Management and assessment of perioperative pain in children with neurocognitive impairment is addressed in Chapter 44.

MALFORMATIONS OF THE NERVOUS SYSTEM

Malformations are common in pediatric neurologic practice and a frequent cause of early mortality. The appearance of the neural plate shows that the central nervous system (CNS) develops very rapidly in the 2-week embryo and continues until several years after birth. The cause of CNS malformations is largely uncertain, but timing appears to be more important than the nature of the insult in producing the specific type of malformation. Causative agents include maternal drugs such as sodium valproate, which is associated with neural tube defects (NTDs); infections such as

cytomegalovirus, which can cause various cerebral lesions, depending on the time in gestation of the infection; toxins such as alcohol; vitamin deficiency (e.g., folic acid), and genetic disorders. Historically, because diagnostic investigation was limited, postmortem examination was required to demonstrate the neuropathologic changes causing the clinical disorder. MRI now can provide adequate images to enable a diagnosis in many instances (e.g., cortical dysplasia).[35]

Neural Tube Defects: Cranial and Spinal Dysraphism

The fetal incidence of NTDs is 17 per 10,000 pregnancies; the live birth incidence is 5.7 to 6.7 per 10,000. NTDs are a group of birth defects presumed to have a common origin in failure of the neural tube to develop properly during the embryonic stage. NTDs include anencephaly, encephaloceles, and spina bifida.

The cause of NTDs is multifactorial, with genetic and environmental factors the most important. Approximately 10% of NTDs are caused by chromosomal abnormalities such as trisomies (i.e., 18, 13, and 21), triploidy, and 22q11 microdeletion. Some of the environmental causes include folate deficiency, maternal antiepileptic drugs (valproate, phenytoin, carbamazepine, and polytherapy), retinoins, and maternal diabetes.

Preconceptual folic acid supplementation has reduced the prevalence of NTDs by 30% to 50%.[36,37] Along with antenatal ultrasound examination, screening is done for increased maternal serum levels of α-fetoprotein, reduced human chorionic gonadotropin levels, and reduced unconjugated estriol levels; termination of pregnancy in cases with positive test results has further reduced the prevalence of NTDs.[38]

Anencephaly is a lethal disorder resulting from the neural tube failing to close between the 23rd and 26th day following conception. This leads to disorganization of neural elements and the absence of skull formation.[35] Some deep cerebral structures may remain intact, and the brainstem may develop normally. With the latter situation, normal respiration and cardiovascular functions may develop, enabling the infant to survive for hours or days after birth. Other structures in the head and brain, including the eyes, face, and pituitary gland, may not develop normally. An infant with anencephaly is usually blind, deaf, and unable to feel pain.

Encephalocele is a herniation of neural tissue and meninges out of the skull through deficient skin and bone (see Fig. 26.12A). They may be associated with other cerebral malformations. Encephaloceles found anteriorly are associated with underlying brain, orbital structures, or pituitary gland anomaly. Posteriorly, encephaloceles are associated with cerebral or cerebellar tissue that herniates through a bony defect in the posterior cranium. Intranasal encephaloceles may be difficult to detect. These defects carry a poor prognosis for long-term survival. The only treatment is reparative surgery; occasionally shunts are placed for resulting hydrocephalus. Most infants die, and in survivors, severe neurodevelopmental disability is common. Most of these children have hydrocephalus.[39]

Spina bifida refers to a group of conditions in which there is abnormal or incomplete formation of the midline structures over the back (see Fig. 26.12B).[35] Skin, bony, and neural elements may be involved singly or in combination. Congenital malformations of the spinal cord may exist in isolation or in association with brain anomalies. These defects may present at birth, as in the case of the more severe and open lesions (i.e., spina bifida) or be identified later in childhood if the skin overlying the spinal defect is intact (e.g., spina bifida occulta). Those who develop a Chiari malformation may present with cervical cord or bulbar deficits, placing them at risk for respiratory embarrassment (see Figs. 26.13, and 26.14). Children with spinal cord lesions are at increased risk for sensory deficits, making meticulous skin care and positioning essential to prevent pressure sores and damage to neuropathic joints.

Spina bifida occulta occurs in the absence of herniation of neural tissue or coverings so that the overlying skin appears to be intact and normal. In many cases, a hairy patch or a dermal sinus (i.e., sacral dimple) may communicate with the meninges or attach to the spinal cord or a lipoma that causes a fatty swelling overlying the bony defect. The spinal cord may be tethered by internal connection to such structures, making it vulnerable to trauma at surgery and during growth, especially at puberty. The spinal cord may be abnormally formed, with cartilaginous or bony spurs that damage or divide the cord during growth as the neural tissue grows at a slower rate than the surrounding bone (i.e., diastematomyelia). These infants may not be candidates for a caudal block because the spinal cord may end at an unusually low position.

Spina bifida cystica, the most common type of spinal dysraphism, manifests as an obvious lesion on the back. The defect may be diagnosed antenatally or at birth. The abnormally developed spinal cord may be covered by a layer of meninges (i.e., meningocele) or remain uncovered (i.e., myelomeningocele). The spinal level of the lesion is the major determinant of morbidity. Myelomeningoceles need to be repaired within a few days of birth to prevent infection and further damage to the neural tissues. A cerebrospinal fluid (CSF) leak or frank dural rupture may develop, leading to intravascular volume and electrolyte abnormalities that should be treated preoperatively.

When the defect is identified at birth, it is optimally managed in a specialist center by a multidisciplinary team (i.e., pediatrician, neurologist, neurosurgeon, orthopedic surgeon, and others) who can anticipate, prevent, and treat complications and assist in the child's long-term care. Children with dysraphism often develop postoperative hydrocephalus because of disrupted CSF flow and require a ventriculoperitoneal shunt. Long-term complications, including paraparesis, neurogenic bladder and bowel, renal insufficiency, trophic limb changes, pressure sores, joint contractures, and scoliosis may require surgical repair and future intervention. Children with NTDs may acquire latex allergy if they are exposed repeatedly to latex products (they do not have a genetic predisposition toward latex allergy). To prevent latex allergy, these children should be cared for in a latex-free environment. The anesthesia considerations for NTDs are presented in Chapter 26.

Chiari Malformation

Chiari malformations of the nervous system may coexist with other anomalies and manifest in the neonatal period or later in the early decades of life (Table 24.3).

Chiari I. This is the mildest of the hindbrain malformations and is characterized by displacement of cerebellar tonsils more than 5 mm caudally through the foramen magnum. The brainstem and fourth ventricle retain a relatively normal position, although the fourth ventricle may be small and slightly distorted. Although the spectrum of Chiari I malformations is not usually associated with other cerebral abnormalities, syringomyelia is found in 20% to 70% of patients, depending on the degree and extent of disruption of normal CSF flow between the spine and cranium. Adequate surgical decompression at the foramen magnum and upper cervical spine is the treatment of choice for neuronal dysfunction,

TABLE 24.3 Chiari Malformations

Type	Main Features	Associated Abnormalities	Neurologic Features
Chiari I	Downward displacement of cerebellar tonsils >5 mm caudally through the foramen magnum	Syringomyelia (in 20%-70%); hydrocephalus	Later onset (>age 12 years), cervical cord signs: tetraparesis, sensory deficits of upper limbs
Chiari II	Downward displacement of cerebellar tonsils, vermis fourth ventricle and brainstem with obstruction of CSF flow	Supratentorial and infratentorial abnormalities; myelomeningocele or meningocoel in virtually all	Present in neonate, macrocephaly, increased intracranial pressure, cranial nerve palsies, cord signs
Chiari III (rare)	Downward displacement of cerebellum into posterior encephalocele; elongation of fourth ventricle	Posterior defects: cervical spina bifida ± cranium bifidum	Present in neonate with signs of hydrocephalus ± brainstem and cervical cord signs
Chiari IV (extremely rare)	Cerebellar hypoplasia or primary cerebellar agenesis	Usually none	± Ataxia

symptomatic syrinx, or hydrocephalus. Ventriculoperitoneal shunting may be required for hydrocephalus and syringostomy or syrinx shunting for cord drainage if the craniocervical decompression alone does not relieve the pressure in the syrinx.

Chiari II. This is a more extensive and complex abnormality than the Chiari I malformation, with infratentorial and supratentorial abnormalities. It affects 0.02% of births, females twice as often as males. The cerebellar tonsils, inferior vermis, fourth ventricle, and brainstem are herniated from a shallow posterior fossa through a wide foramen magnum with obstruction to CSF flow at the exit of the fourth ventricle. Occasionally the fourth ventricle becomes "trapped" or encysted and will enlarge to appear normal or dilated. There is virtually always a meningocele or meningomyelocele present, some with associated hydrocephalus.

Chiari III. This defect is very rare. There is herniation of the posterior fossa contents into an associated occipital or high cervical cephalocele with the other features of a Chiari II malformation. These patients have severe neurologic defects and a poor prognosis.

Chiari IV. This abnormality is controversial and extremely rare. Many authors consider the features of primary cerebellar agenesis as a Chiari IV malformation, but it must be differentiated from a Chiari II malformation associated with a "vanishing" cerebellum. In primary cerebellar agenesis, there are remnants of a residual cerebellum (for example, anterior quadrangular lobule), a normal brainstem, a normal-sized posterior fossa, and a normal spine. The lack of a meningomyelocele virtually excludes a Chiari II malformation.[40]

Syringomyelia

Syringomyelia results from a glial cell–lined cavitation within the spinal cord. Diagnosis has been greatly simplified by the use of MRI, which provides images of the spinal cord and the tubular fluid-filled space within.[35] Although the spectrum of Chiari I malformations is not usually associated with other cerebral abnormalities, syringomyelia is found in 20% to 70% of patients, depending on the degree and extent of disruption of normal CSF flow between the spine and cranium. Syringomyelia manifests with dissociated sensory loss, usually in the upper limbs, causing loss or impairment of pain and temperature sensation, which may cause trophic changes in the fingers and neuropathic joints. It may progress to paralysis and hyporeflexia later in life. The lower limbs may exhibit pyramidal signs; some lesions may extend upward (i.e., syringobulbia) and produce lower brainstem signs, such as stridor and laryngospasm (i.e., vocal cord palsy).

Treatment of syringomyelia is controversial, especially if the lesion is asymptomatic. Management may focus on associated disorders as syringomyelia may progress slowly or not at all.

Adequate surgical decompression at the foramen magnum and upper cervical spine is the treatment of choice for neuronal dysfunction, symptomatic syrinx, or hydrocephalus. Ventriculoperitoneal shunting may be required for hydrocephalus and syringostomy or syrinx shunting for cord drainage if the craniocervical decompression alone does not relieve the pressure in the syrinx.

Hydrocephalus

Hydrocephalus is defined as an increase in the volume of CSF in the brain, particularly the ventricles, associated with an increase in the intracranial pressure (ICP) with classical signs and symptoms. It results from overproduction or impaired drainage of CSF from the brain.[39] In practice, overproduction is an uncommon source of hydrocephalus; these cases most often result from tumors of the choroid plexus. Obstructed drainage of CSF is the far more common source for hydrocephalus. The causes of hydrocephalus include intraventricular hemorrhage, Arnold-Chiari malformation, brain tumor, congenital obstruction, and myelomeningocele. Hydrocephalus may present with chronic or acute symptoms of ICP. Children typically present with a headache and irritability, but signs and symptoms can progress to lethargy, seizures, vomiting, and ophthalmoplegia as pressure within the brain increases. In infants, it presents as accelerated head growth, bulging fontanelle, poor feeding, sunsetting sign, and developmental delay. If left untreated, it may lead to a reduced level of consciousness, oculomotor palsies, sluggish pupillary light reactions, bradycardia, and eventually respiratory arrest. Diagnosis of hydrocephalus is confirmed by neuroimaging, often with computed tomography (CT) in the acute situation, followed by MRI.

Surgery is the definitive treatment for hydrocephalus. It usually involves inserting a drainage system to shunt CSF from the brain to another site in the body (see Fig. 26.11). After insertion of a shunt, children should be closely monitored for shunt complications; these include infection, blockage or fracture of the shunt, and overdrainage of CSF. The anesthesia considerations for treating hydrocephalus are discussed in Chapter 26. An endoscopic cerebral aqueductoplasty or third venticulostomy may be helpful for obstructive hydrocephalus.

DISORDERS OF VENTRAL INDUCTION

Holoprosencephaly is a cephalic disorder in which the forebrain of the embryo fails to develop into discrete hemispheres with normal connections.[35] There are three types:

1. Lobar: There is almost complete separation of the hemispheres, and the corpus callosum is almost absent.
2. Semilobar: The two hemispheres are divided posteriorly, with interhemispheric connections present anteriorly. The corpus callosum is absent anteriorly, and the thalami are fused in the midline.
3. Alobar: An undivided and small forebrain with a dorsal sac may contain some cortex. Severe facial defects may include cyclopia (i.e., single orbit with fused globes), cebocephaly (i.e., single nostril), and a midline cleft lip.

Associated malformations (e.g., congenital heart disease, scalp deficits, polydactyly) are common. Chromosomal anomalies may be identified, and a complex syndromic disorder may occur in some of these children. The diagnosis rests on a careful description of the external and internal morphology using MRI, followed by genetic assessment. Complications include hydrocephalus, endocrine deficits, epilepsy, and severe complex disability, usually with a shortened life expectancy.

DISORDERS OF CORTICAL DEVELOPMENT

Malformations of the cerebral cortex are many and varied. Malformations of cortical development (MCD) are increasingly recognized as an important cause of epilepsy and developmental delay. It is estimated that up to 40% of children with refractory epilepsy have a cortical malformation. MCD encompass a wide spectrum of disorders with various underlying genetic etiologies and clinical manifestations. High-resolution imaging has dramatically improved our recognition of MCD.[41] Disruptions at the various stages of development lead to characteristic MCDs. Disorders of neurogenesis give rise to microcephaly (small brain) or macrocephaly (large brain). Disorders of early neuroblast migration give rise to periventricular heterotopia (neurons located along the ventricles), whereas abnormalities later in migration lead to lissencephaly (smooth brain) or subcortical band heterotopia (smooth brain with a band of heterotopic neurons under the cortex). Abnormal neuronal migration arrest gives rise to overmigration of neurons in cobblestone lissencephaly. Lastly, disorders of neuronal organization cause polymicrogyria (abnormally small gyri and sulci). MRI has advanced the identification of these features and their classification.

Environmental agents and genetic abnormalities have been identified for many of these malformations, and genetic derangements can produce a multisystem syndrome. Some of the genes involved are the *LIS1* gene, 4p– (Wolf-Hirschhorn), and 17p– (Miller-Dieker syndrome). Intrauterine insults in early pregnancy have been implicated in cases in which autopsy is performed. Clinical effects vary, and the severity depends on the site and extent of the lesion. Survivors may have no symptoms or have profound, complex neurodisability. Children may have learning disabilities, epilepsy, focal neurologic deficits, motor dysfunction, and other system involvement.

Progressive Neurologic Disorders

PRIMARY BRAIN TUMORS

The incidence of primary brain tumors is 2.6 per 100,000 children, and they account for 15% to 20% of all childhood malignancies. The male/female ratio is equal except for a male preponderance in medulloblastoma and germ cell tumors. One-third of these tumors occur before 5 years of age, and 75% occur before 10 years of age.[42] CNS tumours are the second most common pediatric tumor, surpassed only by leukemia. Supratentorial tumors are common in the first 2 or 3 years of life, whereas infratentorial tumors predominate from ages 4 to 10 years. Two-thirds of the tumors are located infratentorially and one-third supratentorially (Table 24.4).[43] After the age of 10 years, tumors occur with equal frequency in both locations in the brain. Pathologic classification, which is based on the cell of origin and degree of malignancy, extends from grade I (benign) to grade IV (malignant).[44]

The presentation depends on the age of the child and site of the tumor. Infants are typically irritable, with increasing head circumference, failure to thrive, and developmental regression. Older children develop headaches, nausea and vomiting, seizures, gait disturbances, and visual deficits. Supratentorial tumors can present with seizures, focal neurological deficit, personality change, visual field defects (optic pathway gliomas), and endocrine dysfunction (craniopharyngiomas). Infratentorial tumors present with cerebellar ataxia (medulloblastoma, cerebellar astrocytomas), nausea and vomiting, signs of increased ICP (ependymomas), and cranial nerve and pyramidal tract signs. If the lesion is rapidly expanding and is accompanied by significant cerebral edema or obstructs CSF drainage, ICP will increase. Occasionally, a hemorrhage occurs into the tumor, causing a dramatic increase in ICP with the associated signs and symptoms, necessitating emergency treatment. Ultimately, brainstem decompensation and death ensue if the lesion is left untreated.

Diagnosis of a primary brain tumor is usually confirmed with MRI and magnetic resonance spectroscopy (MRS). Tissue diagnosis by a biopsy is always desirable, although not always achievable. Microscopy of CSF may yield tumor cells and facilitate the diagnosis. Image-guided biopsy may be possible and is preferred for appropriately sited lesions.

Surgery is the mainstay of treatment and is usually combined with radiotherapy or chemotherapy, or both. Preoperatively, cerebral edema should be treated with corticosteroids to reduce ICP, alleviate symptoms and signs, and enable correction of fluid and electrolyte abnormalities. Seizures require anticonvulsant therapy. Nutrition may be poor and necessitate aggressive management with enteral and parenteral feedings. Operative intervention for increased ICP may require CSF diversion by shunting internally or externally. Depending on the tissue diagnosis and location, total resection of the tumor may be indicated, although the timing of the surgery may depend on whether the tumor should first be treated with radiation therapy or chemotherapy. Aggressive surgery with the intent of completely resecting the tumor improves the prognosis for many tumor types but carries with it significant risks of residual neurologic deficits.

The 5-year survival rate of greater than 60% for primary brain tumors largely reflects improved imaging, aggressive surgery, and evidence-based therapy.[45] Unfortunately, children who survive CNS tumors frequently have permanent neurologic deficits, including epilepsy, learning disabilities, visual or hearing impairment, and growth and endocrine disorders. Short-term and long-term follow-up evaluations by specialist teams are required, along with careful emotional and social support for children and their families. Some children have genetic predispositions for CNS tumors, such as neurofibromatosis (i.e., schwannomas of the spinal cord, peripheral nerve tumors, skeletal deformities, carcinoid syndrome, and multiple endocrine neoplasia, including pheochromocytoma) and tuberous sclerosis (i.e., brain tumors,

TABLE 24.4 Common Central Nervous System Tumors in Childhood

Tumor Type	Percentage of All Childhood CNS Tumors	Clinical Features	Treatment	Prognosis or Survival
Medulloblastoma	14–20	Acute ataxia ↑ Intracranial pressure	Surgical excision + radiotherapy or chemotherapy in children <2 years	75% at 5 years 50% at 10 years
Cerebellar astrocytoma (80% cystic)	15–20	Subacute-chronic ataxia Head tilt ± ↑ Intracranial pressure	Surgical excision	100% at 5 years, if totally excised
Posterior fossa ependymoma	6–10	Cranial nerve palsies Stiff neck ataxia ↑ Intracranial pressure	Surgical excision Radiotherapy	40% at 5 years but 14% if <5 years
Brainstem glioma	6–16	Cranial nerve palsies Long tract signs ↑ Intracranial pressure late	(Stereotactic) biopsy if possible Radiotherapy ± chemotherapy, depends on age and cell type	Survival variable and depends on cell type
Craniopharyngioma	6–10	Endocrine disorders ↑ Intracranial pressure Visual impairment	Surgery Hormonal therapy	Survival variable
Visual pathway glioma	3–5	Proptosis, ↓ vision Associated disorders (e.g., neurofibromatosis type I)	Controversial and individualized	Variable
Pineal region tumors	<2	↑ Intracranial pressure Loss of upward gaze	Surgery ± radiotherapy	Variable
Hemisphere glioma	25–30	α Location: ↑ intracranial pressure, seizures, focal neurologic deficit	Surgery ± radiotherapy ± chemotherapy	Depends on cell type
Meningioma	<2	↑ Intracranial pressure Seizures	Surgery	Variable
Ganglioma and dysembryoplastic neuroepithelial tumor (DNET)	1–5	Focal epilepsy	Surgery	Good May cure epilepsy
Primitive neuroepithelial tumor (PNET)	1–2	↑ Intracranial pressure, focal neurologic deficit	Surgery + radiotherapy	Poor
Intraventricular tumors, various cell types	5	↑ Intracranial pressure: hydrocephalus	Shunting and surgical excision	Variable
Basal ganglia tumors, various cell types	5	Hemiparesis, dystonia	Stereotactic biopsy Radiotherapy if malignant	Depends on cell type

CNS, central nervous system; ±, with or without; ↓, decreased; ↑ increased.

cardiac rhabdomyomas, renal abnormalities, tumors, and hepatoma) that require genetic analysis and long-term follow-up.

Tumors of the spinal cord are rare in childhood. They may be benign or malignant, sited within the cord (intramedullary) or outside (extramedullary), and are usually astrocytomas (60%) or ependymomas. Symptoms may initially be nonspecific and vague, especially in young children. These may include pain, paresthesia, paresis, sphincter disturbance, spinal deformity (astrocytomas), torticollis, and hydrocephalus (ependymoma). A diagnosis may be delayed owing to the vagueness of the symptoms, with an increased risk of spinal cord compression. Delayed decompression can cause vascular compromise, which may lead to total and irreversible paralysis of the limbs, bladder, and bowel, and permanent, severe disability. Diagnosis is best made by MRI of the cord, which provides details of the lesion and adjacent structures without the risk of further decompensation, a problem raised by the use of myelography in the past.[43]

Treatment usually involves surgery to decompress the cord and excise or biopsy the lesion. For intramedullary tumors, excision may be impossible, and biopsy may risk further damage to the spinal cord. Cell type may be determined by CSF examination. Follow-up treatment with radiotherapy may be indicated. Children with established neurologic deficits require a program of rehabilitation.

METABOLIC DISEASE

Inborn errors of carbohydrate, protein, or fat metabolism usually are genetic in origin. The molecular defects of many of these metabolic disorders have been identified. Most of these disorders are inherited as autosomal recessive.

Metabolic disorders may present differently depending on the age of the child. In the neonatal period, they present with poor feeding/suck, vomiting, hypotonia, respiratory compromise/apnea, progressive encephalopathy, and seizures, and the clinical picture may be mistaken for sepsis. It is therefore important to also consider metabolic disorders when thinking of infection as a potential cause of these symptoms in a neonate. In childhood, metabolic disorders can present with recurrent unexplained vomiting with

Miscellaneous disorders

dehydration, strokelike episodes, acute liver or renal failure, cardiomyopathy, unexplained encephalopathy, and seizures. These diseases may cause a static encephalopathy but more often produce a progressive course with loss of physical and intellectual skills. Some neurometabolic diseases are associated with intellectual deficits and some with physical deficits; systemic features may be prominent and neurologic signs are common (Table 24.5).

There are three main groups of neurometabolic diseases[46]:

1. Those with a known enzymatic defect, including disorders of amino acid metabolism (e.g., phenylketonuria), peroxisomal disorders (e.g., adrenoleukodystrophy), and lysosomal storage disorders (e.g., Tay-Sachs disease)
2. Those with abnormal storage accumulation in CNS cells, including lysosomal storage disorders and mucopolysaccharidoses
3. Those with no identified biochemical defect (e.g., Cockayne syndrome), a heterogeneous group that is shrinking as research identifies the biochemical and genetic defects.

There is considerable overlap among the three groups. All of these disorders are rare, and although some are treatable, most are relentlessly progressive and associated with early death. Many patients show a steady decline, with a gradual increase in symptoms and loss of function or a stepwise deterioration with bouts of acute illness leading to a sudden loss of function.

There are several basic laboratory tests that should be performed in every child with an acute illness in whom a metabolic disorder is a possibility. Blood glucose, ammonia, acid-base status, lactate, and urinary ketones are essential tests; other tests include plasma amino acids, urine organic acids, acylcarnitine profile, blood cell counts, liver function tests, coagulation studies, creatine kinase and uric acid. In an acute situation, the management consists of stopping feeds and starting an infusion of 10% glucose with appropriate electrolytes (150 mL/kg per day). Glucose supply at this infusion rate equates to normal hepatic glucose production. This is usually sufficient for disorders of reduced fasting tolerance, such as glycogen storage disorders or medium-chain acyl-CoA dehydrogenase deficiency (MCAD) (fatty acid oxidation disorders). Exogenous glucose may not be sufficient in disorders that are exacerbated by catabolism (organic acidurias or urea cycle disorders). However, exogenous glucose administration may be potentially dangerous in mitochondrial disorders (specifically pyruvate dehydrogenase deficiency) as a high glucose supply may enhance lactic acidosis. In most cases, the benefits of high glucose infusion outweigh the risks; however, lactate and acid-base status should be checked regularly.[47]

Treatment is available for only a few of these diseases and consists primarily of dietary strategies, although some pharmacologic treatments are used. Started early, especially in the presymptomatic phase, treatment may prevent neurologic complications. An example is phenylketonuria, a disorder of amino acid metabolism. The prevalence varies by population, with an incidence of 1 case per 100,000 people in the United States. Screening occurs in the neonatal period, and affected children start a special diet. Those who have good dietary management throughout life may develop relatively few problems, although close monitoring by a specialist team of physicians and dieticians is essential to ensure metabolic stability. Unfortunately, treatments may be of questionable benefit for many children.

Disorders that cause lactic acidosis are the most common of these diseases, although many individuals who harbor the genetic substrate for one of these disorders may not express it or may come to diagnosis very late in life.[48] The features of these diseases are extremely varied, and, although the neuropathologic, biochemical, and imaging abnormalities are well recognized, a precise diagnosis may remain elusive.

Anesthesia Considerations for Progressive Neurologic Disorders

The risks associated with general anesthesia for children with progressive neurologic disorders include problems posed by fasting and the need to keep the patient's metabolism stable during a period of stress. Meticulous planning with the child's metabolic specialist is essential before elective procedures. In the case of emergency surgery, the children and parents should be aware of or have written instructions regarding the preferred management of nutrition and metabolic indices, or they should have a resource person to call for specific advice.

Neuromuscular Disorders

Neuromuscular disorders are caused by an abnormality of any component of the lower motor neuron system: anterior horn cell in the spinal cord, axon, neuromuscular junction, or muscle fiber (Fig. 24.1).[49] The cardinal features are weakness of skeletal muscles that is proximal, distal, or generalized in distribution; hypotonia; and reduced deep tendon reflexes. True fatigability suggests a defect of the neuromuscular junction. Neuropathy is characterized by distal weakness and sensory deficit. Joint contractures, scoliosis, and respiratory and cardiac involvement are common complications and some conditions are associated with cognitive deficits.

DISORDERS OF THE ANTERIOR HORN CELL

Spinal Muscular Atrophies

Spinal muscular atrophy (SMA) is one of the most common autosomal recessive diseases, affecting approximately 1 in 10,000 live births, and with a carrier frequency of approximately 1 in 50. SMAs are a group of disorders in which there is progressive degeneration of the anterior horn cells (lower motor neurons) of the spinal cord and brainstem nuclei, leading to death of motor neurons. Recent evidence has shed new light on the involvement of nonmotor neuronal cells both within and outside the CNS in the pathogenesis and phenotypic presentation of SMA.[50] The diagnosis of SMA is based on molecular genetic testing. Mutations in *SMN1* (survival motor neuron 1) are known to cause SMA; increases in the *SMN2* copy number often modify the

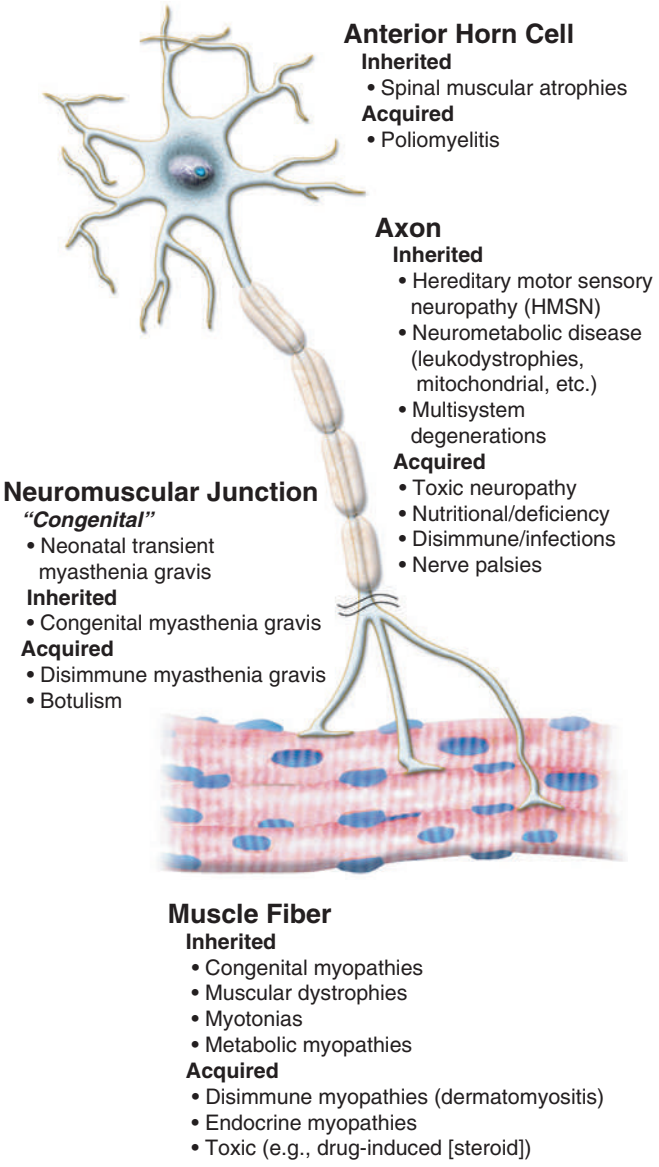

FIGURE 24.1 Diagram of a lower motor neuron. (Modified from Dubowitz V. *Muscle Disorders in Childhood*. Philadelphia: WB Saunders; 1978. Courtesy A. Moosa, MD.)

phenotype. *SMN1* is the primary gene in which mutation causes SMA.

The existent classification by age of onset and maximum function achieved is useful for prognosis and management.[51,52] Subtypes include the following:

- SMA 0 (proposed), with prenatal onset and severe joint contractures, facial diplegia, and respiratory failure.
- SMA 1, with onset before age 6 months
- SMA 2, with onset between age 6 and 12 months
- SMA 3, with onset in childhood after age 12 months and ability to walk at least 25 m
- SMA 4, with adult onset

Curative treatment is not available, but much can be done to improve duration and quality of life, especially for mildly affected children.

Type 0 SMA: In the most severe forms, decreased intrauterine movements suggest prenatal onset of the disease and present with severe weakness and joint contractures at birth, have been labeled SMN 0. Some of these children may have congenital bone fractures and extremely thin ribs.

Type 1 SMA (i.e., Werdnig-Hoffmann disease) manifests at or soon after birth in most cases. The infant may appear neurologically normal at first, but the typical picture soon emerges. Parents may first notice an abnormal breathing pattern as the intercostal muscles are affected, and the respiratory pattern becomes diaphragmatic, with a bell-shaped chest observed clinically and radiographically. The infant is usually very alert and interactive but severely weak and floppy. There is good facial expression and normal eye movements, but the tongue fasciculates, and the tendon reflexes are absent. There is no cardiac involvement. Weakness, hypotonia, and bulbar involvement lead to progressive respiratory insufficiency and swallowing dysfunction, which are frequently complicated by episodes of aspiration. Most children die within the first 2 years of life, mainly owing to respiratory complications. Management is essentially palliative, with gentle physiotherapy to keep the limbs flexible and special care with feeding. Noninvasive nocturnal ventilation is increasingly used, but invasive ventilation through a tracheostomy is not considered appropriate in most medical centers. This issue has provoked considerable debate in the literature.[53]

Type 2 SMA is an intermediate form, but is the most prevalent. Because the weakness is milder, many children survive for years with meticulous multidisciplinary therapy, orthopedic and respiratory management, and care with nutrition. Onset occurs at 6 to 12 months of age. The clinical signs are similar to those of type 1 SMA, and the children are bright, intelligent, and particularly verbal. Patients with type 2 SMA usually achieve independent sitting at some stage, but these children never bear weight or walk. Respiratory infections are a particular problem, and noninvasive nocturnal respiratory support (i.e., biphasic or continuous positive airway pressure) with a face mask and portable ventilator is well tolerated. This improves well-being and enables remarkably full activity despite weakness.[54,55] Joint contractures are almost inevitable, as is progressive scoliosis, which usually appears early, and management is difficult in the very young child. Operative correction and stabilization with instrumentation is delayed as long as possible to prevent the complications of pubertal growth with a fixed spine; children usually tolerate the procedure well if they are carefully prepared and managed. Some children with type 2 SMA develop feeding difficulties because of weakness of bulbar musculature or as a complication of chronic nocturnal hypoventilation. Good nutrition is essential for health, and supplementation and gastrostomy feeding may be required.[56]

Type 3 SMA (i.e., Kugelberg-Welander disease) is a mild variant with similar signs of flaccid and areflexic weakness of lower limbs more so than upper limbs and with proximal predominance. These children attain independent walking, although it may be later than normal and tenuous. There is often deterioration around the time of puberty, when the growth spurt causes the previously precariously balanced muscle groups to become dysfunctional. Obesity and joint contracture also may affect the situation. Aggressive measures to keep the child walking are often effective and delay or prevent scoliosis and lower limb contracture.[57] Respiratory support may be necessary for nocturnal hypoventilation. Prognosis for long-term survival is good.

Type 4 SMA has been added to this classification to describe those patients with adult onset (>18 years) and mild course. This

group includes patients who are able to walk in adulthood and without respiratory and nutritional problems.

Other very rare SMA variants also exist in childhood. The scapuloperoneal SMA with predominant weakness of scapuloperoneal and laryngeal muscles with autosomal dominant (AD) inheritance is due to gene defect 12q24.1-q24.31. SMA with pontocerebellar hypoplasia with brainstem and cerebellar hypoplasia that presents before 6 months with autosomal recessive (AR) inheritance is caused by gene *VRK1*. X-linked infantile SMA with arthrogryposis, presenting with contractures at birth or infancy and leading to early death, has a genetic defect in Xp11.3-q11.2 with AR inheritance. SMA with respiratory distress type 1 presents with eventration of diaphragm, distal weakness, and pes equinas and has an AR inheritance owing to immunoglobulin mu binding protein 2 (IGHMBP2). Congenital distal SMA is nonprogressive and presents with distal contractures, with AD inheritance and gene defect in 12q23-q24.[52]

Anesthesia Considerations for Spinal Muscular Atrophies

Children with SMA present for a variety of surgical and diagnostic procedures, including gastrostomy placement, tracheostomy, and spinal surgery, that will require anesthesia.[58] Rigorous preanesthesia evaluation is essential; perioperative care needs to be tailored to each child's needs, and postoperative respiratory support may be required. A variety of anesthesia techniques have been used successfully with and without muscle relaxants. Various degrees of sensitivity to nondepolarizing neuromuscular blocking drugs (NMBDs) have been described, and it seems prudent to avoid or reduce the dose of these agents. If they are used, neuromuscular function should be assessed continuously and the effect of the relaxant antagonized at the conclusion of surgery. Succinylcholine is contraindicated in these children. Spinal and epidural anesthesia and postoperative epidural analgesia have been used without adverse effects; however, the potential for respiratory depression may be increased with the addition of neuraxial opioids.

Poliomyelitis

Poliomyelitis is a highly contagious, infectious disease caused by poliovirus, a human enterovirus. Most poliovirus infections are asymptomatic. If symptomatic, it occurs in two phases: an acute, nonspecific, febrile illness followed by aseptic meningitis and acute, flaccid, lower motor neuron paralysis. It typically manifests asymmetrically and may affect any muscle group. In children with respiratory involvement, lifelong ventilation may be needed. Fortunately, this situation is almost unheard of in the Western world because polio has been almost eradicated by immunization.[59]

AXONAL DISORDERS

Hereditary Neuropathies

The hereditary neuropathies are a heterogeneous group of disorders that can be divided into two major subgroups: neuropathies in which the neuropathy is the sole or primary feature and neuropathies in which the neuropathy is part of a more generalized neurologic or multisystem disorder. There are five subgroups in the common hereditary neuropathies[60]:

- Charcot-Marie-Tooth disease (CMT): hereditary motor sensory neuropathy (HMSN)
- Hereditary neuropathy with liability to pressure palsy (HNPP)
- Hereditary sensory and autonomic neuropathy (HSAN)
- Distal hereditary motor neuropathy (dHMN)
- Hereditary neuralgic amyotrophy (HNA)

Neuropathies can also be part of a more widespread neurologic or multisystem disorder:

- Familial amyloid polyneuropathy (FAP)
- Disturbances of lipid metabolism (e.g., adrenoleukodystrophy)
- Porphyrias
- Disorders with defective DNA (e.g., ataxia telangiectasia)
- Neuropathies associated with mitochondrial diseases
- Neuropathies associated with hereditary ataxias
- Miscellaneous

Clinical presentation depends on the subtype and can occur at any age. Children usually present with disorders of gait or foot deformity, or they may come to the attention of a neurologist or geneticist through an affected parent. Clinical signs are usually confined to the lower limbs in the early years and may lead to orthopedic intervention before diagnosis. Some neuropathies are associated with multisystem involvement, including cardiac, autonomic, and respiratory systems, and a complete preoperative assessment of these children is essential.[61]

Peripheral neuropathy is a component of various neurometabolic disorders in which there is involvement of other parts of the nervous system or of other organs. For example, in the leukodystrophies (metachromatic and Krabbe disease),[62,63] demyelination affects central and peripheral axons, giving a clinical picture of combined upper and lower neuron features. Refsum disease is a peroxisomal disorder caused by the impaired α-oxidation of branched-chain fatty acids, resulting in buildup of phytanic acid and its derivatives in the plasma and tissues.[64] Individuals with Refsum disease present with neurologic damage, cerebellar degeneration, and peripheral neuropathy. Onset is most commonly in childhood/adolescence with a progressive course. In children with mitochondrial diseases, peripheral neuropathy is often found, along with myriad other features.[65]

Multisystem degenerations are often genetically determined disorders of the nervous system that rarely begin in childhood.[61] Features may include dementia, epilepsy, extrapyramidal signs, brainstem dysfunction, vision and hearing impairment, anterior horn cell involvement, and peripheral neuropathy. They tend to have a progressive course.

Acquired Disorders of the Peripheral Nerves

Acquired disorders of the peripheral nerves are rare in childhood. In clinical practice in the developed world, neuropathies complicating metabolic or nutritional disorders and treatment for cancer are the most common forms. In underdeveloped parts of the world, nutritional deficiencies, especially of vitamins E, B_1, B_6, B_{12}, niacin, and thiamine, are important. The neuropathic features may be overshadowed by the other characteristics of the disease.

Guillain-Barré Syndrome

Guillain-Barré syndrome (GBS) is an acute demyelinating disorder that causes progressive weakness, usually 2 to 4 weeks after an illness with features of a viral infection or after immunization.[38] It has an incidence of 1 to 2 per 100,000. The term acute inflammatory demyelinating polyneuropathy (AIDP) is often used synonymously with GBS. Variants with a similar/related clinical picture include acute motor axonal neuropathy (AMAN), acute motor and sensory axonal neuropathy with prominent sensory features (AMSAN, poor prognosis), and Miller Fisher syndrome (ophthalmoplegia, ataxia, and areflexia). The causal mechanism is an immunologic cross-reactivity process secondary to a prodromal illness within the previous 4 weeks, typically an upper respiratory tract infection or gastroenteritis. Implicated organisms include

mycoplasma, CMV, EBV, vaccinia, variola, *Campylobacter,* vesicular stomatitis virus (VZV), measles, mumps, hepatitis A and B, rubella, influenza A and B, coxsackievirus, and echovirus. Although the precise pathologic process has not been delineated, various antibodies, immune complexes, and complement components have been found, suggesting pathologic heterogeneity.

The disorder is rare in children younger than 3 years of age, and the onset is usually sudden, although subacute presentations have been reported. The first sign is weakness in the lower limbs, which characteristically ascends the body, next affecting the trunk, the upper limbs, and occasionally the cranial nerves. It causes a flaccid paralysis, usually sparing sensory function but causing pain and areflexia at all levels. Autonomic neuropathy may develop, causing instability of blood pressure and cardiac arrhythmias. Involvement of respiratory muscles may produce acute respiratory failure or apnea that necessitates tracheal intubation.

Guillain-Barré syndrome is diagnosed clinically, and the diagnosis is reinforced by finding an increased protein concentration in the CSF (despite a normal cell count) and abnormalities on nerve conduction studies. The studies may confirm demyelination by showing lowered nerve conduction velocity with distal delay, axonal involvement by low-amplitude action potentials, and in early cases, abnormality or absence of the Hoffmann reflex, indicating absence of the spinal reflex arc. MRI of the spine may show thickening and contrast enhancement of the nerve roots and cauda equina.[66]

Pediatric Guillain-Barré is usually a disease of briefer duration and more complete recovery than in affected adults.[67] Patients with very mild symptoms that do not interfere with activities of daily living can be observed for deterioration without treatment. The natural course is improvement, generally in 2 weeks, but progressive weakness can be seen up to 4 weeks. One-third of children may have long-term sequelae, although these are usually mild. Supportive care in the intensive care unit may be needed for children with severe bulbar or respiratory weakness.[68] In those children who are nonambulatory or with respiratory failure, IV immunoglobulin with or without plasmapheresis are the current treatment options.[65] Children with axonal neuropathies usually recover motor function more slowly than those with demyelination; it is believed that early treatment with IV immunoglobulin may speed recovery.[67,69] However, corticosteroids are ineffective and may delay recovery.

Chronic Inflammatory Demyelinating Polyneuropathy

Chronic inflammatory demyelinating polyneuropathy is extremely rare in childhood, and it is usually confined to older age groups. It manifests in a subacute, chronic progressive or relapsing and remitting pattern with prominent sensory involvement. Diagnostic investigations are similar to those for acute GBS. Corticosteroids, IV immunoglobulin, and plasma exchange have been effective.[68] Although these treatments may be effective in the short term, recurrences may take place, and the usual pattern is that of a chronic, disabling, and relapsing and remitting condition that does not threaten longevity but interferes significantly with the quality of life.[70]

Nerve Palsies

Like neuropathies, nerve palsies are uncommon in childhood.[71] The most common palsy encountered in children is neonatal or congenital facial nerve palsy. Babies can present with a paucity of arm movement depending on the site of the brachial plexus injury following difficult deliveries involving traction of head and shoulders. Erb palsy (injury to C5,6), Klumpke paralysis (injury to C8, T1), or commonly an injury to the whole brachial plexus with the arm limp and an associated clavicular fracture. Cranial nerve palsies, especially those that involve the eye muscles, are usually related to intracranial disease such as increased ICP in children, but they may also be isolated findings that result from viral infections; in the latter instances, recovery is the norm.

Peripheral nerve palsies such as carpal tunnel syndrome have been reported in childhood.[72] They may complicate severe juvenile arthritis[73] or storage disorders such as mucopolysaccharidoses. Because symptoms may be difficult to elicit from children at the best of times, identifying palsies may be problematic in children with severe learning disabilities. Young children usually have difficulty with pencil grip or other fine motor tasks. In older children, symptoms may include pain, tingling, or numbness in the hands. Specialist care may require routine assessment of nerve conduction and possible surgical decompression. Concern has been expressed regarding the emergence of carpal tunnel syndrome as a type of repetitive strain injury in children owing to excessive use of video games.[74] Case reviews refer to other types of repetitive strain injury, such as basketball training and skiing, as etiologic factors.[75]

DISORDERS OF THE NEUROMUSCULAR JUNCTION

Myasthenia Gravis

Myasthenia gravis is a disorder of the neuromuscular junction. The term *myasthenia gravis* includes heterogeneous autoimmune diseases, with a postsynaptic defect of neuromuscular transmission as the common feature. The autoimmune disorder is characterized by one of several lesions of acetylcholine-mediated transmission.[76] Weakness results from antibodies that block various receptors, inhibiting the excitatory effects of acetylcholine at the neuromuscular junction. This defective transmission at the junction results in a characteristic pattern of progressively reduced muscle strength with repeated use and recovery of muscle strength after a period of rest. Myasthenia gravis can be classified according to Table 24.6.

Juvenile myasthenia gravis is the childhood form of the adult disease. It is also an autoimmune disease, with the production of antibodies that attack the acetylcholine receptor and sometimes other proteins as mentioned in Table 24.6; management is similar to that for adult myasthenia gravis.

Symptomatic treatment of myasthenia gravis with acetylcholine esterase inhibition (e.g., pyridostigmine) is usually

TABLE 24.6 Classification of Myasthenia Gravis

Based on serum antibody specificity:
1. Acetylcholine receptor (AChR) antibody–positive
2. Muscle-specific tyrosine kinase (MuSK) receptor antibody–positive
3. Low-density lipoprotein receptor–related protein 4 (LRP4) antibody–positive
4. Antibody-negative
Based on thymus histopathology:
1. Thymitis
2. Thymoma
3. Atrophy
Based on degree of involvement:
1. Only eyes: ocular myasthenia
2. Full body: generalised myasthenia
3. Mainly swallow, speech: bulbar myasthenia

combined with immunosuppression. Azathioprine remains the first choice for long-term immunosuppressive therapy, usually along with steroids.[77,78] Alternative immunosuppressive options to azathioprine include cyclosporin, cyclophosphamide, methotrexate, mycophenolate mofetil, and tacrolimus.[79] Rituximab is a promising new drug for severe generalized myasthenia gravis. Emerging therapy options include belimumab, eculizumab, and the granulocyte macrophage colony-stimulating factor. For decades, thymectomy has been performed in younger adults to improve nonparaneoplastic myasthenia gravis.[80] With optimal treatment, the prognosis is good in terms of daily functions, quality of life, and survival.[81]

Neonatal Transient Myasthenia Gravis

Neonatal myasthenia gravis is caused by placental transfer of antibodies to acetylcholine receptors from an affected or previously affected mother.[82] The infant may present with feeding difficulties or respiratory dysfunction.[83] Treatment, which involves anticholinesterase medications, must be tailored to the nature and severity of the weakness, and intensive support occasionally is required. This form of myasthenia gravis is a transient disorder for which treatment is temporary and the risk of recurrence small. It should be anticipated in the offspring of any woman who has active myasthenia gravis or a history of the disorder, because cases have been described in infants of mothers in remission from myasthenia gravis.

Congenital Myasthenic Syndromes

Congenital myasthenic syndromes (CMSs) form a heterogeneous group of genetic diseases characterized by a dysfunction of neuromuscular transmission that usually starts during childhood; this causes muscle weakness that increases with exertion. The prevalence of CMSs is estimated at 1 in 500,000 in Europe and is considered to be less common than autoimmune myasthenia. The classification of CMSs is based on where the defect occurs in the neuromuscular synapse:presynaptic, synaptic, and postsynaptic. Several genes have been identified in which mutations cause the disease. The various CMSs share a common clinical presentation and the onset is generally early. Clinical signs consist of ophthalmoplegia and ptosis, dysphonia and swallowing disturbance, facial paresis, muscle fatigability, and recurrent apneas. The occurrence of such clinical events, worsened by exertion, is characteristic of the disease. Acute respiratory failure may occur, triggered by infectious episodes, and is frequent in the first months of life. In the absence of respiratory assistance, the risk of death is high. The favorable effect of cholinesterase inhibitors is a significant argument in favor of a myasthenic syndrome. However, two types of CMS are worsened by cholinesterase inhibitors: slow channel syndrome and acetylcholinesterase deficiency.[84]

Although rare, CMSs should be considered in the differential diagnosis of any neonate or infant who presents with motor problems (e.g., weakness, hypotonia, fatigability), eye signs (e.g., ptosis, ophthalmoplegia, pupillary abnormalities), and respiratory insufficiency (e.g., recurrent apneas, ventilator dependence). Late-onset muscle weakness has been reported in adolescence or early adulthood. Diagnosis may be difficult because the classic features of myasthenia, including responses to anticholinesterase medications, may be absent.[85] A Tensilon test, electromyography with repetitive nerve stimulation, a muscle biopsy, and molecular analysis in a specialist center should be sought to confirm the diagnosis.

Anesthesia Considerations for Myasthenia Gravis

The anesthesiologist may become involved in the management of children with myasthenia gravis for several reasons[86]:

- Children may suffer a crisis requiring mechanical ventilation
- There is a need for large-bore central access to facilitate plasma exchange transfusion
- They may require thymectomy
- They may undergo elective or emergency surgery unrelated to their myasthenia

The severity of the muscle weakness and the muscle groups affected by the disease should be documented preoperatively, focusing on respiratory and bulbar function. The responses of patients with myasthenia to NMBDs depend on the type of relaxant. Decreased density of acetylcholine receptors at the motor end plate means that children with myasthenia may require up to four times the calculated dose of succinylcholine to establish a depolarizing muscle block. Because succinylcholine is metabolized by acetylcholinesterase, its metabolism is reduced and duration of action is prolonged in the setting of chronic acetylcholinesterase inhibition. For this reason, succinylcholine is best avoided in these children.

The activity of nondepolarizing NMBDs is increased through their increased duration of action. Unfortunately, the degree to which the sensitivity is increased is somewhat unpredictable and depends on an interaction between the severity of the disease (e.g., level of acetylcholine receptor antibodies) and the efficacy of treatment. Inhalational anesthetic agents inhibit neuromuscular transmission, and these effects may be exaggerated in myasthenia gravis patients. However, no clinically significant postoperative neuromuscular depression has been demonstrated with isoflurane, sevoflurane, or desflurane. These potential neuromuscular effects are not shared by propofol, making total intravenous anesthesia (TIVA), in theory at least, the technique of choice for these children. For all but the most minor surgery in the patient with stable myasthenia gravis without significant respiratory or bulbar compromise, a tracheal tube and intermittent positive-pressure ventilation are likely to be required. If possible, intubation of the trachea should be performed without the use of NMBDs. Tracheal intubation with inhalational anesthetics alone or propofol with a short-acting opioid has been described in these children.[87]

Myasthenia-Like Syndrome

The toxin of *Clostridium botulinum* produces a myasthenia-like syndrome that may occur through two mechanisms: ingestion of food contaminated by *C. botulinum* toxin, including contaminated honey, and wound infection by *C. botulinum.* Features include blurring of vision with ptosis, dilated and unresponsive pupils, cranial nerve palsies, limb paralysis with areflexia, feeding difficulty, and respiratory insufficiency. Diagnosis depends on clinical suspicion, identification of the toxin in residual food, and electromyography.

Treatment is supportive, and recovery may take weeks to months.[88] Succinylcholine is contraindicated in children with infections that affect the neuromuscular junction, including botulism and tetanus.[89]

DISORDERS OF MUSCLE FIBERS

Myopathies

Congenital Myopathies

Congenital myopathies are rare disorders that have many variations in the type and severity of features.[90] There can be significant

clinical overlap between congenital myopathies and other neuromuscular disorders. including the congenital muscular dystrophies (CMDs), congenital myotonic dystrophy, congenital myasthenic syndromes (CMS), metabolic myopathies including Pompe disease, SMA, as well as Prader-Willi syndrome. They can all present in the neonatal period with marked weakness and/or hypotonia ("floppy infant"). While it may not be possible to distinguish a congenital myopathy from other disorders, the presence of prominent facial weakness with or without ptosis, generalized hypotonic ("frog-leg") posture with hyporeflexia, and weakness and dysfunction of the respiratory and bulbar muscles are suggestive of congenital myopathy. The severity of weakness and disability varies widely, ranging from profound generalized weakness in neonates to patients with more subtle weakness. This may initially develop during childhood with signs of delayed motor milestones, or even later in life with symptoms of proximal weakness. Reduced muscle bulk is usually observed. In patients with severe weakness, respiratory insufficiency is common and the most severely affected infants require continuous ventilation for survival. The diagnosis usually is confirmed by characteristic findings on muscle biopsy (Table 24.7). Genetic diagnosis, and indeed genetic panels, are now available for many of these myopathies in specialist laboratories as outlined in Table 24.7 and are largely dictated by the pathologic finding.[91] Support of respiration and nutrition may be necessary. Minimally invasive methods, such as noninvasive nocturnal ventilation by face mask, are indicated to assist with management at home. Regular passive movements and careful management of posture and positioning to prevent contractures, especially scoliosis, is essential. Meticulous care of skin, joints, bowels, and teeth help to avoid the need for more invasive management. A complete evaluation of cardiovascular and respiratory status is required before anesthesia and surgery.[92,93]

Malignant hyperthermia (MH) is a disorder of skeletal muscle that manifests in response to anesthetic triggering agents. Core myopathies (central core disease and multi-minicore disease) are closely associated with MH (see Chapter 41), with extreme variation in the severity of its features. MH and core myopathies are primarily disorders of calcium regulation in skeletal muscle. Genetic testing identifies mutations in the ryanodine receptor gene (*RYR1*) in most affected individuals, accounting for their susceptibility to MH.[94] The *RYR1* gene encodes the channel that controls calcium release from the sarcoplasmic reticulum in skeletal muscle and, to a lesser extent, in other organ systems. *RYR1* abnormalities alter the channel kinetics for calcium inactivation, and calcium buildup causes excessive skeletal muscle contraction resulting from disinhibition of the normal actin-myosin interaction. The level of adenosine triphosphate decreases, leading to anaerobic and aerobic metabolism and to acidosis. Early manifestations of MH include hypercarbia or tachypnea and tachycardia. Late signs and symptoms include fever, sympathetic nervous system activation, hyperkalemia, muscle rigidity, disseminated intravascular coagulation, myoglobinuria, and multiorgan dysfunction and failure if not treated early.

The in vitro contracture test (IVCT) was developed to confirm susceptibility to MH by studying the contracture of muscle fibers in response to triggers such as caffeine and halothane.[95] This is an invasive and expensive investigation because an open muscle biopsy is required, and very few specialized centers perform this procedure; it is generally not performed in children younger than 10 years of age because of the size of the muscle biopsy required. Most individuals with core myopathy may be susceptible to MH, as demonstrated by IVCT, which has been the only means to confirm MH susceptibility until the emergence of molecular testing.[96] DNA analysis can provide a fairly reliable test for susceptibility to MH for 60% of affected individuals who have had an IVCT but for only 20% of those who have not had an IVCT (see Chapter 41).[97] However, the complexity of the situation is such that assessment and advice by a specialist is recommended rather than immediately embarking on DNA analysis so that the child and family may benefit from appropriate investigation and interpretation.[98] Any individual with core myopathy, and his or her family, should be informed about the clinical situation, diagnosis, and possible risks and complications, including MH, and should be offered a specialized investigation. An individual who may be susceptible to MH should carry information (e.g., a medical alert bracelet) to inform medical staff in an emergency.[99] Any elective operative procedure must be meticulously planned in advance with the full involvement of the anesthesiologist.

Metabolic Myopathies

Metabolic myopathies (Table 24.8) are uncommon and complex. Most affected children have multisystem involvement of sufficient severity to mask the myopathic features. The most important concerns for the anesthesiologist are the risk of metabolic instability during surgery and the need for close liaison with the child's pediatrician to plan fluid and electrolyte balance and nutritional management.[99,100]

TABLE 24.7 Congenital Myopathies

Pathologic Findings With Genotyping	
Disorder	**Genetics**
Core myopathies (including central core disease and multi-minicore disease)	*RYR1, SEPN1, ACTA1, TTN, MYH7, KBTBD13*
Centronuclear myopathies	*MTM1, RYR1, DNM2, BIN1*
Nemaline myopathy (including cap disease and zebra body myopathy and core-rod myopathy since these appear to be pathologic variants of nemaline myopathy)	*ACTA1, NEB, TPM2, TPM3, TNNT1 ,CFL2, KBTBD13, KLHL40*
Myosin storage myopathy (also known as hyaline body myopathy)	*MYH7*
Congenital fiber–type disproportion	*ACTA1, TPM3, TPM2, RYR1, SEPN1*

TABLE 24.8 Metabolic Myopathies

Disorders of purine nucleotide cycle: myoadenylate deaminase deficiency
Mitochondrial myopathies: chronic progressive external ophthalmoplegia (CPEO)
Kearns-Sayre syndrome (CPEO, conduction disturbance, pigmentary retinopathy)
Myo-neurogastrointestinal encephalopathy (MNGIE)
Glycogen storage disorders: muscle phosphorylase deficiency (glycogen storage disease [GSD] type V: McArdle disease)
Lysosomal acid maltase disease (GSD type II: Pompe disease
Disorders of fatty acid oxidation: carnitine palmitoyl transferase I and II deficiency

Mitochondrial Disorders Underlying Myopathies

Mitochondrial disorders are a common cause of inherited neurologic disease in children, occurring in 1 of 5000 live births. They are caused by mutations in mitochondrial or nuclear DNA. The respiratory chain is under bigenomic control: nuclear DNA codes for 85% of the proteins, and mitochondrial DNA codes for 15%. Nuclear DNA is inherited along Mendelian inheritance patterns, whereas mitochondrial DNA follows maternal inheritance patterns in a ratio of 9 to 1. Most mitochondrial disorders in children are determined by nuclear DNA, whereas those in adults are determined by mitochondrial DNA. The organs involved by mitochondrial disease are determined by the presence of defective nuclear or mitochondrial DNA in the embryo. The relative amount of defective DNA in affected tissues determines the severity of the disease. Disruption of the most fundamental cellular energy process, the mitochondrial respiratory chain, results in a diverse and variable group of multisystem disorders known collectively as mitochondrial disease. Involvement of the brain, nerves, and muscles can occur in isolation or in combination.

Diagnosis relies on characteristic clinical features, an understanding of mitochondrial genetics, and a logical, informed approach to investigations. Abnormalities of the mitochondrial genome are extremely common, and they can cause devastating phenotypes or be completely subclinical; assessment and diagnosis are challenging.[5]

Neurologic symptoms and signs are common. However, they tend to be varied and include myopathy, neuropathy, stroke-like episodes, ataxia, dementia, epilepsy, migraine, sensorineural deafness, and pigmentary retinopathy. The more common clinical scenarios in childhood are outlined in Table 24.9. Involvement of other organ systems, such as diabetes mellitus, gastrointestinal disease, and cardiomyopathy, may coexist or dominate the clinical picture. Evidence of mitochondrial dysfunction, such as lactic acidosis, increased CSF protein, and ragged red fibers on muscle biopsy, may or may not exist. Assessment of the child with atypical and otherwise unexplained features should include a search for evidence of mitochondrial abnormalities. The clinical details determine the investigative plan, which should include cerebral imaging with MRI and MRS (to detect lactate peaks), blood biochemistry (i.e., creatine kinase, lactate, and glucose levels), tests of urinary amino and organic acids, cardiologic assessment (i.e., chest radiography, electrocardiogram, and echocardiogram), electroencephalography, and exercise testing and neurophysiology, leading to mitochondrial studies of blood and muscle tissue.[101] Muscle biopsy investigations include histopathology, electron microscopy, respiratory chain enzymology, and molecular analysis of mitochondrial DNA. Further investigation with respiratory chain enzymes and molecular genetic analysis is indicated in some cases.[102]

Treatment of mitochondrial disorders includes management of specific features such as antiepileptic therapy and efforts to maintain stability of metabolic pathways.[103,104] Vitamins and other supplements such as coenzyme Q_{10} (i.e., ubiquinone), riboflavin, thiamine, and carnitine are referred to as the *mitochondrial cocktail* and are used in most of the mitochondrial disorders.[105] Use of the cocktail is largely based on the assumption that higher doses of these agents may improve mitochondrial energy generation.[106] Arginine has been used in the treatment of patients with mitochondrial encephalopathy with lactic acidosis and strokelike episodes (MELAS).[107]

Anesthesia Considerations for Myopathies

The challenge for the anesthesiologist is to maintain metabolic stability and prevent complications. The main problems associated with anesthetizing children with mitochondrial myopathies include respiratory failure, cardiac depression, conduction defects, and dysphagia.[108] The preoperative fasting period should be kept to a minimum to avoid hypovolemia and depletion of glucose stores. Stresses that may provoke increased energy requirements, such as perioperative pain, hypothermia, or hyperthermia, must be minimized. In children prone to lactic acidosis, IV fluids that contain lactate should be avoided, whereas administration of glucose-containing solutions is essential in any but the shortest of procedures to avoid hypoglycemia.[100,109] However, those children using a ketogenic diet for seizures should not have glucose in their IV fluids. Children with Kearns-Sayre syndrome must have adequate assessment and perioperative monitoring because cardiac conduction abnormalities, as well as myopathy, diabetes, proximal renal tubular acidosis, and other multisystemic abnormalities, are prominent features.[106]

Inhalational and IV anesthesia have been used successfully in many children with mitochondrial disorders, although several cases of untoward complications have been reported in the perioperative period.[109–112] However, the relationships between specific anesthetics and serious adverse effects remain tenuous. Two retrospective reviews of perioperative complications in 180 children with mitochondrial myopathies reported no complications after general anesthesia.[100,113] There is no evidence for either of

TABLE 24.9 Clinical Mitochondrial Syndromes in Childhood

Syndrome	Features
Alper-Huttenlocher, neuronal degeneration	Catastrophic onset of epilepsy, paralysis, ataxia, dementia, visual impairment, liver disease; death usually in months
Leigh encephalomyeloneuropathy	Brainstem signs predominant; relapsing/remitting or steadily progressive to death
Infantile myopathy and lactic acidosis	Hypotonia in infancy, feeding difficulties, respiratory problems, cardiomyopathy; fatal and nonfatal forms
Leber hereditary optic neuropathy (LHON)	Progressive visual loss in childhood, cardiac arrhythmias, dystonia
Kearns-Sayre (KSS)	Progressive external ophthalmoplegia, pigmentary retinopathy, deafness, heart block, choreoathetosis and ataxia, myopathy, endocrine disorders
NARP	Neuropathy, ataxia, retinitis pigmentosa
MELAS	Mitochondrial encephalomyopathy, lactic acidosis, stroke-like episodes, dementia
MERFF	Myoclonic epilepsy, myopathy with ragged red fibers (muscle Gomori trichrome stain), ataxia
MNGIE	Myoneurogenic gastrointestinal encephalopathy

two notions in these children: that inhalational anesthetics pose a particular risk to these children or that those with mitochondrial myopathies are more susceptible to MH than normal children.[114] However, mitochondrial disorders arise from a variety of molecular changes that have varied responses to anesthetics, which precludes blanket statements about the risks of general anesthesia in the entire population of these children.[115]

All inhalational anesthetics and propofol depress mitochondrial function at several levels, including the cytochrome oxidase chain and fatty acid membrane transport.[108] It has been postulated that children who develop metabolic acidosis and myocardial failure after propofol infusions for extended periods (>5 mg/kg per hour for more than 48 hours) [known as propofol infusion syndrome (PRIS)] have a subclinical form of a mitochondrial disorder. The basis for this is thought to be impaired cytochrome oxidases in the respiratory chain and free fatty acid transport in the mitochondria. However, evidence to support this notion is lacking. In a review of 61 patients with PRIS, 7 (4 children and 3 adults) developed PRIS during anesthesia.[116] Impaired tissue perfusion (in association with sepsis) may be a common underlying mechanism. Propofol interferes with the respiratory chain and fatty acid metabolism in the mitochondria, in much the same manner as other anesthetics and medications, suggesting that its use for induction of anesthesia or for brief procedures in children with mitochondrial myopathies is reasonable, a belief that is shared widely.[21,117] However, children with mitochondrial myopathies who are treated with a ketogenic diet may be susceptible to propofol.[118] Sensitivity and resistance to nondepolarizing neuromuscular blocking agents have been reported in children with these myopathies. To ensure appropriate dosing, the drugs should be titrated judiciously while neuromuscular blockade is monitored.

Ventricular dysrhythmias have been reported after a small dose of bupivacaine in a patient who was subsequently discovered to have carnitine deficiency.[119,120] Knowing that bupivacaine inhibits carnitine-acylcarnitine translocase, patients with defects in fatty acid metabolism may be considered to be more sensitive to toxicity from this anesthetic.[120]

Evidence would suggest that any anesthesia technique might be used in children with mitochondrial myopathies. However, mitochondrial myopathies represent a wide variety of molecular defects and thus a wide range of different diseases with similar phenotypes. It is likely that some types of defects are more sensitive to inhibition by anesthetics than others, and therefore possibly more prone to untoward effects.[108] Thus *all* children with mitochondrial myopathies must be monitored closely when administering any type of anesthetic. All medications should be titrated slowly, and great care should be exercised to ensure that the effects of the anesthetic agents have largely dissipated before allowing the patient to resume spontaneous ventilation.

Muscular Dystrophies

Muscular dystrophies represent a group of more than 30 inherited disorders of muscle that may occur in infancy, childhood, or adulthood (Table 24.10). The word *dystrophy* implies a destructive progressive process, and although this is the characteristic clinical course for many of those affected by muscular dystrophies, the course is extremely slow or has no muscle strength deterioration for others.[121]

This area of neurology has undergone substantive advances in molecular genetics and, to a lesser extent, in muscle pathology. Duchenne muscular dystrophy (DMD) was the first inherited disorder for which the causative gene and defective protein were identified.[121] Characterizing defective proteins led to advances in immunohistochemistry that can help to confirm the diagnosis using a muscle biopsy. Detection of genetic mutations enables the diagnosis to be determined using a blood specimen in most instances, removing the need for muscle biopsy in many children. The mutated gene and molecular site of the defect have been identified for most of the common disorders, enabling much more focused management in the form of new drugs, gene therapy using adeno-associated viral vectors and informed counseling of families.[122–124] The characteristic clinical features of muscular dystrophy include muscle weakness, the distribution of which varies from type to type—contractures, sluggish deep tendon reflexes, and involvement of respiratory and heart musculature. Other features often coexist, including learning disabilities, deafness, and ophthalmologic disorders. The serum creatine kinase level may be normal or increased. If it is increased, it provides an important marker for some disorders such as the dystrophinopathies, in which it may be 100 times normal. Diagnosis rests on careful clinical assessment, creatine kinase concentration, molecular

analysis, and muscle biopsy. Although there is no specific curative treatment for these disorders, advances in understanding the molecular genetic defect and the proteins responsible for the disease have focused the search for an effective pharmacologic treatment to reverse the clinical signs and symptoms.[124–126]

For an infant who presents with severe weakness and hypotonia, signs of facial weakness, reduced alertness, poor swallow, and reduced respiratory effort raise the possibility of a congenital myotonic dystrophy (DM1), which is usually inherited from the mother in an autosomal dominant pattern. Clinical suspicion of DM1 may be confirmed by molecular testing for the affected gene (*DMPK*), which codes for myotonic dystrophy protein kinase. The gene is located on the long arm of chromosome 19, expressing a protein primarily in skeletal muscle. This information negates the need for a muscle biopsy. A similar infant with good facial muscle movement, alertness, areflexia, and a diaphragmatic respiratory pattern indicating intercostal weakness is most likely to have SMA. The molecular test for the survival motor neuron is indicated to avoid the need for a muscle biopsy. Similar principles may be applied to children who present later in childhood. For example, a boy with gait abnormalities and a creatine kinase concentration 10 to 100 times normal is most likely to have a dystrophinopathy, and targeted molecular genetic testing can avoid the need for a biopsy.[127]

Myotonic Dystrophy

Myotonic dystrophy is the most common inherited neuromuscular disorder in the general population, and many more cases remain subclinical or undiagnosed.[4] All degrees of severity are possible, from the almost immobile infant with the congenital variant to the elderly adult with minimal motor weakness. Severity of the muscle weakness correlates with the molecular defect.

These children are susceptible to prolonged recovery from anesthesia. Accordingly, the dose of sedative medications and neuromuscular blocking agents should be titrated judiciously.[128] Sensitivity to succinylcholine is increased, and maximal use of regional nerve blocks or local infiltration with local anesthetic agents should be used whenever possible to minimize the need for opioids.

Most children with congenital or later-onset myotonic dystrophy have some degree of learning difficulties, which may be severe. One or the other parent is affected to a greater or lesser extent. In congenital cases (DM1), the mother is always the affected parent and, in most instances, is not aware of the disorder. The diagnosis is confirmed by the pediatrician or pediatric neurologist who examines the child.[129] The infant does not demonstrate signs of myotonia, and a muscle biopsy is not helpful to confirm the diagnosis at this age. The finding of facial weakness and clinical myotonia in the mother strongly suggests this disorder in a weak and floppy neonate.[130] The neonatal literature suggests that shaking the maternal hand (i.e., mother is unable to easily release her grip) may be sufficient to allow the pediatrician to make this diagnosis.[131] However, with the ability to confirm the diagnosis by molecular testing of blood from the infant and mother, it is no longer necessary to rely on clinical expertise in muscle strength testing. Genetic counseling is essential and should be offered to the wider family circle. It is not unusual to uncover a large kindred with previously unsuspected disease in this situation.

These infants may require intensive care in the neonatal period, including respiratory support, but they tend to improve with age. However, significant learning disability is the rule, and the input of the multidisciplinary child development team followed by special schooling is the norm. Surveillance should be in place for cardiac features that include hypotension, syncope, conduction defects, and arrhythmias. Specific conditions requiring surgery include scoliosis and joint contractures, and perioperative care must be carefully planned.[129]

Dystrophinopathies

The next most commonly encountered dystrophies are the dystrophinopathies. DMD is the more severe phenotype, and Becker muscular dystrophy (BMD) is the milder phenotype with a later age of onset (adolescence). Both dystrophies are inherited in an X-linked recessive pattern and affect boys almost exclusively.[132] These disorders are caused by a deficiency of dystrophin (i.e., less than 3% of the normal content in DMD), a muscle membrane protein essential to the skeletal and cardiac muscle cytoskeleton and to neural tissue. Dystrophin reinforces the inner strength of the myocyte during lateral stretching and is involved in signal transduction (Fig. 24.2). DMD occurs as a result of mutations, mainly deletions in the dystrophin gene (*DMD*, locus Xp21.2).[127]

Affected children experience a deterioration in muscle strength between the ages of 6 and 8 years that continues to progress until adolescence, at which age a wheelchair is usually required. Respiratory, orthopedic, and cardiac complications emerge with increasing age. From 10 years of age, annual or biannual echocardiograms should be performed to detect cardiomyopathy. Respiratory surveillance includes overnight sleep studies and early morning blood gas analysis to detect early nocturnal hypoventilation. As the lack of dystrophin affects the integrity of neural tissue, progressive cognitive dysfunction may occur. Also, the absence of dystrophin predisposes the muscle to tearing from normal stretching or from use of depolarizing drugs such as succinylcholine. Additional damage to skeletal muscle cells occurs from increased intracellular calcium concentrations, which may result from a defect in the sarcoplasmic reticulum. Upregulation of acetylcholine receptors has also been reported in these children. Without intervention, children with DMD usually die by a mean age of 19 years. With improvements in care, some are now surviving into the third decade. The mode of death is usually the result of underlying respiratory or cardiac failure.

Coordination of clinical care is a crucial component of DMD management. Care is best provided in a multidisciplinary setting in which the individual and family can collaborate with specialists about the required multisystem management of DMD. Depending on local services, coordinated clinical care can be provided by a wide range of health care professionals, including neurologists, rehabilitation specialists, neurogeneticists, pediatricians, and primary care physicians. The person responsible for coordination of clinical care must be aware of the available assessments, tools, and interventions to proactively manage all potential issues for the child with DMD.

Glucocorticoids are essential in the management of DMD; these agents slow the decline in muscle strength and function in the short term (up to 2 years), which reduces the risk of scoliosis and stabilizes pulmonary function.[133] Cardiac function may also improve; limited data indicate a slower decline in echocardiographic measures of cardiac dysfunction.[134,135] Prednisone is commonly used, although deflazacort is an alternative used in some countries and is probably just as effective. The most effective prednisolone regimen appears to be 0.75 mg/kg per day. International guidelines for initiation of steroids and other pharmacologic agents and the implementation of multidisciplinary care are clearly outlined by

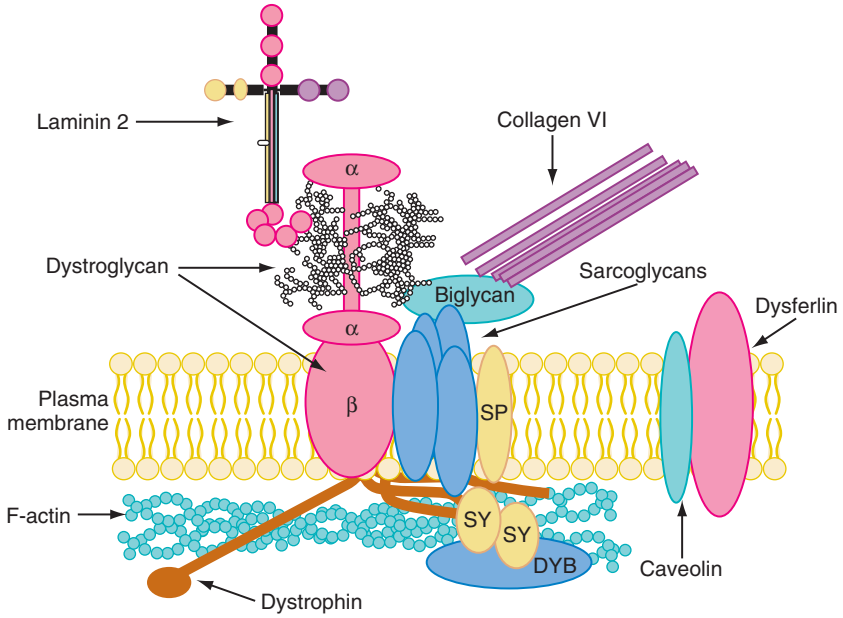

FIGURE 24.2 Schematic diagram of the proteins associated with dystrophin in skeletal muscle cells. The three key elements of the membrane skeleton and signal transduction path are laminin 2, which is the extracellular component; dystrophin-associated protein complex (DAPC) with its α- and β-dystroglycan, sarcoglycan, and cytoplasmic subunits, which is the transmembrane component; and dystrophin, which is the intracellular component. The cytoplasmic subunit of the DAPC consists of syntrophin (*SY*) and dystrobrevin (*DYB*). Sarcospan (*SP*) has four transmembrane-spanning helixes, and its expression is lost in patients with Duchenne muscular dystrophy. Dystrophin is the pivotal element that reinforces the muscle cell cytoskeleton, and it mediates signal transduction across cell membranes through its interactions with syntrophin, dystrobrevin, and neuronal nitric oxide synthase. Notice that the noncontractile F-actin binds to the N terminus of dystrophin. (From Goodwin FC, Muntoni F. Cardiac involvement in muscular dystrophies: molecular mechanisms. *Muscle Nerve* 2005;32:577–588.)

the DMD Care Considerations Working Group.[135,136] Children receiving glucocorticoids should be monitored regularly to prevent secondary complications from this therapy. They must have frequent weight measurements to prevent weight gain, regular blood pressure checks to prevent hypertension, and regular urine analysis for early detection of diabetes. They also require regular bone densitometry or dual-energy x-ray absorptiometry scans and maintenance of vitamin D levels. If there is evidence of reduced bone mineral density or presence of a vertebral fracture, they should be considered for bisphosphonate therapy. They should also be monitored for weight gain and obesity. Annual monitoring for cataracts is also advised. Early dietetic advice and, if necessary, a reduction in the dose of steroids should be undertaken. Prolonged use of steroids (beyond 2 years) does not improve strength and may result in growth failure, which warrants early referral to an endocrinologist.

If lower limb contractures exist despite range-of-motion exercises and splinting, surgery can be considered in some scenarios.[137] The approach must be strictly individualized. Surgical intervention is frequently used to treat lower limb contractures and enable rehabilitation in long leg orthoses so that the ambulatory phase may be prolonged.[138] This is usually indicated for children between 8 and 12 years of age, and it is well tolerated and successful if supported by a specialist team; however, it may increase the burden of care for parents and families.[139]

Children who are not treated with glucocorticoids have a 90% chance of developing significant progressive scoliosis[140] and a small chance of developing vertebral compression fractures caused by osteoporosis. Although glucocorticoids can reduce the risk of scoliosis,[141,142] the risk of vertebral fracture is increased.[143,144] Spinal care should involve an experienced spinal surgeon and consists of scoliosis monitoring, support of spinal and pelvic symmetry, and spinal extension by the wheelchair seating system. Corrective spinal surgery improves posture and seating options, eliminates pain from vertebral fracture resulting from osteoporosis, and slows the rate of respiratory decline.[140,145] The procedure is fraught with difficulty owing to postoperative respiratory weakness and possible cardiac dysfunction.[145] Careful preparation and liaison among the pediatrician or neurologist, surgeon, and anesthesiologist is essential; a plan for postoperative management, including the provision of intensive care, should be made.[99]

Facioscapulohumeral dystrophy (FSHD) is less often encountered in childhood, and specific surgical and anesthesia issues are limited. There are several phenotypes in childhood, including a severe neonatal form and a variably progressive childhood type that may be associated with sensorineural deafness. Irregular alignment between phenotype and genotype implies inconsistent expression of the molecular defect.[146,147] These children may benefit from surgery to fix the scapulae, which improves functionality of the upper limbs.[148,149]

Limb girdle syndromes (LGMD) (no longer a single entity; see Table 24.10) occur infrequently. Some have cardiac and respiratory implications and require preoperative assessment. In Emery-Dreifuss muscular dystrophy (EDMD), a syndrome in which cardiac conduction defects and dysrhythmias are common, syncope is usually the presenting complaint. These children are

followed by a specialist team that includes a cardiologist.[99] A preoperative cardiac workup is essential before embarking on general anesthesia with these children.

CMDs are a group of muscular dystrophies that become apparent at an early age (from birth). They are slowly progressive or can be static, and can be associated with learning difficulties. The two most common forms of CMD are Ullrich congenital muscular dystrophy (owing to defective collagen VI), which affects 50% of people with CMD, and merosin-deficient CMD (CMD 1A), which affects another 25%. These do not affect the intellect. The CMDs with prominent intellectual impairment are caused by a defect in the glycosylation of α-dystroglycan, producing abnormal basal lamina formation in the brain and muscle. There is varying severity of disorganization of the cortical lamination, muscular dystrophy, and eye problems (muscle-eye-brain) depending on the genetic defect. Examples of these are Fukuyama CMD (caused by fukutin defect), muscle-eye-brain disease (caused by a protein *O*-mannosyltransferase 1 *[POMGnT1]* defect) and Walker-Warburg syndrome (due to POMT1). Diagnosis is made from the clinical picture, creatinine kinase levels, dystrophic muscle biopsy, presence or absence of cortical abnormalities, and finally, by the genetic testing. Medical care for patients with CMD remains diverse and is outlined in a Consensus Statement on Standard of Care for Congenital Muscular Dystrophies.[150]

Anesthesia Considerations for Muscular Dystrophies

The anesthesia implications for muscular dystrophies are dictated by the age of the child and severity of the disease. In early childhood, those affected by DMD undergo destruction of skeletal muscle, and when exposed to triggers that include succinylcholine and inhalational anesthetics, they have presented with severe rhabdomyolysis and hyperkalemia that resulted in cardiac arrest. Some children who were not known to have muscular dystrophy had a cardiac arrest during inhalational anesthesia as the first sign of the disorder. In contrast, during adolescence and adulthood, progressive cardiac and respiratory failure are the major concerns. The severity of DMD usually is greater than that of BMD and EDMD.

Despite extensive documentation that inhalational anesthetics or succinylcholine, or both, can trigger life-threatening rhabdomyolysis in children with muscular dystrophy, this problem persists.[151–153] Case reports have described rhabdomyolysis, hyperkalemia, and cardiac arrest with or without the use of succinylcholine in children with DMD. No single inhalational anesthetic appears to be without blame.[154,155]

The defect in dystrophinopathies results from the lack of the membrane-stabilizing protein dystrophin. It has been suggested that the addition of another destabilizing agent, such as an inhalational anesthetic, predisposes these children to mild or severe rhabdomyolysis, hyperkalemia, and death. Those most at risk for these complications are younger children, some of whom are undiagnosed until the perioperative rhabdomyolysis develops and establishes the diagnosis. Adolescents in whom muscle breakdown has waned and muscle mass has been lost and replaced by fatty infiltration have had uneventful perioperative courses when exposed to inhalational anesthetic agents and succinylcholine. Although succinylcholine is infrequently used today, the mortality rate associated with a succinylcholine-induced cardiac arrest is 30%.[155]

Although there is insufficient evidence to contraindicate inhalational anesthetics in young children (<8 years of age and males) with muscular dystrophy, total intravenous anesthesia (TIVA) has emerged as the preferred technique as an alternative to inhalational anesthetics. In the absence of a compelling reason, it seems prudent to generally avoid inhalational anesthetics in young children with known DMD.[153,156] At the same time, without knowledge of the minimum concentration of inhalational anesthetic that triggers muscle breakdown, washing out inhalational anesthetics from anesthesia workstations, as in cases of MH, is unjustified. In some specific clinical situations such as a child with DMD and a difficult airway for whom an IV technique may be contraindicated or IV access cannot be established before induction of anesthesia (or with nitrous oxide alone), a brief exposure to an inhalational anesthetic to secure the airway followed by TIVA is an alternative approach. Consideration should be given to alternative induction approaches (e.g., ketamine IV, orally, intramuscularly), nitrous oxide and/or the addition of ancillary techniques to secure venous access readily (EMLA [eutectic mixture of local anesthetics] cream, ultrasound-guided catheterization). Case reports of rhabdomyolysis during and after inhalational anesthesia[157–159] warrant vigilance for possible sequelae in these children. The child should be monitored for signs of rhabdomyolysis (i.e., urine myoglobin, serum K^+ level) even if the risk is small.[156] If rhabdomyolysis occurs, the inhalational anesthetic should be discontinued and replaced with a TIVA anesthetic. The child should not be discharged home until the signs of rhabdomyolysis resolve; myoglobinuria should be managed with large volumes of IV balanced salt solutions.[156]

Rhabdomyolysis caused by anesthetic agents may mimic MH.[160] The risk of MH in children with DMD is the same as in the general population.[161] Hyperkalemic arrhythmias are most effectively reversed by rapid IV administration of calcium (10 mg/kg of calcium chloride), which may be repeated until the arrhythmias abate. Other therapies, including hyperventilation, administration of bicarbonate, albuterol, insulin and glucose, and sodium polystyrene sulfonate (Kayexalate) are also recommended. The hyperkalemia associated with acute rhabdomyolysis may be refractory to the usual treatments and may require a prolonged resuscitation (see Chapters 9 and 40).

Boys with undiagnosed DMD have been anesthetized with inhalational agents and developed rhabdomyolysis. To minimize the risk of this complication, clinicians should question family members about any history of dystrophinopathies during the preoperative evaluation, mild signs of hypotonia, and motor weakness and delayed motor milestones. However, at least 30% of children present de novo (no family history) and represent new mutations. A brief developmental and neuromuscular history should be obtained, and if there is any question or suspicion, it is reasonable to measure a random serum creatine phosphokinase concentration preoperatively.

Undiagnosed Myopathy

The child with a possible myopathy (e.g., floppy, hypotonic, motor developmental delay) but without a definitive diagnosis can pose a challenge to the anesthesiologist.[162] A careful history and physical examination should be carried out. Serum creatine kinase and lactate concentrations should be evaluated, and the child's pediatrician or pediatric neurologist contacted for advice. If a progressive muscular dystrophy cannot be excluded (in the presence of an increased creatine kinase level), it may be prudent to avoid inhalational anesthetics, although their careful use for induction may be considered. An increased creatine kinase level in an asymptomatic infant or child may suggest a progressive muscular dystrophy, and inhalational anesthetics should be used with caution unless DMD or BMD is excluded.

Epilepsy

Epilepsy is a common disorder in childhood, with a prevalence of 0.5% to 1% in the school-age population. It is defined as the tendency to have recurrent spontaneous seizures. A seizure is a sudden, excessive, uncontrolled electrical discharge of cortical neurons.[163]

Any part or all of the cerebral cortex may be involved, and the manifestations of seizures are numerous. The first and most important step in managing epilepsy is to establish a correct diagnosis by determining whether the episodes are epileptic, classifying the episodes, and identifying the epilepsy syndrome that matches the clinical features (Table 24.11).

Diagnosis of seizures is largely a clinical process, with investigations providing information to determine cause (imaging) or seizure syndrome (electroencephalography). The cause may be a cerebral lesion of any type, in which case neurologic deficits may coexist, such as in cerebral palsy, or it may be a genetic disorder with no other neurologic features.

After a diagnosis of seizures has been made, the next step is to determine the epilepsy syndrome. This is achieved by reviewing the following:

- Seizure type
- Age
- Associated features
- Electroencephalographic features
  - Interval since the last seizure
  - Current medication, timing of the last dose and blood levels
- Check if the patient is using alternate nondrug therapies–for example, a ketogenic diet (KD) or vagal nerve stimulation (VNS).

The details of the epilepsy syndrome can guide further investigations, help to plan treatment, and educate the family regarding the prognosis.[164]

Management is directed at treating the cause if possible and in preventing seizures using antiepileptic drugs. Medication is chosen according to the seizure type and epilepsy syndrome, taking into account the age of the child, associated disorders, and other maintenance medications.[165] Most of the current antiepileptic drugs are licensed for use in childhood, although there are limitations for some drugs, especially in younger children. The aim of the treatment is to eliminate all seizures with the least number of antiepileptic drugs at the minimum doses. When the epilepsy has failed to respond to two or more appropriate antiepileptic drugs and the child is not suitable for epilepsy surgery, the alternate therapies such as KD or VNS are offered. The American Epilepsy Society guidelines and practice parameters are available at www.aesnet.org,[166] and the U.K. Epilepsy guidelines are available at www.nice.org.uk/CG.[167]

For children with epilepsy who are undergoing surgical procedures under anesthesia, the main problems are provocation or increased frequency of seizures, which have several causes:

- Anti-seizure medication missed due to perioperative fasting
- Epileptogenic anesthetics (e.g., enflurane)
- Hypoxia
- Electrolyte disturbance (e.g., hyponatremia)
- A direct effect of neurosurgery on the brain
- Cerebrovascular instability
- Coincidental exacerbation of severe epilepsy
- Postoperative ileus resulting in poor drug absorption
- Loss of ketosis in a well-controlled child using a KD

Certain disorders that cause epilepsy may be associated with other medical conditions, such as cardiorespiratory deficits, nutritional difficulties, and learning disabilities.[168]

Preparation for surgery should include a thorough review of the child's clinical status, including consultation with the physician who manages the child's epilepsy. In addition, it is important to know if the child is using alternate therapies such as a KD or VNS. For most minor elective procedures, there is no need to miss or omit any medication in the perioperative period, and parents should be advised to give regular medications as usual on the morning of surgery and anesthesia. Careful scheduling of the time of surgery may facilitate this because many children receive antiepileptic drugs on twice-daily regimens, with doses given at 8 AM and 8 PM. If surgery is scheduled for late morning or early afternoon, no medication need be missed. For children with complex epilepsy, such as those undergoing neurosurgery for the epilepsy itself, careful preoperative assessment is imperative.[169] In managing surgery and anesthesia in children with epilepsy, the aim is to prevent seizures and enable smooth and effective treatment (Table 24.12).

To avoid interfering with epilepsy control, it would appear prudent to maintain children with a KD in the perioperative period and ensure that all IV solutions are carbohydrate free (e.g., normal saline). In one report, none of the 9 children on a KD who underwent general anesthesia for 24 surgical procedures developed complications or exacerbations of their seizure activity.[170] None of the children experienced any exacerbation of seizure activity perioperatively. Although all the children maintained stable glucose concentrations intraoperatively, they appeared to be at

TABLE 24.11 Epilepsy

Classification of Seizure Types
Self-limited seizures
Generalized
Focal
Continuous seizures
Status epilepticus
Epilepsy Syndromes in Childhood (Some Examples)
Neonatal seizures
Benign neonatal convulsions
Benign neonatal familial convulsions
Early infantile epileptic encephalopathy (EIEE; Ohtahara syndrome)
Early myoclonic encephalopathy (EME)
Childhood syndromes
Epileptic spasms (West syndrome)
Benign myoclonic epilepsy of infancy
Severe myoclonic epilepsy of infancy
Lennox-Gastaut syndrome
Myoclonic astatic epilepsy
Primary generalized epilepsies
Absence seizure syndromes (childhood absence epilepsy, myoclonic absence epilepsy)
Generalized tonic-clonic seizure syndromes
Juvenile myoclonic epilepsy
Juvenile absence epilepsy
Benign focal epilepsy syndromes
Benign rolandic epilepsy with centrotemporal spikes (BRECTS)
Childhood epilepsy with occipital paroxysms (CEOPS)
Lesional focal epilepsies
Temporal lobe epilepsy (mesial temporal sclerosis)
Frontal lobe epilepsy (structural abnormalities)

TABLE 24.12 Perioperative Medication Management for Children With Epilepsy

Preoperative Management
Liaise with child's pediatrician or neurologist.
Clarify usual seizure types, frequency, and trigger factors.
Review and document regular medication regimen (ideally twice daily).
Check antiepileptic drug level (phenobarbitone, phenytoin, or carbamazepine only).
Review rescue medication regimen.
Check drug allergies and adverse reactions.
Management for Minor or Day Surgery
Schedule for early afternoon.
Allow usual morning medication.
Avoid prolonged fasting.
Aim for evening medication as usual.
Management for Major Surgery
Ensure regular medications up to fasting.
Use intravenous preparations of regular drugs (phenytoin, phenobarbitone, valproate, benzodiazepine), if possible; use same doses two or three times daily.
If regular drugs not possible, administer the following: Phenytoin: Give intravenous load of 15–20 mg/kg at a rate of 50 mg/minute and then give twice-daily maintenance dose of 2.5–5.0 mg/kg. Benzodiazepine: Give intravenously as rescue.
If enteral administration is possible, reestablish regular maintenance and wean intravenous phenytoin dose.

risk of developing a metabolic acidosis during anesthesia, particularly during prolonged surgery. For this reason, blood glucose, pH, and bicarbonate levels should be monitored perioperatively, especially in procedures lasting more than 3 hours. If a child develops an acidosis, IV bicarbonate should be used as clinically indicated. If the blood sugar is less than 3 mmol/L (55 mg/dL), a glucose containing IV fluid (glucose 2.5% or 5%) should be used to maintain blood glucose between 3 and 4 mmol/L (55–70 mg/dL).[171] IV fluids should be continued postoperatively until oral fluids are tolerated. Oral fluids should be appropriate for a KD and low in carbohydrate. Finally, the KD should be reintroduced as soon as possible after surgery.

In patients with a VNS implant, it is recommended to use the minimum amount of appropriate energy during each electrical current delivery and to place defibrillation pads as far removed from the generator and implanted lead as possible. Electrocautery or radiofrequency ablation may damage the generator. Although the VNS does not need to be deactivated (via magnet placement) during surgery, it is recommended to position grounding pads to prevent current flow through the system and that they be as far away from the VNS generator as possible.[172]

Summary

Neurologic disease is common in childhood. Many severely disabled children are living longer but with increasingly complex medical and social needs. The challenges for surgeons and anesthesiologists in treating them include consent, complications of anesthesia, and issues related to long-term outcomes. The key to effective management is good basic neurologic and pediatric care with careful preparation, including close liaison with parents and the child's usual clinicians.

Limitations of the Available Clinical Studies
Future Research
Recommendations for Clinical Practice

MILLIONS OF CHILDREN UNDERGO SURGERY with anesthesia every year.[1] During the perioperative period they are exposed to a multitude of stressors capable of interfering with normal brain development. Pain, stress, inflammation, hypoxia, and ischemia have all been shown to adversely affect the immature central nervous system (CNS). However, recent findings from animal studies have indicated that sedatives and anesthetics—the very drugs used to reduce pain and stress—may themselves undesirably influence brain development by triggering structural and functional abnormalities. In fact, this phenomenon is currently one of the most intensely investigated laboratory research fields in anesthesiology and a passionately debated topic (Fig. 25.1). To date, more than 400 animal studies have addressed the effects of anesthetics on the developing brain.[2] However, translating these laboratory findings to humans in clinical settings has been complicated.

To begin with, human epidemiologic studies have found mixed evidence for an association between surgery with general anesthesia in childhood and subsequent neurodevelopmental abnormalities. Some studies identified more frequently occurring learning disabilities in children after surgery with general anesthesia early in life, whereas others have not. Although surgery or comorbidities may affect the developing brain, the mounting laboratory data demonstrating deleterious effects of anesthetic exposure without surgery have forced clinicians to consider the possibility that anesthetics may also play a role in this phenomenon. However, similar to the uncertainties surrounding animal studies, the interpretation of the human data is fraught with substantial limitations.

Any discussion of the long-term effects of anesthetics on the developing brain is further complicated by the fact that anesthetic drugs may be organ protective under certain conditions, and may indeed mitigate brain damage that is due to inflammatory responses, hypoxia-ischemia, or other insults that might occur during the perioperative period.

It is currently impossible to provide any definitive statements about the effects of anesthesia on human neurodevelopment. This chapter provides an overview of the current laboratory and clinical data concerning the affect of sedatives, anesthetics, and analgesics on the immature brain.

Background

About 170 years ago, William T.G. Morton conducted the first successful public demonstration in the Western hemisphere of a drug-induced, reversible coma during a surgical procedure at the Massachusetts General Hospital. After witnessing Morton's demonstration, Oliver Wendell Holmes called the phenomenon

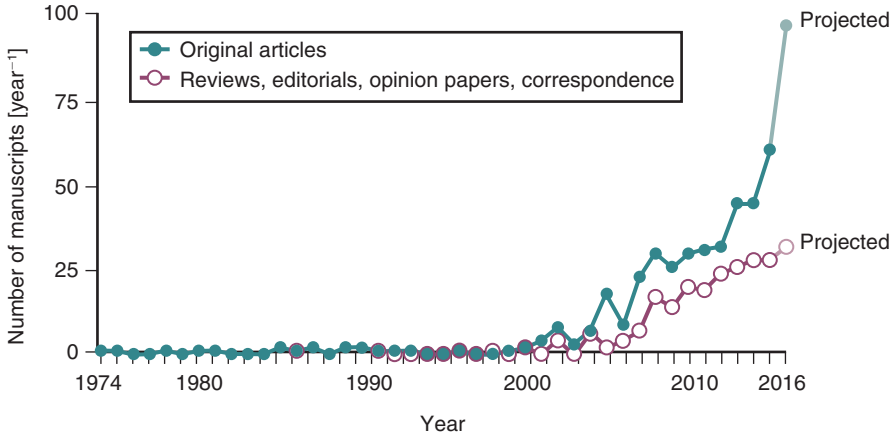

FIGURE 25.1 Research into the effects of anesthetic exposure in immature animals represents one of the most intensely investigated fields in anesthesiology and one of the most hotly debated topics. Graphical depiction of the annual publication of original articles (*solid circles*) and reviews, editorials, letters, commentaries, or opinion papers (*open circles*) spanning from 1974 to 2016, identified in a PubMed database search and screened for relevance using the terms "anesthesia or anesthetic or isoflurane or sevoflurane or desflurane or halothane or enflurane or ketamine or barbiturate or pentobarbital or benzodiazepine or midazolam or propofol or dexmedetomidine or xenon" and "neurotoxicity or apoptosis" and "neuron or brain". (From Lin EP, Lee J-R, Lee CS, et al. Do anesthetics harm the developing human brain? An integrative analysis of animal and human studies. *Neurotoxicol Teratol.* 2017;60:117–128.)

"anesthesia," from the Greek words *an-* (without) and *aisthēsis* (sensibility), and it instantaneously revolutionized the field of surgery. The inscription on Morton's tombstone, *"Inventor and Revealer of Inhalation Anesthesia: Before Whom, in All Time, Surgery was Agony; By Whom, Pain in Surgery was Averted and Annulled; Since Whom, Science has Control of Pain,"* represents a powerful testament to the tremendously positive impact that anesthesiology has made on the field of medicine. The use of general anesthetics to facilitate surgery quickly spread around the world and according to recent estimates, anesthesia currently allows more than 230 million patients of all ages worldwide to undergo major surgical procedures every year.[3] This positive impact is now tempered by the possibility that anesthetics may adversely affect normal brain development. During the first century of their use, general anesthetics were regarded with serious concern because they were combustible and carried substantial hemodynamic and respiratory adverse effects. Accordingly, up until 25 to 30 years ago, general anesthesia was rarely used in critically ill neonates because of the fear of myocardial depression and hemodynamic instability. Perioperative drug regimens were often limited to neuromuscular blocking agents and nitrous oxide. However, with the realization that unopposed pain exerts deleterious effects on the developing brain, that dramatic stress responses to painful stimulation are detectable even in preterm infants, and that modern anesthetics and analgesics can abolish these responses without substantial hemodynamic compromise, pediatric anesthesia, for the past three decades, has afforded critically ill neonates the benefits of amnesia, analgesia, and immobility during increasingly invasive surgeries. These surgical interventions have helped to save countless lives and preserve quality of life in this vulnerable population. All the while, the powerful coma induced by general anesthetics has been thought to be temporary and devoid of serious long-term adverse effects after emergence. This notion of reversibility is now being seriously questioned because of structural abnormalities detected in neonatal animals during and immediately after anesthetic exposure and long-term cognitive abnormalities reported in animals and some children exposed to anesthesia at a young age.

Normal Brain Development

To put the effects of anesthetic exposures into context of brain development, the natural developmental processes must be taken into consideration. The human brain undergoes a complex and extended process of enormous growth in cell number, synapses, and connections during the perinatal period and beyond. Combined with this expansion of cells and connections early in life, subsequently massive regressive processes also occur during normal brain development. These expanding and regressive processes allow the brain to fully develop and eventually execute tasks, such as talking, walking, reading, writing, calculating, acquiring social skills, perfecting fine motor dexterity, and accomplishing complex functions, including learning, abstract thinking, as well as planning and executing long-term objectives.

To accommodate these functions, the human brain initially undergoes a rapid growth in size and cell number both in utero and during the early postnatal period, and is then pared back to achieve an efficient network of about 100 billion neurons in the adult brain. At birth, the size of the immature brain is one-third that of the adult brain, doubling in weight within the first year of life, and reaching 90% of its adult size by 6 years of age.[4] This dramatic growth spurt coincides with a remarkable overabundance of neurons and neuronal connections. In fact, less than half the neurons generated during development survive into adulthood.[5,6] Superfluous neurons that lose in the competition for a limited amount of trophic factors are removed by programmed cell death.[7]

After their rapid growth in number during early brain development, immature neurons subsequently form an excess of connections via synapses. Depending on the brain region, synaptic densities are maximum in infants and young toddlers between 3 and 15 months of age and will undergo a progressive

reduction by about half during adolescence and into adulthood.[8] Connections that are active with continued electrical and chemical signals are sustained, whereas those with little or no activity are lost. Axons are myelinated by oligodendrocytes, leading to maturation of the CNS.

In summary, brain architecture changes rapidly and dramatically throughout early life. Neuronal density is greatest during fetal life, and excess neurons are eliminated via apoptosis or programmed cell death, predominantly in utero, during the neonatal period and throughout infancy.[9] Rapid growth of dendrites and synaptic connections occur during infancy and early childhood, and unneeded dendrites and synapses are trimmed back, predominantly during later childhood and adolescence.[8,9]

While these processes occur at slightly different stages of development for different regions of the brain, the first several years after birth represent a critical period for the entire developing CNS. Recent findings in animals suggest that exposure to anesthetics or sedatives during this period may interfere with proper neuronal development, brain architecture, and subsequent function. Although the exact molecular mechanisms by which anesthetics afford their therapeutic properties of amnesia, analgesia, and immobility are incompletely understood, their interaction with a wide variety of ion channels, such as sodium, calcium, and potassium channels, as well as several cell membrane proteins, including γ-aminobutyric acid (GABA), glycine, glutamate (*N*-methyl-D-aspartate [NMDA]), acetylcholine, and serotonin receptor systems, make it conceivable that anesthetics could create permanent abnormalities by interfering with important processes during critical windows of brain development. In fact, both GABA and NMDA receptors play critical roles in trophic signaling and in the regulation of neuronal maturation and programmed cell death. During early brain development, for example, GABA directs cell proliferation, neuroblast migration, and dendritic maturation.[10] In turn, developmental NMDA receptor stimulation directly fosters survival and maturation of some neurons.[11,12] It is therefore plausible that, by acting as modulators of these receptors, anesthetics might interfere with these critical developmental processes.

Effects of Anesthetic Exposure on the Developing Brain

Concerns regarding neurologic abnormalities after general anesthesia in young children were first raised more than half a century ago, when postoperative behavioral changes were observed after administration of vinyl ether, cyclopropane, or ethyl chloride for otolaryngologic surgery.[13] However, these abnormalities were regarded as psychological in nature because they were alleviated by the timely administration of preoperative sedative drugs.[13,14] Approximately two decades later the focus of research into the long-term effects of anesthetics shifted to animal models representing occupational exposure in pregnant health care workers.[15–18] Delayed synaptogenesis and behavioral abnormalities were observed in neonatal rats born to rodent dams that were chronically exposed to subanesthetic doses of halothane during their entire pregnancy. However, interest in the effects of anesthetics on brain development in children was not elicited until a seminal study observed widespread neuronal degeneration after a prolonged exposure to ketamine in neonatal rat pups.[19] This initial discovery led to numerous editorials and reviews, and more than 400 original articles (see Fig. 25.1) into the brain structural and/or functional effects of almost every sedative and anesthetic in current clinical use in a wide variety of immature animal species.[20–67] However, no discussion about the effects of drug exposure of the developing brain would be complete without examining the effects of opioid analgesics in the developing brain.[56,57] Accordingly, this chapter examines the specific cellular effects that sedatives, anesthetics, and analgesics trigger in the immature brain.

APOPTOTIC CELL DEATH

The most widely studied deleterious structural consequence of exposure to sedatives or anesthetics in immature animals is widespread apoptosis. Although neuronal apoptosis eliminates approximately 50% to 70% of neurons throughout the brain during the entire developmental period, this natural process affects only a small fraction of cells at any particular time point. Exposure to anesthetics or sedatives briefly, but dramatically, increases the number of apoptotic neurons (Fig. 25.2). Some studies demonstrated up to a 68-fold increase in the density of degenerating neurons after a combination of anesthetics in newborn rats compared with control animals,[68] although it remained unclear what fraction of the entire neuronal population these degenerating neurons represented. In newborn mice, a 6-hour exposure to a clinically relevant dose of isoflurane triggers apoptotic cell death in 2% of neurons in the superficial cortex, a substantially affected brain region at this age. Under normal conditions, less than 0.1% of neurons undergo physiologic apoptosis in this region in unanesthetized littermates.[69] The exact mechanism and selectivity of the cell death process remains unknown as dying neurons are located immediately adjacent to seemingly unaffected neighboring cells (Fig. 25.3). Increased neuroapoptosis has now been observed after in vitro and in vivo exposures to a wide variety of sedatives and anesthetics, including chloral hydrate, clonazepam, diazepam, midazolam, nitrous oxide, desflurane, enflurane, halothane, isoflurane, sevoflurane, ketamine, pentobarbital, phenobarbital, propofol, and xenon, as well as opioid receptor agonists in a wide variety of species, including fruit flies, nematodes, chicks, mice, rats, guinea pigs, piglets, and rhesus monkeys (E-Table 25.1). Selective stains such as cupric silver and Fluoro-Jade (EMD Millipore, Billerica, MA) have confirmed the cellular demise in neurons that positively stained for activated caspase 3, the central executioner enzyme of the apoptotic cascade.

Apoptosis represents an inherent, energy-consuming process using a cascade of enzymes called caspases. Apoptosis is highly conserved among species and culminates in self-destruction and elimination of cells, even under physiologic conditions, when these cells are functionally redundant or potentially detrimental to the organism.[242] It involves an orderly breakdown of the cell that includes chromatin aggregation, nuclear and cytoplasmic condensation, and partitioning of cytoplasmic and nuclear material into apoptotic bodies for subsequent phagocytosis, without an extensive inflammatory response. That contrasts with features observed during necrosis, for example during ischemia, which includes energy failure, cellular swelling, membrane rupture, and release of cytoplasmic content into the extracellular compartment, followed by an inflammatory response.[242] However, there seems to exist substantial overlap and common pathways between cell death processes, such as apoptosis, necrosis, and autophagy, which have previously been thought to be entirely separate.[243] Apoptosis, which has also been termed cellular suicide or programmed cell death, is extensively used during tissue homeostasis, endocrine-dependent tissue atrophy, and normal embryogenesis (e.g., cardiac sculpting, ablation of tail tissue as part of tadpole metamorphosis

E-TABLE 25.1 Representative Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Buprenorphine	1.5 mg/kg per day to dam	Rat, E7–E21 or P10	Decrease in striatal nerve growth factor	Wu et al.[70]
Chloral hydrate	50–300 mg/kg × 1	Mouse, P5	Increased neuroapoptosis, ameliorated by lithium	Cattano et al.[71]
Clonazepam	0.5–4 mg/kg × 1	Rat, P7	Increased neurodegeneration	Bittigau et al.[72]
Clonazepam	0.5–4 mg/kg × 1	Rat, P7	Increased neurodegeneration	Ikonomidou et al.[73]
Desflurane	7% for 30–120 minutes	Rat, P16	No increase in neurodegeneration or gross changes in dendritic arborization, increase in number of dendritic spines	Briner et al.[74]
Desflurane	12% for 6 hours	Mouse, cortical neuronal culture	No increase in expression of proapoptotic factors, no accumulation of reactive oxygen species, no activation of apoptosis pathways	Zhang et al.[75]
Desflurane	7.4% for 6 hours	Mouse, P7–P8	Increased neuroapoptosis compared with no anesthesia, but similar to equianesthetic doses of isoflurane or sevoflurane	Istaphanous et al.[76]
Desflurane	8% for 6 hours	Mouse, P6	Increased neuroapoptosis, compared with sevoflurane and isoflurane, and long-term impairment in memory function	Kodama et al.[77]
Desflurane	9% for 2 hours/day × 3 days	Mouse, P6–P8	No increase in inflammatory markers or learning impairment in adulthood	Shen et al.[78]
Dexmedetomidine	1–75 μg/kg × 3	Rat, P7	No increase in neuroapoptosis	Sanders et al.[79]
Dexmedetomidine	25 μg/g every 2 hours × 3	Rat, P7	No increase in cortical neuroapoptosis	Sanders et al.[80]
Dexmedetomidine	75 μg/kg IP × 1 or 25 μg/kg every 2 hours × 3	Rat, P7	No increase in neuroapoptosis in hippocampus, dexmedetomidine ameliorated isoflurane-induced neuroapoptosis	Li et al.[81]
Dexmedetomidine	5 or 10 μg/kg ×1	Rat, P7	Unaltered hippocampal synaptic function in young adulthood	Tachibana et al.[82]
Dexmedetomidine	3 or 30 μg/kg per hour for 12 hours to dam	Cynomolgus monkey, E120	Minimal neuroapoptosis in frontal cortex at both doses	Koo et al.[83]
Dexmedetomidine	25 μg/kg daily × 3	Rat, P7–9	No increase in apoptotic neurons in hippocampus, learning and memory in adulthood unaltered	Duan et al.[84]
Dexmedetomidine	75 μg/kg × 1 or 25 μg/kg × 3	Rat, P7	No increase in apoptosis observed in hippocampus	Li et al.[81]
Dexmedetomidine	75 μg/kg × 1	Rat, P7	No significant increase in neuroapoptosis in hippocampus	Liao et al.[85]
Dexmedetomidine	30 or 45 μg/kg every 90 minutes × 6	Rat, P7	Cellular degeneration and apoptosis in somatosensory cortex and thalamus, but not limbic thalamus	Pancaro et al.[86]
Diazepam	10–30 mg/kg × 1	Rat, P7	Increased neurodegeneration	Ikonomidou et al.[73]
Diazepam	5–30 mg/kg × 1	Rat, P7	Increased neurodegeneration above 10 mg/kg, prevented by flumazenil	Bittigau et al.[72]
Diazepam	5 mg/kg × 1	Mouse, P10	No increased neurodegeneration in cortex, but increased in thalamus, no subsequent behavioral or learning deficits	Fredriksson et al.[87]
Diazepam	20 mg/kg on P6 and on P8	Rat, P6 and P8	Inhibition of neurogenesis	Stefovska et al.[88]
Enflurane	2%–4% for 0.5 hour	Mouse, prenatal E6–E17	Learning impairment in adulthood	Chalon et al.[89]
Fentanyl	50 μg/kg per hour for 72 hours	Rat, P14	Diminished morphine antinociceptive sensitivity in juvenile and adult animals	Thornton et al.[90]
Fentanyl	0.1, 1, or 10 μg/kg × 3	Mouse, P4 and P5	Significant exacerbation of ibotenate-induced white-matter brain lesions at highest dose	Laudenbach et al.[91]
Fentanyl	30 μg/kg + 15 μg/kg per hour for 4 hours	Swine, P5	Slightly increased neuronal apoptosis, not statistically significantly different from control	Rizzi et al.[92]
Fentanyl	90 μg/kg × 1	Male rat, P14	Long-term anxiolytic-like behavior when tested in young adulthood	Medeiros et al.[93]
Halothane	10 ppm for 40 hours/week	Rat, conception to P60	Learning deficits and decrease in synaptic density	Quimby et al.[15]
Halothane	10 ppm for 40 hours/week	Rat, conception to P60	Defects in visual and spatial learning tasks	Quimby et al.[16]

E-TABLE 25.1 Representative Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Halothane	2.5% for 2 hours	Rat, prenatal E3, E10, or E17	More errors in maze task in adult animals exposed on E3 and E10, but not at E17	Smith et al.[94]
Halothane	50–200 ppm continuously	Rat, conception to P28	Dose-dependent decrease in cerebral synapse density	Uemura et al.[17]
Halothane	25–100 ppm continuously	Rat, conception to P60	Decrease in apical and basal dendritic length and numbers	Uemura et al.[18]
Halothane	25–100 ppm continuously	Rat, conception to P60	Decrease in synaptic density, no learning impairment	Uemura et al.[95]
Halothane	1%–2% for 0.5 hour	Mouse, prenatal E6–E17	Learning impairment in adulthood	Chalon et al.[89]
Heroin	10 mg/kg per day to dam	Mouse, E8–E18	Hyperactivity and spatial learning deficits in adulthood	Yanai et al.[96]
Heroin	10 mg/kg per day to dam	Mouse, E9–E18	Increased neuronal apoptosis and impaired spatial learning and memory in juvenile animals	Wang et al.[97]
Heroin	500 µg/mL	Rat, E16–E17 cortical neuronal cultures	Decrease in neuronal viability, increase in apoptosis and DNA fragmentation	Cunha-Oliveira et al.[98]
Isoflurane	0.2–0.3 mmol/L	Mouse, P14 and P60 hippocampal slices	Block of synaptic transmission more pronounced in P14 slices compared with older animals	Simon et al.[99]
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 6 hours	Rat, P7	Increased neuroapoptosis and neurodegeneration, adult learning impairment	Jevtovic-Todorovic et al.[100]
Isoflurane	0.75%–1.5% for 6 hours	Rat, P7	Increased neurodegeneration	Jevtovic-Todorovic et al.[100]
Isoflurane + midazolam + thiopental	1.5% for 4 hours + 1 mg/kg + 7 mg/kg to ewe	Sheep, prenatal E120	No increase in neuroapoptosis, as assessed 6 days postanesthesia	McClaine et al.[101]
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 2–6 hours	Rat, P1–P14	Increased neuroapoptosis following exposure on P7, not P1–P3 or P10–P14	Yon et al.[102]
Isoflurane + nitrous oxide + midazolam	0.55% + 75% + 1 mg/kg for 4 hours	Swine, P5	Increased neurodegeneration in neocortex	Rizzi et al.[92]
Isoflurane	1.5% for 1–5 hours	Rat, organotypic slice culture	Increased neurodegeneration only after 5 hours of exposure	Wise-Faberowski et al.[103]
Isoflurane	2.4% for 24 hours	Rat, primary cortical neuron culture	Increased apoptosis	Wei et al.[104]
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 2–6 hours	Rat, P7	Increased neuroapoptosis, ameliorated by estradiol	Lu et al.[105]
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 6 hours	Rat, P7	Increased neuroapoptosis, ameliorated by melatonin	Yon et al.[106]
Isoflurane	0.75% for 4 hours	Mouse, P5	Increased neuroapoptosis, ameliorated by pilocarpine	Olney et al.[107]
Isoflurane	0.75% for 6 hours	Rat, P7, and mouse organotypic hippocampal slices	Increased neuroapoptosis, exacerbated by nitrous oxide and ameliorated by xenon	Ma et al.[108]
Isoflurane	2.4% for 24 hours	Rat, primary cortical neuron culture	Increased cellular degeneration, blocked by isoflurane or halothane preconditioning	Wei et al.[109]
Isoflurane	1.3% for 6 hours	Rat, prenatal E21	Decrease in neuroapoptosis, no impaired learning, improved memory retention in juvenile animals	Li et al.[110]
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 6 hours	Rat, P7	Decreased neuronal density in multiple brain areas in adulthood	Nikizad et al.[111]
Isoflurane + nitrous oxide + midazolam	0.55% + 75% + 1 mg/kg for 4 hours	Guinea pig, prenatal E20–E50	Increased neuroapoptosis between E35 and E40 and decreased adult neuronal density, not after E50 or in fentanyl control group	Rizzi et al.[112]
Isoflurane	0.75% for 4 hours, 1.5% for 2 hours, or 2% for 1 hour	Mouse, P5–P7	Increased neuroapoptosis	Johnson et al.[113]

E-TABLE 25.1 Representative Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Isoflurane + nitrous oxide	0.75% + 75% for 6 hours	Rat, P7	Increased neuroapoptosis in spinal cord	Sanders et al.[114]
Isoflurane	Dose not specified	Mouse, P4	Increased neuroapoptosis, ameliorated by hypothermia	Olney et al.[115]
Isoflurane + nitrous oxide	0.55% + 75% or individually for 2–8 hours	Rat, P7	Increased neuroapoptosis and neurodegeneration after exposure of 6 hours or longer, ameliorated by L-carnitine, no increase by either agent administered individually	Zou et al.[116]
Isoflurane	1%–2% for 10 minutes	Mouse, P0	Neonatal and adolescent impairment in tests of body coordination and adult learning; decreased hippocampal cellularity and volume, more pronounced in males	Rothstein et al.[117]
Isoflurane	1.2% for 12 hours	Rat, primary cortical neuron culture	Increased cytotoxicity, ameliorated by xestospongin C	Wang et al.[118]
Isoflurane	0.75% for 6 hours	Rat, P7	Increased neuroapoptosis, no effect on short-term, but impairment of long-term memory, ameliorated by dexmedetomidine	Sanders et al.[79]
Isoflurane	0.75% for 6 hours	Mouse, P8 organotypic hippocampal slices	Increased neuroapoptosis, ameliorated by dexmedetomidine, not reversed by gabazine	Sanders et al.[79]
Isoflurane	0.75% for 6 hours	Rat, P7	Increased cortical neuroapoptosis, reduced by dexmedetomidine coadministration	Sanders et al.[80]
Isoflurane	1.5% for 6 hours	Mouse, P7	Increased neurodegeneration early after exposure, no adult learning impairment, no decreased adult neuronal density	Loepke et al.[119]
Isoflurane	1 MAC for 1–4 hours	Rat, P7	Widespread brain cell death following exposure for >2 hours, not 1 hour; adult neurocognitive deficits only after 4-hour exposure	Stratmann et al.[120]
Isoflurane	1 MAC for 4 hours	Rat, P7	Decreased progenitor proliferation, deficits in fear conditioning and memory impairment in adulthood	Stratmann et al.[121]
Isoflurane	3.4% for 4 hours	Rat, neuronal progenitor culture, harvest P2, 2–12 weeks in culture	No neurodegeneration or activation of caspases 3 or 7, decrease in caspase 9, inhibition of proliferation, preferential differentiation to neurons	Stratmann et al.[120]
Isoflurane	1.4%	Rat, cortical and hippocampal neuron culture, harvest P1, DIC 5	Increased neuroapoptosis, reduction in dendritic spines and number of synapses, ameliorated by administration of tPA or inhibition of $p75^{NTR}$	Head et al.[122]
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 6 hours	Rat, P7	Decreased synaptic density in subiculum 2 weeks after treatment	Lunardi et al.[123]
Isoflurane	1.6% for 5 hours	Rhesus monkey, P5	Increase in apoptotic cell death of neurons in neocortex and immature oligodendrocytes in white matter	Olney et al.[124]
Isoflurane	1.3% or 3% for 1 hour to dam	Rat, E21	No increase in neuroapoptosis or S100β blood levels following lower dose, but both increased following higher dose	Wang et al.[125]
Isoflurane	1.7% for 35 minutes × 4 days	Rat, P14 and mouse, P14	No increased immediate hippocampal neuronal cell death, no difference in adult learning of easy task, impairment in adult learning of difficult learning and recognition tasks	Zhu et al.[126]
Isoflurane	1.6% for 5 hours	Rhesus monkey, P5	Increase in neocortical apoptotic cell death	Brambrink et al.[127]
Isoflurane	1.5% for 30–120 minutes	Rat, P16	No increase in neurodegeneration or gross changes in dendritic arborization, increase in number of dendritic spines	Briner et al.[74]
Isoflurane	0.75% for 6 hours	Mouse, P7	Increased neuroapoptosis and serum levels of S100β immediately following exposure, no long-term impairment in learning and memory tests	Liang et al.[128]

E-TABLE 25.1 Representative Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Isoflurane	2% for 2 hours and/or caffeine 80 mg/kg IP	Mouse, P4	Increased neuroapoptosis following caffeine, worse than following isoflurane exposure, demonstrating potentiation following combination exposure	Yuede et al.[129]
Isoflurane	1.5% for 6 hours	Mouse, P7–P8	Increased neuroapoptosis compared with no anesthesia, but similar to equianesthetic doses of desflurane or sevoflurane	Istaphanous et al.[76]
Isoflurane	2% for 90 minutes for each time point	Mouse, P10, P20, P30, P60, and P90	No behavioral or cognitive abnormalities in adulthood	Kulak et al.[130]
Isoflurane + nitrous oxide	0.75% isoflurane + 70% nitrous oxide for 6 hours	Rat, P7	Increased neuroapoptosis and subsequent altered cognitive function, which were ameliorated by xenon pretreatment	Shu et al.[131]
Isoflurane + nitrous oxide	0.75% isoflurane + 70% nitrous oxide for 6 hours	Rat, organotypic hippocampal slice culture	Increased neuroapoptosis, which was ameliorated by xenon pretreatment	Shu et al.[131]
Isoflurane + nitrous oxide + midazolam	0.55% + 75% + 1 mg/kg for 4 hours	Swine, P5	Increased neuroapoptosis in cerebral cortex compared with control or a fentanyl-treated comparison group	Rizzi et al.[92]
Isoflurane	3% for 24 hours	Rat, astroglial culture	Impairment in growth of immature glia, delay in glial maturation, without effects on total actin or GFAP levels	Lunardi et al.[132]
Isoflurane	1.5% for induction + 1% for 4 hours	Mouse, 1 month	Transient decrease in dendritic filopodia elimination in somatosensory cortex, without effects on dendritic spine density	Yang et al.[133]
Isoflurane	0.7%, 1.4%, or 2.8% for 6 hours	Rat, embryonic neuronal stem cells	No effect on neural stem cell viability. Two higher concentrations inhibited cell proliferation	Culley et al.[134]
Isoflurane	1.5% or 5% for 6–12 hours	Mouse, cortical neuronal culture	No cytotoxicity observed, even when adding clinical doses of nitrous oxide or ketamine	Campbell et al.[135]
Isoflurane	1.4% from 15 minutes to 4 hours	Mouse, primary neuronal culture and hippocampal slice culture	Increased apoptosis and cytoskeletal destabilization	Lemkuil et al.[136]
Isoflurane + intrathecal bupivacaine	1% for 1 or 6 hours	Rat, P7, P14, P21	Neuroapoptosis in brain and spinal cord after 6 hours of exposure, but not 1 hour; intact spontaneous motor performance in adulthood	Yahalom et al.[137]
Isoflurane and/or nitrous oxide	1% and/or 70% for 8 hours	Rhesus monkey, P5–P6	No neuroapoptosis observed following either agent alone, neuroapoptosis increased following anesthetic combination	Zou et al.[138]
Isoflurane + nitrous oxide + midazolam	0.75% + 75% + 9 mg/kg for 6 hours	Rat, P7	Enlargement and impairment of structural integrity of mitochondria and decreased density in subiculum, as well as increased autophagic activity	Sanchez et al.[139]
Isoflurane + nitrous oxide	0.75% isoflurane + 70% nitrous oxide for 6 hours	Rat, P7	Increased neuroapoptosis and subsequent altered cognitive function, which were ameliorated by xenon pretreatment	Shu et al.[140]
Isoflurane	Titrated between 0.7% and 1.5% isoflurane for 5 hours	Rhesus monkey, P6	Widespread apoptotic cell death of neurons and oligodendrocytes (6.3% of all myelinating oligodendrocytes in forebrain)	Brambrink et al.[141]
Isoflurane	Isoflurane 1.5% for 6 hours	Mouse, P7	Quantification of apoptotic neuronal cell death in superficial layers of visual cortex finds almost 3% of neurons affected following exposure, compared with less than 0.1% of neurons undergoing natural apoptosis in control animals	Istaphanous et al.[69]
Isoflurane	2% for 6 hours	Mouse, P6	Increased neuroapoptosis, but no long-term impairment in memory function	Kodama et al.[77]
Isoflurane	1.5% for 6 hours	Mouse, P7, P21, or P49	Increased apoptosis in olfactory bulb at all ages and dentate gyrus at the two older time points; neurons younger than 15 days of age particularly vulnerable	Hofacer et al.[142]
Isoflurane	Titrated between 1% and 1.5% for 5 hours to dam	Rhesus monkey, E120	Increased neuroapoptosis, predominantly in cerebellum, caudate, putamen, and amygdala, as well as diffuse apoptotic oligodendrocyte death	Creeley et al.[143]

E-TABLE 25.1 Representative Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Isoflurane	0.75% for 6 hours	Rat, P7	Neuronal apoptosis in hippocampus, dose-dependently inhibited by dexmedetomidine	Li et al.[81]
Isoflurane	0.75% for 6 hours	Rat, P7	Increased neuroapoptosis in hippocampus, inhibited by dexmedetomidine coadministration	Liao et al.[85]
Isoflurane	1.5% for 6 hours	Mouse, P7, P21, or P49	Differential degrees of neuroapoptosis among brain regions dependent on age during exposure; sustained vulnerability into adulthood in regions with continued neurogenesis	Deng et al.[144]
Isoflurane	1.5% for 6 hours	Rats, P7	Apoptotic marker caspase 3 increase in cortex and hippocampus was ameliorated by preconditioning with a 30-minute exposure to 1.5% isoflurane on P6	Peng et al.[145]
Isoflurane	2% for 1 hour	Mouse, P7	Apoptotic cell death increased in inner nuclear layer of retina	Cheng et al.[146]
Isoflurane	Titrated between 1.5% and 3% for 5 hours	Rhesus monkey, P6	Increased neuroapoptosis and oligodendrocytic apoptosis was reduced by lithium coadministration	Noguchi et al.[147]
Ketamine	20 mg/kg × 7	Rat, P7	Increased neurodegeneration	Ikonomidou et al.[19]
Ketamine	25–75 mg/kg × 1–7	Rat, P7	Increased neurodegeneration only after 7 repeated doses of 25 mg/kg	Hayashi et al.[148]
Ketamine	50 mg/kg × 1	Mouse, P10	Cortical neurodegeneration; hypo- and hyperactivity, abnormal habituation in adulthood	Fredriksson et al.[149]
Ketamine	50 mg/kg × 1	Mouse, P10	Neurodegeneration, worsened by coadministration of diazepam	Fredriksson et al.[150]
Ketamine	50 mg/kg × 1	Mouse, P10	Neurodegeneration and impairment in memory tasks in adulthood	Fredriksson et al.[150]
Ketamine	10–25 mg/kg × 1–7	Rat, P7	Neurodegeneration observed after highest dose, plasma levels 7 times higher than during human anesthesia	Scallet et al.[151]
Ketamine	1.25–40 mg/kg × 1	Mouse, P7	Neurodegeneration after doses of 5 mg/kg or higher, no gross neurobehavioral abnormalities 7 days after treatment	Rudin et al.[152]
Ketamine	0.1–20 µmol/L for 6–48 hours	Rat, forebrain neuron culture	Increased DNA fragmentation after higher doses for longer periods of time	Wang et al.[153]
Ketamine	10–40 mg/kg × 1	Mouse, P7	Increased neurodegeneration following doses of 20 mg/kg or higher, worsened by midazolam coadministration	Young et al.[154]
Ketamine	1–20 µmol/L for 2–24 hours	Rhesus monkey, forebrain neuron culture	Increased DNA fragmentation and decreased mitochondrial function after higher doses for longer periods of time	Wang et al.[155]
Ketamine	0.01–40 µg/mL for 1–48 hours	Rat, GABAergic neuron culture	Neuronal cell loss and decrease in dendritic length and branching with higher concentrations for longer exposure times	Vutskits et al.[156]
Ketamine	100 µmol/L for 48 hours	Rat, cortical neuron culture	Increased apoptosis, ameliorated by NMDA, IGF-1, alsterpaullone, or iodoindirubin	Takadera et al.[157]
Ketamine	0.1–30 µmol/L for 24 hours	Rat, cortical neuron culture	Decreased cell viability and increased DNA fragmentation, ameliorated by erythropoietin	Shang et al.[158]
Ketamine	20–50 mg/kg per hour × 24 hours	Rhesus monkey, E122, P5, or P35	Increased neurodegeneration in two younger age groups, ketamine plasma levels higher than in humans	Slikker et al.[159]
Ketamine	10–10 µg/mL for 1–24 hours	Rat, GABAergic neuron culture	Neuronal cell loss with higher concentrations or longer exposure times	Vutskits et al.[160]
Ketamine	2.5 mg/kg × 2 for 4 days	Rat, P1–P4	Minimal neurodegeneration, but ketamine ameliorated pain-induced neurodegeneration and subsequent learning abnormalities	Anand et al.[161]
Ketamine	25 mg/kg × 1	Mouse, P10	No increase in neurodegeneration, but subsequent learning impairment, worsened by coadministration of thiopental or propofol	Fredriksson et al.[162]
Ketamine	1–20 µmol/L for 24 hours	Rat, forebrain neuron culture	Increased DNA fragmentation after higher doses, blocked by nitroindazole	Wang et al.[163]

E-TABLE 25.1 Representative Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Ketamine	5–25 mg/kg × 1	Mouse, P10	Dose-dependent alterations in levels of developmentally expressed proteins and adult behavioral abnormalities	Viberg et al.[164]
Ketamine	2.5 mg/kg × 2 for 4 days	Rat, P1–P4	No increase in neuronal cell death, no change in adult learning and exploratory behavior and ameliorated pain-induced neurodegeneration and behavioral abnormalities	Rovnaghi et al.[165]
Ketamine	20 mg/kg × 6	Rat, P7	Decreased body weight 1–3 days after exposure, no abnormal spontaneous behavior observed during first 4 days	Boctor et al.[166]
Ketamine	30 mg/kg + 15 mg/kg every 90 minutes × 2	Mouse, P15–P90	No increase in neurodegeneration, impairment in dendritic spine development following exposure on P20 or younger	Vutskits et al.[167]
Ketamine	40 mg/kg	Mouse, P5	Increased neuroapoptosis, ameliorated by lithium coadministration	Straiko et al.[168]
Ketamine	5–20 mg/kg × 1–6	Rat, P7	Increased apoptosis and neurodegeneration only observed following 6 repeated doses of 20 mg/kg	Zou et al.[169]
Ketamine	20 mg/kg × 7	Rat, P7	Increased apoptosis and neurodegeneration, decreased weight gain, increase in BDNF and TrkB cDNA	Ibla et al.[170]
Ketamine	20–50 mg/kg per hour for 3–25 hours	Rhesus monkey, P5–P6	Neuronal degeneration only in neocortex following 9-hour exposure or longer, no degeneration in deeper brain areas	Zou et al.[171]
Ketamine	30 mg/kg + 15 mg/kg every 90 minutes × 2	Mouse, P15	Increase in dendritic spine density and decrease in spine head diameter in the somatosensory cortex and hippocampus	De Roo et al.[172]
Ketamine	100 mg/kg per day × 5 days	Mouse, P8–P12	Impaired dendritic spine maturation immediately following exposure, which subsided within 2 weeks	Tan et al.[173]
Ketamine or (*S*)-ketamine	1–8 mmol/L or 0.6–4 mmol/L for 24 hours	Human, neuroblastoma cells	Increased apoptosis, but up to 80% less cell death following (*S*)-ketamine	Braun et al.[174]
Ketamine	5–20 mg/kg × 5	Rat, P7	Increased neuroapoptosis in neocortex and thalamus, increase in cell cycle proteins	Soriano et al.[175]
Ketamine	0.1–1000 μmol/L × 6–48 hours	Rat, cortical neuron culture	Increase in expression of caspase 3 and cell cycle proteins	Soriano et al.[175]
Ketamine	20 mg/kg every 2 hours × 6	Rat, P7	Increased neurodegeneration in frontal cortex	Shi et al.[176]
Ketamine	3–15 mg/kg intrathecal L4-6	Rat, P3, P7, or P21	Increased neuronal cell death and subsequent altered spinal cord function after injection at P3, but not at P7 or P21	Walker et al.[177]
Ketamine	20 mg/kg bolus + 20–50 mg/kg per hour for 24 hours	Rhesus monkey, P5–P6	Decreased performance of the National Center for Toxicological Research Operant Testing Battery and motivation	Paule et al.[178]
Ketamine + fentanyl	20 mg/kg + 90 μg/kg	Rat, P14	Long-term hyperactivity and behavioral changes indicating lower levels of anxiety	Madeiros et al.[179]
Ketamine	20 mg/kg every 2 hours × 6	Rat, P7	Greater accumulation of a radioactive tracer and more cell death in frontal cortex in adulthood	Zhang et al.[180]
Ketamine + xylazine	42.5 + 4.3 mg/kg every 90 minutes × 3	Mouse, 1 month	Transient increase in dendritic filopodia formation in somatosensory cortex, without effects on dendritic spine density	Yang et al.[133]
Ketamine	100 μmol/L, 1 mmol/L, or 3 mmol/L	Mouse, cortical neuronal culture	Cytotoxicity only observed in doses of 1 mmol/L or higher	Campbell et al.[135]
Ketamine	18.4–86.5 mg/kg per hour for 5 hours to dam	Rhesus monkey, E120	Increased neuroapoptosis, especially in cerebellum, caudate-putamen, and nucleus accumbens	Brambrink et al.[181]
Ketamine	18.4–56.0 mg/kg per hour for 5 hours	Rhesus monkey, P6	Increased neuroapoptosis, especially in basal ganglia and thalamus	Brambrink et al.[181]
Ketamine	75 mg/kg daily × 3	Rat, P7–9	Increase in apoptotic neurons in hippocampus, impaired learning and memory in adulthood, both effects ameliorated by coadministration of dexmedetomidine	Duan et al.[84]

E-TABLE 25.1 Representative Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Ketamine	20–50 mg/kg per hour for 12 hours to dam	Cynomolgus monkey, E120	Neuroapoptosis in frontal cortex	Koo et al.[83]
Ketamine	1–500 μM for 24 hours	Rat, neural stem cell culture	No oxidative DNA damage, mitochondrial toxicity, or impaired proliferation observed following exposure to clinically relevant concentration. However, number of differentiated neurons reduced	Slikker et al.[182]
Ketamine	20 mg/kg every 90 minutes × 6	Rat, P7	Significant cellular degeneration and apoptosis in limbic thalamus, but not somatosensory cortex or thalamus	Pancaro et al.[86]
Methadone	10 mg/kg per day to dam	Rat, E5–E21	Decreased brain monoamines in juveniles and hyperresponsiveness in adulthood	Rech et al.[183]
Methadone	10–15 mg/kg per day to dam	Rat, E8–E21	Increased excitability tested in juvenile animals using the acoustic startle reflex	Hutchings et al.[184]
Methadone	9 mg/kg per day to dam	Rat, E7–E21	Increased noradrenergic activity in hippocampus of male juveniles	Robinson et al.[185]
Methadone	9 mg/kg per day	Rat, P1–P10	Reduced activity of dopaminergic neurons in frontal cortex of juvenile males	Robinson et al.[185]
Methadone	9 mg/kg per day to dam	Rat, E7–E21	Reduction in nerve growth factor, disruption of cholinergic neuronal activity	Robinson et al.[186]
Methadone	9 mg/kg per day to dam	Rat, E7–E21 or P10	Reduction in nerve growth factor in striatum	Wu et al.[70]
Midazolam	9 mg/kg × 1	Rat, P7	No increase in neurodegeneration	Jevtovic-Todorovic et al.[100]
Midazolam	9 mg/kg × 1	Mouse, P7	Increased neuroapoptosis	Young et al.[154]
Midazolam	9 mg/kg × 1	Mouse, P5	Increased neuroapoptosis	Olney et al.[107]
Midazolam	3–9 mg/kg × 1	Rat, P1–P14	No increase in neuroapoptosis	Yon et al.[102]
Midazolam	0.25–25 μg/mL	Rat, GABAergic neuron culture	No effect on neuronal survival	Vutskits et al.[187]
Midazolam	25 mg/kg + 15 mg/kg every 90 minutes × 2	Mouse, P15–P90	No increase in neurodegeneration, impairment in dendritic spine development following exposure on P20 or younger	Vutskits et al.[167]
Midazolam	25 mg/kg + 15 mg/kg every 90 minutes × 2	Mouse, P15	Increase in dendritic spine density and decrease in spine head diameter in the somatosensory cortex and hippocampus	De Roo et al.[172]
Midazolam	50 mg/kg	Mouse, P10	No impairment of learning and memory in adulthood	Xu et al.[188]
Midazolam	50 mg/kg per day × 5 days	Mouse, P8–P12	Impaired dendritic spine maturation immediately following exposure, which subsided within 2 weeks	Tan et al.[173]
Midazolam	25 mg/kg IP injections for 6 hours	Rats, P5 or P15	Increased neuroapoptosis in medial prefrontal cortex at both age points without long-term measurable diminution in neuronal density	Osterop et al.[189]
Morphine	10 mg/kg per day	Rat, E12–P5	Gender- and region-specific changes in μ-opioid receptor density, decrease in neuronal density, and reduction in dendritic growth, partially reversed by naltrexone	Hammer et al.[190]
Morphine	5 mg/kg per day	Rat, P1–P4	Decreased μ-opioid receptor density in striatum following exposure	Tempel el al.[191]
Morphine	20 mg/kg per day to dam, except for E11: 10 mg/kg per day	Rat, E11–E18	Decreased μ-opioid receptor density in adulthood	Rimanoczy et al.[192]
Morphine	1 μmol/L for 1–2 days	Mouse, P5–P6 cerebellar neuronal precursor culture	Marked decrease in DNA synthesis, without effect on cell survival	Hauser et al.[193]
Morphine	5 mg/kg × 3 doses, then 10 mg/kg twice a day to dam	Rat, E11–E18	Impairment in spatial learning in adulthood	Slamberova et al.[194]
Morphine	20 mg/kg	Mouse, P4–P5	Suppression of DNA synthesis in astrocytes	Stiene-Martin et al.[195]

Continued

E-TABLE 25.1 Representative Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Morphine	1–100 μmol/L for 5 days	Human, GW16–22 fetal microglial, astrocyte, and neuronal cultures	Progressive increase in apoptosis in neurons after 2-day exposure, or microglia after 3 days, but not in astrocytes. Apoptosis blocked by naloxone	Hu et al.[196]
Morphine	2 mg/kg per day to dam, progressively increased by 2 mg/kg per day	Rat, E0–P21	Impairment in spatial learning in young adulthood	Yang et al.[197]
Morphine	20 mg/kg per day	Chick, E12–E16	Impairment in long-term memory formation	Che et al.[198]
Morphine	2 mg/kg per day	Rat, P3–P7	Impairment in adult cognitive function	McPherson et al.[199]
Morphine	0.5, 1, or 3 mg/kg	Rat, P7	Increased pain behavior to a pain challenge several days after morphine injection	Zissen et al.[200]
Morphine	15 μmol/L for 7 days	Mouse, E16 hippocampal neuronal culture	Increased apoptosis, decreased neuronal density	Svensson et al.[201]
Morphine	4 mg/kg per day	Mouse, P5–P9	Impairment in reward-mediated learning in adulthood	Boasen et al.[202]
Morphine	5 mg/kg × 3 doses, then 10 mg/kg twice a day to dam	Rat, E11–E18	Decreased synaptic plasticity and impaired learning in juveniles	Niu et al.[203]
Morphine	2 mg/kg per day to dam, progressively increased by 2 mg/kg per day, maximum 14 mg/kg per day	Rat, E0–P21	Decreased performance in learning tasks in adulthood	Lin et al.[204]
Morphine	5 μg/kg per day × 8 days	Rat, P8–P14	Increased nociceptive response throughout adulthood, which could be blocked by ketamine	Rozisky et al.[205]
Morphine	10 mg/kg × 1	Rat, P7 or P15	No increase in neuronal apoptosis in deeper layers of medial prefrontal cerebral cortex	Massa et al.[206]
Morphine	10 mg/kg twice daily × 14 days	Rat, P1–14	Long-term decrease in threshold for thermal stimulation and temporary learning impairment	Craig et al.[207]
Nitrous oxide (hyperbaric)	50%–150% for 2–6 hours	Rat, P7	No increase in neurodegeneration	Jevtovic-Todorovic et al.[100]
Nitrous oxide (hyperbaric)	50%–150% for 2–6 hours	Rat, P1–P14	No increase in neuroapoptosis	Yon et al.[102]
Nitrous oxide	75% for 6 hours	Rat, P7, and mouse organotypic hippocampal slices	No increase in neuroapoptosis in rats, increased neuroapoptosis in mice	Ma et al.[108]
Pentobarbital	5–10 mg/kg × 1	Rat, P7	Increased neurodegeneration	Bittigau et al.[72]
Pentobarbital	0.5, 5, or 50 μg/mL	Rat, PC12 pheochromocytoma cell culture	Dose-dependent inhibition of apoptotic cell death triggered by oxygen-glucose deprivation	Morimoto et al.[208]
Pentobarbital	10–20 mg/kg	Rat, P7	Impairment in spatial learning; however, hypercarbia and hypoxia observed during exposure	Tachibana et al.[209]
Phenobarbital	40–100 mg/kg	Rat, P7	Increased neuroapoptosis, ameliorated by β-estradiol	Bittigau et al.[72]
Phenobarbital	50 mg/kg	Rat, P7	Increased neuroapoptosis, ameliorated by β-estradiol	Asimiadou et al.[210]
Phenobarbital	30 mg/kg × 2	Mouse, P6	Long-term alterations in brain protein expression	Kim et al.[211]
Phenobarbital	75 mg/kg	Rat, P7–P8	Increased neuroapoptosis, enhanced by lamotrigine administration	Katz et al.[212]
Phenobarbital	25 mg/kg	Mouse, P0	Neonatal and adolescent impairment in tests of body coordination and adult learning; decreased hippocampal cellularity and volume, more pronounced in males	Rothstein et al.[117]
Phenobarbital	50 mg/kg (P6), 40 mg/kg (P8)	Rat, P6 and P8	Inhibition of neurogenesis	Stefovska et al.[88]
Propofol	0.5–10 μg/mL for 8 hours	Rat, GABAergic neuron culture	Dose-dependent decrease in GABAergic enzyme GAD after higher doses	Honegger et al.[213]
Propofol	10–100 μg/mL for 2 hours to 10 days	Rat, dissociated neuronal culture P1 or P7	Increased cell death in P1 neurons following higher doses, no evidence for neurotoxic effects in organotypic hippocampal culture on P7	Spahr-Schöpfer et al.[214]

E-TABLE 25.1 Representative Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Propofol	1–50 µg/mL	Rat GABAergic neuron culture	Increased neuronal cell death following highest dose, altered dendritic development following lowest dose	Vutskits et al.[187]
Propofol	5–500 µmol/L for 2–24 hours	Chick, neuron explant culture	Dose-dependent neurite growth cone collapse	Al-Jahdari et al.[215]
Propofol	10–60 mg/kg × 1	Mouse, P10	Increased neurodegeneration following highest dose	Fredriksson et al.[162]
Propofol	25–300 mg/kg × 1	Mouse, P5–P7	Increased neuroapoptosis following doses >50 mg/kg	Cattano et al.[216]
Propofol + fentanyl	6 mg/kg per hour + 10 µg/kg per hour for 24 hours	Swine, P0	No increased neurodegeneration	Gressens et al.[217]
Propofol	5 µmol/L for 5 hours	Rat, hippocampal neuron culture	Increased neuroapoptosis	Kahraman et al.[218]
Propofol	50 mg/kg + 25 mg/kg every 90 minutes × 2	Mouse, P15–P90	No increase in neurodegeneration, impairment in dendritic spine development following exposure on P20 or younger	Vutskits et al.[167]
Propofol	25 mg/kg	Rat, P7	Increased neuroapoptosis, decrease in nerve growth factor	Pesic et al.[219]
Propofol	50–100 mg/kg	Mouse, P5	Increased neuroapoptosis, ameliorated by lithium coadministration	Straiko et al.[168]
Propofol	0.01–1 mg/mL for 3–48 hours	Rat, primary cortical neuron culture, harvested E18	Highest concentration improved cell viability after up to 6 hours of exposure, but reduced cell viability after more than 12 hours	Berns et al.[220]
Propofol	30 mg/kg every 90 minutes × 3	Rat, P6	Increase in neurodegeneration in some brain areas, especially in parts of thalamus and subiculum, subtle neurologic impairment in adult animals	Bercker et al.[221]
Propofol	50 mg/kg + 25 mg/kg every 90 minutes × 2	Mouse, P15	Increase in dendritic spine density and decrease in spine head diameter in the somatosensory cortex and hippocampus	De Roo et al.[172]
Propofol	40 mg/kg + 20 mg/kg per hour for 6 hours	Rat, P5, P10, P15, P20, or P30	Decrease in dendritic spine density following exposure between P5 and P10, but increased density at P15–P30	Briner et al.[222]
Propofol	10 or 60 mg/kg	Mouse, P10	Reduction in BDNF, no changes in adult spontaneous behavior, but reduced sedative effect of diazepam in adulthood	Pontén et al.[223]
Propofol	50 mg/kg × 7 days	Rat, P7–P14	No increase in neuroapoptosis, only in hypoxic condition	Tu et al.[224]
Propofol	100 mg/kg × 1	Mouse, P5	Increased neuroapoptosis in hippocampus	Pearn et al.[225]
Propofol	3 µmol/L for 6 hours	Mouse, neuron culture, harvested P1–P3, DIC 5–7	Increased neuroapoptosis, mediated by p75 neurotrophin receptor activation	Pearn et al.[225]
Propofol	300–450 µg/kg per minute for 5 hours	Rhesus monkey, E120 or P6	Apoptotic cell death of oligodendrocytes and neurons; neuroapoptosis predominantly in subcortical and caudal regions during fetal exposure and in neocortex during neonatal exposure	Creeley et al.[226]
Propofol	0.9–50 µg/mL for 1–48 hours	Rat, hippocampal astrocyte culture	Dose-dependent increase in apoptosis and reduction in astrocytic viability	Sun et al.[227]
Propofol		Rat, E20	Increased neuroapoptosis and subsequent learning impairment, attenuated by dexmedetomidine coadministration	Li et al.[228]
Sevoflurane	4% for 24 hours	Rat, primary cortical neuron culture	No increase in apoptosis	Wei et al.[104]
Sevoflurane	2% for 12 hours	Rat, primary cortical neuron culture	No increase in cytotoxicity	Wang et al.[118]
Sevoflurane	1.7% for 2 hours	Mouse, P7	Increased neuroapoptosis	Zhang et al.[229]
Sevoflurane	3% for 6 hours	Mouse, P6	Increased neuroapoptosis, impairments in fear conditioning and social interaction in adulthood	Satomoto et al.[230]

Continued

E-TABLE 25.1 Representative Preclinical Studies Examining Structural and Neurocognitive Effects of Anesthetic Exposure Early in Life—cont'd

Anesthetic Agent	Dose and Duration	Species, Age	Pathology	Study
Sevoflurane	4% or 8% for 12 or 6 hours, respectively	Rat, primary cortical neuron culture, E18	No difference in cell viability compared with untreated controls	Berns et al.[231]
Sevoflurane	3%–5% for 6 hours	Rat, P6	No increase in neurodegeneration immediately after exposure, no long-term neurologic impairment	Bercker et al.[221]
Sevoflurane	2.1% for 0.5–6 hours	Rat, P4–P8	Seizure activity during exposure and neuroapoptosis partially blocked by administration of bumetanide	Edwards et al.[232]
Sevoflurane	2.5% for 30–120 minutes	Rat, P16	No increase in neurodegeneration or gross changes in dendritic arborization, increase in number of dendritic spines	Briner et al.[74]
Sevoflurane	1.1% for 6 hours	Mouse, P7	Increased neuroapoptosis immediately following exposure, no long-term impairment in learning and memory tests	Liang et al.[128]
Sevoflurane	2.1% or 3% for 2 hours or 6 hours	Mouse, P6	Increased neuroapoptosis following the longer, but not the shorter, exposure time. Transgenic Alzheimer disease mice more susceptible	Lu et al.[233]
Sevoflurane	2.9% for 6 hours	Mouse, P7–P8	Increased neuroapoptosis compared with no anesthesia, but similar to equianesthetic doses of desflurane or isoflurane	Istaphanous et al.[76]
Sevoflurane	3.8% for 6 hours	Mouse, P6	Increased neuroapoptosis, less than with desflurane and isoflurane, and long-term impairment in memory function	Kodama et al.[77]
Sevoflurane	1 MAC × 4 hours	Rat, P7	Memory impairment, alleviated by environmental enrichment	Shih et al.[234]
Sevoflurane	3% for 2 hours daily × 3	Mouse, P6–8	Immediate increase in neuroinflammation and subsequent cognitive impairment, ameliorated by environmental enrichment or antiinflammatory treatment (ketorolac)	Shen et al.[78]
Sevoflurane	1.2% for 6 hours	Rat, P7	No increased neuronal apoptosis detected in hippocampus	Li et al.[81]
Sevoflurane	2.5%–3.5% for 6 hours	Mouse, P6–7	Neuroapoptosis immediately following exposure and long-term memory impairment; normal subsequent social behavior, anxiety level, and vocalization	Chung et al.[235]
Sevoflurane	2%–2.5% for 4 hours × 3	Rhesus monkey, between P6 and P28	Exaggerated anxiety behavior in juveniles following repeated anesthetic exposures in infancy	Raper et al.[236]
Sevoflurane	2.5% for 9 hours	Rhesus monkey, P5–6	Increased neuronal degeneration	Liu et al.[237]
Sevoflurane	2%–2.5% for 4 hours × 3	Rhesus monkey, 3 exposures during first 6 postnatal weeks	No differences in maternal behavior towards infants observed	Raper et al.[238]
Sufentanil	2 µg/kg × 3	Mouse, P4 and P5	No exacerbation of ibotenate-induced white-matter brain lesions	Laudenbach et al.[91]
Thiopental	5–25 mg/kg × 1	Mouse, P10	No increase in neurodegeneration by itself, but exacerbation and learning abnormalities in conjunction with ketamine	Fredriksson et al.[162]
Xenon	75% for 6 hours	Rat, P7 and mouse organotypic hippocampal slices	No increase in neuroapoptosis	Ma et al.[108]
Xenon	70% for 4 hours	Mouse, P7	Increased neuroapoptosis, but decreased isoflurane-induced neuroapoptosis	Cattano et al.[239]
Xenon	50% for 24 hours + fentanyl infusions	Swine, P0	No neuroapoptosis detected	Sabir et al.[240]
Xenon	0.75, 1, or 2 MAC for 6 hours	Rat, hippocampal slice cultures	Increased cell death following two higher doses in CA1, CA3, and dentate	Brosnan et al.[241]

BDNF, brain-derived neurotrophic factor; *DIC,* days in culture; *E,* embryological day; *GAD,* glutamic acid decarboxylase; *GFAP,* glial fibrillary acidic protein; *GW,* gestational week; *IGF-1,* insulin-like growth factor 1; *IP,* intraperitoneal; *MAC,* minimum alveolar concentration; *P,* postnatal day; *tPA,* tissue plasminogen activator; *$p75^{NTR}$,* p75 neurotrophin receptor *TrkB,* tyrosine-related kinase B.

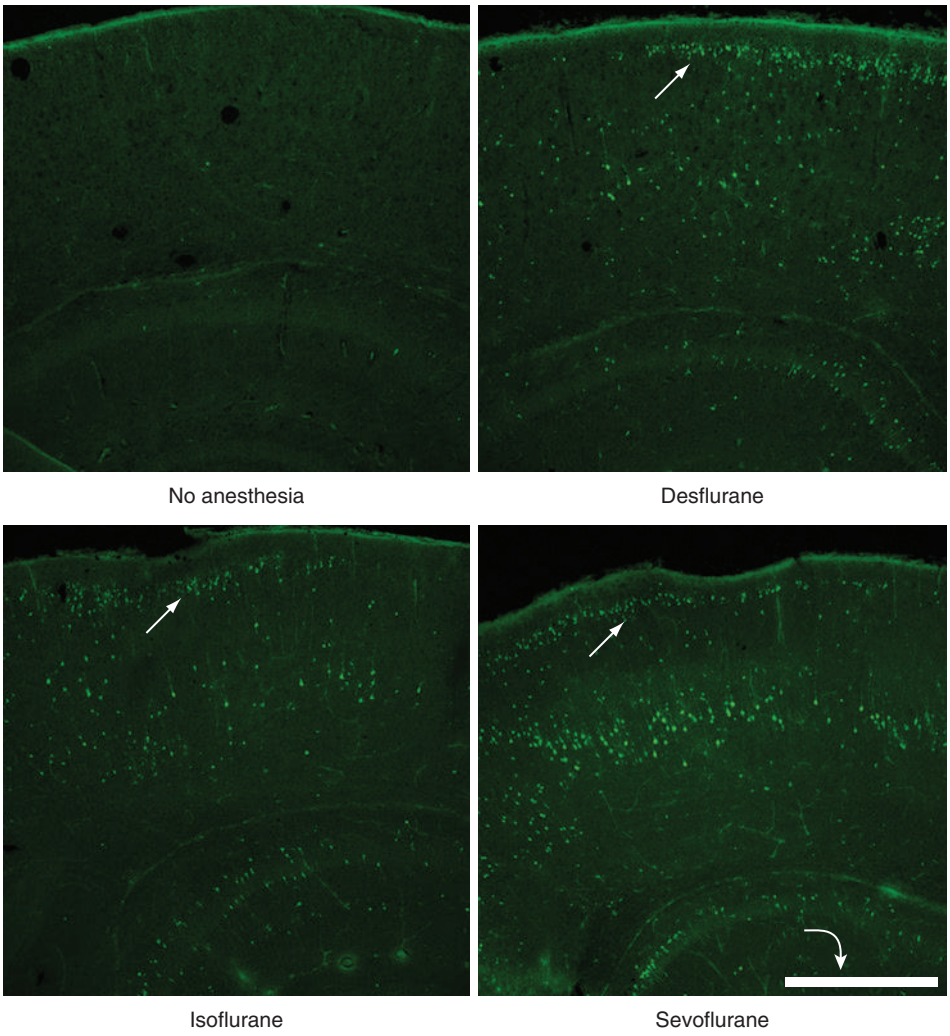

FIGURE 25.2 Prolonged exposure to anesthetics causes widespread apoptotic cell death in the developing animal brain. Representative photomicrographs of brain sections from 7- to 8-day-old mice exposed to 6 hours of equipotent doses of 7.4% *desflurane*, 1.5% *isoflurane*, 2.9% *sevoflurane* in 30% oxygen, respectively, or fasted, unanesthetized litter mates in room air (*no anesthesia*). These doses were previously determined to represent 0.6 minimum alveolar concentration for the respective anesthetics. *Arrows* mark clusters of cells in layer II/III of the neocortex that are dying from programmed cell death and are therefore labeled for the apoptotic marker, activated caspase 3 (*bright green*). Scale bar = 500 µm. (From Istaphanous GK, Howard J, Nan X, et al. Comparison of the neuroapoptotic properties of equipotent anesthetic concentrations of desflurane, isoflurane, or sevoflurane in neonatal mice. *Anesthesiology* 2011;114:578–587.)

in amphibians, or elimination of interdigital mesenchymal tissue of fingers and toes). Similarly, brain cells are produced in excess during normal brain development and are eliminated in large number during normal brain maturation in rodents, nonhuman primates, and humans.[5,6] This physiologic apoptotic cell death is critical to establish proper brain structure and function, and any disruption of this process can lead to massive brain malformations and intrauterine demise.[244] In the developing brain, apoptotic cell death can also be triggered by pathologic, extrinsic factors, such as hypoxia and ischemia.[245] It currently remains unclear whether anesthesia-induced neuroapoptosis accelerates physiologic programmed cell death or whether it eliminates cells not destined to die, as in pathologic apoptosis.

Animal studies have initially identified a narrow window of susceptibility to neuronal cell death induced by several anesthetic drugs, such as the NMDA antagonist ketamine, the GABA agonist isoflurane, or ethanol (a combined NMDA antagonist and GABA agonist). Ketamine-induced neuronal demise is most pronounced during exposure between 5 and 7 days of age in neonatal rodents or before 6 days of age in monkeys.[19,73,159] Similarly, a dramatic increase in neuronal apoptosis was detected in the cortex, thalamus, and amygdala of 3- to 10 day-old rodents after prolonged exposure to isoflurane, but minimal cell death was detected in 1-day-old animals or those older than 10 days of age.[102] However, data from the laboratory of one of the authors challenge the notion that anesthetic-induced neuroapoptosis is limited to a narrow age range. In mice, neuronal apoptosis was similarly observed in the cortex and hippocampus of neonatal animals after a prolonged exposure to isoflurane; however, vulnerability extended into adulthood in brain regions with ongoing neurogenesis, such as the dentate and

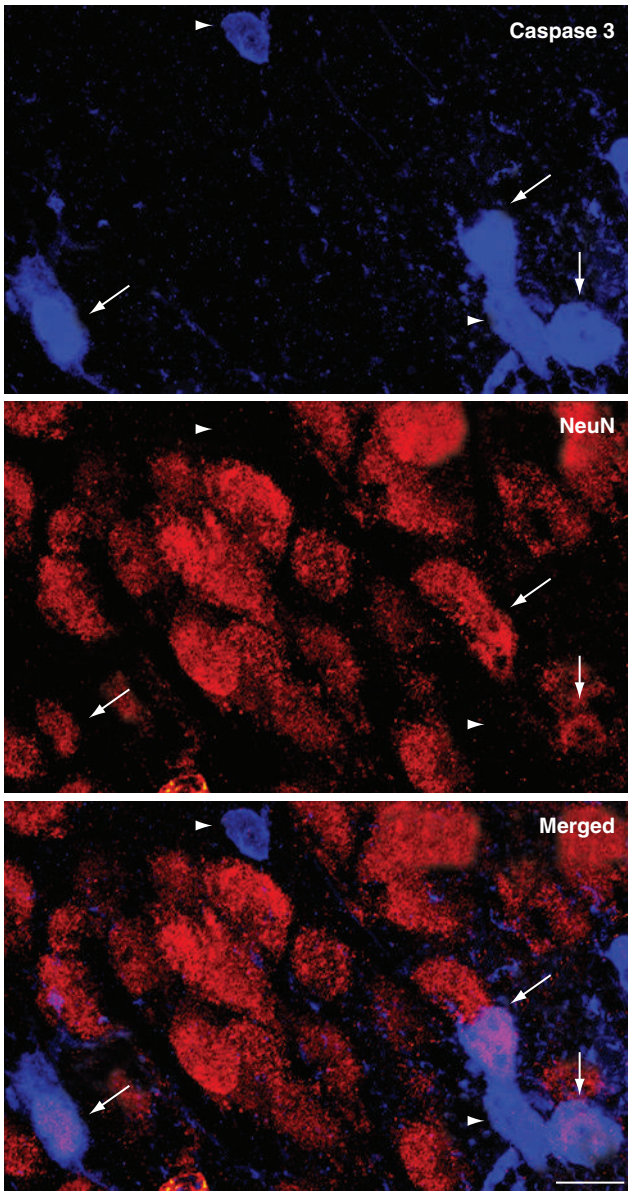

FIGURE 25.3 Neurons affected by apoptotic cell death following anesthetic exposure are surrounded by seemingly unaffected cells. Representative photomicrograph from a 7-day-old mouse following a 6-hour exposure to 1.5% isoflurane, showing neocortical cells stained for the apoptotic cell death marker activated caspase 3 (*blue, top*), the neuronal marker NeuN (*red, middle*), and a merged image of the two stains (*bottom*). The majority of dying cells are identified as postmitotic neurons, as indicated by the purple cells coexpressing activated caspase 3 and NeuN in the bottom (*arrows*), whereas some cells expressing caspase 3 are NeuN-negative (*arrowheads*). Importantly, cells affected by anesthetic-induced neuroapoptosis are surrounded by numerous, seemingly unaffected neurons. Scale bar = 10 µm. (Image courtesy Loepke Laboratory.)

olfactory bulb.[144] This finding could be explained by the fact that neurons were found particularly vulnerable to isoflurane-induced apoptosis before 14 days of cellular age and therefore would be expected to occur throughout the life of the animal in neurogenic niches containing neurons of this particular age.[142] Surprisingly, however, other studies suggest that intrauterine exposure to clinical doses of isoflurane in prenatal rats may actually decrease physiologic apoptosis and improve subsequent memory retention,[110] whereas only supraclinical doses of isoflurane induced neuroapoptosis in this setting.[125] Whereas chronic opioid exposure in immature animal models can lead to long-term neurodegeneration,[98,97,246] a recent study found no neuronal cell death immediately after a brief exposure to morphine in newborn rats.[206] Additional research is needed to elucidate the timing of exposure on cellular demise and the differential effects of anesthetics and analgesics on brain structural integrity.

LONG-TERM BRAIN CELLULAR VIABILITY, NEUROLOGIC FUNCTION, AND BEHAVIOR

To answer the important question of whether anesthetics simply hasten natural apoptosis or whether they induce pathologic apoptosis, long-term neuronal density and neurologic function have to be assessed in adult animals exposed to anesthesia as neonates. If exposure to anesthetics or analgesics only temporarily accelerated physiologic apoptosis, one would expect normal cellular density and function in adulthood. Conversely, permanent neuronal cell loss and long-term neurocognitive impairment after anesthetic exposure early in life would suggest that anesthesia-induced neuronal apoptosis may be pathologic in nature and that the organism was unable to compensate for the neonatal cell loss by postexposure neuronal plasticity and repair. To address these questions, several studies measured neurologic function, assessed behavior, and/or determined neuronal density in adult animals after anesthetic exposure in the neonatal period. Results from these studies, however, are conflicting. A number of studies reported long-term neurocognitive or behavioral abnormalities after neonatal exposure to enflurane, halothane, isoflurane, sevoflurane, propofol, or ketamine, or to a combination of isoflurane, nitrous oxide, and midazolam.[a] Importantly, however, many of these studies only observed abnormalities in very specific tests or subsets of neurocognitive batteries, whereas many other neurobehavioral domains remained intact. For example, a 6-hour exposure to midazolam, isoflurane, and nitrous oxide in neonatal rats transiently impaired learning in a water maze task in young adulthood and in older animals, whereas in the same animals, several other tests of behavior and learning, including acoustic startle response, sensorimotor tests, spontaneous behavior in an open field, and learning and memory in the radial arms maze, remained unimpaired.[100] Similarly, after a 4-hour exposure to one minimum alveolar concentration (1 MAC) of isoflurane in 7-day-old rats, long-term memory retention was abnormal at two time points, whereas performance at several other time points, as well as in other tests of learning and memory, remained intact.[121] Accordingly, the relevance of these temporary and limited learning deficits remains unclear. Similar to humans, the performance of rodents and primates in learning tasks depends to a great extent on maternal behavior and rearing conditions, making them strong confounders during neurocognitive testing.[119,247–249] Moreover, another obvious and important factor in neurocognitive testing is the verification of similar degrees of motivation when comparing separate groups of animals. For example, a 24-hour exposure to ketamine sedation early in life impaired subsequent performance of rhesus monkeys in learning and memory tests, in addition to decreasing their motivation to perform these tasks.[178]

Studies of prolonged opioid administration in immature animals have also found evidence for long-term impairment in learning

tasks,[197–199,202–204] as well as altered pain responses in adult animals after exposure to morphine, fentanyl, heroin, or methadone early in life.[a]

Conversely, several other investigations have observed no neurologic abnormalities after administration of midazolam, isoflurane, sevoflurane, or ketamine, even when using complex neurologic tests in neonatal animals.[b] It remains to be determined whether these differential findings are attributable to the anesthetic doses, exposure times, species, or are related to the specific type of neurologic test used or the timing of the exposure or the assessment. Interestingly, escalating exposure times of isoflurane in neonatal rats caused neuronal apoptosis beginning at 2 hours of anesthesia, but no evidence of long-term neurologic abnormalities until 4 hours of anesthesia.[120] In another study, a 6-hour exposure to isoflurane caused significant apoptosis immediately after exposure in neonatal mice but resulted in no measurable long-term deficits in performance of complex neurologic tests as adult animals.[119] Moreover, in this study, brain neuronal density in adulthood was not diminished in regions significantly affected by anesthesia-induced neuroapoptosis compared with unanesthetized littermates.[119] Studies in mice exposed to 6 hours of isoflurane at 21 days of age did not observe subsequent diminution in dentate granule cells, despite considerable apoptotic cell death immediately after exposure.[250] These findings could either suggest that isoflurane may only accelerate physiologic apoptosis or that the developing brain's plasticity and capacity for repair can compensate for a pathologic insult early in life. Conversely, a study in similarly aged rats observed a permanent elimination of neurons, as well as neurologic abnormalities in adult animals, after exposure to isoflurane, nitrous oxide, and midazolam as neonates, suggesting that either the specific combination of anesthetic drugs (isoflurane alone vs. the combination exposure) or species differences (rats vs. mice) could affect relationships between neonatal neuroapoptosis and long-term function and neuronal density.[111] Alternatively, these conflicting results may be explained by the dissimilar testing environment because neurocognitive tests are not easily transferable among laboratories.[251] Yet another explanation holds that neonatal apoptosis may not be causally linked to adult neurocognitive performance at all, as evidenced by substantial apoptotic cell death observed immediately after carbon dioxide–induced hypercarbia in unanesthetized neonatal rats, which lacked long-term neurologic sequelae.[121]

EFFECTS ON NEUROGENESIS AND GLIOGENESIS

The generation of new neurons, or neurogenesis, as well as new astrocytes–gliogenesis–is most active in the immature brain in utero or soon after birth. Accordingly, several studies have investigated the effects of anesthetic exposure, primarily isoflurane, on progenitor viability and rates of neurogenesis. Although isoflurane did not kill neural progenitor cells in vitro, 3.4% isoflurane for 4 hours decreased the rate of neuronal proliferation and increased neuronal fate selection.[252] These findings have been confirmed as 2.8% isoflurane for 6 hours had no effect on neural stem cell viability, whereas larger doses inhibited cell proliferation.[134] In vivo studies in newborn mice failed to find significant cell death in radial glial-type progenitor cells in the dentate gyrus immediately after a 6-hour isoflurane exposure, although more mature neuroblasts made up a substantial number of cells affected by anesthesia-induced apoptotic cell death.[142] Morphine, on the other hand, did not affect cell survival in a murine cerebellar neuronal precursor culture, although, exposure decreased DNA synthesis.[193]

Isoflurane also impairs the growth of cultured immature astrocytes and delays their maturation after a 24-hour administration of 3% isoflurane, although even this extreme exposure showed no effect on cell viability.[132] Morphine, although increasing apoptosis in neurons and microglia, did not affect astrocytes in a study involving human fetal cell cultures.[196]

ALTERATIONS IN DENDRITIC ARCHITECTURE

The immature brain accumulates an overabundance of neuronal connections in infancy, and the number of dendrites and synapses dramatically decreases after the first year of life. Several studies have examined the effects of a wide variety of anesthetics, such as propofol, isoflurane, sevoflurane, desflurane, midazolam, and ketamine on dendritic arborization and synaptic architecture.[c] A common theme in these studies is that anesthetics can affect dendritic arborization and synaptic density, and that the direction of any change, either an increase or a decrease in the number of dendritic spines, depends on the age at which the animals were exposed to anesthetics and therefore the developmental state of the brain. During the first 2 weeks of life, anesthetic exposure can lead to a decrease in synaptic and dendritic spine density in small rodents, whereas exposure beyond this age can lead to an increase in the number of dendrites.[123,222] Other studies suggest that this differential effect may depend on the maturational switch of GABA from excitation to inhibition, which is related to the switch from the immature form of the potassium-chloride-cotransporter NKCC1 to the mature KCC2. However, the permanence of these dendritic changes remains controversial because some studies have observed only a transient effect after ketamine, midazolam, or isoflurane anesthesia exposure early in life.[133,173]

DECREASE IN TROPHIC FACTORS

Isoflurane- or propofol-based anesthesia in neonatal animals has been associated with a decrease in brain-derived neurotrophic factor (BDNF),[105,122,223] a protein integral to neuronal survival, growth, and differentiation. The cellular mechanism involves a reduction in tissue plasminogen activator and plasmin, which converts proBDNF to BDNF. Accordingly, isoflurane has been found to trigger proBDNF/p75^{NTR} (p75 neurotrophin receptor) complex–mediated apoptosis in neonatal mice.[122] Similarly, prolonged exposure to opioid receptor agonists early in life alters nerve growth factors in the immature brain.[70,186]

DEGENERATION OF MITOCHONDRIA

Ultrastructural morphologic abnormalities have been reported in mitochondria of pyramidal neurons in the subiculum of 7 day-old rats following 6 hours of isoflurane, nitrous oxide, and midazolam.[139] A morphometric analysis demonstrated mitochondrial enlargement, impaired structural integrity, and decreased mitochondrial density, indicating protracted mitochondrial injury after drug exposure.[253,254] Moreover, an ultrastructural examination with electron microscopy revealed increased autophagy, a form of cell death.[139]

ABNORMAL REENTRY INTO CELL CYCLE

Ketamine induces reentry of postmitotic neurons into the cell cycle in immature rats.[175] This could be one trigger for apoptotic cell death, since postmitotic neurons lose the ability of neuronal progenitor cells to enter the cell cycle during proliferation and are committing programmed cell death when forced to reenter the cell cycle.

DESTABILIZATION OF THE CYTOSKELETON

Structural integrity of the cellular cytoskeleton is critical for proper neuronal morphology and function. Actin is one of the major components of the cytoskeleton of all eukaryotic cells and participates in important cellular processes, including cell signaling, motility, and division. It is also essential for the formation of dendritic spines. Isoflurane has been found to depolymerize actin in neurons and astrocytes, initiating cytoskeletal destabilization, impairment of astrocyte morphologic differentiation and maturation, as well as neuronal apoptosis.[132,136]

EFFECTS ON THE DEVELOPING SPINAL CORD

Most animal studies have focused on the effects of general anesthetics and sedatives on the developing brain. However, it is important to also consider the developmental impact of anesthetics on the spinal cord. One study observed increased neuroapoptosis in the lumbar spinal cord of 7-day-old rats after 6 hours of 0.75% isoflurane with 75% nitrous oxide.[114] Increased neurodegeneration was also documented in brain and spinal cord after 6 hours of 1% isoflurane in a similar model, but not after 1 hour of anesthesia or following spinal administration of bupivacaine.[137] Intrathecal ketamine can also cause neuroapoptosis in the developing spinal cord of 3-day-old rats, but not of 7-day-old rats.[177] Preservative-free ketamine caused long-term alterations in spinal cord function and gait disturbances,[177] whereas in a separate study, even high-dose intrathecal morphine produced no signs of spinal cord toxicity.[255]

Putative Mechanisms for Neurotoxicity

The exact mechanisms that trigger the previously listed effects of anesthetics and sedatives on the immature brain and spinal cord remain unresolved. Elucidating these mechanisms will be critical in establishing the relevance of these findings for pediatric anesthesia and neonatal critical care medicine, as well as for developing mitigating interventions, if necessary. The current, overarching hypothesis is that anesthetics and sedatives interfere with normal $GABA_A$ and NMDA receptor–mediated activity, which are the putative targets for unconsciousness, amnesia, and immobility,[256] and at the same time are essential for mammalian CNS development.[11,257] Administering $GABA_A$-receptor agonists and/or NMDA-receptor antagonists could potentially cause abnormal neuronal inhibition during a vulnerable period in neuronal development, triggering apoptosis in susceptible neurons, which in turn leads to neurocognitive impairment and decreased neuronal density into adulthood.[24,62,100,111] Other lines of evidence suggest that the NMDA receptor–blocking properties of ketamine may upregulate NMDA receptors, rendering neurons more susceptible to excitotoxic injury caused by endogenous glutamate action on the increased number of receptors immediately after withdrawal of the anesthetic such as proposed for ketamine.[155,159] However, several observations partly contradict both hypotheses; neuronal cell death has been reported during exposure to anesthetics and not only after their discontinuation. Moreover, several anesthetics with minimal NMDA-receptor interaction, such as propofol and barbiturates, have demonstrated robust neurotoxic properties, whereas the neurotoxic potency of the NMDA-antagonist xenon has been found to be limited, therefore casting doubt on receptor upregulation as the sole mechanism for anesthetic neurotoxicity. In terms of abnormal neuronal inhibition being the main trigger for apoptosis in developing neurons, $GABA_A$-receptor stimulation indeed decreases neuronal activity in the mature brain; however, it also causes excitation in developing neurons,[258] thereby contradicting the inhibition hypothesis. In immature neurons, intracellular chloride (Cl^-) concentration is high; thus GABA-induced opening of Cl^- channels allows this anion to exit the cell, leading to membrane depolarization. On the other hand, the intracellular Cl^- concentration is low in mature neurons. When anesthetics open Cl^- channels in mature neurons, ions enter the cell, thereby hyperpolarizing the membrane. This reversal of the cellular Cl^- gradient occurs as a result of a switch from the immature Na^+-K^+-$2Cl^-$ cotransporter 1 (NKCC1) to the mature brain form, K^+-Cl^- cotransporter 2 (KCC2).[259] Along these lines, studies in neonatal rats demonstrated excitatory properties in the brain and episodes of epileptic seizures during sevoflurane anesthesia.[232] Isoflurane has also been shown to cause an excessive release of Ca^{2+} from the endoplasmic reticulum via overactivation of inositol 1,4,5-trisphosphate receptors (InsP3Rs) in neonatal rats in vivo and in vitro.[260] A similar mechanism may be linked to the production of Alzheimer-associated increases in β-amyloid protein levels after anesthesia.[261] Although xenon and hypothermia cause neuronal inhibition, they do not exacerbate isoflurane-induced neuronal cell death as expected by the cumulative inhibition of neurons, but rather significantly reduce it.[108,115,239]

Importantly, evidence indicates that equianesthetic concentrations of the three contemporary inhalational anesthetics cause similar degrees of neuroapoptosis, suggesting that it is the anesthetic depth and not the specific doses or end-tidal concentrations of the anesthetics that determines cytotoxic potency.[76] However, other studies have failed to link the anesthetic and the apoptotic mechanisms. Specifically, although racemic ketamine and (*S*)-ketamine both elicit their anesthetic effects via NMDA-receptor blockade, (*S*)-ketamine induced up to 80% less cell death in vitro compared with equipotent doses of racemic ketamine.[174] Moreover, concomitant administration of the $GABA_A$-receptor antagonist gabazine failed to attenuate neuroapoptosis induced by the GABA agonist isoflurane, whereas administration of the α_2-agonist dexmedetomidine did.[79] Decreases in anesthetic-induced neuronal activity may therefore be less important than the disruption of the neuronal balance of excitation and inhibition, as demonstrated by studies that examined anesthesia-induced dendritic morphologic changes in mice.[74,172] In a mechanistic study of brain development, simultaneous blockade of excitatory and inhibitory activity with tetrodotoxin did not lead to structural changes during synaptogenesis that would have been expected from a causative relationship between neuronal inhibition and structural abnormalities; the administration of either $GABA_A$-agonistic or NMDA-antagonistic compounds alone did alter synaptogenesis.[172]

It is not entirely clear at this time whether cytotoxicity is a direct effect of the anesthetic itself, of any anesthetic by-products, or if it is related to physiologic derangements observed during anesthesia in small rodents.[119,121,262] Hypercarbia can trigger widespread neuroapoptosis, even in unanesthetized neonatal rats exposed to increased partial pressures of carbon dioxide. Whereas apoptotic cell death was quantitatively indistinguishable from neurodegeneration in isoflurane-treated litter mates, which were also hypercarbic; neurocognitive impairment in adults was observed

only in the isoflurane-treated animals.[121] However, widespread apoptotic neurodegeneration observed in anesthetized nonhuman primates, where carbon dioxide tensions were controlled by tracheal intubation and ventilation, suggests that metabolic derangements may not be sufficient to explain the structural abnormalities observed in immature animal species. Lastly, experimental models of neurodegeneration have implicated reentry of postmitotic neurons into the cell cycle, leading to cell death. Ketamine exposure has been found to induce aberrant cell cycle reentry, leading to apoptotic cell death in the developing rat brain.[175] However, a causative link between neuronal degeneration immediately after exposure and subsequent cognitive abnormalities observed into adulthood have yet to be firmly established.

Specific Anesthetic and Sedative Agents

To provide a succinct overview of the available laboratory data, we briefly review the effects of each class of anesthetics separately. Although the effects of some anesthetics, such as ketamine and isoflurane, have been extensively studied in the developing brain, the effects of others, such as xenon and desflurane, have not been examined in depth. However, current data suggest that all routinely used anesthetics exert deleterious effects to some degree (see E-Table 25.1). When examining the available animal literature, it is important to appreciate that potencies for inhalational anesthetics, as measured in MAC values (a concentration measure), are largely comparable across species, whereas doses for intravenous (IV) medications are not–that is, weight-based dosing rather than concentration varies substantively. Weight-based dosing of most IV medications to effect sedation or anesthesia in animals is approximately 6- to 10-fold greater than comparable doses in humans. The dosing is further complicated by the different routes used to administer these drugs in most neonatal animal models, frequently relying on the subcutaneous (SC) and intraperitoneal (IP) routes as opposed to the oral or IV routes in humans. However, the possible importance of these interspecies pharmacodynamic differences on brain structural and functional outcomes has not yet been adequately addressed.

KETAMINE

The injectable anesthetic most frequently studied in this context is ketamine, an antagonist of the NMDA glutamate receptor that also interacts with other cell membrane proteins, such as muscarinic, nicotinic, and opioid receptors, as well as voltage-gated calcium channels. Ketamine's properties, which include potent analgesia, dissociative anesthesia, and relative hemodynamic stability, have made it a popular choice for procedural sedation and induction of anesthesia in children with concerns for hemodynamic stability, such as critical congenital heart disease or pulmonary hypertension.[263–265] However, about 17 years ago, a seminal study examining the effects of repeated IP injections of ketamine on the brain of neonatal rats observed widespread apoptotic cell death.[19] Seven injections of 20 mg/kg of ketamine, administered to 7-day-old rat pups over a 9-hour period in evenly divided intervals, caused a 3- to 31-fold increase in degenerating neurons, depending on brain region, compared with vehicle-injected control animals. This has led to speculation that these changes might contribute to subsequent neuropsychiatric disorders.[19] These initial findings for ketamine have been confirmed in more than 50 studies in small rodents, as well as nonhuman primates, both in vitro and in vivo (see E-Table 25.1). Several of these studies have identified relationships between neurodegeneration and dose, number of injections, as well as animal species and age during exposure. Single doses up to 75 mg/kg or multiple IP injections up to 17 mg/kg per hour for 6 hours were not neurotoxic to neonatal rats.[148] In contrast, single doses between 20 and 50 mg/kg SC in neonatal mice[150,154] or six or seven repeated injections of 20 to 25 mg/kg IP consistently led to apoptosis in the neonatal rat brain.[19,148,151,169,170] Although these doses appear to be excessive compared with clinical practice and plasma concentrations in these rodents were up to 7 times greater than those in humans,[151] these doses of ketamine were required for sedation owing to increased requirements for IV anesthetics in small animals based on body weight (refer to the later section "Critical Evaluation of Animal Studies and Interspecies Comparisons." Moreover, coadministration of midazolam, diazepam, propofol, or thiopental can compound the neuronal injury caused by ketamine.[150,154,162] Studies in rats, mice, and nonhuman primates suggest that susceptibility to ketamine-induced neurotoxicity may be most pronounced during a brief period after birth, with a maximum impact between 3 and 7 days of age in small rodents and less than 35 days of age in monkeys.[19,159] In addition to neuronal apoptosis, both small rodents and nonhuman primates that were anesthetized with ketamine also exhibited impaired learning tasks later in life.[87,149,178]

In summary, ketamine is the most frequently studied anesthetic, in terms to its neurotoxic effects, and has repeatedly been shown to cause widespread apoptosis (an effect that is exacerbated by the coadministration of other anesthetics), as well as neurologic impairment in adult animals exposed early in life. Importantly, long-lasting learning impairment has also been demonstrated in nonhuman primates, the closest animal model to humans, albeit after an IV exposure of 24 hours.[178] However, this exposure time exceeds most anesthetics in humans.[178] Furthermore, it is unclear whether the observed learning abnormalities could be explained by a reduction in motivation to perform the learning tasks, as also demonstrated in the exposed animals.[178]

INHALATIONAL ANESTHETICS

Another commonly studied class of drugs is the inhalational anesthetics (see E-Table 25.1). Desflurane, sevoflurane, isoflurane, enflurane, and halothane exert their anesthetic properties predominantly by their agonistic effects on the $GABA_A$ receptor, but also to differing degrees on glycine, NMDA, acetylcholine, serotonin ($5\text{-}HT_3$), α-amino-3-hydroxy-5-methyl-4-isoxazole-propionic acid (AMPA), and kainate receptors. Whereas GABA represents the main inhibitory neurotransmitter in the adult CNS, it has excitatory properties in the developing brain,[258] which may have implications for neurotoxicity, as discussed previously. Most studies of inhalational anesthetics examined either isoflurane by itself or in combination with midazolam and nitrous oxide. This combination of GABA agonists and NMDA antagonists has been repeatedly found to cause widespread brain cell degeneration in neonatal animals.[100,102,105,106] In addition to the immediate deleterious effects on brain structure, long-term abnormalities in spatial learning tasks and decreased neuronal cell density in adult rats have also been observed after exposure to this anesthetic combination early in life.[100,111] One MAC of isoflurane administered to neonatal rats as the sole anesthetic for 4 hours led to neurocognitive deficits in rats when they matured to adults,[120,121] whereas up to 0.6 MAC for 6 hours in neonatal mice caused widespread neuronal degeneration immediately after exposure, although it failed to lead to neurocognitive deficits or decreases in neuronal density in adulthood.[119,128] These inconsistencies raise questions of whether neonatal neuronal apoptotic cell death during exposure is causatively linked to long-term behavioral and learning abnormalities observed in adult animals. In fact, similar degrees

of neurodegeneration were observed in 7-day-old rats after a 4-hour exposure to either carbon dioxide or isoflurane; however, long-term neurocognitive deficits were observed only after the anesthetic exposure.[121] Importantly, widespread neuronal cell death has also been observed in neonatal rhesus monkeys after 5 hours of isoflurane in concentrations between 0.75% and 1.5%,[127] although long-term neurologic studies in this species have yet to be published.

Sevoflurane has also induced widespread neuroapoptosis in neonatal mice similar to isoflurane,[76,128,230] although the long-term effects on learning and behavior are conflicting.[77,128,230] To date, few studies have examined desflurane in this context. Desflurane causes age- and species-dependent neuronal cell death in 7-day-old mice, but not 16-day-old rats.[74,76]

Several studies have attempted to compare the neurotoxicity of contemporary inhaled anesthetics. Equianesthetic concentrations of 0.6 MAC of desflurane, isoflurane, or sevoflurane for 6 hours in neonatal mice caused a similar degree of neuronal degeneration in superficial neocortex, a brain region significantly affected in this model.[76] These results contrast with studies in which neonatal mice were exposed to much lower concentrations of sevoflurane that resulted in significantly less neuronal loss immediately compared with isoflurane, albeit no neurocognitive performance deficits were observed in adult animals with either regimen.[128] In yet another comparative mouse study, desflurane caused greater injury than isoflurane or sevoflurane, which demonstrated comparable degrees of neurodegeneration, and long-term neurologic impairment occurred only after exposure to desflurane.[77] The significance of these differential findings remains unclear but could be related to methodologic differences in the assessment of brain injury. Importantly, however, these conflicting results prohibit any clinical recommendations for choosing one particular volatile anesthetic over another.

Although largely phased out from clinical anesthesia practice, halothane and enflurane have also been shown to induce brain abnormalities. These anesthetics were initially studied in rat models of chronic occupational exposure during pregnancy, causing delayed synaptogenesis as well as behavioral and learning abnormalities.[15–18,89]

In summary, inhalational anesthetics represent one of the most frequently used classes of anesthetics in pediatric anesthesia, and their neurotoxic properties have been extensively studied. Widespread apoptosis immediately after exposure in a wide variety of animal models, including nonhuman primates, is a consistent finding. However, neurologic impairment in adult animals exposed to anesthesia early in life has not been consistently found, and in fact, some studies have observed no neurologic impairment at all. Accordingly, long-lasting learning impairment has not been convincingly linked to neonatal neuroapoptosis. Primate studies on long-term neurocognitive outcomes after inhalational anesthesia early in life have yet to be published.

NITROUS OXIDE

Nitrous oxide, an NMDA antagonist, is the oldest anesthetic still in clinical use, although its low potency (MAC of 115% in adult humans) necessitates the coadministration of other anesthetics to provide surgical anesthesia. Anesthetic combinations studied in this context have often included the GABA agonist midazolam, and the mixed GABA-agonist/NMDA-antagonist isoflurane.[a] In rats, nitrous oxide alone did not induce neuronal apoptosis,[100,102,108] whereas in an in vitro study, it caused neuronal cell death in hippocampal slices in mice.[108] When administered in combination with other anesthetics, however, nitrous oxide exacerbated neuronal cell death induced by isoflurane and also contributed to long-term neurologic abnormalities in rats when combined with isoflurane and midazolam.[100]

XENON

Because of the cost differential between other inhalational anesthetics and this rare, colorless, and odorless noble gas, xenon has not achieved widespread clinical use, despite its NMDA-antagonistic anesthetic properties.[266] Xenon has a relatively low anesthetic potency, with a MAC measuring between 65% and 70% in adults,[267,268] but a very low blood-gas solubility that facilitates a rapid onset and emergence from anesthesia.[269] Xenon's effects on neuronal apoptosis have been examined in two in vivo studies, with slightly differing results. Although 75% xenon for 6 hours did not cause neuronal apoptosis in 7-day-old rat pups,[108] 70% xenon for 4 hours increased neuroapoptosis in 7-day-old mice.[239] Interestingly, both studies demonstrated that xenon decreased the neurodegeneration induced by isoflurane anesthesia,[108,239] which may have relevance to the phenomenon's putative mechanism (see later text). An investigation of xenon's effects on neuronal viability in hippocampal slice cultures observed neuronal cell death after exposure to more than 0.75 MAC of xenon for 6 hours.[241] In this setting, isoflurane pretreatment reduced neuronal cell death caused by 1 MAC of xenon,[241] again demonstrating the confusing finding that combinations of anesthetics can have both exacerbating and ameliorating effects related to their respective neurotoxic properties.

BENZODIAZEPINES

Benzodiazepines, such as clonazepam, diazepam, and midazolam, have been investigated regarding their effects on the immature brain, either alone or in combination with other drugs. These GABA agonists are most frequently used for anxiolysis in toddlers and older children in the perioperative setting, but they are also used in premature neonates in the critical care setting. Studies have shown that repeated exposure can increase neuronal degeneration in small-animal models, depending on the dose, region of the brain, species, and age of the animal studied. Repeated injections for a 6-hour exposure to midazolam increased neuronal cell death in neonatal rats,[189] whereas single doses of 5 mg/kg of diazepam or 9 mg/kg of midazolam IP did not.[72,100] While 5 mg/kg SC of diazepam caused neuronal cell death in some brain regions in mice, this was not associated with learning deficits in adulthood.[87] In these studies, the neuroapoptosis associated with diazepam was significantly augmented by the coadministration of other sedatives, such as ketamine.[87] The dose-dependence of neuroapoptosis observed in neonatal rats is highlighted by the fact that diazepam doses of 10 mg/kg or greater have been found to be injurious,[73,72] an effect that was prevented in one study by the coadministration of the benzodiazepine-antagonist flumazenil.[72] Two studies reported no neurocognitive learning disabilities in adult mice after they were sedated with diazepam or midazolam as neonates.[87,188] It is therefore unclear whether dose- or species-specific factors are responsible for the disparate findings.

CHLORAL HYDRATE

The sedative chloral hydrate, a chlorination product of ethanol that acts as a combined GABA agonist and NMDA antagonist, has been largely supplanted by barbiturates and benzodiazepines in pediatric clinical practice. However, it is still used in doses of up to 120 mg/kg for sedation for some imaging studies,[270] and

[a]References 92, 100, 102, 105, 106, 111, and 112.

its neurotoxic properties have been investigated in an animal study. Preliminary results indicate that it causes neuroapoptosis in the cerebral cortex and the caudate-putamen complex in immature mouse pups in doses of 100 mg/kg or greater.[71] The neurofunctional outcome in adult mice, however, has not as yet been investigated.

BARBITURATES

Barbiturates act primarily via the $GABA_A$ receptor but also exert effects via nicotinic acetylcholine, AMPA, and kainate receptors. Thiopental in doses of 25 mg/kg SC does not induce apoptosis in neonatal mice, although when doses as small as 5 mg/kg are combined with 25 mg/kg of ketamine SC, neuronal degeneration occurs and is associated with long-term impairment of learning and memory.[162] Pentobarbital and phenobarbital induce neurodegeneration in mouse and rat pups. Furthermore, after receiving these sedatives as neonates, long-term alterations in brain protein expression and abnormalities in learning and memory have been observed,[117,209,211] although in one study these long-term alterations may be attributed in part to hypoxia and hypercarbia during the neonatal sedation.[209] Interestingly, estradiol has been shown to attenuate phenobarbital-induced neuroapoptosis.[72,210]

PROPOFOL

Propofol predominantly acts via GABA and glycine receptor–agonistic properties, but also weakly on nicotinic, AMPA, and NMDA receptors. Its neurotoxic profile has been repeatedly studied both in vitro and in vivo. Propofol has consistently caused neuroapoptosis after single doses greater than 50 mg/kg (SC or IP) or repeated doses greater than 20 mg/kg per hour for 4 to 5 hours in neonatal rodents.[162,168,216,221] Interestingly, lithium prevents propofol-induced neuroapoptosis in neonatal mice.[168] However, after 24 hours of IV anesthesia with propofol (6 mg/kg per hour) and fentanyl (10 µg/kg per hour), no evidence of apoptosis was found in a pig model.[217] Apart from overt neuronal cell death, propofol also decreased the effect of GABAergic enzyme glutamic acid decarboxylase,[213] diminished nerve growth factors,[219,223] and caused neurite growth cone collapse in tissue culture.[215] In addition, propofol alters dendritic spine architecture in developing rats, depending on the age at the time of anesthetic exposure.[222] Specifically, dendritic spine density decreased during exposures in the first week of life, but increased if exposure took place during week 3 of life; the mechanism of these differing responses remains elusive.[222] Propofol has also been found to cause significant apoptotic degeneration of neurons and oligodendrocytes in fetal and neonatal rhesus monkeys after a 5-hour exposure.[226] Accordingly, the overall consensus of this body of literature is that propofol, in a dose- and exposure time-dependent fashion, can dramatically affect the developing brain of animals.

DEXMEDETOMIDINE

Unlike other anesthetics and sedatives, dexmedetomidine is a sedative and analgesic that does not interact with GABA, NMDA, or opioid receptors, but rather interacts presynaptically with α_2-adrenergic receptors. Given this dissimilar mechanism of action and the fact that all anesthetics acting on GABA or NMDA receptors have been found deleterious to the developing brain, there has been substantial interest in the use of dexmedetomidine as an alternative sedative since it may not cause neurocognitive dysfunction. Several initial studies that examined the brain structure after dexmedetomidine administration in rodents and monkeys reported none to minimal neurodegeneration.[79–85,228] However, one study observed increased neuroapoptosis after a prolonged exposure to dexmedetomidine, albeit in brain regions distinct from those vulnerable to ketamine-induced apoptosis.[86] Furthermore, dexmedetomidine has been found to reduce or even ameliorate brain structural or long-term cognitive abnormalities caused by isoflurane, sevoflurane, ketamine, or propofol.[79–81,84,228] These results clearly warrant conducting additional studies comparing dexmedetomidine and standard anesthetic regimens with particular attention to comparable levels of sedation.

OPIOID ANALGESICS

Since all currently used general anesthetics can dramatically alter the structure of the developing brain, opioid analgesics represent a class of drugs that reduces anesthetic requirements and could therefore diminish the deleterious effects of anesthetics in the developing brain. To date, only one study has investigated neurotoxic properties of opioids compared with an inhalational anesthetic regimen. Mechanically ventilated, neonatal pigs, injected with an IV bolus of 30 µg/kg fentanyl followed by 15 µg/kg per hour for 4 hours, exhibited less neuroapoptosis in several regions of the brain compared with a balanced anesthetic of 1 mg/kg of midazolam, followed by 4 hours of 0.55% isoflurane and 75% nitrous oxide.[92] These initial findings are encouraging, although future neurotoxicity studies with opioid infusions need to also include adjuvants that produce amnesia as this is an expectation during clinical anesthesia. However, whether neonates and infants require the same level of amnesia as adults during surgery remains a hotly debated subject.[271,272] Finally, it is critical to confirm that equipotent anesthetic doses are used when comparing the effects of different regimens (e.g., IV versus inhalational anesthetics) on neurotoxicity.

The long-term consequences of opioid administration to the immature brain need to be elucidated before recommending such a regimen as an alternative strategy for clinical practice. Similar to GABA and NMDA receptors, opioid receptors are also intimately involved in early brain development and synaptogenesis,[273,274] which would make it plausible that opioids could similarly affect brain development during the critical period of synaptogenesis. Moreover, repeated neonatal exposures could alter long-term opioid receptor composition. Increased neuronal cell death and decreased neuronal density after perinatal exposure to µ-receptor agonists, such as morphine and heroin, have been observed in developing animals after prolonged exposures.[98,125,246] Long-term buprenorphine and methadone treatment early in life diminished the concentrations of nerve growth factors in the immature brain.[70,186] Moreover, perinatal exposure to morphine has immediately and permanently reduced µ-opioid receptor density[191,192] and may be associated with long-term impairment of memory and cognitive function in small animals,[194,197–199,202–204] as well as exaggerated nociceptive responses to a pain challenge later in life.[200,205] Stimulation of the κ-opioid receptor may amplify neuronal cell death induced by proapoptotic agents.[275] High-dose fentanyl significantly exacerbated white-matter brain lesions induced by glutamatergic overstimulation in mice.[91] However, a single morphine injection of up to 10 mg/kg in 7- or 15 day-old rats failed to affect survival or dendritic differentiation of pyramidal neurons in the medial prefrontal cortex.[206] These animal data suggest that prolonged perinatal exposure to opioid analgesics could potentially cause structural and long-term functional alterations in the developing brain and may amplify proapoptotic stimuli, whereas a brief or single exposure may not. These data support the need for further studies into the interactions of opioid analgesics and anesthetics in the developing brain.

Exposure Time, Dose, and Anesthetic Combinations

Similar to opioid analgesics, the impact of developmental anesthetic exposure seems to depend on the dose and/or duration of anesthesia for inhalational anesthetics, as well as the dose, route of administration, and number of doses (i.e., exposure time) for injectable anesthetics. Moreover, combinations of several anesthetics and sedatives have, in general, caused more neuroapoptosis and long-term cognitive changes than have single drugs. For example, combinations of midazolam, nitrous oxide, and isoflurane cause a much greater degree of neuroapoptosis in neonatal rats than isoflurane alone, even when the latter is administered at a greater inspired concentration.[100] In the case of ketamine, its neurodegenerative potency is amplified when coadministered with thiopental or propofol.[162] Anesthetic combinations of mixed GABA agonists and NMDA antagonists demonstrate exaggerated effects. This evidence supports the notion that a deeper level of anesthesia increases the neuroapoptotic injury. However, coadministration of two anesthetics, xenon and dexmedetomidine, as well as isoflurane before treatment (all of which attenuated the neurotoxic effects of isoflurane anesthesia[79,108,239]), somewhat contradict this hypothesis. The effects of muscle relaxants on neurologic outcomes, while unlikely related to their insignificant permeation of the intact blood-brain barrier, have not yet been studied. Moreover, the study of local anesthetic toxicity has been limited to the developing spinal cord and has not yet been expanded to the developing brain. This line of investigation will require greater emphasis if the use of regional anesthetic techniques are expanded in infants and young children to reduce requirements for general anesthetics.

Deleterious Effects of Untreated Pain and Stress

Given the evidence for deleterious effects of anesthetics and analgesics on the developing brain and the paucity of complete anesthetics devoid of cytotoxicity, one approach would be to reduce or even withhold potentially toxic drugs at the expense of children experiencing pain and stress during surgery. Such practice would not only be unethical, but animal and clinical research actually suggest that these recurrent stressful and painful experiences also adversely affect the developing brain. Noxious stimulation in neonatal rodents has been associated with subsequent hyperalgesia as well as hypoalgesia, depending on the type and severity of injury.[276] In human neonates, repetitive painful skin lacerations for procedures as minor as blood draws lead to long-term, local sensory hyperinnervation.[277] In immature animals, in addition to these local responses, repetitive, inflammatory pain early in life results in hyperalgesia and lasting changes in nociceptive circuitry of the adult dorsal horn.[278] Repeated painful injections into the paws of rat pups resulted in a generalized thermal hypoalgesia.[276] In addition to altered pain processing and sensory perception, repetitive or persistent pain in the neonate alters behavior and cognitive function in adulthood, decreases pain thresholds, and increases vulnerability to stress and anxiety disorders or chronic pain syndromes later in life.[161,279–282]

In addition to painful stimulation, early adverse emotional experiences can also induce long-lasting abnormalities in animals such as imbalances of the inhibitory nervous system,[283] impairment of normal development of the nociceptive system, long-term behavioral changes,[284] and persistent learning impairment.[202] Therefore fetuses, neonates, and infants subjected to pain and stresses associated with invasive procedures without adequate anesthesia and analgesia may also be at risk for long-term adverse outcomes.

Accordingly, preemptive administration of analgesics and sedatives such as morphine or ketamine has been found to ameliorate the deleterious effects of neonatal pain in some of the animal studies.[161,202,282] Either the presence of painful stimulation or 5 days of morphine administered to neonatal mice without pain independently impaired adult rewarded behavior, although the combination of pain and analgesia did not cause behavioral abnormalities.[202]

Clinical reports have also demonstrated that human neonates and infants can mount a substantial metabolic and endocrine response to perioperative stress and painful stimulation, which include surges in catecholamine, cortisol, β-endorphin, insulin, glucagon, and growth hormone levels.[285–287] Some of these markers, such as cortisol, can remain increased for more than a year after the insult, possibly as a result of cumulative stress related to multiple painful procedures early in life.[288] Inhalational anesthetics, opioid analgesics, as well as regional anesthesia, inhibit intraoperative stress and improve postoperative outcomes.[286,289,290] Moreover, adequate perioperative anesthesia reduced the incidence of other complications, such as the incidence of sepsis and disseminated intravascular coagulation, leading to a decrease in overall mortality.[291] Even less invasive procedures, such as circumcisions performed without analgesia in young boys, can exaggerate responses to painful challenges (e.g., immunizations) later in life.[292] Conversely, topical or regional anesthesia for circumcision not only mitigated the immediate humoral stress response during the procedure[293] but also blunted the pain-induced, long-term hyperalgesia.[292] In preterm neonates, painful stimulations early in life have also been associated with subsequent diminished cognition and motor function.[294] In a retrospective study of children older than 1 year of age who were born at less than 32 weeks gestational age without significant neonatal brain injury or major sensorineural impairment, an increased number of skin-breaking procedures from birth to term (including heel sticks, intramuscular injections, chest tube placements, and central line insertions) predicted poorer subsequent cognitive and motor development (as assessed using the Bayley Scales of Infant Development II) when compared with term controls. Importantly, after controlling for severity of illness, duration of morphine administration, and exposure to postnatal dexamethasone, gestational age at birth was not significantly associated with poorer cognitive or motor outcomes. These findings suggest that repetitive pain-related stressful experiences and not prematurity per se were in part responsible for the altered neurodevelopmental outcome.[294] Although this study did not examine the effects of anesthetic or analgesic administration during painful stimulation on subsequent outcome, a small, retrospective report suggested an improvement in outcome after administering anesthesia during painful stimulation.[295] In this study, painful stimulation during reduction of herniated bowel without anesthesia in infants suffering from gastroschisis tended to more frequently lead to serious adverse events, such as bowel ischemia, the need for total parenteral nutrition, and unplanned reoperation, than in infants undergoing the same procedure with general anesthesia.[295] Surprisingly, despite the persistently large numbers of painful and stressful procedures performed in vulnerable neonates, data indicate that the majority of these procedures are still not accompanied

by adequate analgesia or anesthesia.[296] In clinical practice, the relative effects of anesthetic exposure or inadequate anesthesia or analgesia during painful stimulation as the potential basis for cognitive abnormalities remain open to speculation.

Together, the data from animals and humans convincingly demonstrate that pain-related stress experienced early in life is deleterious to the developing nervous system, that pain in children remains undertreated, and that analgesics and/or anesthetics may alleviate many of the degenerative effects of unopposed pain and improve outcomes. However, if anesthetics protect from the deleterious effects of painful stimulation but at the same time confer their own cytotoxic effects, the quintessential question is whether other adjuvant compounds can alleviate these adverse effects.

Potential Alleviating Strategies

Whereas the translational relevance of anesthetic-induced neurotoxicity observed in neonatal animals to humans remains unresolved, several laboratory studies have investigated strategies to alleviate some of the deleterious effects of anesthetics and sedatives in animals, which may have relevance for clinical practice. These protective strategies have been directed at both the structural effects observed immediately after anesthesia, such as neuronal cell death, as well as the long-term abnormalities, such as neurocognitive impairment and learning abnormalities. Importantly, many animal studies administered adjuvants immediately before or during anesthesia, thereby maintaining an adequate level of anesthesia and analgesia to avoid the deleterious effects of unopposed pain.

The sedative dexmedetomidine and the anesthetic xenon possess limited neurotoxic potencies themselves but seem to significantly reduce isoflurane-induced neuroapoptosis.[79–81,84,108,228,239] The coadministration of dexmedetomidine also prevented long-term memory impairment after 6-hour isoflurane exposure in rats.[79] Interestingly, preconditioning with a brief exposure of isoflurane conferred protection from the deleterious effects of a subsequent prolonged exposure to the same drug, both in vitro and in vivo.[109,145] In in vitro studies, the inositol triphosphate–receptor antagonist xestospongin C, tissue plasminogen activator, plasmin, inhibition of the neurotrophic receptor $p75^{NTR}$ or RhoA receptor, as well as prevention of cytoskeletal depolymerization with either jasplakinolide or TAT-Pep5 significantly attenuated isoflurane-mediated neuroapoptosis.[118,122,136] In addition, L-carnitine attenuated neuronal apoptosis after 6 hours of isoflurane and nitrous oxide in 7-day-old rat pups.[116] Moreover, supplementation with the naturally occurring hormones β-estradiol or melatonin prevented the deleterious effects on neuronal survival of a prolonged exposure to midazolam, isoflurane, and nitrous oxide.[102,105] Similarly, coadministration of β-estradiol significantly reduced phenobarbital-induced neuroapoptosis.[72,210] Conversely, blocking the GABA receptor with the antagonist gabazine has not been found to ameliorate isoflurane-induced neurodegeneration.[79] On the other hand, pilocarpine reduces neuroapoptosis induced by the GABA agonists isoflurane and midazolam, while augmenting the damage after administration of the NMDA antagonist phencyclidine, based on preliminary results from neonatal mice.[107] Preliminary data from the same laboratory also suggest that whole-body hypothermia with a targeted brain temperature of less than 30°C may protect from the neuroapoptotic ramifications of a 4-hour exposure to 0.75% isoflurane or to 40 mg/kg of IP ketamine in neonatal mice.[43,115] Another therapy that has been successfully tested in mouse pups as well as nonhuman primates that either received ketamine, propofol, or isoflurane was lithium, which abolished the anesthetic-induced neuroapoptosis in cortex and the caudate-putamen complex.[147,168]

Because the applicability and extent of anesthetic neurotoxicity has not been established in humans, it seems premature to recommend any of these protective strategies for children. Moreover, the safety of many of these drugs and interventions has yet to be determined in human neonates and infants. For example, tissue plasminogen activator and plasmin promote fibrinolysis and may not be first-line treatments during invasive surgical procedures. The sex hormone β-estradiol may not be a feasible adjuvant in prepubescent boys. The safety of pilocarpine in young children may be hampered by its proconvulsant activity observed in some animal studies.[297,298] Lithium has been labeled harmful to the human fetus and may cause neurocognitive abnormalities in young children.[299–301] Whole-body hypothermia below 30°C is not a clinically feasible modality, because even mild perioperative hypothermia, at least in adults, has been causally linked to numerous complications, including increased blood loss and transfusion requirements, morbid myocardial outcomes, prolonged postanesthetic recovery and hospitalization, thermal discomfort, as well as an increased risk of surgical wound infections.[302] Therefore hypothermia to treat anesthesia-induced neurotoxicity is unlikely to play a substantive role during routine pediatric anesthesia, but it may have a role in infants undergoing hypothermic cardiopulmonary bypass for heart surgery to treat congenital defects. Unfortunately, the latter population often presents with neurocognitive abnormalities even before anesthetic exposure, which confounds the potential effects of anesthetics.[303] Xenon's scarcity renders it a very expensive adjuvant or anesthetic, although dexmedetomidine's more widespread availability and increasing familiarity among pediatric anesthesiologists makes it a more attractive option for further research into protective strategies.[304,305]

Anesthetic Neuroprotection

Complicating any discussion about the deleterious effects of anesthetics on the developing brain are their potential protective effects during noxious stimulation. Because of the limited tolerance of the brain to ischemia, even relatively brief periods of inadequate oxygen or blood flow to the brain may lead to neuronal injury and long-term neurologic impairment. Importantly, animal studies have repeatedly confirmed the protective properties of anesthetics when administered during episodes of brain hypoxia-ischemia, albeit most of these studies have been conducted in adult animals and the longevity of the protective effects are controversial.[306] In immature animal models, anesthetics have also been found to reduce neurologic injury and improve functional outcome after brain ischemia.[67] Desflurane alleviates neuronal cell death and early neurologic dysfunction in a neonatal pig model during hypothermic cardiopulmonary bypass and deep hypothermic circulatory arrest.[307,308] Isoflurane treatment before hypoxia-ischemia protects the brain and improves survival in neonatal rats and mice.[309–311] Both xenon and sevoflurane protect the immature brain during simulated hypoxia-ischemia in vitro.[312] Furthermore, sevoflurane combines with mild hypothermia to protect brain structure and function in neonatal mice during hypoxia-ischemia.[313] These findings in immature animals suggest that critically ill human neonates could potentially benefit from these protective properties during clinical scenarios of greater risk for neurologic injury, such as cardiopulmonary bypass, neurologic surgery, or perioperative cardiocirculatory arrest; these potential benefits therefore should

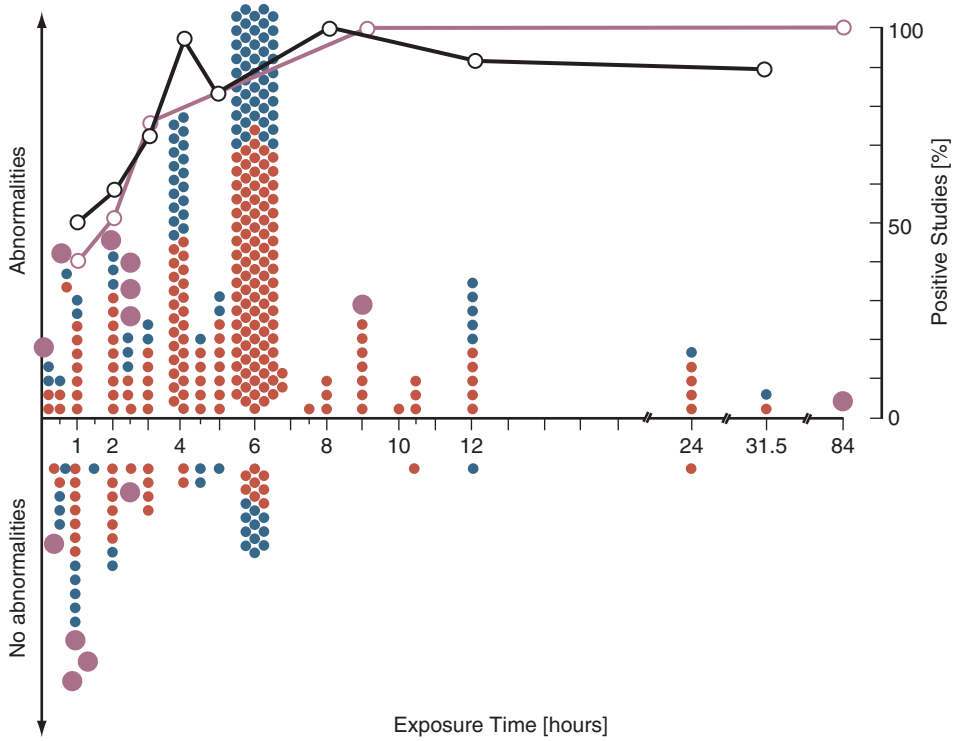

FIGURE 25.4 The majority of in vivo animal studies into the effects of anesthetic exposure on brain structure and function examine substantially longer exposure times than occurring in clinical practice. However, longer exposures trend toward more positive findings in both animal and human studies. Animal studies, inclusive of various anesthetic drugs and doses, reporting abnormal findings (above the horizontal line) or negative findings (below the horizontal line) for brain structural (*solid red circles*) or cognitive outcomes (*solid blue circles*), as a function of exposure time. *Solid purple circles* represent clinical studies of long-term cognitive outcomes in humans demonstrating abnormalities (above the horizontal line) or lack thereof (below the horizontal line). Exposure times denote all reported anesthetic durations, either single or cumulative, or estimated exposure times based on injection schedules, ranging from 10 minutes to 31.5 hours. For the purpose of analysis, results are reported separately for structural and functional outcomes, resulting in up to two circles, if both outcomes were reported, and may include opposing results, if structural and functional findings diverged. The graphs express the ratio of positive to negative studies in animals (*black*) or humans (*purple*); circles represent the percentage of positive studies for respective exposure epoch ranging from specific data point to next lower data point on the graph. Note that positive studies outnumber negative studies for all exposure times in both animals and humans, except for only 40% of human studies demonstrating cognitive abnormalities following anesthetic exposures of 1 hour or less. (From Lin EP, Lee J-R, Lee CS, et al. Do anesthetics harm the developing human brain? An integrative analysis of animal and human studies. *Neurotoxicol Teratol*. 2017;60:117–128.)

be weighed against the theoretical neurotoxic properties of current anesthetic regimens in young children.

Critical Evaluation of Animal Studies and Interspecies Comparisons

To determine whether findings from animal studies can inform clinical practice, it is critically important to evaluate how well animal studies represent the perioperative experience of young children.[a]

To date, no animal model exists covering all aspects of human physiology and pathophysiology during surgical procedures. The task of modeling potential vulnerabilities of the developing human brain in animals is complicated by the fact that human CNS development is much more protracted than that of any of the model species. However, human neurocognitive performance is also much more complex compared with lower animals, and any potential neurologic injury might therefore have a greater impact on such an intricate system.

DURATION OF EXPOSURE

To elicit toxic effects, the designs of many animal studies include durations of anesthesia from 1 to 31.5 hours (Fig. 25.4). The majority of animal studies used exposure times of 6 hours–a duration extending far beyond the average time required for most routine pediatric anesthetics.[2] However, expressing the duration of anesthesia as a fraction of a subject's life span, thereby equating a 6-hour anesthetic in mice to a 2-week or greater anesthetic in humans, is probably an oversimplification. Life expectancy or even the relative duration of neurodevelopment may not be immediately relevant when considering the likelihood of injury at a cellular level. Nonetheless, the extent of the injury and its

[a]References 4, 25, 100, 119–121, 178, and 314–319.

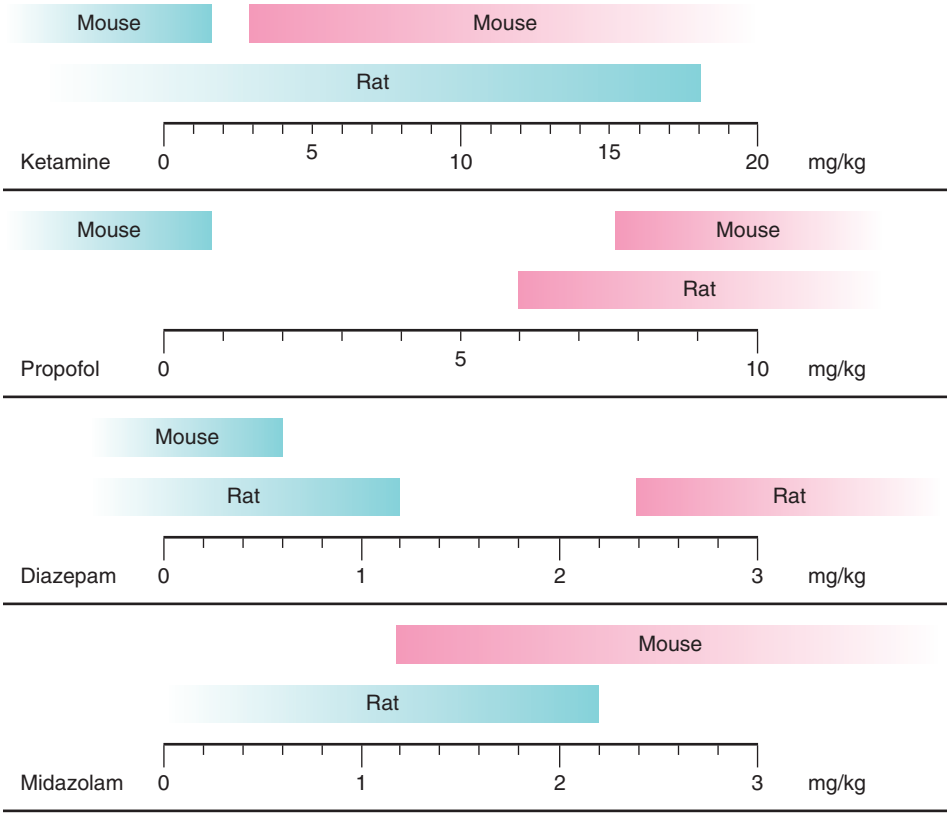

FIGURE 25.5 Neurodegenerative effects of injectable anesthetics in developing animals are dose-dependent. *Blue bars* represent doses of the respective anesthetics not causing neurodegeneration in rats and mice; *pink bars* represent doses causing neurodegeneration in animals. The figure includes only studies using single injections of anesthetics, and doses used in animals were scaled to doses for children by using an allometric scaling technique, based on calculations outlined in reference 325. Neurotoxic data are based on experiments described in references 19, 72, 73, 87, 100, 148, 151, 154, 159, 162, 171, and 219.

functional implications may potentially be related to the duration of the entire brain developmental period, even though the mechanism of anesthetic-induced neurodegeneration is unknown. Because human brain development occurs at a much slower pace than in any of the other species, similar exposure times could potentially result in differential susceptibility and ability for postexposure repair among species. For example, the brain reaches adult size at 20 days of age in rats, 3 years of age in rhesus monkeys, 7 years of age in chimpanzees, and not until 15 years of age in humans.[4,320,321] Exposure to anesthesia during a larger proportion of the period of development could result in a greater impact on total development and maturation. Similarly, given the plasticity of the developing brain, it seems conceivable that brains with slower growth rates are afforded more time for repair.[322,323] Conversely, in complex organisms, such as humans, relatively minor injuries in crucial areas or at critical times during development could have profound effects on long-term cognitive and executive function. Accordingly, cognition may be altered by briefer periods of anesthetic exposure in children, compared with animals functioning on a simpler cognitive level.

ANESTHETIC DOSES

Animals are subjected to greater weight-based doses of injectable anesthetics, sometimes by orders of magnitude, compared with doses commonly used in human clinical practice. In the discussion of whether these doses have applicability to pediatric anesthesia practice, it is important to understand that small animals require significantly greater weight-based doses of IV anesthetics to produce immobility than larger animals or humans. These differences can be explained, in large part, by the animals' smaller size, greater metabolic rate, and shorter physiologic time compared with humans.[324] Using a process called allometric scaling, which takes the differences among species into account, doses for injectable drugs in animals comparable with human doses have been estimated to be approximately 3-, 6-, or 12-fold greater for monkeys, rats, or mice, respectively (see also Chapter 7).[324,325] Whereas drug doses used in anesthetic neurotoxicity studies frequently still exceed these comparable doses calculated using allometric scaling, they do not include a significant safety margin (Fig. 25.5). Using allometrically scaled doses, plasma concentrations for ketamine, for example, were approximately 3 to 10 times greater in small rodents and monkeys than those observed during clinical human practice.[151,159] This might suggest that the neurotoxic properties observed with large doses of injectable anesthetics, such as ketamine, could potentially have direct applicability to humans only if the anesthetic and the neurotoxic effects were based on the same molecular mechanism, which has yet to be verified. Otherwise, animal studies would expose subjects to much greater plasma concentrations of potential neurotoxicants than those used during anesthesia in humans, thereby leading to an

overestimation of the neurotoxic effects of IV anesthetics in laboratory studies.

Doses for inhaled anesthetics generating immobility in animals, on the other hand, are much closer to clinically used doses. Moreover, similar to human anesthesia, potency of inhaled anesthetics increases with subject age, necessitating larger doses in younger animals,[76,262,326] which could suggest closer clinical applicability of laboratory data using these compounds.

EXPERIMENTAL VERSUS CLINICAL CONDITIONS

Another important distinction between laboratory studies in animals and clinical practice in humans is the presence of significant comorbidities and underlying disease, the genetic diversity in human populations, as well as the frequent occurrence of stress and pain associated with surgical procedures. Very few laboratory studies have examined the effects of surgical stress and pain on anesthesia-induced neurotoxicity. When tail clamping or injection of caustic substances were used to model surgical stress, results have varied; one study reported no influence of the painful stimulus on anesthesia-induced apoptosis,[234] whereas a second reported that painful stimulation increased anesthetic-induced neuroapoptosis.[140] Conversely, pain-induced neurodegeneration was ameliorated by coadministration of small doses of analgesics or sedatives.[161,202] It is therefore unclear whether noxious stimuli in the perioperative setting exaggerate the anesthesia-induced toxicity or whether the two deleterious effects cancel each other out.

Studies that measured metabolic and respiratory variables during anesthetic exposure in small rodents reported significant abnormalities not routinely observed during pediatric anesthesia practice, such as extensive hypercarbia, metabolic acidosis, and hypoglycemia.[119,121,262] Tracheal intubation and mechanical ventilation do not necessarily completely obviate all of these abnormalities in rodents.[262] In stark contrast to anesthesia in children, administering clinical doses of anesthetics for periods greater than 4 hours can be lethal for up to 20% of small rodents,[119] even when intermittent painful stimuli are applied.[121] However, the growing evidence from nonhuman primate studies, in which animals were tracheally intubated, ventilated, had vital signs stringently monitored, and lacked mortality during anesthetic exposure, but still demonstrated comparable neuronal injury patterns observed in rodents,[141,181,226] suggests that the short-comings in physiologic conditions in small animal studies does not eliminate their potential biologic relevance to humans. Moreover, rearing conditions after anesthesia have a profound impact on the brain's repair mechanisms after injury. Environmental enrichment and exercise dramatically increase neurogenesis in rodents and therefore may facilitate plasticity and repair after anesthesia, compared with the customary bare cage housing environment of rodents.[327,328] Comparably, children face daily cognitive challenges in their normal "enriched" environment, substantially different from normal laboratory animal housing,[92,127,159,178] which could attenuate the postulated neurocognitive effects of anesthesia in humans. This is highlighted by recent animal studies in which environmental enrichment reversed the deleterious effects of prolonged or repeated anesthetic exposures on subsequent neurologic performance in rats.[234,329] These studies suggest that neurobehavioral outcomes depend on multiple factors, of which anesthesia represents only one of many other events important for the developing brain.

COMPARATIVE BRAIN DEVELOPMENT

A major challenge in translating any animal data to human clinical practice is properly matching brain maturational stages between model species and young children. The ongoing discussion regarding these comparisons is somewhat reminiscent of the cliché of 1 "dog year" being equivalent to 7 "human years." Because earlier animal studies have suggested that anesthesia-induced structural abnormalities may be most pronounced during very defined, early stages of development, such as neuroapoptosis in cortex and thalamus peaking between 3 and 10 days of age in small rodents[19,102] or between gestational day 120 and day 6 of life in rhesus monkeys, it becomes imperative to appropriately identify the equivalent period during human brain development to assess human applicability of the animal data and to adequately design clinical studies.

Brain architecture and development, however, both in magnitude and timing, vary widely among mammalian species. Small rodents, such as mice and rats, have a smooth (or lissencephalic) brain surface, whereas humans and monkeys exhibit the typical fissured, gyrencephalic brain surface of gyri and sulci. Overall brain size and the number of neurons differ by orders of magnitude between humans and animal species; the mature human brain contains approximately 86 billion neurons, compared with the rhesus macaque's 6 billion and the adult mouse brain's 70 million neurons.[330] Other important species differences exist in timing and duration of critical developmental events. Rodents are altricial species, meaning considerable steps of brain development occur postnatally during their first 2 to 3 weeks of life, whereas numerous critical developmental steps take place in utero in monkeys and humans.[314] Given these substantial differences, it is difficult to unequivocally associate specific ages in animals to humans. Older data based on simple species comparisons of brain growth equated the first week of life in small rodents, when the peak of vulnerability to anesthetic neuroapoptosis occurs for most brain regions, to an extended time span in humans from the third gestational trimester all the way to the third year of life.[4,24,315] However, more contemporary approaches using computational models have approximated the 7-day-old rat or mouse to be closer in brain maturity to human fetuses during the third trimester of pregnancy, whereas the immature rhesus monkey 5 to 6 days old seems closer to the postnatal human brain in infancy (Fig. 25.6).[316–318,331] According to these models, stages of brain maturity equivalent to term human neonates are not reached until after postnatal days 10 to 14 in rats or mice (online calculator available at http://www.translatingtime.net, accessed October 2016). In general, the majority of in vivo laboratory studies examine animals during developmental stages equivalent to the very immature human brain (Fig. 25.7). Importantly, in aggregate, animal data do not clearly identify a "safe" age beyond which no deleterious anesthetic effects can be observed.[2]

Interestingly, limited human data seem to suggest that postnatal brain development may be most susceptible to anesthetic or sedative exposure, whereas animal studies, including a recent nonhuman primate study,[141] demonstrate a greater degree of neuroapoptosis after exposures that model the premature human brain. However, substantial differences in brain development still exist between humans and nonhuman primates. In general, development progresses at a much slower pace in humans compared with any other model species, including nonhuman primates, and developmental stages are up to 50% longer. Even on a cellular level, remarkable differences exist between humans and all other animals; cell cycle duration during cortical neurogenesis is approximately 17 hours in mice, 28 hours in macaque monkeys, and 36 hours in humans.[323] All these differences indicate that it is not sensible to directly equate observations of anesthetic effects in the developing animal brain of any species to human clinical

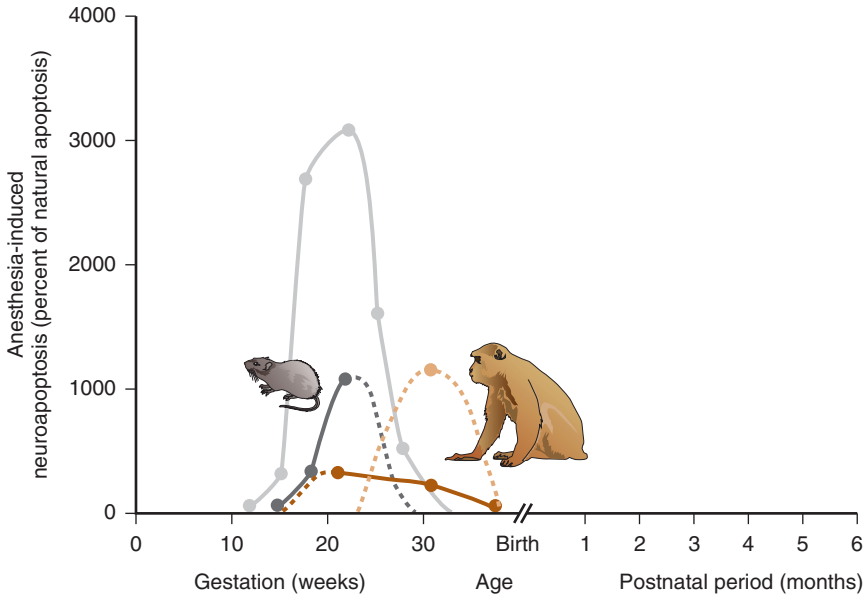

FIGURE 25.6 The degree of neuronal apoptotic cell death following anesthetic exposure is highly dependent on the age of the animal during exposure. Graphs demonstrate the percent increase of apoptotic cell death compared with natural apoptosis following an exposure to an isoflurane/nitrous oxide–based anesthetic in immature rats (*dark grey*) or very young macaque monkeys (*dark brown*) or prolonged exposure to ketamine in immature rats (*light grey*) or macaque monkeys (*tan*). *Solid lines* connect the available data points; *dashed lines* represent extrapolations of the available data. Neurotoxicity data were derived from references 19, 105, 127, and 159. To infer the potential age of anesthetic vulnerability in humans, respective brain maturity in the animal species during exposure was equated to the corresponding state of the developing human brain, and relative human ages for each data point were plotted accordingly, using a mathematical model outlined in references 317, 318, and 331, which is available in the online calculator at http://www.translatingtime.net (accessed May 2016).

anesthesia practice. The potential long-term effects of anesthetics therefore have to be carefully examined in clinical studies before accepting results obtained in animals.

ASSESSING NEUROBEHAVIORAL OR COGNITIVE OUTCOMES

Translating neurodevelopmental outcomes from animals to humans is difficult. Human cognitive performance includes the vast capacity for learning, the ability for abstract thinking, the aptitude for solving complex mathematical equations, and even the capability of inventing and operating complex machinery. Cognition is a complex process that includes such diverse processes as perception, attention, motivation, working memory, long-term memory, executive function, language, and social cognition. These brain functions are all difficult to model in animals.[319] It is therefore imperative to critically evaluate any animal model attempting to replicate human cognitive performance. Moreover, it is important to assess the validity of these models in the context of the critical period for human brain development that they are trying to represent. Current assessment of neurocognitive performance after developmental exposure largely relies on hippocampal-dependent tests administered to adult animals after anesthetic exposure early in life.[100,119–121,178] However, it remains unclear whether these are the same domains that may potentially be targeted in children during anesthesia. Brain regions maximally affected by anesthesia may depend on their state of development and therefore change with the age of the organism during exposure.[92,181] Accordingly, subsequent neurobehavioral abnormalities may vary, depending on the age at which anesthesia was administered.

This discussion, however, does not entirely discredit the results from small animal studies, but rather seriously limits the generalizability of their findings to clinical practice. More closely resembling clinical pediatric anesthesia practice, several large-animal models have used tracheal intubation and mechanical ventilation.[92,127,141,181] However, these large-animal studies have only included minor stimulation, such as skin clamping, but not surgical stimulation during the anesthetic exposure.[92,127,159,178]

Long-Term Outcome in Children Exposed to Anesthesia and Surgery

The difficulties in translating animal data to clinical anesthesia in human infants increase the importance of identifying potential clinical evidence for or against neurologic abnormalities in children after otherwise uneventful anesthesia early in life. Unfortunately, this question is not easily answered.

Examining outcomes reported for surgical cohorts, there is evidence for an association between surgery with anesthesia in early childhood and subsequent altered neurodevelopmental outcome.[39] Some human cohort studies have demonstrated an association between major surgery in the neonatal period and poor neurodevelopmental outcome.[332] Children born with esophageal atresia, for example, had a lower IQ and more frequently suffered from depression, emotional, and behavioral problems compared with the general population.[333] Children with congenital diaphragmatic hernia repair also have a high rate of neurologic sequelae.[334] Extremely premature, low–birth-weight neonates who

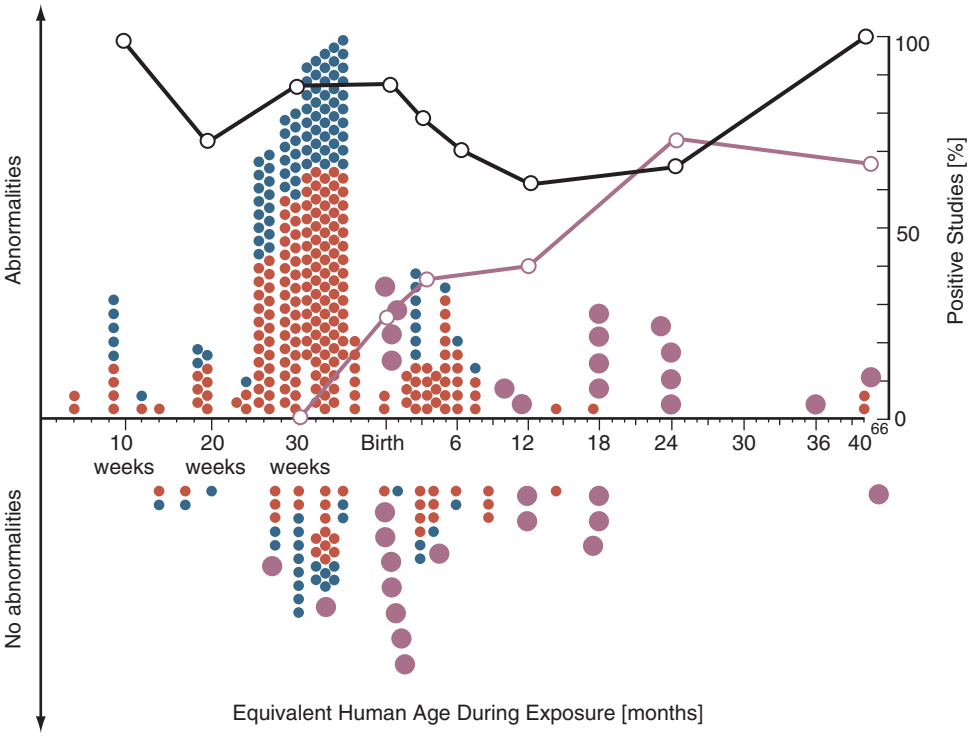

FIGURE 25.7 The majority of in vivo animal studies into the effects of anesthetic exposure on brain structure and function focus on brain developmental stages equivalent to premature neonates. Studies with negative results never outnumber those with positive results at any time point, suggesting that no age can be clearly identified at which anesthetics do not cause abnormalities. Animal studies, inclusive of various anesthetic drugs and doses, reporting abnormal findings (above the horizontal line) or negative findings (below the horizontal line) for brain structural (*solid red circles*) or cognitive outcomes (*solid blue circles*) are depicted as a function of maturational age of the animals' brain relative to the human brain during exposure. *Solid purple circles* represent clinical studies into long-term cognitive outcomes in humans. The animals' age during exposure was converted to the corresponding maturational stage of the human brain by using a computational neurodevelopmental model (www.translatingtime.net, translating "neurogenesis" for "whole brain," accessed 10/6/2016). For the purpose of analysis, reports with separate anesthetic protocols consisting of different anesthetic regimens or multiple exposure times of the same anesthetic were classified as separate studies. For repeated exposures at different ages, the equivalent mean age of the human brain is reported. The graphs express the ratio of studies with positive findings to those with negative finds in animals (*black*) or humans (*purple*); *open circles* represent the respective percentage of positive studies for age epochs ranging from specific data points to next lower data point on the graph. Note that animal studies with positive findings outnumber those studies with negative findings from conception until 40 months' equivalent age in humans, while this ratio does not turn positive for human studies until exposures between 12 and 24 months of age. (From Lin EP, Lee J-R, Lee CS, et al. Do anesthetics harm the developing human brain? An integrative analysis of animal and human studies. *Neurotoxicol Teratol.* 2017;60:117–128.)

underwent laparotomy exhibited poorer neurodevelopmental outcomes compared with matched controls.[335] A cohort of infants who underwent major surgery did not perform as well in school as a matched control group of healthy infants or with infants who had major nonsurgical medical conditions.[336] In a randomized trial of indomethacin treatment in 426 infants less than 1000 g at birth, neurologic impairment was present in significantly more of the 110 children who had undergone surgery (53%) compared with that in the 316 children who had received medical therapy (34%).[337] In a study of extremely preterm infants, the IQ of those who had undergone surgery was lower at 5 years of age and exhibited more sensorineural disability than those who had not undergone surgery.[338]

These studies all included infants with major confounding factors, such as congenital malformations or very preterm birth, which might increase the risk of poor neurodevelopmental outcome independent of surgery and anesthesia. Preoperative brain lesions and white-matter injury have been observed in a substantial number of neonates suffering from major congenital heart disease.[339–343] Moreover, surgery itself can lead to poor outcome as a result of the perioperative neurohumoral and inflammatory response, or the hemodynamic instability associated with major surgery. Severity of illness may have also been greater in surgical patients compared with their respective control groups. Moreover, selection bias may have resulted in the sicker children being treated with surgery, while less severely ill children received medical therapy. Thus, whereas these studies suggest that some infants undergoing major surgery are at increased risk of poor neurodevelopmental outcome, none of the studies provide conclusive evidence that surgery or even anesthesia is the cause of the increased risk of poor neurodevelopmental outcome.

Several recent cohort studies and one randomized controlled trial have focused primarily on the effects of anesthesia in healthier children undergoing surgical procedures early in life. In an

established population–based, retrospective birth cohort, Wilder and colleagues studied the association between anesthetic exposure before 4 years of age and the subsequent development of learning disabilities.[344] Regression was used to calculate hazard ratios (HRs) for anesthetic exposure as a predictor of learning disability, with adjustment for gestational age at birth, sex, and birth weight. Of 5357 children in the cohort, 593 had been exposed to general anesthesia before 4 years of age. Compared with those not exposed to anesthesia, a single exposure was not associated with an increased risk of learning disability (HR 1.0; 95% confidence interval [CI] of 0.79–1.27). However, children who underwent two separate episodes of anesthesia had an increased risk of a learning disability (HR 1.59; 95% CI 1.06–2.37) and those who underwent 3 or more separate anesthetics had an even greater risk (HR 2.60; 95% CI 1.60–4.24). The association between learning disability and multiple episodes of anesthesia remained after adjusting for American Society of Anesthesiologist physical status. The risk for a learning disability also increased according to the cumulative duration of anesthesia. However, this study suffered from several limitations. Because the study reported anesthetics administered between 1976 and 1982, the most common anesthetic treatment was halothane and nitrous oxide, and none of the children were monitored with pulse oximetry or capnography. It is not possible to determine in how many of these children excessive hyperventilation or unrecognized desaturation had occurred. Furthermore, the maternal birth histories were not described (e.g., magnesium may cause neuroapoptosis or be neuroprotective). Three different learning disabilities were considered with equipoise in the final analysis, and these disabilities were not tested in all children, but only when a teacher or parent requested testing. These questions limit the external validity of these data.

To reduce the impact of confounding factors, using the same population-based, retrospective birth cohort, the same group conducted further studies with a matched cohort design.[345] The researchers matched 350 children exposed to anesthesia before the age of 2 to 700 children not exposed to anesthesia. The matching was based on several known risk factors for learning disabilities: gender, mother's education, birth weight, and gestational age at birth. Outcomes of interest were learning disability, need for individualized education program for an emotional or behavioral disorder, and group-administered achievement tests. In the analysis, an adjustment was also performed for burden of illness. The primary finding was that children exposed to two or more occurrences of anesthesia (but not a single occurrence) were at increased risk for having a learning disability (HR 2.12; 95% CI of 1.26–3.54), and an amplified need for individualized education programs for speech and language impairment. However, there was not an increased need for a program for emotional or behavioral disorders. The authors also detected an association between multiple exposures to anesthesia and lower mathematical scores. The same criticisms apply to this study as to the earlier study from this institution.[344]

To investigate a potential association between perinatal exposure to general anesthesia during cesarean delivery and subsequent diagnosis of learning disability,[346] the risk of a learning disability was compared in the 193 children delivered via cesarean section with general anesthesia, the 304 delivered via cesarean section with regional anesthesia, and 4823 delivered vaginally without any anesthesia. The association between mode of delivery and learning disability was adjusted for sex, birth weight, gestational age at birth, exposure to anesthesia before 4 years of age, and maternal education. The risk of disability was similar between children delivered vaginally with no anesthesia and cesarean delivery with general anesthesia, but risk of disability was less in children delivered via cesarean with regional anesthesia than vaginal delivery with no anesthesia (HR 0.64; 95% CI 0.44–0.92; P = .017). The results implied that brief exposure to general anesthesia during delivery was not associated with subsequent learning disability, but the reason the risk was less with regional anesthesia compared with no anesthesia is unclear, although this may suggest the possibility of substantial confounding influences. To explore the possibility that the regional blockade was protective, the authors subsequently compared those born without general anesthesia by vaginal delivery with and without regional analgesia and found no difference in risk of learning disability.[347] Using the same epidemiologic cohort, the same research group detected an increased prevalence of attention deficit hyperactivity disorder in children who had undergone repeated surgical procedures with anesthesia, compared with none or only one exposure.[348]

A small pilot study (in 314 children) to test the feasibility of using a cohort of children who had urologic surgery to test the association between age at surgery and neurobehavioral outcomes (measured with the Child Behavior Checklist)[349] found no evidence of an association between the timing of surgery and neurobehavioral outcomes.

Another retrospective cohort analysis using the New York State Medicaid records matched 383 children who underwent hernia repair before 3 years of age with 5050 children who did not undergo inguinal hernia repair.[350] After adjustment for sex, age, and complicating birth conditions (such as low birth weight), children who had hernia repair were more than twice as likely to have a subsequent diagnosis of a developmental or behavioral disorder (HR 2.3; 95% CI 1.3–4.1).

To reduce environmental confounding effects, the authors then proceeded to use the data from the New York State Medicaid program to construct a retrospective sibling birth cohort.[351] Once again, they assessed the association between exposure to anesthesia in children younger than 3 years of age and the subsequent risk of diagnosis of developmental or behavioral disorders. A total of 10,450 siblings were identified, 304 of whom underwent surgery before 3 years of age, with no history of behavioral or developmental disorders before the surgery, and 10,146 children who did not undergo surgery. The association of exposure to anesthesia with subsequent developmental or behavioral disorders was assessed with both proportional hazards modeling and pair-matched analysis. As with their previous study, they found evidence for an association between surgery and poor neurodevelopmental outcome. The incidence of developmental or behavioral disorders was 128.2 diagnoses per 1000 person-years for those who had surgery and 56.3 diagnoses per 1000 person-years for those who did not. This association persisted when adjusted for sex, history of birth-related medical complications, and clustering by sibling status; the estimated HR of developmental or behavioral disorders associated with any exposure to anesthesia was 1.6 (95% CI 1.4–1.8). The risk increased from 1.1 (95% CI 0.8–1.4) for one operation to 2.9 (95% CI 2.5–3.1) for two operations and 4.0 (95% CI3.5–4.5) for three or more operations. The number of siblings available for a matched analysis was relatively small. There were only 138 sibling pairs. In the pair-matched study, there was no evidence of an association between surgery and poor outcome, with a relative risk of 0.9 (95% CI 0.6–1.4); however, the small numbers may limit the power of this analysis.

Even better than sibling studies are investigations involving identical twins, which may further reduce confounding environmental and genetic influences. Performing such a study, Bartels

and associates examined the possible association between anesthesia exposure before 3 years of age and school performance in 1143 monozygotic twin pairs.[352] In the identical twins who were discordant for exposure to anesthesia (one twin was exposed to anesthesia and the other was not), their school performance was identical. This would suggest that surgery with anesthesia may not be the cause of poor school performance. Interestingly, the school performance in both the discordant pairs and the pairs where both twins underwent surgery was poorer than that for concordant twin pairs where neither twin was exposed to anesthesia. This finding could imply that there may exist an unknown genetic factor that increases the risk of both the need for surgery and poor school performance.

The Western Canadian Complex Pediatric Therapies Follow-Up Group published a prospective follow-up study of 95 infants at 2 years of age who underwent surgical correction for congenital heart disease at the Alberta Children's Hospital from April 2003 to December 2006.[353] A multiple logistic regression analysis of variables associated with developmental delay found that only more days of ventilatory support postoperatively and older age at surgery were associated with significant developmental delay. There was also no evidence for an association between the sedation variables and significant motor delays. However, the use of two neurocognitive assessment tools during the study period precluded an analysis of the cognitive and motor scores as continuous variables, which may have been a more sensitive way to detect subtle impairment.

Hansen and colleagues used a very large Danish birth cohort to compare academic performance in 2689 children who had inguinal hernia repair in infancy with 14,575 children who were randomly selected as an age-matched sample from the general population.[354] Those who had hernia repair performed worse at school, although after adjusting for likely confounding variables, there was no evidence of any association between surgery and school performance. A similar but smaller study conducted in Iowa[355] in which investigators reviewed school test scores in 287 children who had surgery in infancy determined that scores in surgical infants were slightly less than in the general population. However, 12% had scores in the lowest 5th centile in the general population. In a subset of 58 children with no risk factors for neurodevelopmental issues, test scores were not below the average for the population, although 14% still scored in the lowest 5th percentile. These results suggest that a subset of the population may be particularly vulnerable.

Two similar population-based Canadian cohort studies examined the association between surgery in young children and their Early Development Index (EDI). The EDI is a test of readiness for school. The 103-item questionnaire is completed by teachers when children are 5 years of age. It has five domains: physical health and well-being, social knowledge and competence, emotional health and maturity, language and cognitive development, and communication skills and general knowledge. Both studies assessed the association between surgery and their EDI using data from the entire province of Ontario. The 28,366 children who had surgery before they performed the EDI[356] were compared with 55,910 controls who did not have surgery but were matched for gestational age at birth, mother's age at birth, rurality, gender, and year and quarter of birth, and excluded children with known physical disability health-related causes of impaired development, and those with a diagnosis of behavioral, learning, or developmental disorder. The primary outcome was defined as vulnerable (scoring in the lowest 10th percentile in any domain). They also adjusted for aboriginal status, age, and household income. Vulnerability was increased slightly in those who had surgery: 7,259/28,366 (25.6%) compared with 13,957/55,910 (25%) controls (odds ratio 1.05; 95% CI 1.01–.08). Interestingly, the odds of vulnerability were increased in those younger than 2 years at the time of surgery (odds ratio 1.05; 95% CI 1.01–1.10), whereas the odds were not increased in those older than 2 years at the time of surgery (odds ratio 1.04; 95% CI 0.98–1.10). They also found no evidence of increased vulnerability in those who had multiple surgeries. In another study, 4470 children who had surgery in Manitoba before the age of 4 were matched with 13,586 controls for gestational age at birth, mother's age at birth, rurality, income quintile, gender, and year of birth.[357] They excluded children with a diagnosis of any developmental disability. In their analysis, the authors adjusted for welfare status, gestational age, small or large for dates, mother's age at birth, child's age and Johns Hopkins Resource Utilization Band. As in the Ontario study, these investigators reported a small difference with children who had surgery performing worse than those who had not had surgery. However, the domains in which they performed poorly were not consistent with the Ontario study. Like the Ontario study, the Johns Hopkins study detected evidence for an association in children who had surgery at age greater than 2 years of age but no evidence for any association if surgery occurred at less than 2 years of age. They also found no evidence of a greater risk in those who had multiple surgeries compared with those who underwent only one surgery. While findings in these two studies may seem inconsistent with nonhuman studies, suggesting a greater risk in younger children, exposures in the older patients could have more severely affected vulnerable neuronal networks used in the later performance of the assessed tasks. Alternatively, the association seen in these cohort studies could be due to factors other than the neurotoxicity observed in animal studies.

The above studies relied on a diagnosis of a learning or behavioral disorder or school grades as an outcome measure. Although important outcomes for daily activities, these measures are not sensitive and may miss more subtle deficits in specific neurodevelopmental domains.[358] Several studies have used more detailed neuropsychological tests.

A number of investigations examined the association between surgery and neurodevelopmental outcome using the Western Australian Pregnancy Cohort (Raine). In one analysis they found an association between language and abstract reasoning deficits in 10-year-old children who were exposed to one or more anesthetics before age 3 years compared with unexposed children. After adjusting for confounders, any anesthetic before age 3 years increased the risk ratio of disability in receptive, expressive, or total language as measured by the Clinical Evaluation of Language Fundamentals (CELF-3) test, as well as abstract reasoning (Raven's Colored Progressive Matrices) to between 1.7 and 2.1 of unexposed controls, whereas other tests of vocabulary, behavior, and motor function were unaffected by exposure.[359]

The same authors performed a subsequent analysis, comparing the diverse outcome measures of neuropsychological testing, International Classification of Diseases, Ninth Revision (ICD-9)-coded diagnoses, and academic performance.[360] Of the 781 children who had all outcome measures, 211 had received an anesthetic before 3 years of age. Compared with the unexposed children, those who had received anesthesia demonstrated an increased risk of deficit in neuropsychological language assessment and an increased risk of an ICD-9-coded diagnosis of language or cognitive disorder. However, they did not demonstrate poorer academic performance. This finding highlights the limitations of using school

performance as a measure of neurodevelopmental outcome. In the subset of children who were exposed at older ages (3- to 5-year-olds and 5- to 10-year-olds), there was no association between exposure and any deficit in any neuropsychological test except for children exposed between 3 and 5 years of age who demonstrated worse scores on motor function tests.[360]

Another study used an established cohort of children 5 to 18 years of age that had magnetic resonance imaging (MRI) scans as part of a large language development study.[361] The cohort did not include children with any risk factors for poor neurodevelopmental outcome. Within this cohort, they found 53 children who had undergone surgery before the age of 4 and matched these to 53 peers who had not, matching on age, gender, and socioeconomic status. All children underwent a battery of neuropsychological tests and brain MRI. Exposed children scored lower in listening comprehension and performance IQ. Exposed children did not exhibit comparably decreased grey-matter density in the thalamus or retrosplenial cortex, as previously seen in rodent studies, but instead demonstrated diminished grey-matter volumes in the occipital cortex and cerebellum, associated with lower-performance IQ.

Studies in animals have also identified deficits in recognition memory tasks after general anesthesia. Recognition is based on recollection and familiarity. To test if humans had similar deficits in recollection, investigators studied 28 children aged 6 to 11 years who had undergone anesthesia in infancy compared with 28 age- and gender-matched controls.[362] They found that scores in tests of recollection in exposed children were less than in unexposed children, but scores in tests of IQ, behavior, and familiarity were similar.

Perhaps the most important cohort study is the Pediatric Anesthesia and Neurodevelopment Assessment (PANDA) study.[363] In this bidirectional cohort study, 105 children aged 8 to 15 years who had surgery for inguinal hernia repair before 3 years of age were compared with 105 matched siblings who were of similar age at testing but did not undergo surgery early in life. Children underwent a range of well-validated neuropsychological tests. The choice of tests was based on their psychometric properties and on their relevance to animal data and previous cohort study findings. The primary outcome was full-scale IQ. The median duration of anesthesia exposure was 80 minutes. There was no evidence for a difference in any of the IQ domains. In the exposed cohort, full-scale IQ was 111, performance IQ was 108, and verbal IQ was 111, while in the unexposed siblings full-scale IQ was 111, performance IQ was 107, and verbal IQ was 111. Differences in mean IQ scores between exposed and unexposed siblings for full-scale IQ were 0.2 (95% CI, –2.6 to 2.9); performance IQ, 0.5 (95% CI, –2.7 to 3.7); and verbal IQ, –0.5 (95% CI, –3.2 to 2.2). There was also no evidence of differences in secondary outcomes that included memory and learning, motor and processing speed, visuospatial function, attention, executive function, or language. Exposed children did, however, have poorer scores in some aspects of behavior even when adjusted for gender. Subanalyses that addressed age at the time of exposure and duration of exposure reported no effects of either variable on outcome, although these analyses had limited power. This study is by far the most rigorous cohort study and provides strong evidence that approximately 1 hour of exposure to anesthesia in early childhood is unlikely to cause significant cognitive impairment at a later age.

Cohort studies are inherently limited by the risk of confounding. Adjustments in the analyses can never completely remove the risk that the association is due to a factor apart from anesthesia. Only randomized trials can reliably reduce the risk of confounding. Randomized trials are obviously difficult to perform as it is impossible to randomize to anesthesia versus no anesthesia for children undergoing surgery. It is, however, possible to randomize to two different anesthetic techniques. To date, the General Anaesthesia compared to Spinal anaesthesia trial (GAS) is the only randomized trial that has examined the effect of different anesthetic regimens in infancy on neurodevelopmental outcome.[364] In the GAS study, 722 infants younger than 60 weeks postmenstrual age were randomly assigned to awake-regional (nearly always spinal anesthesia) or sevoflurane general anesthesia for inguinal hernia repair. In this study, the median duration of sevoflurane exposure in the general anesthesia group was 54 minutes. The spinal failure rate was 19% and the loss to follow-up was 14%. The primary outcome was the Wechsler Preschool and Primary Scale of Intelligence, Third Edition (WPPSI-III) full-scale IQ at 5 years of age. These data will be available in 2018. The cognitive score of the Bayley-III scale at 2 years of age was a prespecified secondary outcome and these results have been published.[364] The Bayley-III has five domains: cognitive, language, motor, social emotional, and adaptive behavior. There was strong evidence of equivalence in all domains. In the per-protocol analysis using multiple imputation, the mean difference (awake regional – general) in the cognitive composite score adjusted for gestational age at birth was 0.17 (95% CI –2.30 to 2.64). This was within the predefined equivalence margin of 5 points. The difference in language was 1.15 (95% CI –1.59 to 3.88), motor 0.60 (95% CI –1.77 to 2.97), social emotional 1.0 (95% CI –3.12 to 5.13) and adaptive behavior –0.89 (95% CI –3.52 to 1.73). The results were similar in intent-to-treat and complete case analyses, implying spinal failure and loss to follow-up did not bias the results. However, the trial had three important limitations: first, the relatively brief anesthetic exposure (54 minutes), second, the lack of sensitivity to test higher executive function and memory with the Bayley scale at 2 years of age, and third, only one anesthetic was administered.[365] Accordingly, future studies are need to address these limitations.

Outcome After Exposure to Anesthesia Outside of the Operating Room

The operating room is not the only area where anesthetic neurotoxicity may be relevant. Ketamine and benzodiazepines are frequently administered in the emergency room and in neonatal and pediatric intensive care units. These drugs may be administered for a prolonged period of time, in theory increasing the risks of neurotoxicity.[55,57]

Unfortunately, determining the clinical relevance of any neurotoxicity in intensive care patients is even more difficult than in the operating room. The total number of children who can be examined is smaller, the children tend to be a heterogeneous population, and most importantly, they often have multiple significant confounding comorbidities including exposure to anesthesia, which could significantly affect interpretation of adverse outcomes. To date, there is mixed evidence that exposure to anesthetic or sedative drugs is associated with poorer neurobehavioral outcome in this patient population. A Cochrane review found some evidence for worsened short-term outcome in neonates who had prolonged exposures to midazolam infusions.[366] In contrast, after correction for severity of illness, another study (using the Etude EPIdémiologique sur les Petits Ages GEstationnels [EPIPAGE] cohort) found no evidence of an association between prolonged sedation and adverse neurologic outcomes.[367] In that

study, however, many children received opioids for sedation rather than benzodiazepines and the study was not powered to detect performance differences of less than 10%.

Limitations of the Available Clinical Studies

There are numerous reasons the clinical data on neurobehavioral outcomes after anesthesia are difficult to interpret, and it is perhaps not surprising that the earlier clinical studies return conflicting results. Because of their retrospective nature, several of these studies require mathematical adjustments, such as multiple logistic regression analyses for confounding variables. This limits the findings to known or suspected confounders and does not address as yet unknown variables that may be more important to the outcome.

Epidemiologic studies are generally unable to separate the effects of surgery or the need for surgery from the potential anesthetic effects. As previously discussed, surgery may result in significant neurohumoral stress and/or inflammatory responses that may influence neurocognitive outcome in addition to metabolic, hemodynamic, and respiratory events that occur perioperatively. Data collection for several of the epidemiologic studies occurred before continuous pulse-oximetry and capnography monitoring were standard monitors and at a time when inhalational anesthetics with profound adverse cardiovascular effects such as halothane, were used.[344,345] Prospective studies of capnography and pulse oximetry have demonstrated that the very population considered to be at increased risk (those <2 years of age) had the greatest incidence of desaturation events, hypercarbia, and hypocarbia.[368–370]

Children undergoing surgery or diagnostic procedures early in life may suffer more frequently from concomitant chromosomal and genetic abnormalities or comorbidities such as prematurity, which have been linked to abnormal neurobehavioral outcomes. For example, children with cyanotic congenital heart disease often have abnormal neurocognitive development and some have smaller brain volumes before any surgical or anesthesia intervention.[303] The indication for surgery or for a diagnostic procedure requiring anesthesia, such as injury or infection, may artificially increase the incidence of neurodevelopmental abnormalities in the anesthetized cohort.[303] On the other hand, it has been argued that subjects suffering from underlying abnormalities adversely affecting neurodevelopment who do not receive the required surgery may be introduced into the pool of unanesthetized children, and therefore mask potentially toxic effects of anesthesia.[59]

Further complicating the interpretation of retrospective data is the substantial gap in time between exposure and neurologic assessment. The advantage of performing neurologic assessments in school-age children includes the increased precision and greater predictive value of such assessments compared with neurobehavioral testing performed for children younger than 2 years of age, for both prospective and retrospective studies.[371] However, especially in retrospective studies that cannot adequately control for confounders, the protracted time interval between surgery and the neurocognitive assessment may introduce even more "noise" into the study by increasing the time for negative influence of other environmental confounders of brain development or, conversely, the positive effects of repair mechanisms and plasticity to affect neurologic outcome.

Current animal studies do not provide sufficient guidance on the most vulnerable brain regions, the individual neurocognitive domains that may be affected, or the particular age at which the human brain may potentially be most susceptible to the neurotoxic effects of anesthetic exposure.

No consensus exists, even in the animal literature, concerning the duration of anesthesia exposure required to induce long-lasting injury. Although the anesthetic exposure may represent a much larger fraction of an animal's life than a human's, at the cellular level apoptosis is likely triggered by a more similar duration of exposure. However, both cell cycle duration and the developmental period of the brain are considerably greater in humans than in rodents. It is therefore plausible, if an anesthesia-induced increase in apoptosis does occur in humans during a prolonged anesthetic exposure, that it may be functionally less important than the same increase in apoptosis over the same period of time in a rodent. Similarly, the plasticity and capacity for recovery may differ between species. On the one hand, it can be argued that the period of development in humans is greater than it is in animals, and hence there may be more time for recovery, but on the other hand, this may extend the potentially vulnerable period in humans into adolescence. Moreover, human development and subsequent cognitive performance are far more complex than in animal species and humans may therefore be more vulnerable, even following less severe neurodegeneration than that observed in laboratory studies. Injuries during critical periods of development may have an exaggerated effect compared with the same injury outside of these periods.[314,372] Accordingly, studies that find no evidence of association with shorter exposures may not be generalizable to all applications of anesthesia.

As children grow they develop additional skills and abilities, and wider arrays of psychometric tests can be applied to evaluate these more extensive neurobehavioral domains. However, we currently lack adequate information on which specific domains to examine in humans following anesthetic exposure, complicating the interpretation of human cohort studies. Many of these studies use summary scores, such as IQ or average school grades. These outcome measures may miss subtle effects confined to specific neurobehavioral domains. Similarly, a diagnosis of developmental delay or behavioral problems may also miss more subtle changes in particular areas. In contrast, broad batteries of detailed tests are increasingly likely to find at least one association purely by chance.

The vulnerable period in humans, if it exists, has not been clearly identified. Animal data seem to suggest that anesthetic exposure may be most relevant during pregnancy or in early infancy, but it could be possible that the period of vulnerability may extend beyond infancy and young age for some brain regions with ongoing neurogenesis. These critical uncertainties not only complicate the interpretation of published studies, but they also make the design of future prospective studies very difficult.

Lastly, the possible neuroprotective effects of anesthesia complicate this conundrum even further. Infants undergoing surgery who experience major intraoperative adverse events, such as cardiopulmonary arrest, are generally expected to suffer from abnormal neurologic outcomes, irrespective of their anesthetic exposure. Neurologic abnormalities observed after an otherwise uneventful procedure are considered neurotoxic effects of anesthesia. However, because anesthetics may also, at least partially, protect from the harmful metabolic, immunologic, and humoral responses to surgery and pain,[286] an alternative explanation may be that inadequate levels of anesthesia, insufficient postoperative pain relief, or unabated inflammation may be the culprit for the neurodevelopmental abnormalities observed in epidemiologic studies. It is also possible that anesthetics may protect in major adverse settings but may be deleterious in the absence of toxic

stimuli, causing injury during minor procedures but ameliorating injury during major surgery, such as complex heart surgery involving cardiopulmonary bypass.

In summary, for exposures of less than 1 hour in otherwise healthy infants, there is increasing evidence that there is no association between anesthetic exposure and poor neurobehavioral outcome in human studies. This is consistent with animal studies not detecting brain structural abnormalities or functional deficits after exposures of 1 hour or less. It is pertinent, however, to note that more prolonged exposures (up to several hours) more consistently lead to deficits in preclinical studies. Since there are no data in humans reporting the neurobehavioral effects of several hours of exposure to anesthesia, this should be addressed in future studies. However, collection of more definitive data supporting a deleterious role for anesthetics during brain development will continue to be complicated by uncertainties regarding the toxic threshold dose for anesthetics, the lack of information about the age of maximum susceptibility, and ambiguity related to the most appropriate neurobehavioral domains to examine. On the other hand, the positive associations between anesthetic exposure and learning abnormalities seen in cohort studies may be spurious because of sampling bias in selecting children in need of early-life surgery and the inability to separate anesthetic effects from those of surgery and related comorbidities.

Future Research

Further animal data will continue to provide information on the mechanisms of and susceptibility to anesthetic neurotoxicity. Understanding the mechanisms will be critical in translating the animal findings to clinical settings. Moreover, future animal work may also assist in determining which domains of neurobehavioral outcome are most likely to be affected, and this would assist in the design of human clinical trials. If neurotoxicity is found to be clinically relevant, animal data will also guide in devising prevention strategies.

Further human clinical studies must also be performed. Cohort studies will better identify children most at risk and characterize the neurobehavioral changes that occur.[373] Future cohort studies should focus on those with multiple or prolonged exposures. Because of the multiple confounding factors, cohort studies will always have great difficulty determining if the outcomes are a result of the surgery, the comorbidities, or the anesthetic exposure. Finding evidence for a lack of neurologic abnormalities in certain populations would provide some reassurance that laboratory studies in animal models lack immediate clinical relevance; however, it is important to note that such findings may not be automatically generalizable to all clinical settings.

To definitively answer this important health concern, clinical trials provide the strongest evidence. However, such trials are difficult to perform, as randomization to anesthesia or no anesthesia is impossible. It is, however, feasible to randomize to different types of anesthetic agents or approaches, such as regional versus general anesthesia. Finding a "nontoxic" anesthetic for longer procedures will be challenging. High-dose opioid with or without α_2-agonists might be a feasible nontoxic anesthetic for a trial. An international collaboration, the Trial of an alternative technique of Remifentanil and dEXmedetomidine (T-REX) study, is designed to investigate an alternative anesthetic for infants consisting of dexmedetomidine, remifentanil, and caudal anesthesia with either ropivacaine or bupivacaine for lower abdominal/extremity surgery (https://clinicaltrials.gov/ct2/show/NCT02353182). The study is now completed with 60 patients enrolled. Data at the time of this writing are being analyzed for feasibility and safety.

Even if anesthesia-induced neuroapoptosis is found to be clinically irrelevant, it is still important to recognize that there is a strong association between major surgery in neonates and abnormal neurobehavioral outcomes. Thus the questions become which other factors may be causing the poor outcome and which perioperative interventions could be performed by anesthesiologists to improve outcomes in these children.

Recommendations for Clinical Practice

The currently available laboratory data are not sufficient to make definitive recommendations for clinical pediatric anesthesia practice. As outlined previously, numerous laboratory studies have unequivocally documented deleterious effects of anesthetic exposure on the developing animal brain, including in nonhuman primates undergoing anesthetic management closely simulating clinical practice. Although these results should not be easily dismissed, the problems in translation from animal to human are substantial. Epidemiologic studies in children are contradictory; however, there is increasing evidence suggesting that a single, short exposure does not cause significant neurodevelopmental problems. However, as mentioned earlier, essentially no data exist about the neurobehavioral effects of prolonged exposure and the evidence pertaining to multiple exposures remains mixed and of poor quality.

SmartTots, a collaboration between the U.S. Food and Drug Administration (FDA) and the International Anesthesia Research Society (IARS) has produced a consensus statement endorsed by many pediatric anesthesia societies. (http://smarttots.org/about/consensus-statement/). The statement indicates that

The effect of exposure to anesthetic drugs in young children is unknown; however, some but not all studies have suggested that problems similar to those seen in animals could also occur in infants and toddlers. It is important to recognize that the studies in children suggest that similar deficits may occur. These studies in children have limitations that prevent experts from understanding whether the harmful effects were due to the anesthetic drugs or to other factors such as the surgery or related illness…. Because there is not enough information about the effects of anesthetic drugs on the brains of young children, it is not yet possible to know whether use of these medicines poses a risk, and if so, whether the risk is large enough to outweigh the benefit of the planned surgery, procedure, or test.

The statement goes on to advise health care providers to consider that

Clearly, anesthetic drugs are a necessary part of the care of children needing any surgery, procedure, or test that cannot be delayed. Decisions regarding the timing of a procedure requiring anesthesia should be discussed with all members of the care team as well as the family or caregiver before proceeding. The benefits of an elective procedure should always be weighed against all of the risks associated with anesthesia and surgery.

Parents are advised to

Discuss the timing of planned procedures with your child's primary care physician, surgeon/proceduralist and anesthesiologist. Concerns regarding the unknown risk of anesthetic exposure to your child's brain development must be weighed against the potential harm associated with cancelling or delaying a needed procedure.

Pediatric surgery is rarely entirely elective, and in neonates may be required to preserve life, such as for critical congenital heart disease, necrotizing enterocolitis, or congenital diaphragmatic

hernia. Accordingly, calls to postpone infant surgery are not easy to accommodate. Delaying surgery is also problematic, as no vulnerable or safe period has been clearly identified in animal studies to guide this practice. It might be reasonable to delay purely elective surgeries; however, these represent only a very small fraction of surgeries performed in children.

It is well documented that neonates are at an increased risk for respiratory and cardiovascular complications during anesthesia, which influences the choice of anesthetic technique and drugs used in this population. It would be very unwise to change practice based on concerns over anesthetic neurotoxicity, while potentially increasing the risks of cardiovascular or respiratory complications. Similarly, it must be stressed that insufficient anesthesia and analgesia are definitely associated with poor neurologic outcomes.

Lastly, when discussing the risks and benefits of anesthesia with parents, pediatricians, and surgeons, anesthesiologists need to be cautious not to cause undue alarm, while taking the matter of potential toxicity seriously and not hastily dismissing parental concerns.

ANNOTATED REFERENCES

Davidson AJ, Disma N, de Graaff JC, et al. Neurodevelopmental outcome at 2 years of age after general anaesthesia and awake-regional anaesthesia in infancy (GAS): an international multicentre, randomised controlled trial. *Lancet*. 2016;387:239-250.

The first human randomized trial to examine neurotoxicity comparing infants having awake regional or sevoflurane anesthesia; the authors found no evidence of a difference in neurodevelopmental outcome measured at 2 years of age.

Deng M, Hofacer RD, Jiang C, et al. Brain regional vulnerability to anaesthesia-induced neuronal cell death shifts with age during exposure and extends into adulthood for some regions. *Br J Anaesth*. 2014;113(3):443-451.

This animal study demonstrates that anesthesia-induced neuronal cell death varies by brain region, dependent on the age during exposure, and extends into adulthood in brain regions with ongoing neurogenesis.

Hofacer RD, Deng M, Ward CG, et al. Cell age-specific vulnerability of neurons to anesthetic toxicity. *Ann Neurol*. 2013;73(6):695-704.

This animal study supports the hypothesis that anesthesia-induced neurodegeneration is dependent on the age of the neuron, rather than the age of the animal, by demonstrating that 2-week-old neurons were most vulnerable to apoptosis during anesthetic exposure.

Ikonomidou C, Bosch F, Miksa M, et al. Blockade of NMDA receptors and apoptotic neurodegeneration in the developing brain. *Science*. 1999;283:70-74.

This paper represents the first study to examine the effects of anesthetic exposure early in life on brain structure, demonstrating widespread neuronal degeneration following repeated administration of ketamine in newborn rats.

Istaphanous GK, Howard J, Nan X, et al. Comparison of the neuroapoptotic properties of equipotent anesthetic concentrations of desflurane, isoflurane, or sevoflurane in neonatal mice. *Anesthesiology*. 2011;114:578-587.

This is the first study in animals to compare the neurodegenerative properties of equipotent doses of the three contemporary inhaled anesthetics with each other, finding no advantage of using one agent over another in regards to the degree of apoptotic neuronal cell death caused during exposure.

Jevtovic-Todorovic V, Hartman RE, Izumi Y, et al. Early exposure to common anesthetic agents causes widespread neurodegeneration in the developing rat brain and persistent learning deficits. *J Neurosci*. 2003;23:876-882.

This is a seminal study into the brain structural and long-term functional effects of a combined exposure to isoflurane, nitrous oxide, and midazolam in newborn rats, showing both increased neuroapoptosis immediately following exposure and long-term learning impairment.

Paule MG, Li M, Allen RR, et al. Ketamine anesthesia during the first week of life can cause long-lasting cognitive deficits in rhesus monkeys. *Neurotoxicol Teratol*. 2011;33:220-230.

This is the first study in nonhuman primates to link a prolonged exposure to ketamine very early in life to long-term neurobehavioral abnormalities.

Sun LS, Li G, Miller TL, et al. Association between a single general anesthesia exposure before age 36 months and neurocognitive outcomes in later childhood. *JAMA*. 2016;315:2312-2320.

This is the most definitive cohort study that compared children aged 5 to 8 years who had hernia repair before the age of 3 years with their siblings and found no evidence of a difference across a battery of neuropsychologic tests.

Wilder RT, Flick RP, Sprung J, et al. Early exposure to anesthesia and learning disabilities in a population-based birth cohort. *Anesthesiology*. 2009;110:796-804.

The authors provide one of the earliest epidemiologic studies to suggest an association between repeated exposure to surgery with anesthesia early in life to long-term neurobehavioral abnormalities in children.

CHILDREN WHO REQUIRE NEUROSURGICAL PROCEDURES present unique challenges to pediatric anesthesiologists. In addition to addressing problems common to general pediatric anesthesia practice, anesthesiologists must consider the effects of anesthesia on the developing central nervous system (CNS) of children with neurologic disease. This chapter reviews the age-dependent physiology of the CNS of children undergoing neurosurgical procedures requiring anesthesia and addresses some of the unique situations that anesthesiologists must face when anesthetizing children for neurosurgical procedures.

Pathophysiology

INTRACRANIAL COMPARTMENTS

The skull can be compared to a rigid container with almost incompressible contents. Under normal conditions, the intracranial space is occupied by the brain and its interstitial fluid (80%), cerebrospinal fluid (CSF, 10%), and blood (10%). In pathologic states, space-occupying lesions such as edema, tumors, hematomas, or abscesses alter these proportions. The Monro-Kellie hypothesis, elaborated in the 19th century, states that the sum of all intracranial volumes is constant. An increase in the volume of one compartment must be accompanied by an approximately equal decrease in the volume of the other compartments, except when the cranium can expand to accommodate a larger volume. Gradual increases in intracranial volumes, such as a slow-growing tumor or hydrocephalus, can be compensated by the compliant nature of open fontanelles and sutures in young children; increasing head circumference can result.[1] However, herniation can occur even in children with open fontanelles if large increases in intracranial pressure (ICP) develop acutely. In the nonacute situation, the brain can compensate for pathologic increases in intracranial volume by intracellular dehydration and reduction of interstitial fluid.[2–4]

Under normal conditions, CSF exists in dynamic equilibrium, with absorption balancing production. The rate of CSF production in adults is approximately 0.35 mL/minute or 500 mL/day.[5] The average adult has 100 to 150 mL of CSF distributed throughout the brain and subarachnoid space. Children have correspondingly smaller volumes of CSF, but the rate of CSF production is similar to that of adults.[5,6]

Production of CSF is only slightly affected by alterations of ICP and is usually unchanged in children with hydrocephalus.[6] Some drugs, including acetazolamide, furosemide, and corticosteroids, are mildly effective in transiently decreasing CSF production.[1,7,8] There is an inverse relationship between the rate of CSF production and serum osmolality; an increase in serum osmolality causes a decrease in CSF production. Choroid plexus papillomas causing overproduction of CSF are rare but are more likely to occur during childhood.

Absorption of CSF is not well understood, but the arachnoid villi appear to be important sites for reabsorption of CSF into the venous system. One-way valves between the subarachnoid space and the sagittal sinus appear to open at a gradient of about 5 mm Hg. Some resorption may occur from the spinal subarachnoid space and from the ependymal lining of the ventricles. Resorption increases with an increase in ICP. However, CSF absorption is decreased by pathologic processes that obstruct arachnoid villi or interfere with CSF flow, such as intracranial hemorrhage, infection, tumor, and congenital malformations.[9,10]

INTRACRANIAL PRESSURE

Increased ICP causes secondary brain injury by producing cerebral ischemia and ultimately causing herniation. Ischemia occurs when

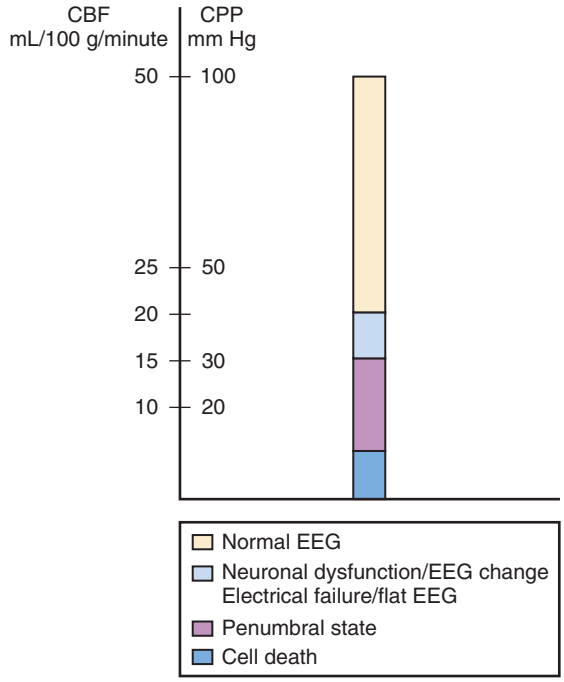

FIGURE 26.1 Cerebral blood flow (*CBF*), cerebral perfusion pressure (*CPP*), and brain ischemia. Changes in CBF and CPP affect neuronal synaptic function and cellular integrity. When CBF decreases to 15 to 20 mL/100 g per minute, there is distinct neuronal dysfunction on the electroencephalogram (*EEG*). At 15 mL/100 g per minute, the EEG is essentially flat, and electrical activity ceases to function. At 6 to 15 mL/100 g per minute, a penumbral state occurs in which there is energy for cellular integrity but insufficient energy for synaptic function. Neuronal survival is unlikely if this low CBF is allowed to persist for more than an ill-defined but critical period. At less than 6 mL/100 g per minute, there is no energy for cellular membrane integrity. Infarction occurs at this stage unless reperfusion is accomplished immediately.

ICP increases and cerebral perfusion pressure (CPP) decreases. As cerebral blood flow (CBF) and the supply of nutrients are curtailed, cell damage and death occur, leading to increased intracellular and extracellular water and further increases in ICP. When ICP increases, CPP decreases, the brain becomes ischemic, and cell death can ensue (Fig. 26.1).[11]

Herniation Syndromes

Several herniation syndromes exist. The most common is *transtentorial* herniation, in which the uncus of the temporal lobe is displaced from the supratentorial to the infratentorial space. Compression of the third cranial nerve and brainstem results in pathognomonic signs of pupillary dilatation, hemiparesis, and loss of consciousness. If this compression is not promptly relieved, apnea, bradycardia, and death occur.

In *cerebellar* herniation, the cerebellar tonsils herniate through the foramen magnum from the posterior fossa to the cervical spinal space. This can lead to obstruction of CSF circulation and ultimately to hydrocephalus. Compression of the brainstem results in cardiorespiratory failure and death.

Signs of Increased Intracranial Pressure

The clinical signs of increased ICP vary in children. Papilledema, pupillary dilation, hypertension, and bradycardia may be absent despite intracranial hypertension, or these signs may occur with normal ICP.[9,12] When associated with increased ICP, they are usually late and dangerous signs.[13] Chronic increases in ICP are often manifested by complaints of headache, irritability, and vomiting, particularly in the morning. Papilledema may not be present even in children dying as a result of intracranial hypertension.[14] A diminished level of consciousness and abnormal motor responses to painful stimuli are frequently associated with an increased ICP.[9] Computed tomography (CT) or magnetic resonance imaging (MRI) can reveal small or obliterated ventricles or basilar cisterns, hydrocephalus, intracranial masses, and midline shifts. Diffuse cerebral edema is a common finding when increased ICP is associated with closed-head injury, encephalopathy, or encephalitis.

Monitoring Intracranial Pressure

Techniques to monitor ICP in adults have been successfully used in children.[15–17] Noninvasive techniques seem to be less accurate than invasive methods.[18] Ventricular catheters are generally accepted as the most accurate and reliable means of measurement, permitting removal of CSF for diagnostic or therapeutic indications. The major risks of intraventricular catheters are infection and hemorrhage; although rare, they can lead to devastating complications. These catheters may be difficult to insert precisely when they are needed most, as in a child with severe cerebral edema and small ventricles. Compared with intraventricular catheters, subarachnoid bolts can be placed even when the ventricles are obliterated. This procedure minimizes trauma to brain tissue and poses less risk of serious infection and hemorrhage. The major disadvantages are that subarachnoid bolts may underestimate ICP, particularly in areas distant from their insertion site, and they are difficult to stabilize in infants with thin calvarias.

Epidural monitors that do not require a fluid interface can be implanted outside the dura, avoiding the risks of CSF contamination and the limitations of fluid-dependent systems.[19,20] Most epidural systems correlate well with intraventricular measurements, but they cannot be recalibrated after insertion. Epidural monitors have also been secured noninvasively to the open anterior fontanelle of infants and appear to reflect changes in ICP. Fiber optic catheters with self-contained transducers can also be used to measure ICP from intraventricular, subarachnoid, or intraparenchymal sites. These monitors avoid some of the problems of external fluid-filled transducers, but like epidural transducers, they cannot be recalibrated after insertion.

The normal ICP in children is less than 15 mm Hg. In term neonates, normal ICP is 2 to 6 mm Hg; it is probably even less in preterm infants. Children with intracranial pathology but normal ICP values occasionally exhibit pressure waves, which are considered abnormal.[9] In children with open fontanelles, the ICP may remain normal despite a significant intracranial pathologic process; increasing head circumference may be the first clinical sign. Bulging fontanelles may not develop, especially when the process evolves slowly.

Intracranial Compliance

The absolute value of ICP does not indicate how much compensation is possible. If the ICP increases significantly, compensatory mechanisms have failed. However, pathologic states may be present despite an ICP within the normal range. Intracranial compliance (i.e., the change in pressure relative to a change in volume) is a valuable concept. Fig. 26.2 is a schematic diagram of the relationship between the addition of volume to intracranial compartments and ICP. The shape of the curve depends on the time over which the volume increases and the relative size of the compartments. At normal intracranial volumes (point 1 in the figure), ICP is low,

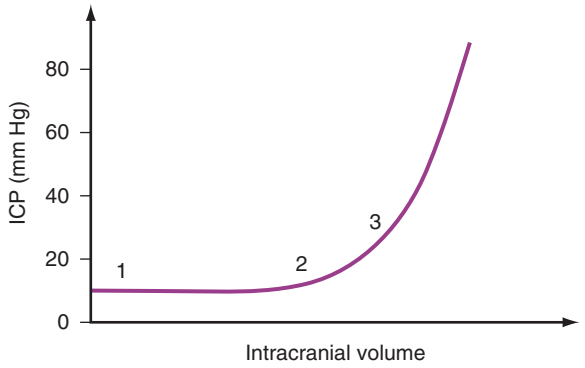

FIGURE 26.2 Idealized intracranial compliance curve for intracranial pressure (*ICP*) plotted against intracranial volume.

but compliance is high and remains so despite small increases in volume. If volume increases rapidly, compensatory abilities are surpassed, and further increases in volume are reflected as increases in pressure. This can occur when the ICP is still within normal limits but the compliance is low (point 2). If the ICP is already increased, further volume expansion causes a rapid increase in ICP (point 3). In clinical practice, compliance can be evaluated with a ventriculostomy catheter or by observing the response of ICP to external stimulation (e.g., tracheal suction, coughing, agitation).

Several physiologic and mechanical factors such as a greater percentage of brain water content, less CSF volume, and a greater percentage of brain content to intracranial capacity contribute to a relatively decreased intracranial compliance in children compared with adults.[2] Children may be at increased risk for herniation compared with adults when similar relative increases in ICP have occurred. However, infants faced with a slowly increasing ICP may have a greater compliance because of their open fontanelles and sutures.

CEREBRAL BLOOD VOLUME AND CEREBRAL BLOOD FLOW

In addition to CSF, cerebral blood volume (CBV) represents another compartment in which compensatory mechanisms influence ICP. Although the CBV occupies only 10% of the intracranial space, changes related to dynamic blood volume occur, often initiated by anesthesia or intensive care procedures. As with other vascular beds, most intracranial blood is contained in the low-pressure, high-capacitance venous system. Increases in intracranial volume are initially met by decreases in CBV. This response is apparent in hydrocephalic infants, in whom venous blood shifts from intracranial to extracranial vessels, producing distended scalp veins.[21]

In the normal adult, CBF is approximately 55 mL/100 g of brain tissue per minute.[22–24] This represents almost 15% of the cardiac output for an organ that accounts for only 2% of body weight. Estimates of CBF are less uniform for children. Normal CBF in healthy awake children is approximately 100 mL/100 g of brain tissue per minute, which represents up to 25% of cardiac output.[25,26] CBF in neonates and preterm infants (approximately 40 mL/100 g of brain tissue per minute) is less than in children and adults.[27,28] In infants, CBF is subject to modification by sleep states and feeding.[29]

Understanding CBF in neonates, infants, and other children is fundamental to being able to safely care for these most vulnerable patients during procedures requiring sedation and general anesthesia. Recent work has focused on delineating the factors that contribute to adequate CBF in children undergoing general anesthesia. Classically, teaching has focused on a variety of factors that underlie maintenance and autoregulation of CBF—mean arterial pressure (MAP), Pa_{CO2}, and so on. While these concepts remain critical underpinnings of neurophysiology, it is also incumbent upon anesthesia providers to have a broader understanding and approach to the idea of CBF. Regulation of CBF is best understood as the nexus of different physiologic systems. These systems include the respiratory, cardiovascular autonomic, nervous, and endocrine systems, metabolic processes, and the intracranial environment itself.[30] In light of this approach, CBF is regulated by integrative processes that involve respiratory gas exchange, hemodynamic parameters and their consequent effects on cerebrovascular resistance. In adults, the cerebral metabolic rate for oxygen consumption ($CMRO_2$) is 3.5 to 4.5 mL O_2/100 g per minute; in children, it is greater.[25] General anesthesia reduces $CMRO_2$ by as much as 50%.[31] Coupling of CBF and $CMRO_2$ is probably mediated by the effect of the local hydrogen ion concentration on cerebral vessels. Conditions that cause acidosis (e.g., hypoxemia, hypercarbia, ischemia) dilate the cerebral vasculature, which augments CBF and CBV. A reduction in brain metabolism (i.e., $CMRO_2$) similarly reduces CBF and CBV. When autoregulation is impaired, CBF is determined by factors other than metabolic demand. If the CBF exceeds metabolic requirements, luxury perfusion or hyperemia exists. Many pharmacologic agents act directly on the cerebral vasculature to alter CBF and CBV.

CEREBRAL PERFUSION PRESSURE

CPP is a useful and practical estimate of the adequacy of the cerebral circulation, because CBF is neither easily nor widely measured. Defined as the pressure gradient across the brain, CPP is the difference between the systemic MAP at the entrance to the brain and the mean exit pressure (i.e., central venous pressure [CVP]). When ICP exceeds CVP, it replaces CVP in the calculation of CPP. In supine children, the mean CPP is the difference between the MAP and the mean ICP (CPP = MAP – ICP). If the brain and heart are positioned at different heights, all pressures should be referenced at the level of the head (e.g., external auditory meatus).

Alterations in cerebral perfusion under general anesthesia make anesthetizing neonates and infants a particularly challenging endeavor. Neonates already have an increased perioperative morbidity and mortality. Recent concerns for the risks of adverse neurocognitive outcomes from exposure to common anesthetic drugs have evolved into greater efforts in optimizing the physiologic management of neonates undergoing general anesthesia (see Chapter 25). It comes as no great surprise that part of this renewed effort to improve the care of neonates has focused on understanding the role of an adequate cerebral perfusion. Problems include difficulties with accurate blood pressure measurement, knowledge of appropriate hemodynamic goals, maintaining said normal hemodynamic ranges and hemodynamic goals while avoiding hypocapnia.[32,33]

CEREBROVASCULAR AUTOREGULATION

Effects of Blood Pressure

Classical teaching has maintained that, in adults, CBF remains relatively constant within an MAP range of 50 to 150 mm Hg (Fig. 26.3). There is growing evidence that this concept that blood flow is constant over this MAP range is not necessarily correct. Interpretation of a constant flow is the result of limitations to this research that include methods of measuring and the assumptions made by such methods (e.g., transcranial Doppler [TCD]

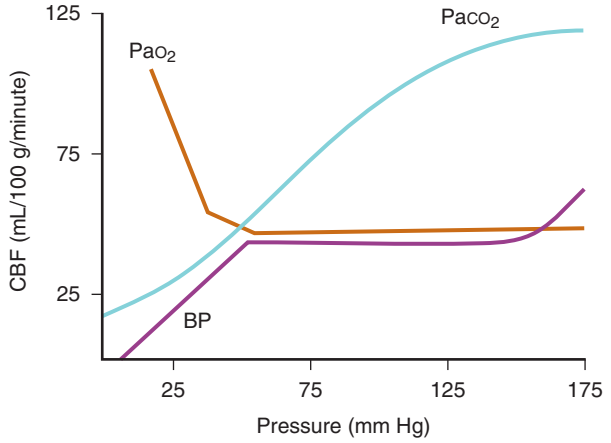

FIGURE 26.3 The effects of increasing mean blood pressure (*BP*), arterial partial pressure of oxygen (Pao_2), and arterial partial pressure of carbon dioxide ($Paco_2$) on cerebral blood flow (*CBF*) in the normal brain. (From Shapiro HM. Intracranial hypertension: therapeutic and anesthetic considerations. *Anesthesiology* 1975;43:447.)

and the assumption that the diameter of the measured vessel remains constant), the manipulation of CBF pharmacologically (the influence on cerebrovascular tone is not well understood and controversial), and the confounding effect of the arterial partial pressure of carbon dioxide ($PaCO_2$) alterations during pharmacologic manipulations of blood pressure.[30] Despite these limited data, as clinicians we still depend on published evidence to optimize the care of our patients under anesthesia. It is useful to understand these new concepts but try to not simply disregard older, probably too basic, ideas of maintenance of CBF in our patients under anesthesia.

We can view autoregulation as a mechanism that enables brain perfusion to remain relatively stable despite changes in MAP or ICP. There is recent evidence that this relationship between MAP and CBF is likely more pressure passive than originally thought. In fact, it seems as if stricter autoregulation occurs at greater values of MAP than smaller values.[34] Autoregulation is mediated by autonomic and myogenic control of vascular resistance, although there remains considerable debate regarding the exact mechanism and exact location of this modulation. When CPP decreases, cerebral vessels dilate to maintain CBF, thereby increasing CBV. When CPP increases, cerebral vasoconstriction occurs, maintaining the CBF with a reduced CBV. When ICP and CVP are low, MAP normally approximates CPP. Beyond the range of autoregulation, CBF becomes more pressure-dependent. In children with chronic hypertension, the upper and lower limits of autoregulation are increased. Cerebral autoregulation can be abolished by acidosis, medications, tumor, cerebral edema, and vascular malformations, even at sites far removed from a discrete lesion.[22]

The limits of autoregulation for normal infants and children are unknown, but autoregulation probably occurs at lower absolute values than in adults.[35] Although the lower limit of autoregulation in adults is approximately 50 mm Hg MAP, this blood pressure may be beyond that of the neonate. Intact autoregulatory mechanisms have been demonstrated within lower blood pressure ranges in newborn animals compared with mature animals.[36] Children younger than 6 months during sevoflurane anesthesia had a decrease in CBF velocity that was not present until the MAP was 38 mm Hg.[37] That study has not been repeated, so results should perhaps be taken with a degree of skepticism. Cerebral autoregulation may even be abolished in critically ill humans.[38]

Effects of Oxygen

CBF is constant over a wide range of oxygen tensions. When the partial pressure of arterial O_2 (PaO_2) decreases to less than 50 mm Hg, CBF increases exponentially in adults; for example, at a PaO_2 of 15 mm Hg, CBF is doubled compared with normal (see Fig. 26.3).[39] The resulting increase in CBV increases ICP when intracranial compliance is low; the lower limit for PaO_2 is probably less in neonates. Oxygen delivery is more important than the actual PaO_2. Evidence suggests that hyperoxia decreases CBF. Kety and Schmidt[40] demonstrated a 10% decrease in CBF in adults breathing 100% O_2, although decreases of 33% have been reported in neonates.[41] However, a decrease in MAP with sevoflurane anesthesia has also been reported to increase regional brain oxygenation as measured by near-infrared spectroscopy (NIRS).[42] This lends further credence to the idea that various physiologic systems have complex interactions that lead to modulation of CBF.

Effects of Carbon Dioxide

The relationship between the arterial partial pressure of carbon dioxide ($PaCO_2$) and CBF typically is linear (see Fig. 26.3). In adults, a 1-mm Hg increase in $PaCO_2$ increases CBF by approximately 2 mL/100 g per minute.[40] The direct effect of changes in $PaCO_2$ on CBF and the consequent effect on CBV are the basis for the fact that hyperventilation reduces ICP. Likewise, increases in $PaCO_2$ increase the CBF, although the limits at which this occurs in neonates differ from those in adults. In lambs and monkeys, CBF does not seem to change in response to decreased $PaCO_2$.[43] There are no data to suggest the lower limits of $PaCO_2$ effect on CBF in human infants and children. Similarly, there is little information about the extent and duration of cerebrovascular responsiveness to hyperventilation in brain-injured and critically ill children. Moderate hyperventilation has been used to rapidly reduce ICP, but several reports have demonstrated worsening cerebral ischemia in children with compromised cerebral perfusion.[44–46]

Autoregulation of CBF is impaired in regions of damaged brain.[47] Blood vessels in an ischemic zone are subject to hypoxemia, hypercarbia, and acidosis, which are potent stimuli for vasodilation. These vessels develop maximally reduced cerebrovascular tone or vasomotor paralysis. Small, localized lesions may impair autoregulation in areas far removed from the site of injury.[22] The extent of autoregulatory impairment varies in children with brain damage.

Management of Anesthesia

PREOPERATIVE EVALUATION

History

Preoperative evaluation of infants and children is discussed in Chapter 4. Children who are scheduled for neurosurgery might have been healthy until the onset of their symptoms, might have been developmentally delayed from birth, or may have impaired neuromuscular function. The anesthetic plan, including postoperative care, needs to consider the particular issues of each child and the disease state.

A history of food or drug allergies, eczema, or asthma may provide warning of an adverse reaction to contrast agents frequently used in neuroradiologic procedures. Special attention should be given to symptoms of allergy to latex products, such as lip swelling after blowing up a toy balloon or tongue swelling after insertion

of a rubber dam into the mouth by a dentist, because latex anaphylaxis has been reported in some children who have undergone multiple operations, especially those with a meningomyelocele.[48] Children with latex allergy may also report allergies to fruits (e.g., kiwi, banana, avocado, strawberry, and others).[49]

Concurrent pediatric diseases and symptoms of neurologic lesions may influence the conduct of anesthesia. Protracted vomiting, enuresis, and anorexia related to intracranial lesions should prompt evaluation of hydration and electrolytes. Diabetes insipidus or inappropriate secretion of antidiuretic hormone are common. A history of the use of aspirin or aspirin-containing remedies for headaches or respiratory tract infections is information that is not usually forthcoming but may have important implications for operative and postoperative bleeding. Corticosteroids are often initiated at the time of diagnosis of intracranial tumors, and they should be continued and a pulse dose administered during the perioperative period. Therapeutic concentrations of anticonvulsants should be verified preoperatively and maintained perioperatively. Children receiving long-term anticonvulsants may develop toxicity, especially if seizures are difficult to control; this is frequently manifested as abnormalities in hematologic or hepatic function, or both. Children receiving long-term anticonvulsant therapy may also require increased amounts of sedatives, nondepolarizing muscle relaxants, and opioids because of enhanced metabolism of these drugs (see also Chapters 7 and 24).[50–52]

Physical Examination

The physical examination should encompass a brief neurologic evaluation, including level of consciousness, motor and sensory function, normal and pathologic reflexes, integrity of the cranial nerves, and signs and symptoms of intracranial hypertension. Examination of pupillary size and responsiveness can detect benign anisocoria. Preoperative respiratory assessment should include the effects of motor weakness, impaired gag and swallowing mechanisms, and evidence of active pulmonary disease, such as aspiration pneumonia. Muscle atrophy and weakness should be documented, because upregulation of acetylcholine receptors may precipitate sudden hyperkalemia after administration of succinylcholine and induce resistance to nondepolarizing muscle relaxants in the affected limbs.[53]

Laboratory and Radiologic Evaluation

In all but the most minor procedures, laboratory data should include a hematocrit determination. Blood typing and crossmatching should be performed for any major procedure. The need for additional studies, such as evaluation of coagulation parameters, serum electrolyte levels and osmolality, blood urea nitrogen and creatinine values, arterial blood gas analysis, chest radiography, or electrocardiography (ECG), is determined on an individual basis. Liver function tests and a hematologic profile should be obtained if not recently reviewed in children receiving long-term therapy with anticonvulsants. Specific neuroradiologic studies are usually obtained by the neurosurgeon and should be reviewed by the anesthesiologist. For example, the anesthesiologist should know which children with a ventriculoperitoneal shunt have "slit ventricles" because these children have special risks in the perioperative period[54] (see "Hydrocephalus"). Information on the amount of sedation needed to perform radiologic studies may also be helpful in planning the induction of anesthesia. Preoperative neurophysiologic studies, including electroencephalography (EEG) and evoked potentials, may provide a baseline for comparison of intraoperative and postoperative evaluations.

PREMEDICATION

Sedation is usually withheld from pediatric neurosurgical patients until they arrive in the preoperative area to allow titration of drug to desired effect while under direct supervision. Opioids are usually withheld preoperatively because they may cause nausea or respiratory depression, especially in children with increased ICP, and sedatives alone usually are adequate to relieve anxiety.

Sedatives are administered in the parents' presence to facilitate a smooth separation and induction. Midazolam (~0.5-1.0 mg/kg) may be given orally; it usually requires 10 to 20 minutes to take effect. Incremental doses of intravenous (IV) midazolam (0.05 mg/kg) may also be useful in children who tolerate IV placement.

MONITORING

Minimal monitoring for pediatric neuroanesthesia requires a stethoscope (precordial or esophageal), electrocardiograph, pulse oximeter, sphygmomanometer, capnograph, and thermometer. Neuromuscular blockade monitoring is also important, but nerve stimulators may give misleading information about the extent of relaxation if applied to a denervated extremity. If the child has paresis, nerve stimulation should be at a site of normal neurologic function. Precordial Doppler ultrasound is recommended in children undergoing craniotomy, especially in the head-up position, because the relatively large head size of children places them at increased risk for air emboli. Monitoring devices for ICP are used for the same indications as in adults. Intraoperative EEG and electrophysiologic monitoring require advanced coordination among the neurosurgeon, anesthesiologist, and neurophysiologist. Urinary output should be measured during prolonged procedures, in cases with anticipated large blood loss, and when diuretics or osmotic agents are administered.

An arterial catheter is placed for craniotomies in which there is a potential for sudden and severe hemodynamic changes. Small child size should not preclude the use of invasive monitoring and may actually be an indication for a more aggressive approach. An increase in the paradoxical arterial pressure waveform with positive-pressure ventilation is often an excellent indication of intravascular volume deficiency and the need for fluid replacement (see Fig. 12.10). Intraarterial catheters can be placed percutaneously in the radial, dorsalis pedis, or posterior tibial arteries even in small infants, and it is rarely necessary to resort to surgical cutdown. The arterial transducer should be zeroed at the level of the head if the head and heart positions are different so that CPP can be accurately assessed. The lateral corner of the eye or the external auditory meatus approximate the level of the foramen of Monro and either is a convenient landmark. In the first days of life, the umbilical artery and the umbilical vein can be cannulated. These catheters should be discontinued as soon as alternative access is established because of the potential for serious complications.

Percutaneous central venous cannulation (i.e., external or internal jugular, femoral, or subclavian veins) using the Seldinger technique is possible even in the smallest infants (see Chapter 49). However, in children undergoing neurosurgical resections, consideration should be given to sites other than neck veins, such as the femoral vein, thereby avoiding the Trendelenburg position during catheter insertion and the risk of accidental carotid artery puncture and hematoma formation, which may compromise CBF and intracranial venous drainage. If there is no issue with ICP, the subclavian vein is a reasonable alternative. Cannulation of antecubital veins may provide central venous access, but threading the catheter into the inlet of the right atrium may be technically

difficult in small children. When rapid blood loss is a consideration in a small child in whom adequate peripheral venous access is difficult to obtain, a single-lumen, large-bore catheter is most commonly inserted in a femoral vein. Catheters inserted into the femoral veins usually are accessible to the anesthesiologist during most neurosurgical procedures. Multiple-lumen central venous catheters are inadequate for rapid blood transfusion. All central catheters should be removed as soon as possible after the procedure to minimize the risk of venous thrombosis.

INDUCTION

For children with intracranial hypertension, the primary goals during induction are to minimize severe increases in ICP and decreases in blood pressure. Most IV drugs decrease $CMRO_2$ and CBF, which consequently decreases ICP.[55] Historically, sodium thiopental (4–8 mg/kg) was the default induction agent for neurosurgical cases. However, sodium thiopental is no longer available in the United States, although it remains available in other countries. In the United States, propofol has become the IV induction agent of choice for most children. Propofol (2–4 mg/kg) appears to have similar cerebral properties and an antiemetic effect; however, its antiemetic effect is usually not relevant for lengthy procedures. Etomidate, a possible neuroprotective agent, can be used if hemodynamic stability is a concern.[56–58] Ketamine should be avoided because of its known ability to increase cerebral metabolism, CBF, and ICP. Sudden increases in ICP have been reported after ketamine administration, especially in infants and children with hydrocephalus.[59,60]

Other measures to reduce ICP during induction include controlled hyperventilation and administration of opioids (e.g., fentanyl, remifentanil, or sufentanil) and supplemental hypnotics before laryngoscopy and intubation. Lidocaine (1.5 mg/kg) limits the increase in ICP when administered intravenously just before laryngoscopy.[61]

Sevoflurane has replaced halothane for inhaled inductions because of its more rapid onset, acceptability for pediatric patients, and hemodynamic stability. Similar to isoflurane in its cerebral physiologic effects, sevoflurane with hyperventilation appears to blunt the increase in ICP related to cerebral vasodilatation from inhalational anesthetic agents alone.[62–64] Sevoflurane offers an additional advantage because it causes less myocardial depression compared with halothane.[65] As stated earlier, sevoflurane anesthesia, while decreasing MAP, can also lead to an increase in regional cerebral oxygenation.[42] However, sevoflurane when combined with hyperventilation produces epileptiform activity as measured by EEG. This may occur even in children with no history of clinical seizure activity (see Chapter 7).[66]

A common presentation is an uncooperative toddler who has an intracranial tumor and moderately decreased intracranial compliance and who is agitated and resistant to separation from parents. Some clinicians would argue that a crying, agitated child has demonstrated a tolerance to increased ICP and that an IV induction is safer. Fortunately (for the anesthesiologist, although not for the child), children who have severe intracranial hypertension typically have a decreased level of consciousness, and it becomes easier to insert an IV catheter in those situations when it is most necessary.

AIRWAY MANAGEMENT AND INTUBATION

Airway management must be effective and smooth to avoid the ICP-increasing effects of hypoxemia, hypercarbia, and coughing. Opioid administration and supplemental hypnotics before intubation improve cerebral compliance and minimize increases in ICP caused by laryngoscopy and intubation.

Either oral or nasal intubation may be appropriate. Nasotracheal intubation offers the advantage of increased stability and increased comfort for children when postoperative intubation is necessary. Nasotracheal tubes are often used for children who will be in the prone position (e.g., for a posterior fossa craniotomy), children whose airway will be inaccessible during the surgical procedure, and for smaller children. Nasotracheal tubes also offer the advantage of a decreased risk of kinking intraoperatively, especially in prone positioning of small children for whom a smaller-sized endotracheal tube is necessary. The angle is more gentle using the nasopharynx compared with the angle using an oral approach, particularly in a prone patient whose neck is flexed. In this position, it is essential that the direction of the tube is toward the chin to avoid excessive and prolonged pressure on the alae and ischemic necrosis of the ala nasae.

Contraindications to nasal intubation include choanal stenosis, possible basilar skull fracture, transsphenoidal procedures, and sinusitis. If nasotracheal intubation is planned, it is advantageous to prepare the nares with topical vasoconstrictors, recognizing that systemic hypertension can occur in response to nasally administered vasoconstrictors. Placing a few drops of 0.25% phenylephrine (Neo-Synephrine) or oxymetazoline on cotton-tipped applicators and positioning them in the nares against the nasal mucosa can prevent overdosage and help to gauge the patency of the nasal passage when anesthesia has been induced. It may also be useful to use a red rubber catheter or a nonlatex nasal trumpet (the Robertazzi nasopharyngeal airway [Rusch Nasal Airway, Teleflex, Morrisville, NC) to gently dilate the nares and minimize the risk of a nosebleed.[67] Directly spraying the nares with 0.25% phenylephrine should be avoided as there are reports of development of lethal cardiopulmonary compromise in children after such delivery.[68] Whichever route is chosen for intubation, it is important to secure the tracheal tube with care because loss of the airway intraoperatively in a child with head pins in the prone position or a child with limited airway access can result in disaster.

In prolonged, combined neurosurgical and craniofacial reconstructions, the tracheal tube may be sutured to the nasal septum or wired to the teeth. A nasogastric or orogastric tube is inserted after intubation to decompress the stomach and evacuate gastric contents; leaving it open to gravity drainage during the case can prevent positive pressure from building up in the stomach if air leaks around an uncuffed tracheal tube. The child's eyes should be closed, lubricated with eye ointment, and covered with a large, clear, waterproof dressing.

NEUROMUSCULAR BLOCKING DRUGS

Because of its rapid onset and brief duration of action, succinylcholine is frequently used to facilitate intubation in children with a full stomach. The intubating dose is 1 to 2 mg/kg given intravenously or 4 to 5 mg/kg given intramuscularly.[69] In children, succinylcholine should be preceded with atropine (0.01–0.02 mg/kg) to prevent bradycardia. Succinylcholine does not significantly increase ICP in humans,[70] and any effect may be minimized by pretreatment with a nondepolarizing muscle relaxant.[71] However, this may make succinylcholine less effective, even when the dose of succinylcholine is increased. Succinylcholine is contraindicated when it may induce life-threatening hyperkalemia in the presence of denervation injuries related to various causes, including severe head trauma, crush injury, burns, spinal cord dysfunction,

encephalitis, multiple sclerosis, muscular dystrophies, stroke, or tetanus,[72] but it has no impact on the serum potassium concentration in children with cerebral palsy.[73]

Alternatively, nondepolarizing muscle relaxants such as rocuronium, cisatracurium, or vecuronium may be used, but all have a slower onset of action than succinylcholine. However, when rocuronium is administered in sufficiently large doses (1.2 mg/kg), the onset of action approaches that of succinylcholine, with equivalent intubating conditions achieved in about 1 minute.[74]

POSITIONING

Positioning is an especially important consideration in pediatric neuroanesthesia. Children with increased ICP should be transported to the preoperative holding area and operating room with the head elevated in the midline position to maximize cerebral venous drainage.

After the child is in the operating room, the neurosurgeons and anesthesiologists must have adequate access to the child. In infants and small children, slight displacement of the tracheal tube can result in extubation or endobronchial intubation. During prolonged procedures, it is important for the anesthesiologist to be able to visually inspect the tracheal tube and circuit connections and to suction the tracheal tube when necessary. Using proper draping and a flashlight, the operator can usually create a "tunnel" to ensure access to the airway. All but very small children are placed in pins in a Mayfield head holder (Integra, Plainsboro, NJ). The direction of the tube exiting the nares should be adjusted to remove pressure and avoid the risk of ischemia, particularly for cases that will continue for several hours. Neonates and small infants have thin calvaria, so head-pinning systems are often avoided. Instead, there are a variety of non–pin-based headrests available for these children. Adequate padding should be used in such situations (Figs. 26.4 and 26.5). Extreme head flexion can cause brainstem compression in children with posterior fossa pathology, such as a mass lesion or Arnold-Chiari malformation. Extreme flexion can also cause high cervical spinal cord ischemia and tracheal tube kinking and obstruction.[75]

Extremities should be well padded and secured in a neutral position (i.e., palm supinated or neutral to avoid ulnar nerve compression). It is important to avoid stretching peripheral nerves and to prevent skin and soft tissue pressure injury because of direct contact with surgical accessories such as instrument stands and grounding wires (see Fig. 26.5). It is also important to ensure that extremities that are not directly visible to the anesthesiologist (e.g., those on the opposite side of the operating room table) cannot fall off the table during surgery, even if the table is rotated. In older children and adolescents undergoing prolonged procedures, deep vein thrombosis prophylaxis should be considered using compression or pneumatic stockings.[76,77]

Prone Position

The prone position is commonly used for posterior fossa and spinal cord surgery. The torso should be supported to ensure free abdominal wall motion because increased intraabdominal pressure may impair ventilation, cause vena cava compression, and increase epidural venous pressure and bleeding. This is achieved most easily by placing silicone rolls or rolled blankets laterally on each side of the child's chest running from the shoulders toward the pelvis. A separate silicone roll or rolled blanket under the pelvis may occasionally be necessary in larger children. These rolls must not press into the flexed hips or compress the femoral nerve or genitalia. Placing the rolls in this position should also allow a precordial Doppler monitor to be easily placed on the anterior chest without undue pressure.

FIGURE 26.4 **A,** The child is positioned prone before surgery. Extreme head extension was needed for correction of craniosynostosis, but the equipment for securing the head was the same as that used for a prone craniotomy. **B,** This particular frame uses gel pads to support the chin, ears, and forehead.

The head position depends on the surgical procedure. If surgery is limited to the lower spine, the head may be rotated and supported by padding, with care taken to avoid direct pressure on the eyes and nose and to keep the ears flat. For posterior fossa surgery, the head usually is suspended in pins to maintain central alignment of the head and maximal flexion. For infants and toddlers, a cerebellar head frame is another alternative when the cranium is too thin for pins. In this situation, the child's forehead and cheeks rest on a well-padded head frame, and the eyes are free in the center of a horseshoe-shaped support (see Fig. 26.4). Ensure that the tracheal tube is properly positioned (after taping) and does not migrate to a main-stem position while positioning the child prone. This can be confirmed before turning the child prone by flexing the child's head maximally onto the chest and auscultating for equal air entry bilaterally. Tape used to fix other tubes (e.g., gastric, esophageal) in place should be separate from the tape used to secure the tracheal tube so that if these other tubes are accidentally dislodged, an extubation will not occur. An emergency plan should be formulated to turn the child supine if it suddenly becomes necessary.[78]

Significant airway edema may develop in a child who is in the prone position for an extended period. Oral airways are best avoided because they can cause edema of the tongue. Alternatively,

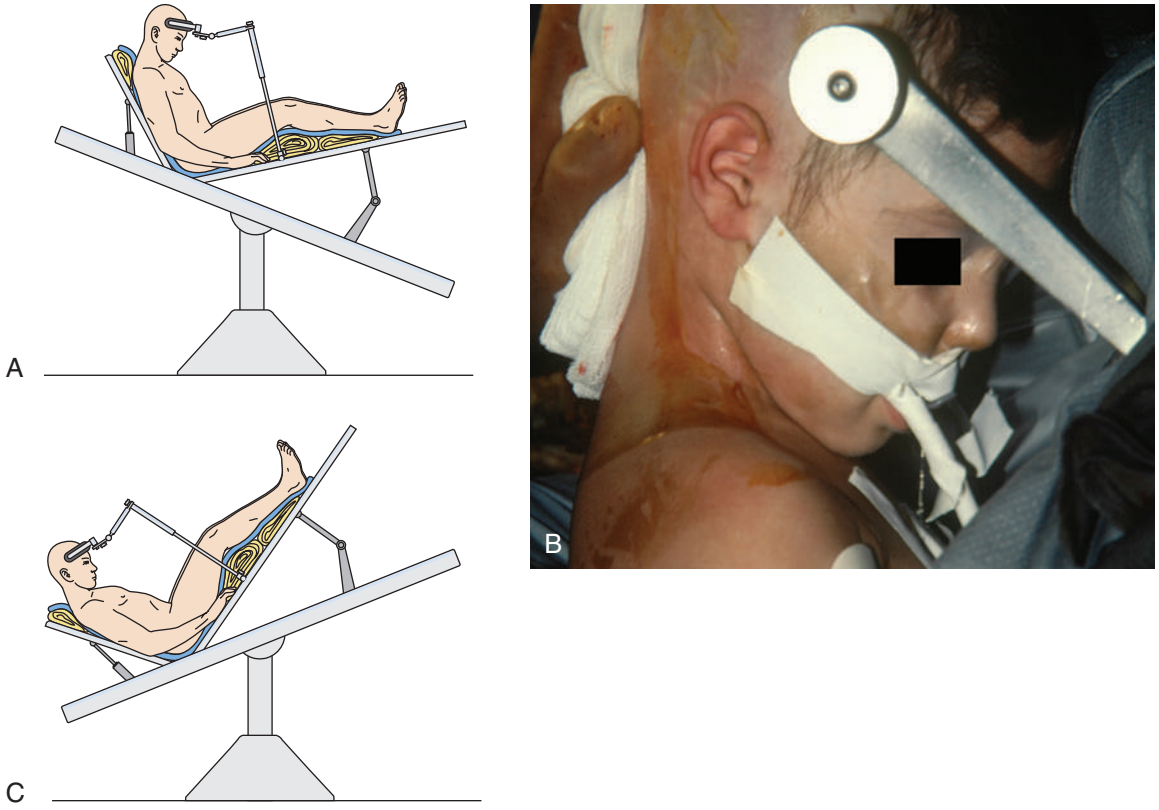

FIGURE 26.5 Resuscitation from the modified standard sitting position. The normal operative position (**A** and **B**) is compared with the resuscitation position (**C**). The position can be expeditiously changed by one control of the operating table.

a folded roll of gauze can be inserted between the lateral incisors to prevent the tongue from extruding. The latter maneuver is essential if cortical motor potentials are used intraoperatively as the nerve stimulation may trigger the child to bite his or her tongue, resulting in a bloody laceration. Rarely, prophylactic postoperative intubation may be necessary if a great deal of facial swelling has developed during a prolonged surgery. Postoperative vision loss has been linked with prolonged spine surgery in the prone position and significant blood loss.[79] Avoidance of direct pressure on the globe of the eyes, staged procedures to decrease surgical time, and maintenance of stable hemodynamics with avoidance of excessive intraoperative fluid administration should be ensured in prone children.[80]

Modified Lateral Position

Insertion or revision of ventriculoperitoneal shunts may require the child to be rotated from the supine to the semilateral position. This is achieved by placing a roll under the child's dependent axilla (to prevent a brachial plexus injury). The knees should be supported in a slightly flexed position and the heels padded. This position is also used for some temporal and parietal craniotomies.

Sitting Position

The sitting position is now used less commonly in pediatric neurosurgical procedures and is rarely used in children younger than 3 years of age. However, this position may be used for morbidly obese children who cannot tolerate the prone position because of excessive intrathoracic and abdominal pressures. When the sitting position is used, precautions to prevent hypotension and air embolism must be followed. The lower extremities should be wrapped in elastic bandages. The head must be carefully flexed to avoid kinking the endotracheal tube, advancing it into a bronchial position, or to avoid compressing the chin on the chest, which can block venous and lymphatic drainage of the tongue. Extreme flexion can also result in brainstem or cervical spinal cord ischemia, or both. As in the prone position, nasotracheal tubes are often used because they are more secure. The child's upper extremities are supported in the child's lap. Control levers to lower the head position should be easily accessible to the anesthesiologist and unencumbered by wires and drapes (see Fig. 26.5).

LOCAL ANESTHESIA

Local anesthetic should be injected subcutaneously before a skin incision to provide analgesia, and epinephrine is included in the local anesthetic to reduce cutaneous blood loss. If 0.25% bupivacaine with 1:200,000 epinephrine is used, the dose should be limited to 0.5 mL/kg. When greater volumes are required, the solution can be diluted with normal saline. This dilute solution is still effective for vasoconstriction and provides a prolonged sensory block postoperatively. Specific blocks of supraorbital and supratrochlear nerves can provide analgesia from the frontal area to the midcoronal portion of the occiput.[81] Blockade of the great occipital nerve provides analgesia from the posterior of the occiput to the midcoronal area of the occiput, whereas block of the supraorbital nerve provides analgesia to the front of the occiput (see Figs. 42.9 and 42.10).[82,83]

MAINTENANCE OF GENERAL ANESTHESIA

General anesthesia is required for most therapeutic and many diagnostic procedures in pediatric neurosurgery. Ventilation is controlled if intracranial hypertension is a concern. Although spontaneous ventilation provides another indication of brainstem function, its disadvantages (e.g., hypoventilation, increased potential for air embolism) are usually outweighed by the safety of controlled ventilation.

Maintenance of general anesthesia can be accomplished using inhalational anesthetics, IV infusions, or a combination of these drugs. Anesthetics that decrease ICP and $CMRO_2$ and maintain CPP are most desirable (Table 26.1). The commonly used inhalational agents uncouple CBF and $CMRO_2$ such that CBF increases while $CMRO_2$ decreases. All potent inhalational agents are cerebral vasodilators, which increase both CBF and ICP. Low concentrations of isoflurane, sevoflurane, or desflurane, combined with ventilation to maintain normocarbia, minimally affect CBF and ICP.[62,63,84] Isoflurane is often the inhalational agent of choice for maintenance of neuroanesthesia. At two times the minimal alveolar concentration (MAC), this dose of isoflurane induces a level of anesthesia that is associated with an isoelectric EEG while, unlike several other inhalational agents, maintaining hemodynamic stability. Enflurane is no longer used and may be epileptogenic, especially when combined with hyperventilation.[85] Other studies have demonstrated a similar effect with sevoflurane and hyperventilation, but the clinical implications of this are yet to be defined.[86]

Practitioners debate the routine use of nitrous oxide for intracranial neurosurgical procedures. Opponents cite the increased risk of postoperative nausea and vomiting (PONV) with nitrous oxide in a surgical population already at greater risk for PONV.[87] Proponents cite studies that failed to demonstrate an increased risk of PONV.[88] Nitrous oxide can increase CBF in humans in a dose-dependent fashion through cerebral vasodilatation.[89,90] This increase in CBF can lead to an increase in ICP, which can be deleterious if the child already has reduced intracranial compliance.[91] Nitrous oxide can also suppress somatosensory and motor evoked potentials, especially when inspired concentrations exceed 50%.[92–94] Animal data have shown that nitrous oxide can counteract the protective effects of thiopental in a model of cerebral ischemia.[95]

Proponents of the use of nitrous oxide for intracranial procedures cite its long track record of safety. There are no outcome studies in humans that distinguish between using nitrous oxide or not using it. It is often of great clinical interest to obtain a neurologic assessment immediately after the conclusion of an intracranial procedure, and some practitioners prefer the use of nitrous oxide to aid in achieving this goal. Studies have demonstrated the safety of using nitrous oxide in a variety of combinations with other agents during intracranial procedures.[96] Nitrous oxide is relatively contraindicated, however, if the child has undergone a craniotomy within the past few weeks because air can remain in the head for prolonged periods after previous neurosurgery.[97]

Fentanyl is often administered as part of an opioid-based technique because it is easily titratable with minimal adverse effects. A common loading dose is 5 to 10 µg/kg, with a dose of 2 to 5 µg/kg per hour usually adequate for maintenance, recognizing that the context-sensitive half-life of fentanyl increases dramatically after 2 hours in adults.[98] Adverse effects, including hypotension, can be avoided by giving the loading dose incrementally. Practitioners commonly use other opioids such as remifentanil and sufentanil. Total intravenous anesthesia (TIVA) using propofol and remifentanil is popular when rapid emergence is required at the end of surgery (see Chapter 8). Note that the context-sensitive half-life for propofol increases with time but is particularly steep in younger age infants and children[99]; in contrast, the context-sensitive half-life of remifentanil is unchanged with time or age of the child, including neonates. Dexmedetomidine, an α_2-agonist sedative, has also been used in children for neurophysiologic

monitoring, for awake craniotomies, to facilitate smooth wake-ups after neurosurgical procedures, and for neuroprotection.[100–103] These pharmacokinetic limitations of IV infusion agents must be appreciated if the surgeons expect a timely arousal to ensure that the CNS is intact.

APOPTOTIC NEURODEGENERATION

Several investigators have demonstrated that commonly used anesthesia drugs accelerate programmed cell death (i.e., apoptosis) in the CNS of immature rodents and rhesus monkeys.[104–106] This laboratory observation has provoked a heated debate about its relevance to anesthetizing neonates,[107–110] which has been extended to the lay press.[111] Although these experimental paradigms have yielded some surprising findings, extrapolating these data to the practice of anesthetizing human neonates is questionable (see Chapter 25).

The animal and in vitro studies have significant limitations with respect to the experimental model, agent dosage or concentration, duration of exposure (absolute and compared with human exposures), lack of surgical stimulation, and developmental age and stage. No detectable clinical marker or syndrome is associated with early anesthesia exposure in former neonates who have undergone surgery and anesthesia at birth or in the first several years of life during rapid brain growth (i.e., synaptogenesis). In the only primate study, the degree of apoptosis after 3 hours of a ketamine infusion was similar to that of the control but significantly less than after a 24-hour infusion.[106] This occurred in the presence of blood concentrations of ketamine that were 10-fold to several hundred-fold greater than those reported after a single dose of ketamine in infants. These findings suggest that in this model, ketamine-associated neurodegeneration is a time-dependent, dose-dependent phenomenon whose limits in human neonates have not been established.

Despite the confounding effects of prematurity and coexisting congenital anomalies, clearly characterized syndromes have been associated with maternal consumption of alcohol and anticonvulsant drugs. Discrepancies in neurocognitive outcomes exist.[105,112] Most neonatal and infant surgery is urgent, and anesthesia care is essential to proceed safely. Several retrospective database studies suggest that multiple anesthesia episodes are associated with learning disabilities and cognitive dysfunction, but most of these children were anesthetized before pulse oximetry and capnography were a standard of care. Unrecognized episodes of hypoxemia or excessive ventilation with reduced CBF might have contributed. It is also unclear whether children who required more than one surgical procedure when younger than 4 years of age might have had neurocognitive developmental issues that were associated with the pathology requiring surgery and were totally separate from exposure to anesthetic agents.[110,113,114] One retrospective study demonstrated that identical twins who were discordant for general anesthesia and surgery showed no evidence of cognitive dysfunction in follow-up assessments.[115]

Two recent major, well-designed studies were published that examined the effects of exposure to general anesthesia in infants. The first of these studies, the General Anaesthesia versus Spinal anaesthesia (GAS) study, was an international, multicenter, randomized study that compared young infants (<60 weeks postconception age born at >26 weeks) requiring inguinal herniorrhaphy. The infants were randomly assigned to receive either general anesthesia with sevoflurane or awake-regional anesthesia (i.e., spinal). Neurocognitive outcomes were assessed at 2 years of age. The researchers concluded from this interim analysis that brief general anesthesia with sevoflurane (≤1 hour) resulted in no increased risk of adverse neurodevelopmental outcome compared with infants who underwent awake-regional anesthesia.[116]

The second landmark study was published in 2016: the Pediatric Anesthesia and Neurodevelopment Assessment (PANDA) study. This multicenter study examined a sibling-matched cohort across four university-based U.S. pediatric tertiary care hospitals. The researchers studied siblings within 36 months of age in whom one healthy sibling had undergone a single general anesthetic 20 to 240 minutes in duration before age 3 years. No statistical difference in a variety of metrics of neurocognitive development scores was demonstrated. The authors concluded that among healthy children with a single exposure to a general anesthesia before age 3, there was no statistically significant difference in measured neurocognitive abilities compared with unexposed children.[117]

Additionally, two large population studies of children were examined using an early development instrument tested at age 5 to 6 years.[118,119] Combined, more than 32,000 exposed children from the two studies were matched with 70,000 unexposed children. The results of the studies showed no effect of anesthesia on either a single- or multiple-anesthetic exposure in children younger than 2 years, whereas the results of both studies showed a small impairment in cognition and general language in children older than 2 years at the time of surgery.

A growing body of evidence supports the idea that some anesthetic agents are harmful to the developing brain in various species of neonatal animals. Evidence from the above studies[116,117] suggests that a short, single exposure to general anesthesia in a developing human neonate does not increase the risk of adverse neurocognitive outcomes. That said, this question is far from definitively answered. The neurocognitive effect of multiple exposures or the modulating effects of severe multisystem disease on such outcomes remain unclear. Thus, this remains an area of great interest and research.

BLOOD AND FLUID MANAGEMENT

Blood loss is difficult to estimate accurately during neurosurgery because most of the losses are absorbed by the operative drapes and the surgical field is difficult for the anesthesiologist to visualize. Accuracy can be improved if all suctioned blood is collected in calibrated containers visible to the anesthesiologist and an overhead camera provides a view of the operative field at all times. Blood loss is usually greatest at the beginning of surgery, when the scalp is incised, and when a large bone flap is removed.

Fluid and blood product management are discussed in Chapters 9 and 12. Disruption of the blood-brain barrier by underlying pathologic processes, trauma, or surgery predisposes neurosurgical patients to cerebral edema, which may be exacerbated by excessive administration of IV fluids. IV fluid management during neurosurgical anesthesia affects cerebral perfusion, cerebral edema, water and sodium homeostasis, and serum glucose concentration.

In most cases, blood transfusions are not planned and attempts are made to avoid administration of blood products with their associated risks. Crystalloid solutions are commonly administered. Lactated Ringer's solution is not considered truly isotonic because its osmolality is 273 mOsm/L (normal: 285–290 mOsm/L). Normal saline solution, which is slightly hypertonic (308 mOsm/L), is the fluid of choice because reduction of serum osmolality is not desirable. However, rapid infusion of large volumes of normal saline has been associated with a hyperchloremic non–anion gap metabolic acidosis.[120] The clinical significance of this acidosis is unclear. If there are large fluid requirements during surgery,

alternating bags of lactated Ringer's solution with normal saline solution can minimize the risk of hypernatremia and acidosis and avoid hypoosmolality.

Inducing dehydration with osmotic and loop diuretics is a useful strategy to minimize cerebral edema and provide an optimal surgical field. However, hypotension and rebound effects may be associated with their use. Rapid administration of hypertonic solutions can cause profound but transient hypotension as the result of peripheral vasodilation.[121] Glucose-containing solutions are usually unnecessary during neurosurgical procedures because blood glucose concentrations are well maintained even in small children in the absence of IV glucose administration during typical (balanced) neurosurgical anesthetics. However, glucose may be indicated when hypoglycemia is a concern, such as in diabetic children, children receiving hyperalimentation, preterm and full-term neonates, and malnourished or debilitated children. In these situations, glucose solutions should be administered at or slightly below maintenance rates (by constant infusion pump) and serum glucose concentrations should be monitored periodically throughout surgery. The potential association of larger cerebral infarct size with hyperglycemia (i.e., blood glucose values >250 mg/dL) during ischemia is of particular concern.[122]

Meticulous management of fluids and blood products to minimize cerebral edema is a cornerstone of pediatric neuroanesthesia. Although cerebral hemorrhage is fortunately a rare event, when it does occur, it can be sudden and catastrophic. All children should have secure, large-bore IV access, and blood products should be available along with the means for warming the blood.

TEMPERATURE CONTROL

Because the head accounts for a large proportion of an infant's body surface area, infants are particularly susceptible to heat loss during neurosurgical procedures. Attention should be focused on maintaining normal temperature from the time the child is brought into the operating room, although moderate hypothermia during neurosurgery may be useful to decrease the $CMRO_2$. Ambient room temperature should be increased before the child enters the operating room. Infrared warming lights may be helpful for infants, and warming blankets may be useful for infants weighing less than 10 kg. Forced-air warming devices remain the most effective means to maintain body temperature in infants and children.[123]

VENOUS AIR EMBOLI

Venous air embolism (VAE) is a potential danger during intracranial procedures. The larger the pressure gradient between the operative site and the heart, the greater the potential for clinically significant entrainment of air into the central circulation.[124] For example, when the operative site is far above the heart (e.g., in a seated craniotomy) or when the CVP is low (e.g., acute blood loss during craniofacial procedures), it creates an environment for a VAE. Intracranial procedures are a particular concern because intracranial venous sinuses have dural attachments that impede their ability to collapse. Other potential air entry sites during neurosurgical procedures include bone, bridging veins, and spinal epidural veins. The sequence of events that should be followed when a VAE occurs is to identify the problem, stop further air entrainment, and support the circulation. Understanding the cause, prevention, and treatment of VAE is crucial because the consequences can be life-threatening.

When air enters the central circulation, it can accumulate in the right atrium or the right ventricular outflow tract. Cardiac output may be reduced, depending on the size of the air lock. If enough air is entrained into the circulation, the preload to the right ventricle decreases, or the right-sided heart afterload increases acutely, which can lead to cor pulmonale, acutely decreasing left ventricular preload and ultimately causing cardiovascular collapse. One study in dogs demonstrated that as little as 1 mL/kg of air could increase pulmonary artery pressure 200% to 300%.[125] Intracardiac shunts such as a patent foramen ovale, atrial or ventricular septal defects, and other congenital cardiac defects, may allow air to access the systemic circulation, including the coronaries and brain. The risk of VAE is even greater in infants and children because potential intracardiac shunts exist in many otherwise healthy infants and children. They may become clinically important if pulmonary hypertension develops acutely after a large air embolism. Some clinicians recommend preoperative echocardiographic screening for patent foramen ovale in any child being considered for a sitting craniotomy; others regard a patent foramen ovale to be an absolute contraindication to the sitting position.[126,127]

Although the incidence of VAE is greatest in the sitting position, the lateral, supine, and prone positions are not free of risk. VAE have also been observed during craniotomy for craniosynostosis, even when the operating room table is flat and rarely when the surgery involved endoscopic strip craniectomy, although most occur without clinical sequelae.[128,129] The incidence of VAE in children undergoing suboccipital craniotomy in the sitting position is not significantly different from that in adults, but children appear to have a greater incidence of hypotension and a smaller likelihood of successful aspiration of central (intravascular) air.[130]

Several techniques may be used to detect VAE. Depending on the study design, the usual order of sensitivity of detecting air in the heart is transvenous intracardiac echocardiography (0.15 mL/kg) > transesophageal echocardiography (0.19 mL/kg) = precordial Doppler probe (0.24 mL/kg) > pulmonary artery pressure (0.61 mL/kg) = end-tidal CO_2 tension (0.63 mL/kg) = arterial O_2 tension > MAP (1.16 mL/kg) = arterial CO_2 tension.[131,132] Transvenous intracardiac echocardiography is commonly used to guide catheters in cardiac ablation procedures or insertion of foramen ovale occlusion devices, but it is invasive and infrequently used in pediatric anesthesia. A precordial Doppler probe has been traditionally placed over the fourth or fifth intercostal space at the right sternal border to best monitor right heart sounds, although evidence suggests that placing the Doppler probe at the left parasternal border may be at least as sensitive (Fig. 26.6).[133,134] Appropriate Doppler positioning can be confirmed by listening for the characteristic change in sounds after rapid administration of a few milliliters of saline solution into a venous catheter. The precordial Doppler probe is particularly valuable because it is inexpensive, easy to use, benign, and noninvasive. Although transthoracic or transesophageal echocardiography is the most specific method for detecting small air emboli, it is not easily used intraoperatively, especially in children during neurosurgical procedures.[126,135,136]

Monitoring end-tidal gas tensions is important during neurosurgical procedures. When VAE occur, there is a ventilation-perfusion mismatch caused by the air blocking passage of blood through the pulmonary circulation, increasing dead-space ventilation with a sudden decrease in end-tidal CO_2 partial pressure ($ETCO_2$) and activation of complement resulting in pulmonary interstitial edema, neutrophil infiltration, and lung injury (Fig. 26.7).[131] The $ETCO_2$ remains a useful and cost-effective strategy in diagnosing massive VAE, although its sensitivity has been surpassed by other approaches (see Fig. 26.6). An increase in

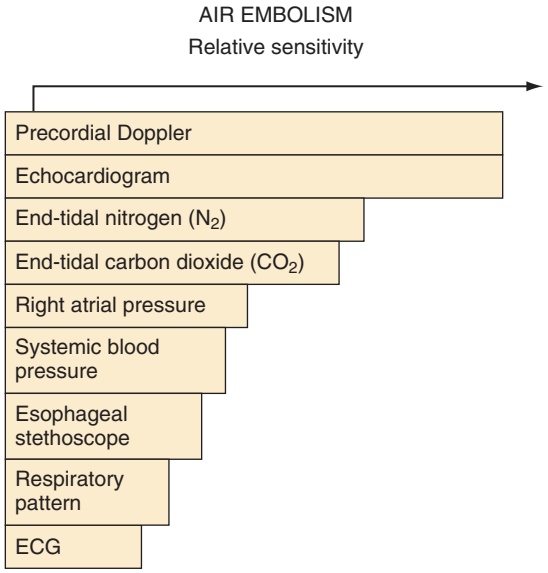

FIGURE 26.6 Relative sensitivities of air embolism–monitoring modalities. *ECG*, electrocardiogram.

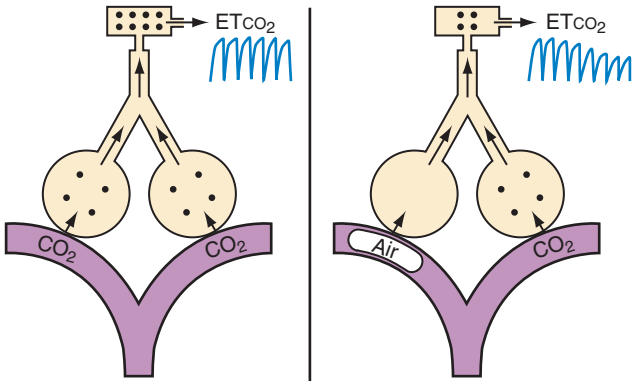

FIGURE 26.7 Mechanism of decreased end-tidal carbon dioxide ($ETCO_2$) after an air embolus. (Courtesy J. Drummond, MD.)

end-tidal nitrogen partial pressure during continuous monitoring is a specific sign of air emboli. Although slightly more sensitive than a decrease in $ETCO_2$, an increase in end-tidal nitrogen is not detected by most infrared analyzers in practice and is usually of such small magnitude that it may be difficult to detect.

Less sensitive or more invasive methods to detect VAE include ECG changes, changes in heart rate, decreases in systemic blood pressure, and increases in right atrial and pulmonary arterial pressures. Right atrial and pulmonary artery pressures increase quickly after the emboli develop (within 30 seconds). The magnitude of these increases correlates with the size of emboli, although these findings should not be relied on alone for monitoring and diagnosis.

On suspicion or diagnosis of VAE, immediate measures must be taken by the surgeons and anesthesiologists to prevent continued entrainment of air and consequent hemodynamic deterioration. The surgeon should immediately flood the field with saline solution and apply bone wax to exposed bone edges. The anesthesiologist should discontinue nitrous oxide and place the child in the Trendelenburg position, which has the effect of increasing cerebral venous pressure, stopping entrainment of air, augmenting the child's peripheral venous return, and increasing systemic blood pressure. Occlusion of the internal jugular veins in an attempt to increase cerebral venous pressure should be done with great care because occlusion of the carotid arteries can lead to cerebral ischemia. The application of positive end-expiratory pressure increases CVP but also decreases cardiac filling pressure, cardiac output, and blood pressure; extreme increases in positive end-expiratory pressure are usually unwarranted. Chest compressions, vasopressors, and aggressive fluid resuscitation may be required.

Aspiration of air from a central venous catheter is rarely successful unless massive amounts have been entrained. When central venous catheters are necessary, such as for a child in the sitting position or when massive blood loss is anticipated, an attempt should be made to place the tip at the junction of the superior vena cava and right atrium to provide the optimal location for aspiration of entrained air. More importantly, a central venous catheter is useful to estimate maintenance of circulating blood volume and to rapidly administer fluids and resuscitative medications when necessary. The position of a central venous catheter near the heart should be confirmed by radiograph, by transducing CVPs, or with the aid of ECG monitoring (i.e., biphasic P waves develop in a lead at the tip of the catheter). The threshold for aspirating air may be increased by properly positioning a multiple-orifice central venous catheter using a transvenous intracardiac echocardiography probe.[131] Because erosion of the catheter tip through the heart causing fatal pericardial tamponade has occurred after surgery in small children, soft silicone catheters are recommended.[137,138]

EMERGENCE

Protecting the brain is a major concern during neurosurgical procedures (Table 26.2). Emergence and extubation should be smooth and controlled to prevent fluctuations in ICP and in venous and arterial pressures.[139] To avoid vomiting during emergence, a multimodal antiemetic approach is advised.[140] Despite this approach, the incidence of PONV is high, which may be attributed to several factors: blood in the CSF is a potent emetic, opioids are often used to treat postoperative pain, and headache itself can precipitate emesis.

IV lidocaine (1.0–1.5 mg/kg) given before extubation may help to suppress coughing and straining on the tracheal tube, although fentanyl appears to be equally effective and may be less sedating. Labetalol, an α- and β-adrenergic blocking agent, can be administered incrementally for the control of blood pressure during the acute period of emergence, but this is rarely necessary in children who have received adequate doses of opioids during surgery. For adolescents, IV labetalol (0.1–0.4 mg/kg given every 5 to 10 minutes until the desired effect is achieved) may be necessary, but this usually does not have to be repeated in the postoperative period. Esmolol is used by some practitioners and has been as effective as labetalol in controlling hypertension after intracranial surgery in adults.[141] However, esmolol should be used with caution in infants and smaller children because their cardiac output depends on heart rate. There are no studies evaluating the use of esmolol in children for such an application. Dexmedetomidine may be useful in facilitating a smooth emergence while still allowing evaluation of the child's neurologic status.

Neuromuscular blockade should be pharmacologically reversed because even the slightest residual weakness is poorly tolerated and may interfere with the neurologic examination. Adequate spontaneous ventilation and oxygenation and an awake mental

TABLE 26.2 Maneuvers of Neuroprotection

Goals	Avoid cerebral edema
	Avoid cerebral hypoxia
	Avoid cerebral hypoperfusion
	Avoid cerebral hypermetabolism
	Avoid neuronal membrane damage
Maneuvers	
Head of bed at 30 degrees in midline	Increases cerebral venous drainage while maintaining CPP
Corticosteroids	May improve outcome in spinal cord injury Decrease vasogenic cerebral edema in children with tumors Stabilize neuronal membranes Free-radical scavengers
Controlled ventilation	Maintain $Paco_2$ at normal to slightly low levels: prevents both cerebral vasodilation and increased ICP
Muscle paralysis	Avoids coughing, straining, child movement, and other causes of increased ICP
Ventricular drainage	Decreases ICP
Antihypertensives	Prevent further cerebral edema, ischemia, and cerebral hemorrhage. Severe hypotension can significantly decrease CPP.
Anticonvulsants	Prevent seizure activity and increased ICP
Hypothermia	Decreases $CMRo_2$ and CMRglu consumption
Barbiturate coma	Membrane-stabilizing effect Decreases CBF and $CMRo_2$

CBF, cerebral blood flow; *CMRglu*, cerebral metabolic rate for glucose; *$CMRo_2$*, cerebral metabolic rate for oxygen; *CPP*, cerebral perfusion pressure; *ICP*, intracranial pressure; *$Paco_2$*, partial pressure of arterial carbon dioxide.

status are required before extubation. If postoperative intracranial hypertension is possible or if the child does not meet respiratory or neurologic criteria for extubation, the tracheal tube should be left in place, sedation administered, and the child transported to an intensive care unit.

The child should be as fully alert as possible immediately after the operation to permit repeated neurologic examinations to assess recovery and to detect a deteriorating status. In unconscious children, ICP can be monitored invasively. CT scans can help to evaluate the cause of an increased ICP or deteriorating mental status.

Pain is usually not severe after a craniotomy, but it can be treated with incremental doses of opioids. Ketorolac is best avoided in the early postoperative period because of its effects on platelet function. Acetaminophen may be administered orally, rectally, or intravenously for mild pain.[142]

Diabetes insipidus or inappropriate secretion of antidiuretic hormone may complicate postoperative fluid and electrolyte management, particularly when surgery is in the region of the hypothalamus and pituitary gland (see Chapter 27). Careful observation of fluid status and repeated laboratory evaluation of blood and urine osmolality and sodium levels are important in this situation. When diabetes insipidus occurs, it can be managed with a continuous infusion of dilute aqueous vasopressin (0.001–0.01 U/kg per hour).[143] In such circumstances, large volumes of hypotonic IV solutions must be avoided because they may rapidly decrease the serum sodium concentration and osmolality. If normal saline solution is administered in strictly limited volumes, aqueous vasopressin can control the electrolyte and fluid balances of children with diabetes insipidus until they resume oral fluids. At that time, intranasal or oral desmopressin (DDAVP) can be substituted. When diabetes insipidus develops after surgery in the pituitary region (e.g., during resection of a craniopharyngioma), it may only be transient; it is important to repeatedly assess the need for vasopressin.

Portable EEGs and evoked auditory, somatosensory, and less commonly, visual potentials may be helpful in assessing children who are deeply sedated or paralyzed. Observation in an intensive care unit capable of managing children is essential for the prevention or early detection and treatment of postoperative complications. CT and/or MRI are often performed 1 or 2 days after a craniotomy or earlier if neurologic deterioration develops.

Special Situations

TRAUMA

Head Injury

Among children, trauma is the primary cause of death, and head injuries produce most of this mortality and cause much of the morbidity in survivors.[144–146] Motor vehicle accidents continue to be the most frequent preventable cause of head injury, although domestic violence and sports-related head injury are also common in children (see Fig. 39.1). Assaults and suicide attempts have become increasingly common among adolescents.

Children with head trauma may have minimal neurologic abnormalities at the time of initial evaluation. However, increased ICP and neurologic deficits may progressively develop. They develop slowly because brain injuries occur in two stages. The primary insult that occurs at the time of impact results from the biomechanical forces that disrupt the cranium, neural tissue, and vasculature. The secondary insult is the parenchymal damage caused by the pathologic sequelae of the primary insult. These changes can result from hypotension, hypoxia, cerebral edema, or intracranial hypertension. Whereas prevention of primary injuries must be addressed in a sociopolitical forum such as through seat-belt laws, sports injury prevention, and domestic violence legislation, anesthesiologists are instrumental in preventing or minimizing secondary insults (see Chapter 39).

There are significant differences between children and adults in the pattern of CNS injuries. Although intracranial hematomas (i.e., epidural, subdural, or intraparenchymal) are common in adults, they are less common in children. In contrast, diffuse cerebral edema after blunt head trauma occurs more often in children than in adults.[147]

Scalp Injuries

One of the most common head injuries in children is the scalp laceration. Most can be managed in the emergency department, but more serious injuries may require the operating room to provide immobility and comfort. Children can lose a considerable amount of blood from a scalp injury because a larger fraction of the cardiac output perfuses the head compared with adults. Infants younger than 1 year of age may become hemodynamically unstable from blood loss from a subgaleal hematoma alone, as in a closed scalp injury, and hypovolemia should always be considered and treated before induction of anesthesia. Coexisting intracranial or other injuries must be considered, and a preoperative CT scan may be warranted.

Skull Fractures

Skull fractures are a common manifestation of head trauma in children. Most are linear and do not require surgical treatment. These fractures are of concern primarily because the force required to produce them may damage the underlying brain and vasculature. A linear fracture over a major blood vessel (e.g., middle meningeal artery) or a large dural sinus may result in intracranial hemorrhage. Most children have an uneventful course after sustaining a simple skull fracture. A few develop a leptomeningeal cyst or growing fracture that eventually requires surgical treatment. Multiple skull fractures in the absence of documented major trauma should always raise the suspicion of child abuse (see Fig. 39.2), which is also referred to as *nonaccidental trauma*.

Depressed skull fractures often require surgical repair. They may occur even in the absence of a scalp laceration. However, displacement of the inner table of the skull requires greater force than that needed to produce a simple linear fracture and has greater potential to damage underlying tissues. Approximately one-third of all depressed fractures are uncomplicated, another third are associated with dural lacerations, and the remaining third are associated with cortical lacerations. The extent of cortical injury is the primary determinant of morbidity and mortality. Surgical débridement and elevation of the depressed bone are usually performed as soon as possible after the injury (Fig. 26.8A).

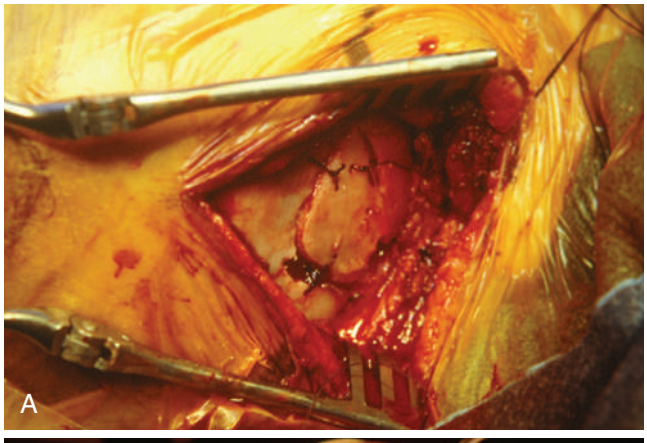

FIGURE 26.8 **A,** This depressed skull fracture required surgical intervention. **B,** Children with severe head trauma (in this case, a shaken baby) may present with marked increases in intracranial pressure.

Basilar skull fractures are less common in children. Despite the force needed to produce these fractures, they typically have an excellent prognosis and rarely require surgical intervention. However, the possibility of a basilar skull fracture should be considered when caring for children with altered mental status, seizures, or associated trauma requiring surgery. Findings include periorbital ecchymoses ("raccoon eyes"), retroauricular ecchymosis (i.e., the Battle sign) (see Fig. 39.2B), hemotympanum, clear rhinorrhea, or otorrhea. Unless absolutely necessary (e.g., mandibular wiring), nasotracheal intubation or passage of a nasogastric tube is best avoided because these tubes have inadvertently traversed these skull fractures and entered the cranium.[148–150] Complications of basilar skull fracture include meningitis from a CSF leak, cranial nerve damage, and anosmia.

Epidural Hematoma

Epidural hematomas most commonly develop in the temporoparietal region as a result of arterial bleeding from a severed middle meningeal artery. They can also develop in the posterior fossa as a result of bleeding from a venous sinus. Epidural hematomas are not necessarily associated with an overlying skull fracture. The classic natural history in adults is a "lucid interval" between the initial loss of consciousness and subsequent neurologic deterioration. Infants and children may not demonstrate an altered mental status in the early stages after the injury. However, as the hematoma expands, it can lead to a loss of consciousness, hemiparesis, and pupillary dilatation. This deterioration can be quite rapid once a mass effect occurs. Treatment is prompt surgical evacuation because delays are associated with increased morbidity. Medical therapy directed at decreasing ICP should be instituted as soon as a diagnosis is suspected but should not delay surgical repair (see Fig. 26.8B). Children recover well after these hemorrhages, although morbidity is usually a reflection of underlying brain injury or lengthy delay in treatment.

Subdural Hematoma

Subdural hematomas are usually associated with cortical damage resulting from direct parenchymal contusion or laceration of venous blood vessels. Acute subdural hematomas are almost always traumatic and are frequently a result of abuse, such as shaking of small children, particularly those younger than 1 year of age. Shaken baby syndrome occurs when an infant is shaken so vigorously that significant neuronal disruption occurs and tears in the cortical bridging veins cause subdural hematomas.[151–153] These infants suffer brain damage complicated by episodes of apnea and further hypoxic insult.

Subdural hematomas occasionally result from birth trauma within the first hours of life. Vitamin K deficiency, congenital coagulopathies, and disseminated intravascular coagulation are considerations in these situations. Great force is required to produce a subdural hematoma, whether by direct impact, laceration of blood vessels, or traumatic separation of the brain and overlying dura. Cerebral edema, uncontrolled intracranial hypertension, and persistent neurologic deficits often characterize the postoperative course. Chronic subdural hematomas or effusions may also develop in infancy, although these children do not usually present with acute symptoms. Children are often diagnosed because they are irritable and vomiting or have an increased head circumference. Chronic subdural hematomas can increase in size, causing slow but significant increases in ICP. Although a craniotomy is sometimes performed, most children undergo some form of hematoma drainage or shunting procedure as definitive treatment.

Intracerebral Hematoma

Intracerebral hematomas fortunately are rare but have a poor prognosis. Deep parenchymal hematomas are most often extensions of cortical contusions in a child with severe neurologic injury. Rarely, a localized hematoma may be appropriate for surgical evacuation to decompress the brain. However, intraparenchymal hematomas are not evacuated for fear of damaging viable brain tissue. Anticonvulsants are usually administered prophylactically, and it is safest in the initial period after injury to avoid any medications that interfere with coagulation (e.g., ketorolac).

Spinal Injury

Although isolated cervical spine injuries are uncommon in children, those with severe head trauma should always be managed as if they also have a cervical spine injury.[154,155] Different causes of spinal injuries are associated with specific age groups. Motor vehicle accidents produce the largest number of injuries in older children and adolescents, whereas birth injuries and falls are the most common cause in infants and young children.[156] Spinal cord injury itself may be caused by a variety of forces, including hyperflexion, hyperextension, rotation, vertical compression, flexion rotation, and shearing. The injury may involve bony, ligamentous, cartilaginous, vascular, or neural components of the spine or adjacent structures. The biomechanics and functional anatomy of the pediatric spine depend on the age of the child. Older children and teenagers are more likely to sustain injuries in the thoracolumbar region of the spine, whereas infants and younger children are more likely to suffer injuries in the high cervical region, particularly in the atlantoaxial region. The cervical spine is at greater risk in the infant and younger child because of the relatively weak and flexible neck muscles that support a proportionally large and heavy head, with the atlantooccipital area acting as a pivot point. Atlantooccipital dislocations are major neurologic injuries, leaving children neurologically devastated but not necessarily dead.

As with brain injury, spinal cord injury occurs in two phases. The primary insult results from biomechanical forces and bony fragments directly impacting the spinal cord. The secondary insult results from the pathologic sequelae of the primary insult: edema and ischemia owing to cortical compression, hypotension, or hypoxia. Inappropriate manipulation of a child with an unstable fracture can exacerbate primary and secondary injuries. Anesthesiologists who provide care for a child with a potential cervical spine injury should be aware that spinal cord injuries in children commonly occur without actual evidence of spinal bone fractures on plain cervical radiographs. These injuries are known as spinal cord injuries without radiologic abnormality (SCIWORA).[157] Injuries to the cervical spine in particular are often difficult to recognize but may be identified by odontoid displacement or prevertebral swelling on radiographs. As a result, a CT scan is frequently indicated when a spinal injury is initially suspected in a child with trauma. After a child with a potential spinal injury is determined to be medically stable, these studies should be obtained as soon as possible. The child's airway and cardiorespiratory function must be continuously and closely monitored until a spinal cord injury can be ruled out. Sometimes, as with brain injury, there can be a delay in the onset of neurologic deficits with SCIWORA injuries.[158]

Respiratory failure is the most common cause of death after isolated cervical spine injury. The level of injury determines the degree of impairment. The phrenic nerve originates primarily from C4 but receives contributions of fibers from C3 and C5. Lesions at C5 leave partial diaphragmatic innervation but impair abdominal and intercostal accessory muscles. Lesions between C6 and T7 preserve diaphragmatic innervation but diminish accessory muscle function.

Children with a cervical spine injury may rapidly develop respiratory failure owing to decreased vital capacity, increased dead space, retention of secretions, and respiratory muscle fatigue. Resultant hypercarbia and hypoxia aggravate the secondary injury to the brain and spinal cord. Respiratory status may be further impaired by associated trauma to the chest, causing pulmonary contusion or pneumothorax, or by aspiration of gastric contents.

Prompt airway management is essential to avoid hypoxia, ensure adequate respiratory mechanics, preserve neural function, and prevent extension of spinal injury (see Figs. 39.5–39.7). The head and neck must be immediately immobilized; restraint of the extremities may also be required. Various tracheal tubes and laryngoscope blades should be available, as well as equipment and personnel for an emergency tracheostomy. Insertion of a laryngeal mask airway may be lifesaving until a more secure airway can be achieved with fiberoptic or other means.[159–164] Small fiberoptic bronchoscopes (2.2-mm diameter) can fit through infant-sized tracheal tubes. Retrograde intubation using a guidewire introduced through the cricothyroid membrane may be useful in older children or adolescents (see Chapter 14). However, an unstable infant or child whose airway cannot be secured by conventional means is probably best managed by an emergency tracheostomy. As a temporizing measure, a cricothyroidotomy can be performed (see Figs. 14.25–14.27).[165] This permits oxygenation (although inadequate ventilation) until personnel and equipment for tracheostomy are assembled. An emergent surgical airway can be extremely difficult to perform on a small child or infant, even by experienced and skilled hands.

Hemodynamic instability may be a problem owing to hypovolemia from other injuries or severe head trauma. Other sites of bleeding such as long bone fractures and abdominal trauma should be ruled out. Children with spinal shock exhibit loss of vasomotor tone or loss of normal neurocardiac function with associated bradycardia and decreased myocardial contractility; IV fluids and vasopressors may be necessary.

The use of high-dose steroids as treatment of spinal cord injury remains controversial. Many centers have abandoned such protocols because of questions of increased complications and concerns over lack of efficacy. Although there are few data for adults and children, corticosteroids are often administered to patients with spinal injuries as soon as possible after the initial trauma in the hope of reducing the neurologic injury. The most commonly used drug is methylprednisolone; 30 mg/kg is administered over the first 15 minutes, followed by an infusion of 5.4 mg/kg per hour for the next 23 hours.[166,167] Methylprednisolone is thought to be effective through multiple mechanisms, including improved spinal blood flow, inhibition of the arachidonic acid cascade, and modulation of the local immune response.[168] Some evidence suggests that GM_1 ganglioside, with or without methylprednisolone, may be advantageous in decreasing demyelination and promoting neurologic recovery if administered soon after a spinal injury.[169–175]

If the spinal cord injury is more than 24 hours old, succinylcholine should be avoided because it can result in massive hyperkalemia.[176] Physiologic changes may result from autonomic hyperreflexia, which frequently develops after cervical or high thoracic spinal lesions. Autonomic hyperreflexia can produce severe and life-threatening vasomotor instability with hypertension and arrhythmias.[177,178]

CRANIOTOMY

Tumors

Brain tumors are the most common solid tumors in children, exceeded only by the leukemias as the most common pediatric malignancy.[179,180] Between 1500 and 2000 new brain tumors are diagnosed annually in children in the United States. Unlike those in adults, most brain tumors in children are infratentorial in the posterior fossa. They include medulloblastomas, cerebellar astrocytomas, brainstem gliomas, and ependymomas of the fourth ventricle. Because posterior fossa tumors usually obstruct CSF flow, increased ICP occurs early. Presenting signs and symptoms include early morning vomiting and irritability or lethargy. Cranial nerve palsies and ataxia are also common findings, with respiratory and cardiac irregularities usually occurring late. Sedation or general anesthesia may be required for radiologic evaluation or radiation therapy.

Surgical resection of a posterior fossa tumor presents a number of anesthetic challenges. Children are usually positioned prone, although the lateral or sitting positions are used by some neurosurgeons. In any case, the head is flexed, and the position and patency of the tracheal tube must be meticulously ensured. In the event that the tracheal tube does become dislodged when the child is in a head holder and prone, successful emergent airway management has been described using a laryngeal mask airway.[181]

Arrhythmias and acute blood pressure changes may occur during surgical exploration, especially when the brainstem is manipulated or irrigated (Fig. 26.9). The electrocardiogram and arterial waveform should be closely monitored. Altered respiratory control may be masked by neuromuscular blocking drugs (NMBDs) and mechanical ventilation. Even when ICP is only marginally increased, intracranial compliance is presumed to have decreased. This warrants precautions against further increases in ICP. If ICP is markedly increased or acutely worsens, a ventricular catheter may be inserted before the tumor is resected. VAE is a potentially serious complication that is not eliminated by the prone or lateral position because head-up gradients of 10 to 20 degrees are frequently used to improve cerebral venous drainage. In infants and toddlers, large head size relative to body size accentuates this problem.

Supratentorial tumors in the midbrain include craniopharyngiomas, optic gliomas, pituitary adenomas, and hypothalamic tumors and account for approximately 15% of intracranial tumors. Hypothalamic tumors (i.e., hamartomas, gliomas, and teratomas) frequently manifest with precocious puberty in children who are large for their chronologic age. Craniopharyngiomas are the most common parasellar tumors in children and adolescents and may be associated with hypothalamic and pituitary dysfunction. Symptoms often include growth failure, visual impairment, and endocrine abnormalities.

Signs and symptoms of hypothyroidism should be sought and thyroid function measured. Corticosteroid replacement (i.e., dexamethasone or hydrocortisone) usually is administered because the integrity of the hypothalamic-pituitary-adrenal axis may be uncertain. Diabetes insipidus can occur preoperatively and is a common postoperative problem. The history usually reveals this condition preoperatively, especially if attention is focused on nocturnal drinking and enuresis. Evaluation of serum electrolytes and osmolality, urine specific gravity, and urine output is helpful because hypernatremia and hyperosmolality, along with dilute urine, are typical findings. If diabetes insipidus does not exist preoperatively, it usually does not develop until the postoperative period because there is an adequate reserve of antidiuretic hormone in the posterior pituitary gland capable of functioning for many hours, even when the hypothalamic-pituitary stalk is damaged intraoperatively.

Postoperative diabetes insipidus is marked by a sudden large increase in dilute urine output associated with an increasing serum sodium concentration and osmolality. Protocols have been developed to guide intraoperative and postoperative management of diabetes insipidus (see Chapters 9 and 27).[143] Return of

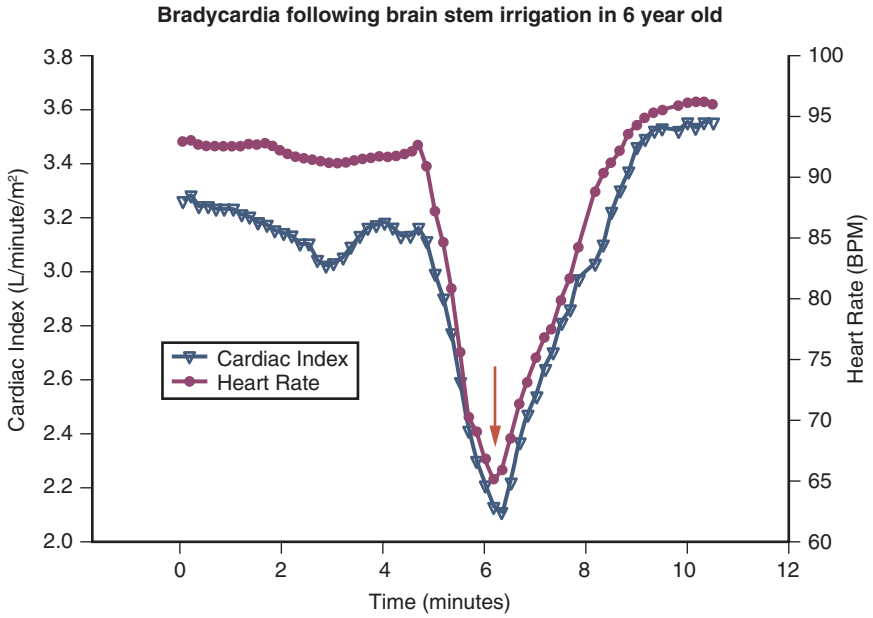

FIGURE 26.9 This graph illustrates the dramatic bradycardic response and accompanying decrease in cardiac index measured by a continuous noninvasive cardiac output monitor (Cardiotronic, Osypka Medical Inc., La Jolla, CA) in a 6-year-old child following brainstem irrigation. As soon as the surgeon stopped irrigation and atropine was administered, the heart rate and cardiac index were restored. (Courtesy Charles J Coté, MD.)

antidiuretic hormone activity a few days postoperatively may cause a marked decrease in urinary output, water intoxication, seizures, and cerebral edema if it is not recognized and fluid administration is not adjusted appropriately.

Transsphenoidal surgery typically is performed only in adolescents and older children with pituitary adenomas. However, it should be treated like other midbrain tumors in terms of monitoring and vascular access. Children are usually intubated orally to give the surgeon optimal access to the nasopharynx, and preparations for an emergent craniotomy should be anticipated in case unexpected massive bleeding develops. Because nasal packs are inserted at the end of surgery, the child should be fully awake before tracheal extubation.

Gliomas of the optic pathways occur with increased frequency in children with neurofibromatosis. Presenting symptoms include visual changes and proptosis; increased ICP and hypothalamic dysfunction are usually late findings. Neurofibromas tend to be highly vascular, and the anesthesiologist should be prepared for considerable blood loss.

Approximately 25% of intracranial tumors in children involve the cerebral hemispheres. They are primarily astrocytomas, oligodendrogliomas, ependymomas, and glioblastomas. Neurologic symptoms are more likely to include a seizure disorder or focal deficits. Succinylcholine should be avoided if motor weakness is present because it can cause sudden severe hyperkalemia. Nondepolarizing NMBDs and opioids may be metabolized more rapidly than usual in children who are receiving chronic anticonvulsants. Choroid plexus papillomas are rare but occur most often in children younger than 3 years of age. They usually arise from the choroid plexus of the lateral ventricle and produce early hydrocephalus as a result of increased production of CSF and obstruction of CSF flow. Hydrocephalus usually resolves with surgical resection. When lesions lie near the motor or sensory strip, a special type of somatosensory evoked potential monitoring called *phase reversal* may be used to delineate the locations.[182] If cortical stimulation is planned to help identify motor areas, NMBDs must be permitted to wear off and the anesthetic technique adjusted to achieve immobilization without paralysis.

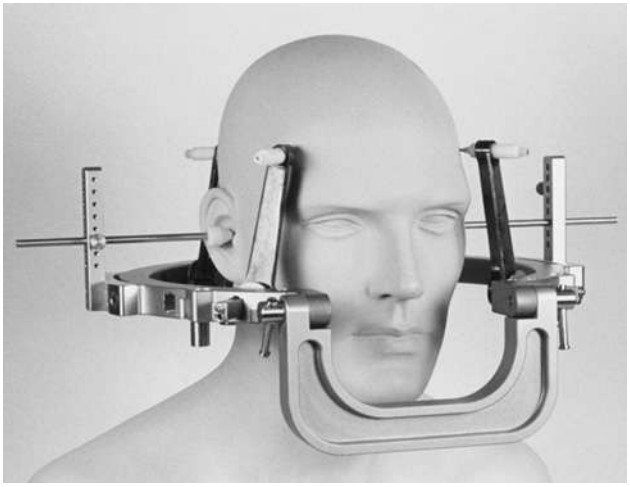
Stereotactic biopsies or craniotomies present special concerns regarding airway accessibility. Newer head frames have adjustable anterior positions so that the airway is readily accessible (E-Fig. 26.1). They are especially useful for stereotactic neurosurgery. It is more comfortable and less distressing for the child to be anesthetized before the head frame is applied, even though this means the anesthesiologist must induce anesthesia in the radiology suite and then transport the child from the CT scanner to the operating room. The wrench that is used to apply and remove the head frame should be taped to the frame at all times so that it is always readily available if emergent removal of the head frame becomes necessary (e.g., during transport).

Vascular Anomalies

Arteriovenous Malformations

Arteriovenous malformations consist of large arterial feeding vessels, dilated communicating vessels, and large draining veins carrying arterialized blood. Large malformations, especially those involving the posterior cerebral artery and vein of Galen, may manifest as congestive heart failure (i.e., high-output heart failure, often with pulmonary hypertension) in the neonate. Consumption of coagulation factors and platelet destruction may further complicate the clinical picture. The prognosis for these types of arteriovenous malformations is quite poor. Saccular dilation of the vein of Galen may manifest later in infancy or childhood as hydrocephalus owing to obstruction of the aqueduct of Sylvius. Malformations not large enough to produce congestive heart failure usually remain clinically silent unless they cause seizures or a stroke or until the acute rupture of a communicating vessel results in subarachnoid or intracerebral hemorrhage.[183] Intracranial hemorrhages are the most common presentation in this population, with an associated mortality rate of ~25%.

Treatment usually consists of embolization or irradiation of deep malformations, surgical excision (usually of the more superficial ones), or a combination of these modalities. Recent evidence supports surgical intervention. The surgical technique may require coordination between multiple locations and a prolonged anesthetic. However, the extra time and transport is worth the generally good outcome and avoidance of subsequent craniotomies for further resection if there is a residual arteriovenous malformation. A postoperative obliteration rate of 100% using a protocol of immediate postcraniotomy cerebral angiography to confirm obliteration has been reported.[184]



Management for elective embolic procedures involves general anesthesia. Moderate hyperventilation may enhance visualization of abnormal blood vessels that do not respond with vasoconstriction. The anesthesiologist should be knowledgeable about the types of embolic agents that can be used and their potential complications. Anticonvulsant therapy is routine. Neonates in cardiac failure may be receiving inotropic agents. Bleeding, especially from the femoral arterial puncture site (which cannot always be visualized), should always be a consideration. Fluid overload may result from the large amount of contrast agents administered, especially in a young infant who may already be in high-output cardiac failure. The anesthesiologist should be prepared for the possibility of an emergency craniotomy if a vessel ruptures.

Aneurysms

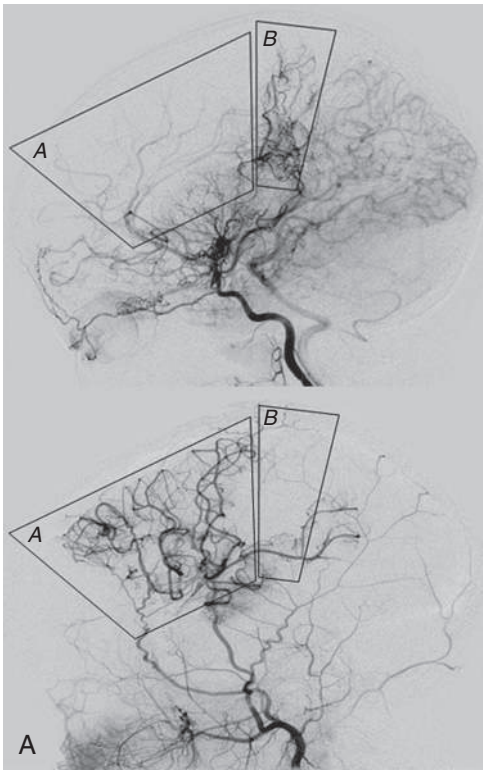
Intracranial aneurysms most often result from a congenital malformation in an arterial wall. Children with coarctation of the aorta or polycystic kidney disease have an increased incidence of these aneurysms. They usually remain asymptomatic during childhood; most ruptures that occur in childhood are fatal. Symptoms of subarachnoid or intracerebral hemorrhage frequently appear suddenly in a previously healthy young adult. When technically feasible, surgical ligation or clipping constitutes the treatment of choice.[185]

Anesthesia for surgical resection of vascular malformations and aneurysms in children presents unique challenges, especially if the diagnosis has been preceded by an intracranial hemorrhage. Blood products should be in the operating room and verified before the start of the procedure. An adequate depth of anesthesia should be ensured before any invasive maneuver to prevent precipitous hypertension. Adequate venous access to respond to sudden and massive blood loss is crucial but can wait until after induction of anesthesia. A blood-warming device, such as a rapid transfusion device, should be immediately available.

Controlled hypotension may be valuable in some situations for brief periods to reduce tension in the abnormal blood vessels and improve the safety of surgical manipulation.[186] It is not clear, however, whether the benefits of controlled hypotension are worth the risks, especially in small children (see Chapter 12). Controlled hypotension should not be used in children with increased ICP because of the risk of decreasing CPP, with resulting ischemia and further increased ICP. Although the absolute limits of acceptable hypotension are unknown, a mean blood pressure greater

E-FIGURE 26.1 The modified Brown-Roberts-Wells stereotactic head frame (Radionics, Burlington, MA) has an adjustable face piece that provides enhanced access to the airway. (From Stokes MA, Soriano SG, Tarbell NJ, et al. Anesthesia for stereotactic radiosurgery in children. *J Neurosurg Anesthesiol*. 1995;7:100–108.)

than 40 mm Hg for infants or 50 mm Hg for older children appears to be safe; teenagers should have a target MAP no less than 55 mm Hg. At the conclusion of the procedure, the blood pressure is returned to normal, but before closing the dura, the operative site should be inspected for bleeding.



Hemodynamic stability is important during emergence to avoid bucking, coughing, straining, and hypertension during extubation. Excessive hypertension can result in postoperative bleeding, although in most cases of aneurysm clipping, a slightly increased blood pressure may be desirable postoperatively to minimize the risk of vasospasm. After resection of an arteriovenous malformation, there can be serious postoperative complications related to cerebral edema with increased ICP or hemorrhage. This *normal perfusion pressure breakthrough* is probably caused by hyperemia of the areas surrounding the previous arteriovenous malformation site, where vessels suffer from continued vasomotor paralysis and cannot vasoconstrict. Treatment is controversial but usually involves therapy for increased ICP (e.g., diuretics, moderate hyperventilation, head elevation) in addition to judicious use of moderate hypotension (while maintaining CPP) and moderate hypothermia. When surgery is completed, it is important that children are able to cooperate with a neurologic examination and that there is careful control of blood pressure in the intensive care unit.

Moyamoya Disease

Moyamoya disease is an anomaly that results in progressive and life-threatening occlusion of intracranial vessels, primarily the internal carotid arteries near the circle of Willis.[187] An abnormal vascular network of collaterals develops at the base of the brain, and the appearance of these many, small vessels on angiography was originally described by the Japanese name *moyamoya*, which roughly translates as "puff of smoke" (Fig. 26.10A). The congenital form of the disease can involve the systemic vasculature, including pulmonary, coronary, and renal vessels; affected renal arteries are the most commonly identified angiographic lesion. The acquired variety (i.e., moyamoya syndrome) may be associated with meningitis, neurofibromatosis, chronic inflammation, connective tissue diseases, certain hematologic disorders, Down syndrome, or prior intracranial radiation.[188] Some children with neurologic symptoms from sickle cell disease may also have moyamoya.[189] Moyamoya disease appears to be more common among children of Japanese ancestry. Associated intracranial aneurysms are rare in children but may occur in more than 10% of affected adult patients. Abnormal ECG findings have been described with the syndrome in adults.

Moyamoya disease usually manifests as transient ischemic attacks progressing to strokes and fixed neurologic deficits in children. These attacks may be precipitated by hyperventilation.[190] The morbidity and mortality rates are high if the condition is left untreated. Medical management consists of antiplatelet therapy, such as aspirin, or calcium channel blockers. The most common surgical operation for correction in children is pial synangiosis, which involves suturing a scalp artery (usually the superficial temporal artery) directly onto the pial surface of the brain to enhance angiogenesis (Fig. 26.10B).[191]

Careful and continuous monitoring of $ETCO_2$ is essential in anesthesia management.[192] Children with moyamoya disease have reduced hemispheric blood flow bilaterally, and hyperventilation may further reduce regional blood flow and cause EEG and neurologic changes.[193] *Normocapnia must be maintained throughout all phases of the procedure,* including induction of anesthesia. Adequate hydration and maintenance of baseline blood pressure are

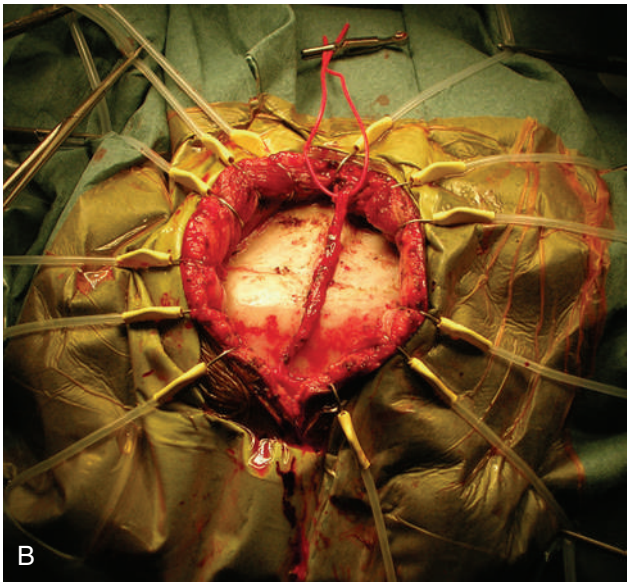


FIGURE 26.10 Moyamoya disease. **A,** The top angiogram shows the pattern of arterial filling after injection of the internal carotid artery in a child with moyamoya disease before pial synangiosis. *Area A* shows poor filling from the middle cerebral artery as a result of the disease process. *Area B* shows the characteristic hazy collaterals, or moyamoya vessels. The bottom angiogram is from the same child after pial synangiosis. The angiogram was obtained after injection of the superficial temporal artery, and it shows good filling in the middle cerebral artery distribution in *area A. Area B* does not fill from the middle cerebral artery. **B,** Pial synangiosis. The superficial temporal artery is prepared to be sutured to the pia of the cerebral cortex. After the craniotomy is completed, this artery can be sewn directly onto the underlying pia mater. The result of this procedure is improvement of blood flow to ischemic areas of the cerebral cortex.

indispensable. Most of these children have an IV catheter inserted the night before surgery and are given 1.5 times the amount of maintenance fluids to avoid dehydration during the perioperative period. EEG monitoring during these procedures can detect and help to treat ischemia that appears to be a result of cerebral vasoconstriction in response to direct surgical manipulation of the brain.[194] Normothermia is maintained, particularly at the end of the procedure, to avoid postoperative shivering and an exaggerated stress response. As with most neurosurgical procedures, a smooth extubation without hypertension or crying is desirable. Although scant literature exists regarding intraoperative and postoperative complications during moyamoya surgery, it appears that most complications (e.g., strokes) occur postoperatively and are associated with dehydration and crying (i.e., hyperventilation) episodes.[195] Those centers that regularly perform this surgery have better outcomes,[196] indicating that higher-volume centers are able to provide improved care and reduced mortality in children with moyamoya disease. The most marked benefit displayed was for those patients who underwent surgical revascularization.

Seizure Surgery

Epilepsy is one of the most common neurologic disorders of childhood. Despite the development of new drugs and regimens, the prevalence of pharmacologically intractable seizures remains high. Advances in neuroimaging, functional MRI, and EEG monitoring provide epileptologists anatomic targets that mediate some medically intractable seizure disorders.[197] Advances in pediatric neurosurgery have exploited these technologies and dramatically improved the outcomes for infants and children.[198]

Children presenting for surgical management of seizures take anticonvulsant medications, which can have serious adverse effects, including abnormalities of hematologic function such as abnormal coagulation, depression of red or white blood cell production, and decreased platelet counts.[199] Other problems may arise from altered hepatic function. Specific anticonvulsant concentrations should be determined preoperatively to detect subtherapeutic or toxic concentrations. Many anticonvulsants enhance metabolism of nondepolarizing NMBDs and opioids, increasing (up to 50%) the amount of these drugs needed during a surgical procedure. The preoperative evaluation should detect underlying conditions that are causing the seizures and the disabilities that can result from progressive neurologic dysfunction.

A major concern during resection of seizure foci is avoiding harming brain tissue that controls vital functions, such as motion, sensation, speech, and memory (the so-called eloquent cortex), especially if a seizure focus is adjacent to cortical areas controlling these functions. Cooperative adolescents and adults can assist in determination of the limits of safe cortical resection if they can be continually assessed during the surgical procedure. The technique of awake craniotomy is often performed in carefully selected adolescents. An awake craniotomy encompasses a wide variety of techniques whose common goal is to allow intraoperative assessment and feedback to determine if the eloquent cortex is at risk during resection.

Children are selected for this procedure on an individual basis. Most children younger than 12 years of age and many teenagers cannot tolerate an awake craniotomy. However, selected individuals may do well. The anesthesiologist should have detailed conversations with the child and parents to determine appropriateness before initiating such a procedure.

Some practitioners perform the entire procedure, including line placement, infiltration of local anesthetic, skull and dural opening, and resection, with the child completely awake or with minimal sedation. This particular approach requires an extremely motivated child. A variation on this technique uses short-acting sedatives and analgesics, such as propofol and fentanyl or remifentanil, titrated to induce unconsciousness but maintain spontaneous ventilation for instillation of local anesthetics, insertion of monitoring catheters, placement of head pins, and skull opening.[200] Subsequently, children can be allowed to awaken during surgical resection. They can then have sedatives and opioids reinstituted for the craniotomy closure.

Alternatively, some anesthesiologists use the asleep-awake-asleep technique. It consists of inducing general anesthesia and maintaining airway control with a supraglottic device (i.e., laryngeal mask airway). General anesthesia is maintained for line placement, placement of head pins, and skull and dural opening. The child is then awakened, the supraglottic airway is removed, and the surgeons proceed with resection. At the conclusion of the resection, general anesthesia is again induced and the supraglottic airway is reinserted for closure of the dura, skull, and skin. There are several disadvantages to the asleep-awake-asleep approach. One of the major concerns with this approach is airway management during emergence and induction while the child is in head pins. If the child coughs or bucks while immobilized, cervical spine injuries or scalp lacerations can occur. Brain swelling is also a concern in a child who is breathing spontaneously under general anesthesia with an inhalational anesthetic and possibly with nitrous oxide.

Regardless of the technique chosen, the anesthesiologist must have an in-depth discussion with the child or adolescent about intraoperative needs and expectations.[201] The preoperative period is the time to decide whether the child is a candidate for an awake craniotomy. There are no randomized, controlled trials comparing the safety or effectiveness of the techniques described.

Younger children (<12 years of age) or uncooperative children of any age do not tolerate this approach and require general anesthesia throughout. In these circumstances, intraoperative electrophysiologic studies, such as somatosensory evoked potentials, EEG, and motor stimulation, may be used to help localize and determine the function of the site of planned resection. If EEG studies are to be performed, the anesthetic technique should be adjusted to maximize EEG signals. If direct cortical motor stimulation is planned, NMBDs must be permitted to wear off. Occasionally, a seizure focus is difficult to identify intraoperatively. In these situations, hyperventilation or methohexital (in small doses, 0.25–0.5 mg/kg) may be helpful in lowering the seizure threshold and producing EEG seizure activity.[202,203]

In some children, the site of origin of generalized seizures is difficult to determine. When this occurs, evaluation with intracranial EEG monitoring ("grids and strips") may be accomplished with direct electrocorticography (E-Fig. 26.2). The leads are placed on the surface of the cortex after a craniotomy performed with general anesthesia. Intraoperative EEG monitoring is limited during these procedures to ensuring that all leads are functional; monitoring for seizures takes place over the next several days to identify a focus that is amenable to resection. These children need to be observed carefully in the postoperative period because complications can develop from having intracranial electrodes in place. Because air frequently persists in the skull for up to 3 weeks after a craniotomy,[97] these children should not have nitrous oxide administered for a subsequent procedure (e.g., to resect a seizure focus, to remove the electrocorticography leads) until their dura has been opened to prevent the development of tension pneumocephalus.

The development of intraoperative MRI (iMRI) has aided in the surgical treatment of epilepsy. There continues to be great

E-FIGURE 26.2 Skull radiograph of a child with intracranial electrocorticography grids in place.

interest in the development of this technology to assist perioperatively with a variety of neurosurgical procedures and aid in facilitating optimal outcomes. This technology naturally lends itself to seizure surgery when a focal lesion can be identified. There is evidence in the adult literature supporting the use of iMRI in seizure surgery to facilitate higher resection volumes and consequently improved postoperative seizure outcomes.[204] A retrospective review of the role of iMRI in children undergoing resection for peri-eloquent cortical dysplasias and heterotopias has suggested that, comparison with conventional surgical approaches in these patients, iMRI led to elevated rates of gross total resection and a seizure-free postoperative course. Further, the use of iMRI in these patients led to a decrease in postoperative neurologic deficits.[205] Similar results have been published using iMRI in pediatric patients undergoing surgical resection of focal cortical dysplasia.[206]

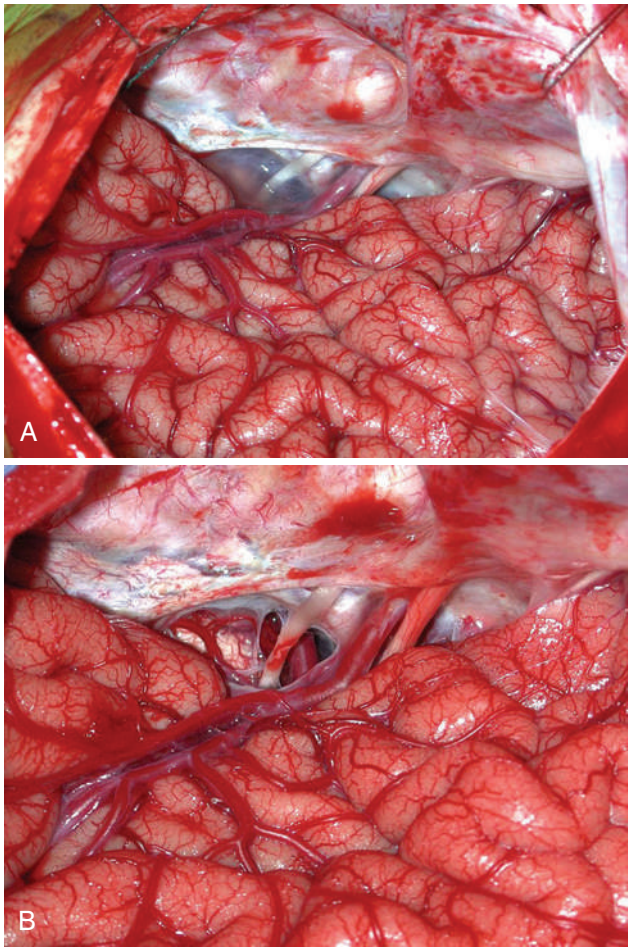
When a focal resection is not possible, a lobectomy or corpus callosotomy may be attempted. However, children undergoing the latter procedure are often somnolent for the first few postoperative days, especially if a complete callosotomy is performed. This also occurs in children who have undergone insertion of multiple subdural grids and strips. Occasionally, small children undergo a hemispherectomy because their seizures are attributed to an abnormal hemisphere that is already severely dysfunctional, as when affected by hemiparesis. These can be challenging cases for the anesthesiologist because much blood can be lost (from one-half to multiples of the estimated blood volume).[207] This procedure is usually performed when children are very young to permit the other hemisphere to take over the function of both sides. Large-bore IV access is necessary in these cases to facilitate rapid replacement of blood, crystalloid solutions, and medications. Arterial pressure monitoring is routine, and many practitioners also use CVP monitoring.

An advance in the treatment of epilepsy has been the development of the vagal nerve stimulator. Although its exact mechanism of action is not well understood, it appears to inhibit seizure activity at brainstem or cortical levels.[208,209] It is becoming a popular form of treatment because it has shown benefit with minimal side effects in many children who are disabled by intractable seizures. Large, randomized trials are being conducted to determine the overall efficacy of this treatment. There are few published series of vagal nerve stimulation in children, but it is estimated that there is a 60% to 70% improvement in seizure control, with the best results achieved in those with drop attacks.[210,211]

The vagal nerve stimulator is a programmable device similar to a cardiac pacemaker and is placed subcutaneously under the left anterior chest wall. Bipolar platinum stimulating electrode coils, which are implanted around the left vagus nerve, are connected to the generator by subcutaneously tunneled wires. The device automatically activates for up to 30 seconds every 5 minutes. Although stimulation of the vagal nerve in this manner may affect vocal cord function, sudden bradycardia or other side effects are uncommon.[212] When children with vagal nerve stimulators return for subsequent operations, it may be appropriate to deactivate the stimulator while the child is receiving general anesthesia in order to prevent repetitive vocal cord motion.

A recently implemented technique of ablating deeper brain seizure foci such as hypothalamic hamartomas involves stereotactic placement of a laser catheter into the lesion in question and real-time thermal ablation under MR guidance. This so-called laser-induced thermal therapy (LITT) has been used for several years but its use in children is more recent. This technique offers potential for surgical treatment of lesions previously deemed too dangerous to operate on or even simply unresectable. There is some evidence of its efficacy and safety in children, especially for epilepsy surgery.[213,214]

HYDROCEPHALUS



Hydrocephalus is a condition involving a mismatch of CSF production and absorption, resulting in an increased intracranial CSF volume. It can be caused by a variety of pathologic processes, including arachnoid cysts (E-Fig. 26.3). Except for rare instances of excess CSF production, such as in choroid plexus papillomas, most cases of hydrocephalus result from some type of obstruction or an inability to absorb CSF appropriately. Commonly, this is a result of neonatal intraventricular or subarachnoid hemorrhage, congenital problems (e.g., aqueductal stenosis), trauma, infection, or tumors, especially those in the posterior fossa. Hydrocephalus can be classified as nonobstructive/communicating or obstructive/noncommunicating based on the ability of CSF to flow around the spinal cord in its usual manner.

Intracranial hypertension or decreased intracranial compliance typically accompanies untreated hydrocephalus in children. How much intracranial compliance exists and how acutely hydrocephalus develops are both factors in how severe the signs and symptoms of hydrocephalus become. If hydrocephalus develops slowly in the young infant, the skull will expand and the cerebral cortical mantle will stretch until massive craniomegaly (often with irreversible neurologic damage) occurs. However, if the cranial bones are fused or the cranium cannot expand fast enough, neurologic signs and symptoms rapidly become apparent. The child may become progressively more lethargic and develop vomiting, cranial nerve dysfunction (i.e., setting sun sign), bradycardia, brain herniation, and death.

Unless the cause of the hydrocephalus can be definitively treated, treatment usually involves surgical placement of an extracranial shunt. Most shunts transport CSF from the lateral ventricles to the peritoneal cavity (i.e., ventriculoperitoneal [VP] shunts). The distal end of the shunt occasionally must be placed in the right atrium or pleural cavity, usually because of problems with the ability of the peritoneal cavity to absorb CSF. Newer shunt systems with programmable valves reduce the need for shunt revisions.[215]

The use of a percutaneous flexible neuroendoscope through a burr hole in the skull has provided an alternative to extracranial shunt placement.[216,217] During these procedures, a ventriculostomy may be made to bypass an obstruction (e.g., aqueductal stenosis) by forming a communicating hole from one area of CSF flow to another using a blunt probe inserted through the neuroendoscope (Video 26.1). Common locations for a ventriculostomy are through the septum pellucidum (allowing lateral ventricles to communicate) or through the floor of the third ventricle into the adjacent CSF cisterns. Complications such as damage to the basilar artery or its branches or neural injuries can be life-threatening when they occur, and the anesthesiologist should be prepared for an emergency craniotomy during these procedures. Hemodynamic instability may occur intraoperatively if excessive cold irrigating solutions or large volumes are infused through the endoscope. As endoscopic techniques become more commonplace, it is important for anesthesiologists to understand the unique challenges endoscopic neurosurgical procedures present.[218]

The anesthetic plan for a child with hydrocephalus should be directed at controlling ICP and relieving the obstruction as soon as possible. Children with an increased ICP are at risk for vomiting and pulmonary aspiration. Rapid-sequence induction and tracheal intubation should be performed. Ketamine is generally avoided

E-FIGURE 26.3 Arachnoid cysts can cause hydrocephalus in children. **A**, Before decompression, the mass effect is obvious. **B**, After fenestration of the cyst, cerebrospinal fluid has a path of egress from inside the cyst to the normal cerebrospinal fluid circulation. The mass effect is resolved.

because of its potential to cause sudden massive intracranial hypertension[219]; however, there is some evidence that ketamine may ameliorate the increased ICP in some children.[220,221] In infants, hydrocephalus often produces large, dilated scalp veins, and they can be used for induction of anesthesia if necessary. If IV access cannot be established, induction with sevoflurane and gentle cricoid pressure may be an alternative, although less desirable, method of induction.[222] This method results in venodilation and usually facilitates establishment of IV access. After an IV catheter is inserted, the child may be paralyzed, the lungs ventilated, the trachea intubated, and the inhalational agent decreased or discontinued. The possibility of VAE during placement of the distal end of a ventriculoatrial shunt should always be considered. Postoperatively, children should be observed carefully because an altered mental status and recent peritoneal incision place them at increased risk for pulmonary aspiration after feeding begins. Analgesia may be provided with a variety of easily performed blocks of the head (see Figs. 42.9–42.11).

Anesthesiologists should be familiar with a few special situations involving shunts. Children who develop a shunt infection usually have the entire shunt system removed and external ventricular drainage established. They return to the operating room for insertion of a new shunt several days after the infection has been treated with antibiotics. While an external drain is in place, the operator must be careful not to dislodge the ventricular tubing. The height of the drainage bag should not be significantly changed in relation to the child's head to avoid sudden alterations in ICP. For example, suddenly lowering an open drainage bag can siphon CSF rapidly from the head, resulting in collapse of the ventricles and rupture of cortical veins. When transporting children with CSF drainage or when moving them from a stretcher to an operating room table, it is best to close off the ventriculostomy tubing during these brief periods.

Anesthesiologists should be aware of the condition known as slit ventricle syndrome (Fig. 26.11). This situation develops in 5% to 10% of children with CSF shunts and is associated with overdrainage of CSF and small, slit-like, lateral ventricular spaces. Children with this condition do not have the usual amount of intracranial CSF to compensate for alterations in brain or intracranial blood volume. Special attention should be paid when CT scans identify this condition. It is probably safest to avoid the administration of excess or hypotonic IV solutions in these situations in the intraoperative and postoperative periods to minimize the potential for brain swelling. Some of these children cannot

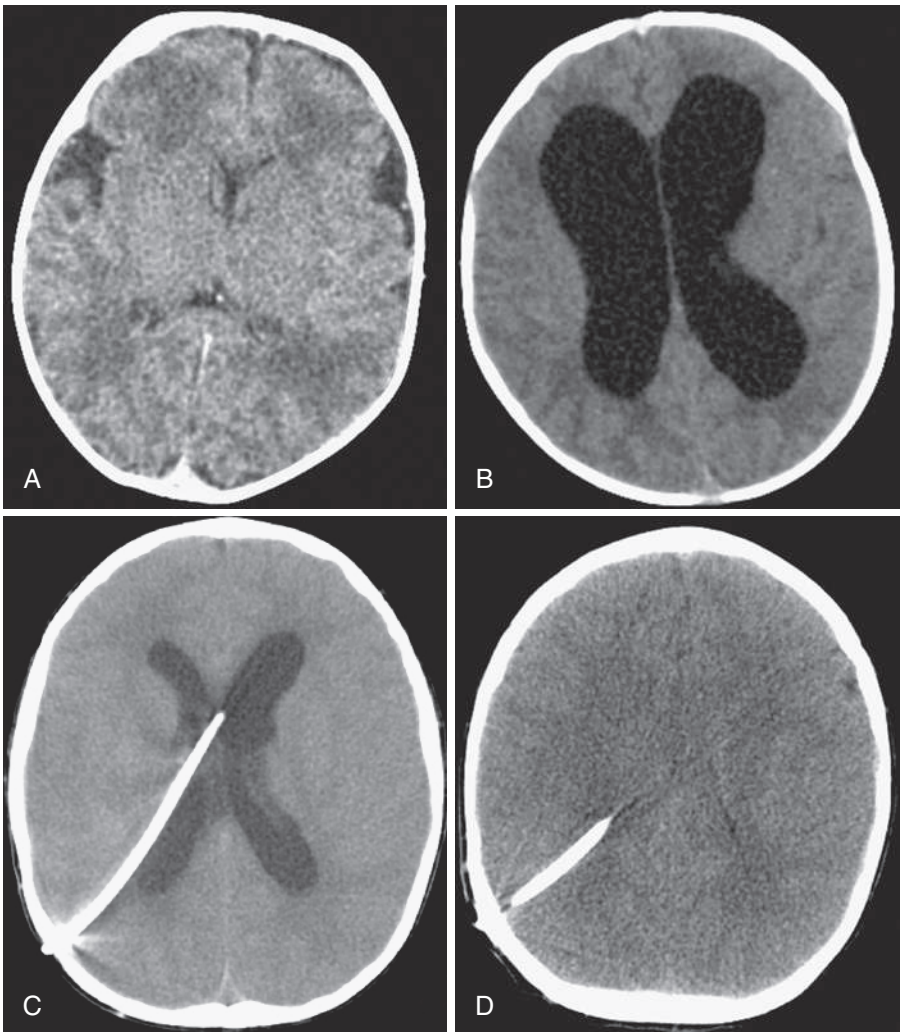


FIGURE 26.11 Computed tonographic scans of children with normal-sized ventricles **(A)**, untreated hydrocephalus **(B)**, hydrocephalus treated with a ventricular shunt **(C)**, and hydrocephalus treated with a ventricular shunt, resulting in slit ventricles **(D)**. (Courtesy Ellen Grant, MD.)

accommodate to situations that otherwise healthy children can easily tolerate. Episodes of postoperative cerebral herniation have been reported after uneventful surgical procedures.[54]

CONGENITAL ANOMALIES

Congenital CNS anomalies typically occur as midline defects. This dysraphism may occur anywhere along the neural axis, involving the head (i.e., encephalocele) (Fig. 26.12A) or spine (i.e., meningomyelocele) (Fig. 26.12B). The defect may be relatively minor and affect only superficial bony and membranous structures, or it may include a large segment of malformed neural tissue.

Encephalocele

Encephaloceles can occur anywhere from the occiput to the frontal area. They can even appear to be nasal polyps if they protrude through the cribriform plate. They are rarely filled with so much CSF that the defect can be almost as large as the head itself (see Fig. 26.12A). Large defects may present challenges to tracheal intubation. Blood loss can be severe, especially if venous sinuses are involved. Adequate IV access should be ensured and blood products readily available. If hemodynamic instability is anticipated, an arterial catheter is indicated.

Myelodysplasia

Defects in the spine are known as *spina bifida*. Meningoceles are lesions containing CSF without spinal tissue. When neural tissue is also present within the lesion, the defect is called a *meningomyelocele*. Open neural tissue is known as *rachischisis*. Hydrocephalus is usually present and is often associated with a type II Chiari malformation.

Most children with a meningomyelocele present for primary closure of the defect within the first 24 hours of life to minimize the risk of infection. Many are now scheduled electively before birth for repair because the defect is usually apparent on prenatal ultrasonography. Many neurosurgeons prefer to insert a ventriculoperitoneal shunt at the time of initial surgery. Alternatively, a shunt may be inserted a few days later or is occasionally deferred if there is no evidence of hydrocephalus at birth.

A major anesthesia consideration is positioning the neonate for induction at surgery. In most cases, tracheal intubation can be performed with the infant in the supine position and the uninvolved portion of the child's back supported with towels (or a donut ring) so there is no direct pressure on the meningomyelocele. For very large defects, it is occasionally necessary to place the infant in the left lateral decubitus position for induction and tracheal intubation. Succinylcholine is rarely needed for tracheal intubation, although it is not associated with hyperkalemia because the defect develops early in gestation and is not associated with muscle denervation.[223] Airway management, mask fit, and intubation may be difficult in infants with massive hydrocephalus or very large defects. In such cases, a sedated "awake" intubation after preoxygenation and administration of atropine occasionally may be the safest alternative. Blood loss may be considerable during repair of a larger defect when skin is undermined to cover the defect.

Children with myelodysplasia are at high risk for latex sensitivity and possibly anaphylaxis.[48] This likely results from repeated exposure to latex products encountered during frequent bladder catheterizations and multiple (usually more than five) surgical procedures, during which latex gloves have been in contact with large mucosal surfaces. These children should be managed in a latex-free environment from birth to minimize the chances for sensitization.[224] Latex allergy should be suspected if signs and symptoms of anaphylaxis develop during surgery. Suspected anaphylaxis should be treated with IV epinephrine in a dose of 1 to 10 µg/kg, as required. Many hospitals have replaced most or all of their latex-containing supplies with nonlatex alternatives; this has resulted in complete elimination or marked reduction of latex anaphylactic reactions during anesthesia in some institutions.[225] Children who develop latex allergy exhibit cross-reactivity with some antibiotics[226,227] and foods, especially tropical fruits such as avocados, kiwi fruit, and bananas.

Postoperatively, respiratory status should be carefully assessed. Pulse oximetry is valuable during recovery from anesthesia because

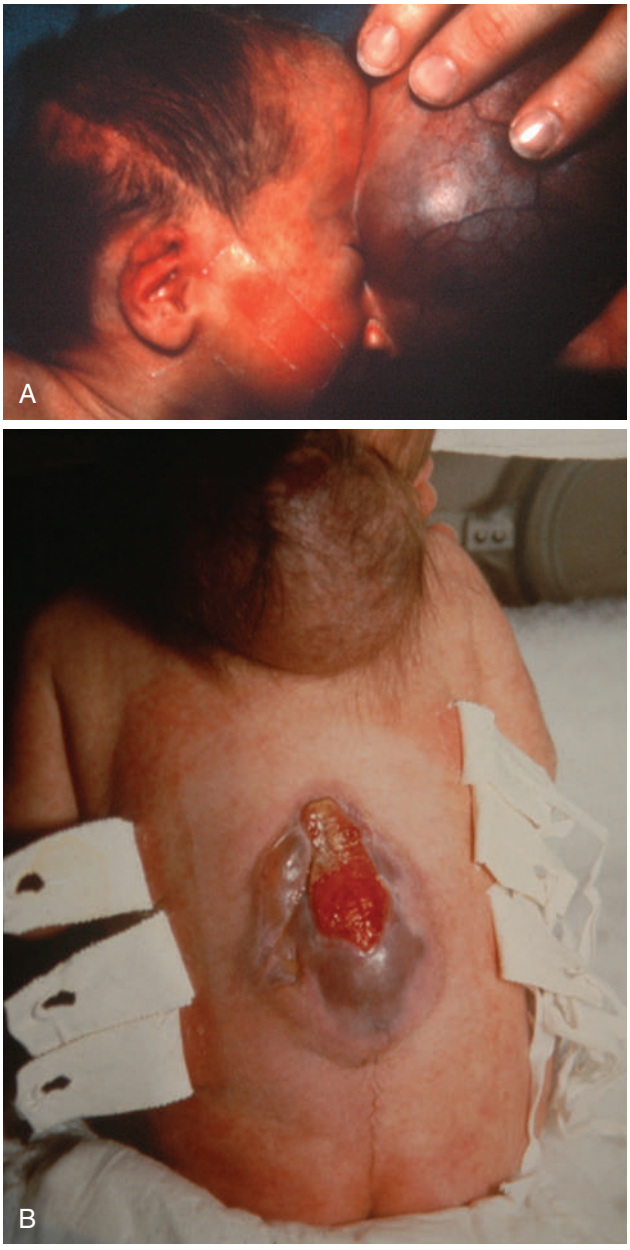

FIGURE 26.12 **A,** An infant with an anterior encephalocele. **B,** An infant with a posterior encephalocele and myelomeningocele defects. Notice the large exposed surface areas that make this child prone to dehydration. Difficulty may be encountered in positioning for induction of anesthesia and intubation; significant loss of blood and cerebrospinal fluid during surgical correction should be anticipated.

breathing difficulties may occur after a tight skin closure and the ventilatory responses to hypoxia and hypercarbia may be diminished or absent when a Chiari malformation coexists.[228] Intrauterine surgery has been advocated as a way of diminishing the degree of damage caused by myelodysplasia.[229–231]

Chiari Malformations

There are several types of Chiari malformations (Table 26.3). The Arnold-Chiari malformation (type II) usually coexists in children with myelodysplasia. This defect consists of a bony abnormality in the posterior fossa and upper cervical spine with caudal displacement of the cerebellar vermis, fourth ventricle, and lower brainstem below the plane of the foramen magnum. Medullary cervical cord compression can occur (Figs. 26.13 and 26.14). Vocal cord paralysis with stridor and respiratory distress, apnea, abnormal swallowing and pulmonary aspiration, opisthotonos, and cranial nerve deficits

TABLE 26.3 Types of Chiari Malformation

Type I	Caudal displacement of cerebellar tonsils below the plane of the foramen magnum
Type II (Arnold-Chiari; associated with myelomeningocele)	Caudal displacement of the cerebellar vermis, fourth ventricle, and lower brainstem below the plane of the foramen magnum Dysplastic brainstem with characteristic kink, elongation of the fourth ventricle, beaking of the quadrigeminal plate, hypoplastic tentorium with small posterior fossa, polymicrogyria, enlargement of the massa intermedia
Type III	Caudal displacement of the cerebellum and brainstem into a high cervical meningocele
Type IV	Cerebellar hypoplasia

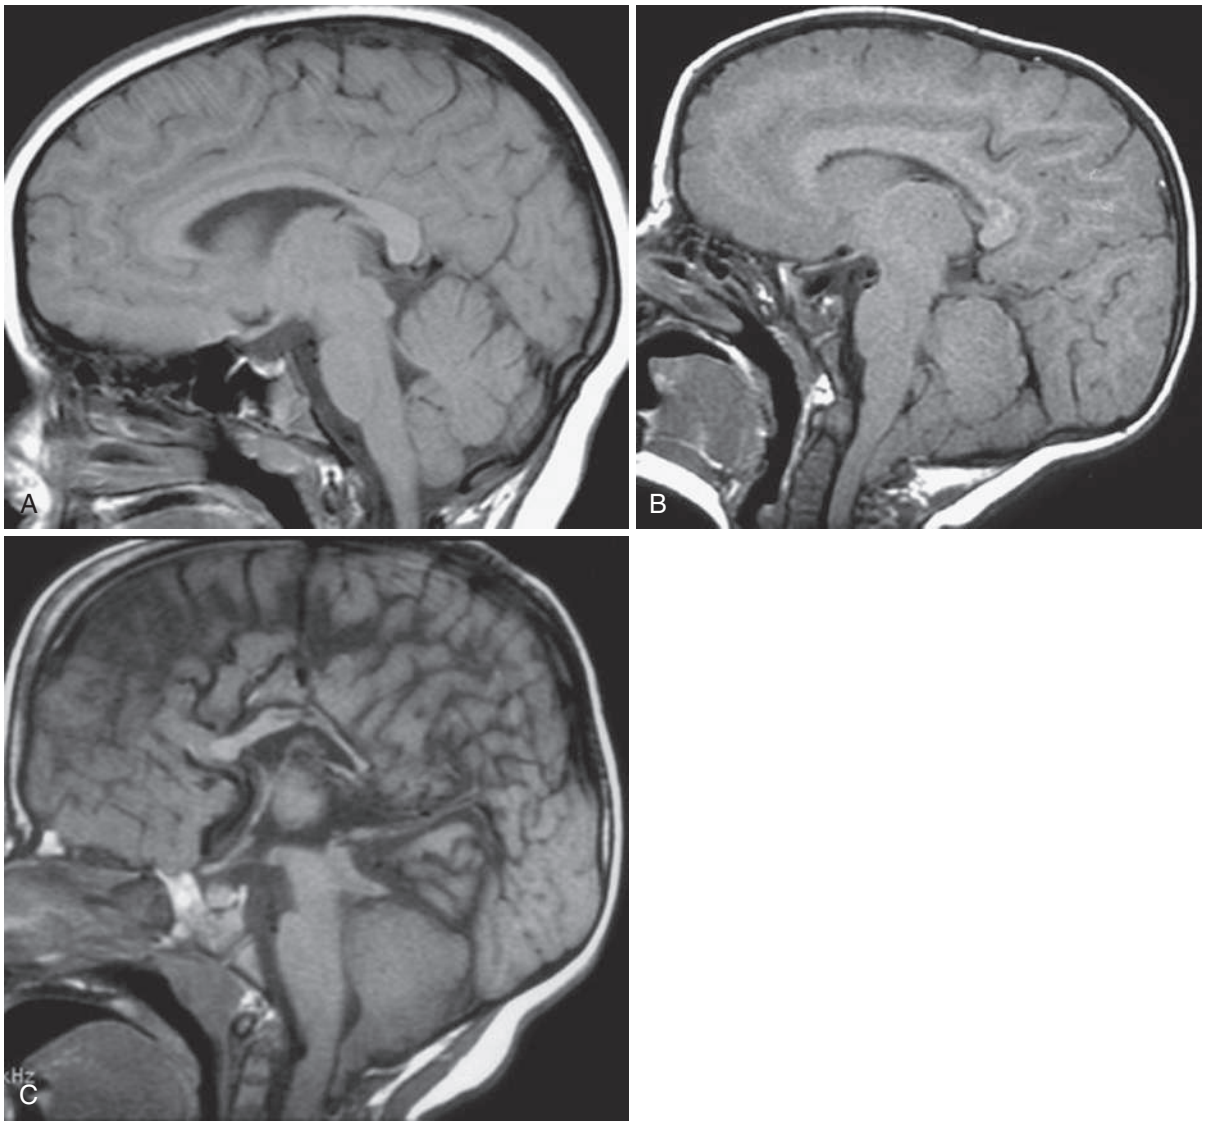

FIGURE 26.13 **A,** Sagittal, T1-weighted magnetic resonance imaging (MRI) of a normal child. **B,** Sagittal, T1-weighted MRI of a child with a Chiari I malformation, which consists of caudal displacement of the cerebellar tonsils at least 5 mm into the upper cervical spinal canal, often with no clinical symptoms. **C,** Sagittal, T1-weighted MRI of a child with a type II Chiari malformation, which is characterized by caudal displacement of the cerebellar tonsils, additional brain anomalies, and a meningomyelocele deformity. (Courtesy Ellen Grant, MD.)

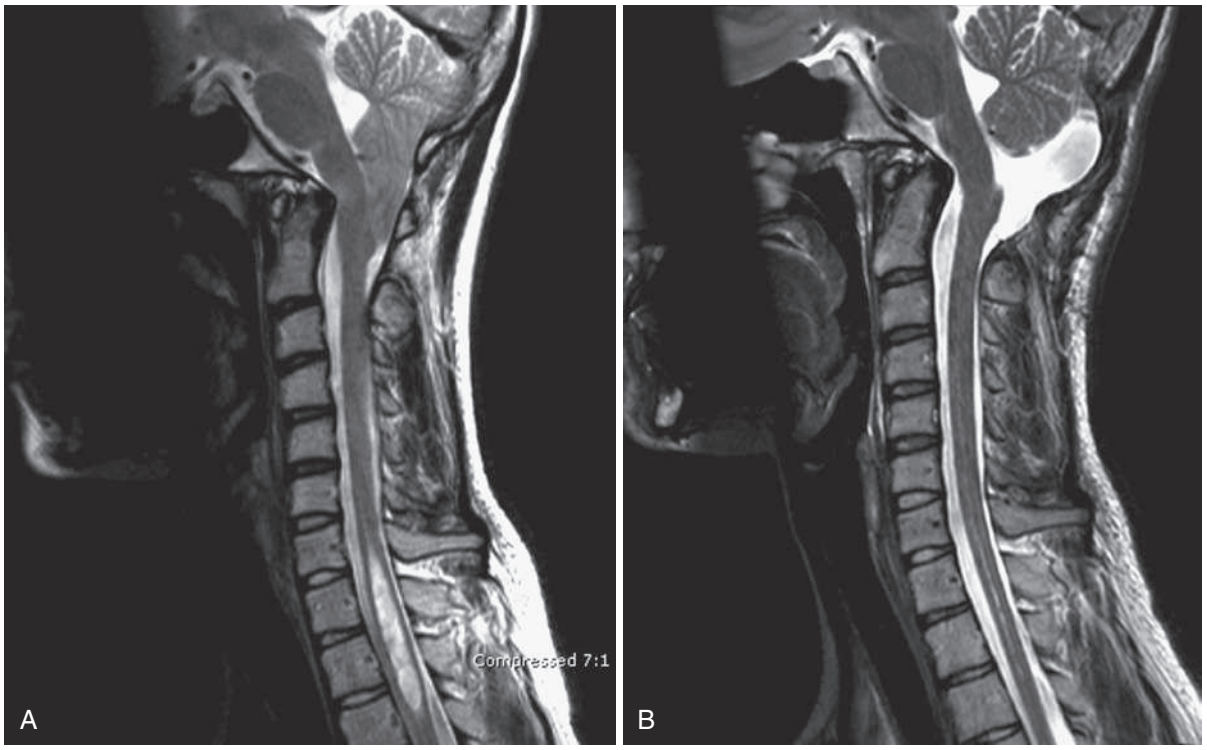

FIGURE 26.14 The images show the posterior fossa in a child with a Chiari II malformation before and after posterior fossa decompression. **A,** Notice the downward herniation of the cerebellar tonsils. **B,** Resolution of cerebellar tonsillar herniation after posterior fossa decompression.

may be associated with the Arnold-Chiari malformation and usually manifests during infancy. Children with vocal cord paralysis or a diminished gag reflex may require tracheostomy and gastrostomy to secure the airway and to minimize chronic aspiration. Children of any age may have abnormal responses to hypoxia and hypercarbia because of cranial nerve and brainstem dysfunction.[228,232] Extreme head flexion may cause brainstem compression in otherwise asymptomatic children.

Type I Chiari malformations can occur in healthy children without myelodysplasia. These defects also involve caudal displacement of the cerebellar tonsils below the foramen magnum, but children usually have much milder symptoms, sometimes manifesting only as headache or neck pain.[233] Surgical treatment usually involves a decompressive suboccipital craniectomy with cervical laminectomies.

Other Spinal Defects

Other spinal anomalies (e.g., lipomeningoceles, lipomyelomeningoceles, diastematomyelias, dermoid tracts) may manifest as tethered cords. Skin defects, typically over the lower lumbar region, may occur as dural sinus tracks or lipomeningoceles. Midline hair tufts, skin dimples, or fat pads may be associated with spinal defects. These anomalies sometimes manifest when toilet training or ambulation is observed to be abnormal or later in childhood when children complain of back pain. Children who have had a meningomyelocele repaired after birth may also develop an ascending neurologic deficit from a tethered spinal cord during growth. Early detection of a tethered cord is easily diagnosed with MRI. Prophylactic surgical untethering is common.

Anesthesia management for surgical release of a tethered cord usually entails monitoring the innervation of the lower extremities and bowel and bladder with nerve stimulators and rectal electromyelograms or manometry. Muscle relaxants should be avoided or permitted to dissipate before intraoperative assessment.

NEURORADIOLOGIC PROCEDURES

Many neuroradiologic procedures are performed in children. Anesthetic considerations for neurodiagnostic procedures (e.g., CT, MRI) are discussed elsewhere (see Chapters 46 and 48), but certain therapeutic neuroradiologic procedures are addressed here.

To improve intraoperative navigation during intracranial procedures, the concept of iMRI was introduced in the mid-1990s. The technology has advanced to include a variety of operating room suite designs that encompass MRI machines (E-Fig. 26.4). These procedures present special challenges for neurosurgeons and anesthesiologists.[234–238] As with anesthesia for diagnostic MRI scans, special monitors, infusion pumps, and an MRI-safe or MRI-conditional anesthesia machine are required. It is challenging to do surgical procedures in this environment, especially because these procedures may take many hours, they may be associated with significant blood loss, and access to the child is severely limited. Some monitoring equipment found in conventional operating rooms (e.g., precordial Doppler ultrasonography, core temperature probes, fluid warmers) is not MRI safe or conditional. Nevertheless, numerous neurosurgical procedures have been safely performed in children in these MRI operating rooms, and the equipment for these procedures is rapidly evolving.

ACKNOWLEDGMENTS

The authors wish to thank Mark A. Rockoff, Veronica Miller, MD, and Elizabeth A. Eldredge, MD, for their prior contributions to this chapter.

E-FIGURE 26.4 Intraoperative magnetic resonance imaging (MRI) unit. A child undergoing a craniotomy for tumor resection is being prepared to undergo an intraoperative MRI to assess the extent of resection needed. The child currently has an open craniotomy. The surgical field is kept sterile under the clear plastic drape. The mobile, 1.5-Tesla MRI unit is moving out over the child and will be completely over the child's head during imaging. The information provided by the intraoperative scan helps to guide intraoperative decision making, such as the need for continued resection if residual tumor is found. Although this technology represents an advance in intraoperative navigation, the technical difficulties of anesthetizing a child for a major surgical procedure in a high-strength magnetic field environment are significant.

ANNOTATED REFERENCES

This study and that by Sun et al. (see later) represent the current best knowledge regarding concerns of anesthetic exposure in children. Both studies demonstrated no difference in neurocognitive outcomes between the general anesthesia groups and controls. They both conclude that a single, relatively brief general anesthetic does not appear to put a child at risk of adverse neurocognitive outcomes. Both of these studies will continue to be cited and discussed frequently. It is important for pediatric anesthesiologists to be familiar with them.

Jevtovic-Todorovic V, Hartman RE, Izumi Y, et al. Early exposure to common anesthetic agents causes widespread neurodegeneration in the developing rat brain and persistent learning deficits. *J Neurosci*. 2003;23:876-882.

This extremely important paper addresses the controversies surrounding the use of common anesthetic agents in neonates. The authors present compelling animal data showing that commonly used anesthetic agents such as isoflurane cause histologically evident neurodegeneration and cause behavioral and cognition problems. This reference is commonly cited when this discussion arises. However, directly extrapolating these data to the practice of anesthetizing neonates is questionable, especially in light of recently published studies. This is an issue that will require much more research to clearly define.

This classic review article discusses the various physiologic mechanisms of control of cerebral blood flow.

Pollack IF. Brain tumors in children. *N Engl J Med*. 1994;331:1500-1507.

Although this review is from the 1990s, it provides a comprehensive overview of the epidemiology of pediatric brain tumors and treatment approaches. Knowledge of various treatment approaches to different histologic types of tumors can inform the anesthesiologist about the extent of the process behind the procedure and how aggressive the surgery needs to be to achieve a desired outcome.

Reasoner DK, Todd MM, Scamman FL, Warner DS. The incidence of pneumocephalus after supratentorial craniotomy: observations on the disappearance of intracranial air. *Anesthesiology*. 1994;80:1008-1012.

This well-conceived study evaluates the length of time pneumocephalus persists after supratentorial craniotomy. The take-home message is that air persists in the head for several weeks after craniotomy, and care should be taken not to exacerbate the situation during subsequent administration of anesthetics. Nitrous oxide should be avoided in these children, because tension pneumocephalus could develop.

Diabetes Mellitus*

The incidence of type 1 diabetes mellitus in children is increasing worldwide,[1–3] and while type 2 diabetes in children remains a less common disorder, its prevalence is also increasing.[4,5] The use of insulin pumps and various multicomponent insulin regimens has increased the complexity of perioperative management of children with diabetes. Anesthesiologists must carefully consider the pathophysiology of the disease, as well as each child's specific diabetes treatment regimen, glycemic control, intended surgery, and anticipated postoperative course, when devising an appropriate perioperative management plan. Standardized algorithms for perioperative diabetes management improve care[6–9] without significantly increasing costs[8]; several guidelines and studies of perioperative management of children with diabetes are available in the literature and examples are included.[10–16]

*Adapted and updated from Rhodes ET, Ferrari LR, Wolfsdorf JI. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg.* 2005;101:986–999.

CLASSIFICATION AND EPIDEMIOLOGY IN CHILDREN

Type 1 and type 2 are the most common, but not the only, forms of diabetes (Table 27.1).[17,18] Type 1 diabetes is characterized by absolute deficiency of insulin, which usually results from immune-mediated destruction of pancreatic beta cells.[18] In contrast, type 2 diabetes is characterized by a combination of insulin resistance and a relative deficiency of insulin.[17,18] Children with type 2 diabetes typically are overweight and frequently have a first- or second-degree relative with type 2 diabetes.[17] However, the high prevalence of obesity in children[19] has blurred the distinction between type 1 and type 2 diabetes. Children with phenotypic characteristics of type 2 diabetes may have pancreatic autoimmunity,[20–23] and approximately 35% of children with diabetes who require exogenous insulin at diagnosis are overweight or obese[24,25]; these data are consistent with the prevalence of childhood overweight and obesity in the general U.S. pediatric population.[19]

Other forms of diabetes are less commonly encountered (see Table 27.1). Monogenic diabetes, formerly referred to as maturity-onset diabetes of the young (MODY), occurs in approximately 2% to 3% of the pediatric diabetes population, and with improvements in care, patients with cystic fibrosis–related diabetes account for a small, but significant, fraction of the diabetes population at major pediatric medical centers. Additional modifications to

TABLE 27.2 Insulin Preparations Classified According to Their Pharmacokinetic Profiles[a]

Insulin Type	Onset (h)	Peak (h)	Duration (h)
Rapid-Acting[b]			
Insulin lispro (Humalog)[c]	<0.25	0.5–2.5	≤5
Insulin aspart (Novolog)[c]	<0.25	1–3	3–5
Insulin glulisine (Apidra)[c]	<0.25	0.5–1.5	3–5
Short-Acting[b]			
Regular (soluble)	0.5–1	2–4	5–8
Intermediate- and Long-Acting[b]			
NPH (isophane)	1–2	2–8	14–24
Insulin glargine (Lantus)[c]	2–4	No peak	20–24
Insulin detemir (Levemir)[c]	1–2	3–9	Up to 24
Insulin degludec (Tresiba)[c]	1–2	No peak	>42

NPH, neutral protamine Hagedorn.
[a]Times of onset, peak, and duration of action vary within and between patients and are affected by numerous factors, including dosage, site, depth of injection, dilution, temperature, and other factors.
[b]Premixed combinations of intermediate-acting and either rapid- or short-acting insulins are available whose pharmacodynamic profiles have a bimodal pattern reflecting the two insulin components.
[c]Insulin analog developed by modifying the amino acid sequence of the human insulin molecule.
Adapted from Rhodes ET, Ferrari LR, Wolfsdorf JI. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg.* 2005;101(4): 986–999.

the perioperative treatment regimen may be necessary when diabetes is associated with genetic syndromes and/or other endocrinopathies, such as adrenal insufficiency (see later discussion).

Although the worldwide incidence of type 1 diabetes is quite variable,[26] the incidence is increasing in almost all populations.[27] The SEARCH for Diabetes in Youth Study, which began in 2000, provides the most comprehensive estimates of the prevalence and incidence of type 1 and type 2 diabetes among U.S. youth younger than 20 years of age.[28–32] Type 1 diabetes remains the most common form of diabetes observed among U.S. youth, with the greatest prevalence (2.55 per 1000) among non-Hispanic white youth.[4] The epidemic of obesity contributed to a progressive increase in the incidence and prevalence of type 2 diabetes in U.S. children.[4] In the SEARCH study, the prevalence of type 2 diabetes in 10- to 19-year-old youth ranged from 0.17 per 1000 among non-Hispanic white youth to 1.20 per 1000 among Native American youth, and the incidence ranged from 3.7 per 100,000 per year among non-Hispanic white youth to 27.7 per 100,000 per year among Native American youth.[4,31–33] Increases in the prevalence and incidence of type 2 diabetes have also been noted in other parts of the world.[5,34–40]

GENERAL MANAGEMENT PRINCIPLES

Understanding both the pharmacokinetic and pharmacodynamic properties of insulin preparations and antihyperglycemic medications is critical to developing an appropriate perioperative plan.

Type 1 diabetes always requires treatment with insulin. However, an increasing number of insulin preparations (Table 27.2) and delivery systems are available.[41] The least complex regimens consist of two or three insulin injections per day. They incorporate a combination of an intermediate-acting insulin (e.g., neutral protamine Hagedorn [NPH]) and/or a long-acting insulin (e.g., insulin detemir [Levemir] or insulin glargine [Lantus]) for basal coverage with a short- or rapid-acting insulin (e.g., regular, insulin aspart [NovoLog], insulin lispro [Humalog], or insulin glulisine [Apidra]) to provide prandial glycemic coverage. More intensive multicomponent insulin regimens are being used with greater frequency and typically consist of insulin glargine, a long-acting insulin, which provides a relatively constant 24-hour basal concentration of circulating insulin without a pronounced peak to simulate basal insulin secretion,[42] in conjunction with rapid-acting insulin administered with food. Some studies have demonstrated superior glycemic control with such regimens compared with regimens using NPH insulin and regular insulin,[43] although the ideal insulin regimen for children with type 1 diabetes remains controversial and outcomes may differ geographically.[44–46] Another long-acting insulin, insulin detemir, may be used in intensive insulin regimens and has demonstrated more predictable glucose-reducing effects than both NPH[47–49] and insulin glargine.[47] The newest long-acting insulin, degludec (Tresiba), is approved for use in adults in many parts of the world[50] and recently received FDA approval for use in children and adolescents.[51,52]

Many children with type 1 diabetes are managed with an insulin pump.[46,53,54] This device administers a continuous subcutaneous infusion of insulin (typically a rapid-acting insulin, see Table 27.2) at a basal rate that is supplemented by bolus doses of rapid-acting insulin given with meals and snacks. In appropriately selected children, pump therapy has shown superiority over injection regimens.[55–59] Standard insulin preparations are U100, meaning that there are 100 units of insulin per milliliter. However, very young patients with type 1 diabetes may require diluted insulin (e.g., U10) to achieve accurate dosing.[60–62] Parents of preschool-aged

children, especially toddlers, with type 1 diabetes should be specifically questioned and educated about their use of diluted insulin.

Most children with type 2 diabetes are managed with insulin and/or oral metformin, the only oral agent approved for use in children with diabetes in the United States.[63–65] Metformin's primary action is to decrease hepatic glucose production and, secondarily, to increase insulin sensitivity in peripheral tissues. Occasionally, other oral agents including sulfonylureas, which promote insulin secretion, and thiazolidinediones, which increase insulin sensitivity in muscle and adipose tissue, are used in adolescents.[66,67] Nutritional therapy is always included in the management of children with type 2 diabetes.[65] The **T**reatment **O**ptions for Type 2 **D**iabetes in **A**dolescents and **Y**outh (TODAY) trial,[68,69] evaluated the optimal treatment for type 2 diabetes in children and adolescents, age 10 to 17 years. In the TODAY trial, monotherapy with metformin was associated with durable glycemic control in approximately 50% of children and adolescents with type 2 diabetes. The addition of rosiglitazone, but not an intensive lifestyle intervention, was superior to metformin alone.

Increasingly, other medications used to manage adults with type 2 diabetes are being evaluated for use in children, although none are yet approved in the United States.[70,71] Incretins, including glucose-dependent insulinotropic polypeptide and glucagon-like peptide-1 (GLP-1), are gastrointestinal hormones released after eating that stimulate insulin secretion and are necessary for normal glucose tolerance.[72] GLP-1 acts through a G protein–coupled receptor to promote glucose-dependent insulin secretion, suppression of glucagon secretion, slowing of gastric emptying, and reduction in food intake.[70,73] Exenatide (Byetta) is a GLP-1 receptor agonist widely used in adults with type 2 diabetes as an adjunctive therapy for those taking metformin and/or a sulfonylurea.[74] Inhibitors of dipeptidyl peptidase-IV,[75] the enzyme that degrades GLP-1, are also increasingly being used for the treatment of type 2 diabetes in adults, but have not been approved for use in children. Pramlintide acetate (Symlin) is a synthetic amylin receptor agonist that can be used as an adjunct to insulin therapy in adults with type 1 or type 2 diabetes.[76–79] Amylin, a 37-amino acid polypeptide islet hormone cosecreted with insulin from islet beta cells,[70] has three effects: delay of gastric emptying, inhibition of glucagon secretion, and modulation of satiety.[70]

METABOLIC RESPONSE TO SURGERY

Trauma of any kind, and surgery in particular, triggers a complex neuroendocrine stress response that includes suppression of insulin secretion and increased production of counterregulatory hormones (frequently referred to as "stress hormones"), particularly cortisol and catecholamines.[80,81] Insulin is the primary anabolic hormone that promotes glucose uptake in muscle and adipose tissue while suppressing glucose production (glycogenolysis and gluconeogenesis) by the liver.[82] The counterregulatory hormones, which include epinephrine, glucagon, cortisol, and growth hormone, exert the opposite effects, resulting in resistance to insulin action[83–85] and an increase in blood glucose concentration by (1) stimulating glycogenolysis and gluconeogenesis in the liver, (2) increasing lipolysis and ketogenesis, and (3) inhibiting glucose uptake and utilization in muscle and fat. Glucagon, secreted by alpha cells in the pancreatic islets, suppresses insulin secretion while stimulating hepatic glycogenolysis, gluconeogenesis, and ketogenesis.[82,83] Epinephrine, which acts via β_2- and α_2-adrenergic receptors, stimulates glucagon production, increases glycogenolysis and gluconeogenesis, stimulates lipolysis, decreases insulin secretion, and decreases glucose utilization in insulin-sensitive tissues.[82] Cortisol stimulates gluconeogenesis, proteolysis, and lipolysis and decreases glucose utilization.[83,86] Growth hormone augments glucose production, decreases glucose utilization, and accelerates lipolysis.[87] Proinflammatory cytokines may further stimulate secretion of counterregulatory hormones and alter insulin receptor signaling.[85] These changes increase catabolism, as evidenced by increased hepatic glucose production and breakdown of protein and fat. In the patient with diabetes with absolute or relative insulin deficiency, the enhanced catabolism resulting from surgical trauma can lead to marked hyperglycemia and even diabetic ketoacidosis.[88] These metabolic effects may be exacerbated by a prolonged fast before surgery.

METABOLIC RESPONSE TO ANESTHESIA

Although adequate analgesia is essential to minimize the neuroendocrine stress response to surgery, some anesthetics may also independently contribute to perioperative hyperglycemia.[10,89] Inhalation anesthetics, such as isoflurane and sevoflurane, may cause hyperglycemia by inhibiting insulin secretion[90–92]; the hyperglycemia results from both impaired glucose uptake and increased glucose production.[89] In contrast, epidural analgesia with local anesthetics prevents this hyperglycemic effect[93,94] through an inhibitory effect on endogenous glucose production.[89] Similarly, intravenous (IV) anesthesia with opioids mitigates the hyperglycemic response to surgery[89,95,96] through its apparent neutral effect on endogenous glucose production but decrease in glucose clearance.[89] Although these differences are important to consider, the metabolic effects of anesthesia per se are relatively minor compared with the direct effects of surgery.[10]

ADVERSE CONSEQUENCES OF HYPERGLYCEMIA

Hyperglycemia can impair wound healing by hindering collagen production, which may decrease the tensile strength of the surgical wound.[97] Hyperglycemia may also have adverse effects on neutrophil function, including decreased chemotaxis, phagocytosis, and bactericidal killing.[98–101] Evidence from controlled experimental studies in rabbits demonstrated that these effects may be reversed, in part, by glycemia-independent effects of insulin.[102] However, the overall benefits of intensive insulin therapy, including a reduction in mortality, were derived mainly from maintenance of normoglycemia, whereas glycemia-independent actions of insulin exert only minor, organ-specific effects.[102]

Several pediatric clinical trials have investigated whether a strategy of tight glycemic control with IV insulin should be used to normalize blood glucose concentrations in nondiabetic children after major surgery.[103–106] Unless combined with continuous glucose monitoring, this approach increases the risk of severe hypoglycemia.[105] The preponderance of published data indicates that tight glycemic control is not recommended as standard treatment for children who have undergone cardiac surgery because it does not significantly change the infection rate, mortality, length of stay, or measures of organ failure compared with standard care.[107] Similarly, in a 35-center trial in critically ill children, excluding postcardiac surgery patients, there was no evidence of observed benefit of tight glycemic control and the possibility of harm.[107]

Clinical studies in adults with diabetes mellitus have not consistently supported the relationship between perioperative glycemic control and short-term risk of infection or morbidity.[108,109] However, several studies in adults with diabetes undergoing surgery have shown an association between postoperative hyperglycemia and infectious complications.[110,111] A meta-analysis showed that patients in surgical intensive care units (ICUs) benefit from

intensive insulin therapy, whereas patients in other ICU settings do not.[112] These outcomes have obfuscated the specific glycemic targets and the means for achieving them in both critically and noncritically ill patients. A recent consensus statement[113] recommended that an insulin infusion should be used to control hyperglycemia in the majority of critically ill patients in the ICU setting, with a starting threshold of no greater than 180 mg/dL. Once IV insulin therapy has been initiated, the serum glucose concentration should be maintained between 140 and 180 mg/dL. There have been no prospective, randomized controlled trials to establish guidelines in noncritically ill patients treated with insulin. The current clinical strategy for these patients includes premeal glucose targets of less than 140 mg/dL and random blood glucose values less than 180 mg/dL, as long as these targets can be safely achieved. To avoid hypoglycemia, one should reassess the insulin regimen if the blood glucose concentration decreases below 100 mg/dL. The insulin regimen should be modified if the blood glucose concentration is less than 70 mg/dL, unless the event is easily explained by other factors (such as a missed meal).[113] These perioperative blood glucose goals are also recommended in an Endocrine Society Clinical Practice Guideline for the management of hyperglycemia in hospitalized patients in the noncritical care setting[114] and are supported by the International Society for Pediatric and Adolescent Diabetes (ISPAD) Clinical Practice Consensus Guidelines 2014 for management of children and adolescents with diabetes requiring surgery.[16]

In the 1980s and 1990s the dogma of tight glucose control replaced an era in which the mantra of caring for diabetic surgical patients was "keep them sweet," but in more recent years perioperative glucose control for patients with diabetes has become controversial and is unresolved, with conflicting evidence. A systematic review of the literature concluded that there are insufficient data regarding the best strategy or regimen to attain target blood glucose concentrations in ambulatory surgical patients with diabetes mellitus.[115] The recommended practice for subspecialties, such as cardiac, neurosurgical, and solid organ transplant surgical patients, requires still more study, and it must be highlighted that few of the published investigations and meta-analyses have focused specifically on children.

PREOPERATIVE ASSESSMENT

When feasible, children with diabetes should not undergo elective surgery until they are metabolically stable (Fig. 27.1)–that is, there is no ketosis, serum electrolytes are normal, and the glycated hemoglobin (HbA1c) value approximates the recommended goal of less than 7.5% across all age groups.[116] A more stringent target of less than 7% is recommended for young adults provided this can be achieved without excessive hypoglycemia[116]; a similar target applies for those with type 2 diabetes.[17] The preoperative consultation to assess the adequacy of metabolic control should be scheduled at least 10 days before the procedure (see Fig. 27.1). If metabolic control is poor, surgery should be delayed if possible. Both the endocrinology and anesthesiology services should participate in this assessment. Whenever possible, surgery for children with diabetes should be scheduled as the first case in the morning so that prolonged fasting is avoided and diabetes treatment regimens may be most easily adjusted.

Children who present for emergent surgery (e.g., trauma or acute surgical conditions) require a multidisciplinary preoperative assessment with collaborative involvement of both the endocrinology and anesthesiology services. Surgery often cannot be delayed even if metabolic control is poor–for example, a child requiring emergent surgery who presents in diabetic ketoacidosis. This has implications for the intraoperative management of such children; described later under "Special Surgical Situations."

PREOPERATIVE MANAGEMENT

The regimen for managing diabetes before, during, and after a surgical or diagnostic procedure that requires the child to fast should aim to maintain near-normoglycemia–that is, a blood glucose concentration of 100 to 200 mg/dL. Blood glucose in this range reduces the risks of osmotic diuresis, dehydration, electrolyte imbalance, metabolic acidosis, infection, and hypoglycemia in the sedated child who may be unable to communicate with staff.[117] The child need not be admitted before the day of surgery, but rather early on the same morning as the surgery or procedure. Parents should receive explicit written instructions regarding appropriate modifications of their child's diabetes regimen before and for the day of surgery. On admission to the hospital, metabolic control should be assessed, including a preoperative determination of the blood glucose concentration. On the morning of surgery, no rapid- or short-acting acting insulin should be administered *unless* the blood glucose concentration exceeds 250 mg/dL. However, admission to the hospital before *major* surgical procedures in children[10] and adults has been recommended if the metabolic status needs to be optimized preoperatively.[83] If the surgery must be delayed for any reason, frequent blood glucose monitoring is mandatory to prevent perioperative hypoglycemia or hyperglycemia.

If the blood glucose exceeds 250 mg/dL and no rapid-acting insulin has been given in the prior 3 hours, a conservative dose of rapid-acting insulin (e.g., insulin lispro, insulin aspart, or insulin glulisine) is administered to restore near-normoglycemia. This is achieved using the child's usual insulin "correction factor," which refers to the decrease in blood glucose concentration expected after administering 1 unit of rapid-acting insulin. This can be calculated using the "1500 rule": divide 1500 by the child's usual total daily dose (TDD) of insulin. For example, if a child typically receives 30 units of insulin daily, this child's "correction factor" would be 1500 ÷ 30 = 50. In this example, 1 unit of rapid-acting insulin would be expected to decrease the child's blood glucose concentration by approximately 50 mg/dL. Various correction factors have been described, including a "1500 rule" for short-acting insulin (regular) and an "1800 rule" for rapid-acting insulin, such as insulin lispro.[118,119] For simplicity and because of insulin resistance caused by surgical stress, the "1500 rule" is appropriate in this setting, even with the use of a rapid-acting insulin. To then calculate an appropriate corrective dose of insulin to restore near-normoglycemia, the anesthesiologist should aim for a target blood glucose concentration of 150 mg/dL.

A "correction factor" rather than a sliding scale is also used to manage a child with hyperglycemia and restore the blood glucose concentration to 150 mg/dL. For example, if the child has a correction factor of 1 unit of rapid-acting insulin to reduce the blood glucose concentration by 50 mg/dL, and the current blood glucose value is 300 mg/dL, to reduce the blood glucose concentration from 300 mg/dL to 150 mg/dL, a total dose of (300 – 150)/50 or 3 units of insulin would be required. At the start of the procedure, the "correction" dose may be administered subcutaneously (using rapid-acting insulin) or by IV infusion using short-acting (regular) insulin in those children who will be managed with an IV insulin infusion during the procedure. For children with type 2 diabetes who do *not* require insulin (but who are, by definition, insulin resistant), an insulin dose of

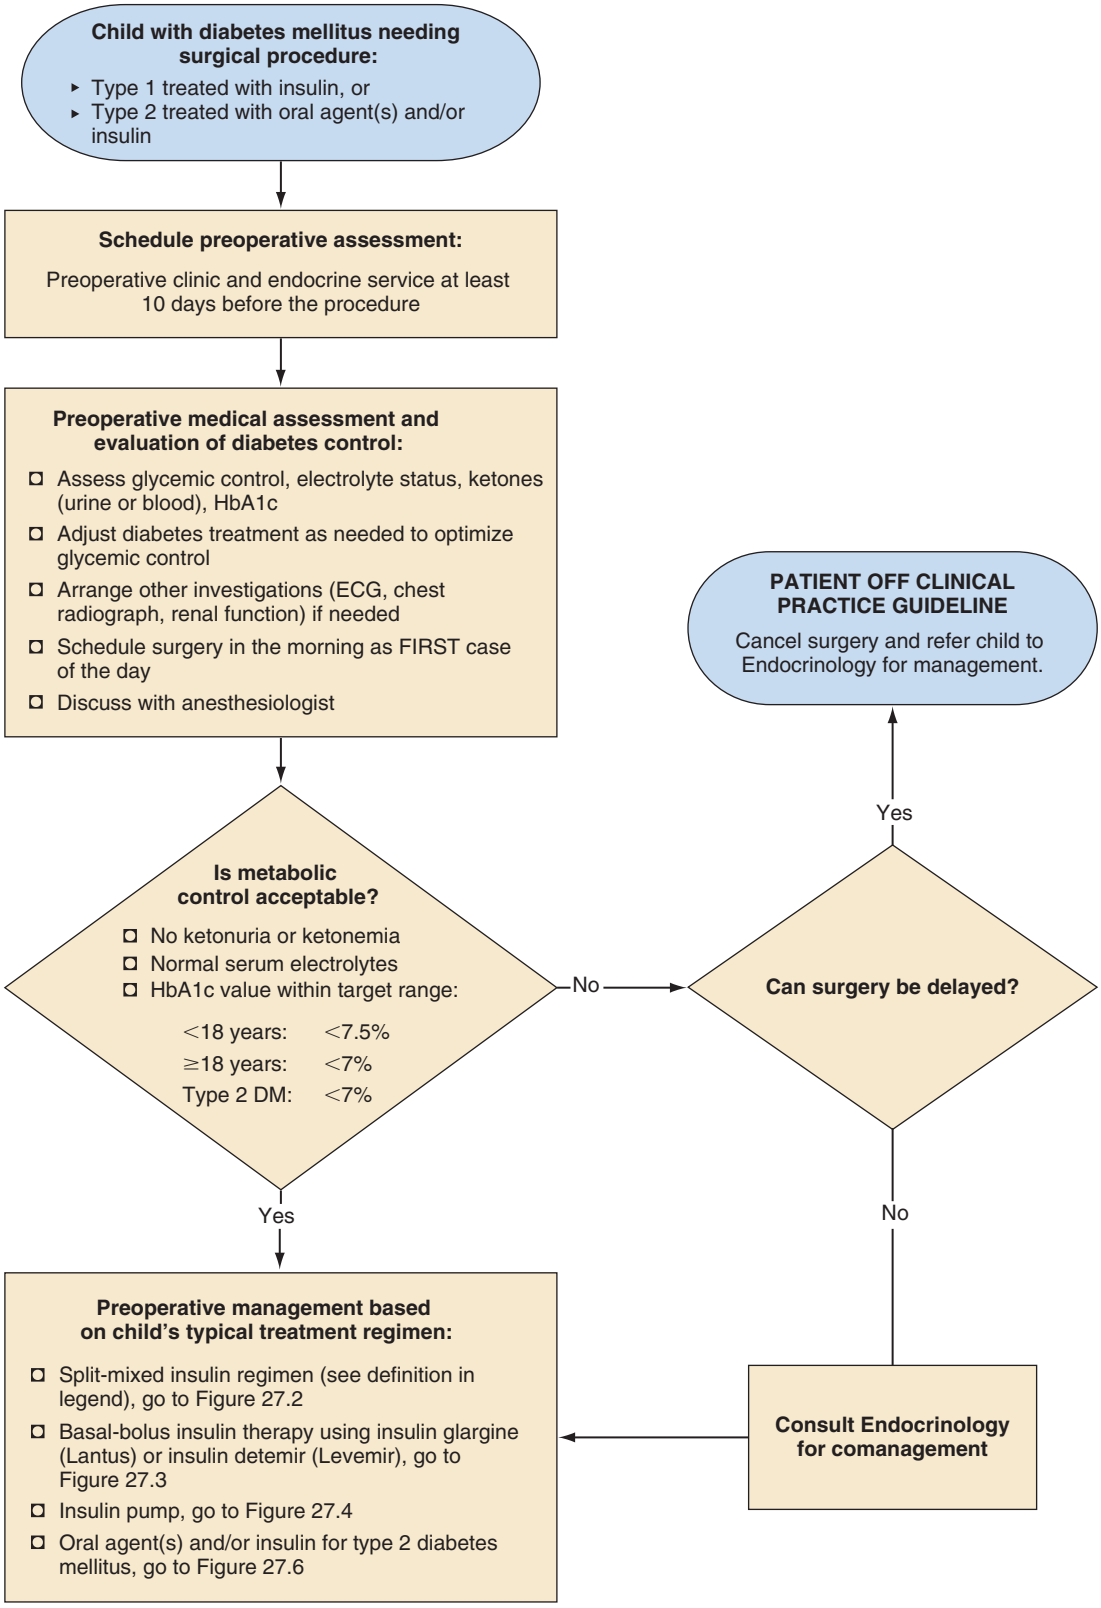

FIGURE 27.1 Clinical practice guideline for perioperative management of diabetes mellitus. Split-mixed insulin regimen refers to a regimen combining multiple daily injections of intermediate-acting insulins (e.g., neutral protamine Hagedorn) and multiple injections of rapid- or short-acting insulins (regular, insulin lispro [Humalog], insulin aspart [NovoLog], or insulin glulisine [Apidra]). *ECG,* electrocardiogram. (Modified from Rhodes ET, Ferrari LR, Wolfsdorf JI. Perioperative management of pediatric surgical patients with diabetes mellitus. *Anesth Analg.* 2005;101:986–999.)

0.1 unit/kg of rapid-acting insulin may be administered subcutaneously to correct a blood glucose concentration greater than 250 mg/dL.

More detailed preoperative recommendations must be based on the individual child's usual treatment regimen. For most children with diabetes undergoing minor outpatient surgical procedures, insulin can be provided perioperatively with subcutaneous injections. In adults, especially those with type 2 diabetes, this practice is commonly,[117] although not universally, preferred.[120] Others routinely recommend insulin infusions even for minor outpatient surgical procedures in children.[10] Several reports suggest that better glycemic control can be achieved in the perioperative period with a continuous IV infusion rather than subcutaneous insulin administration.[12,121,122] However, these studies were conducted before the availability of rapid-acting insulins whose rapid and reproducible effects after subcutaneous administration[123] may more closely match the ability to titrate IV-administered short-acting insulin. Subcutaneous insulin lispro is as effective as regular IV insulin to treat uncomplicated diabetic ketoacidosis in children.[124] Whatever the management strategy for the diabetes, it is most important that it is coordinated between the anesthesiology and endocrinology services, and that the modifications to the child's diabetes regimen at home need to be communicated clearly and in a timely manner to the family.

Split-mixed insulin regimens involve two to three injections per day with a combination of intermediate-acting insulin (NPH) plus a rapid- or short-acting insulin. For children who use such a regimen, 50% of the usual morning dose of NPH should be administered on the morning of the procedure (Fig. 27.2). For the child using a basal-bolus regimen that includes rapid-acting insulin with meals and basal insulin once-daily with insulin glargine or once- or twice-daily with insulin detemir, a dose of basal insulin may be required on the morning of the surgery based on the child's regimen and what insulin he or she received on the evening of the previous day (Fig. 27.3). For example, if insulin glargine or detemir is typically administered only once-daily in the morning, the full dose must be administered on the morning of the procedure to prevent hyperglycemia and ketosis.

Management of the child with an insulin pump depends on the duration of the surgical procedure (Fig. 27.4). Those undergoing minor procedures expected to last 2 hours or less can continue to receive their usual basal rate via their insulin pump. However, this approach requires the anesthesiologist to become familiar and comfortable with the use of an insulin pump in the operating room. Other protocols include transitioning patients who use an insulin pump to IV insulin infusion or subcutaneous insulin glargine.[83] For procedures expected to last longer than 2 hours, children should be transitioned to an IV insulin infusion, as described in the next section.

MAJOR SURGERY AND INTRAVENOUS INSULIN INFUSIONS

Children who require major surgery, especially procedures anticipated to last more than 2 hours, should have an IV insulin infusion as the preferred perioperative diabetes management plan (Fig. 27.5). Studies in children[12] and adults[6] have demonstrated that glycemic control is superior with infusions of IV insulin compared with subcutaneous injections. These children should receive their usual doses of insulin on the day before the procedure. On the morning of the procedure, an IV infusion of 5% dextrose in half-normal saline should be started at a maintenance rate, and an IV insulin infusion should also be provided to accommodate the dextrose infusion to maintain blood glucose in the target range of 100 to 200 mg/dL (see Fig. 27.5). The maintenance rate for IV fluids depends on body size: 20–40 mL/kg lactated Ringer's solution over 2–4 hours of surgery and then 2, 1, and 0.5 mL/kg for each 10 kg body weight if the patient remains NPO postoperatively (see Chapter 9). The insulin dose varies with the child's pubertal status; prepubertal children are relatively more sensitive to insulin than pubertal adolescents.[125] In prepubertal children with type 1 diabetes, after the remission (honeymoon) period, the insulin requirement is typically 0.6 to 0.8 unit/kg per day, whereas in adolescents, the requirement is 1 to 1.5 units/kg per day.[126,127] Children with type 2 diabetes may require even greater doses of insulin because of their insulin resistance. The IV insulin infusion can be started at 0.025 units/kg per hour if blood glucose is less than 140 mg/dL, 0.05 units/kg per hour if blood glucose is between 140 and 220 mg/dL, 0.075 units/kg per hour if blood glucose is between 220 and 270 mg/dL, and 0.1 units/kg per hour if blood glucose is more than 270 mg/dL.[16] Only regular insulin should be used for IV infusions.

SPECIAL CONSIDERATIONS FOR PREOPERATIVE MANAGEMENT OF TYPE 2 DIABETES

Children with type 2 diabetes may require insulin or one of several oral antihyperglycemic agents (Fig. 27.6). Metformin should be discontinued 24 hours before a major surgical procedure (e.g., expected to last more than 2 hours) because of its long duration of effect and the risk of lactic acidosis in the presence of dehydration, hypoxemia, or poor tissue perfusion.[128–131] For minor procedures, expected to last 2 hours or less, metformin may be discontinued on the day of the procedure.[16] Similarly, other oral agents, such as sulfonylureas and thiazolidinediones, may be discontinued on the morning of the procedure. Fig. 27.6 outlines additional recommendations for children with type 2 diabetes who use a split-mixed or basal-bolus insulin regimen. Adjustments for other insulin regimens or oral hypoglycemic agents in type 2 diabetes should be determined in consultation with an endocrinologist or diabetologist.

INTRAOPERATIVE MANAGEMENT

The insulin and fluid regimen during and after surgery depends on the duration of the procedure. If the procedure is likely to be brief (e.g., ≤1 hour) and one can reasonably anticipate that the child will be able to drink soon after the procedure, it may not be necessary to start a glucose-containing IV infusion. If the duration of fasting is likely to be more prolonged, an IV infusion should be started at a maintenance rate as described earlier (Fig. 27.7). Intraoperative maintenance fluid should then be replaced with a comparable glucose-containing solution. Replacement of insensible losses and intravascular volume owing to blood or other body fluid losses should be with an appropriate isotonic solution (e.g., lactated Ringer's solution or normal saline solution).

Although some protocols include potassium chloride in the maintenance IV fluid solution,[10,83,117] this practice should generally be avoided because of the danger of inadvertent intraoperative administration of large quantities of potassium during fluid resuscitation. Children undergoing a brief procedure with a baseline normal serum potassium concentration and well-controlled diabetes have a small risk of hypokalemia. Those undergoing more prolonged surgeries or emergent surgeries during which metabolic decompensation is more likely, require intraoperative assessment of electrolytes and appropriate adjustment of the electrolyte composition of their IV solution. *In all cases, blood glucose*

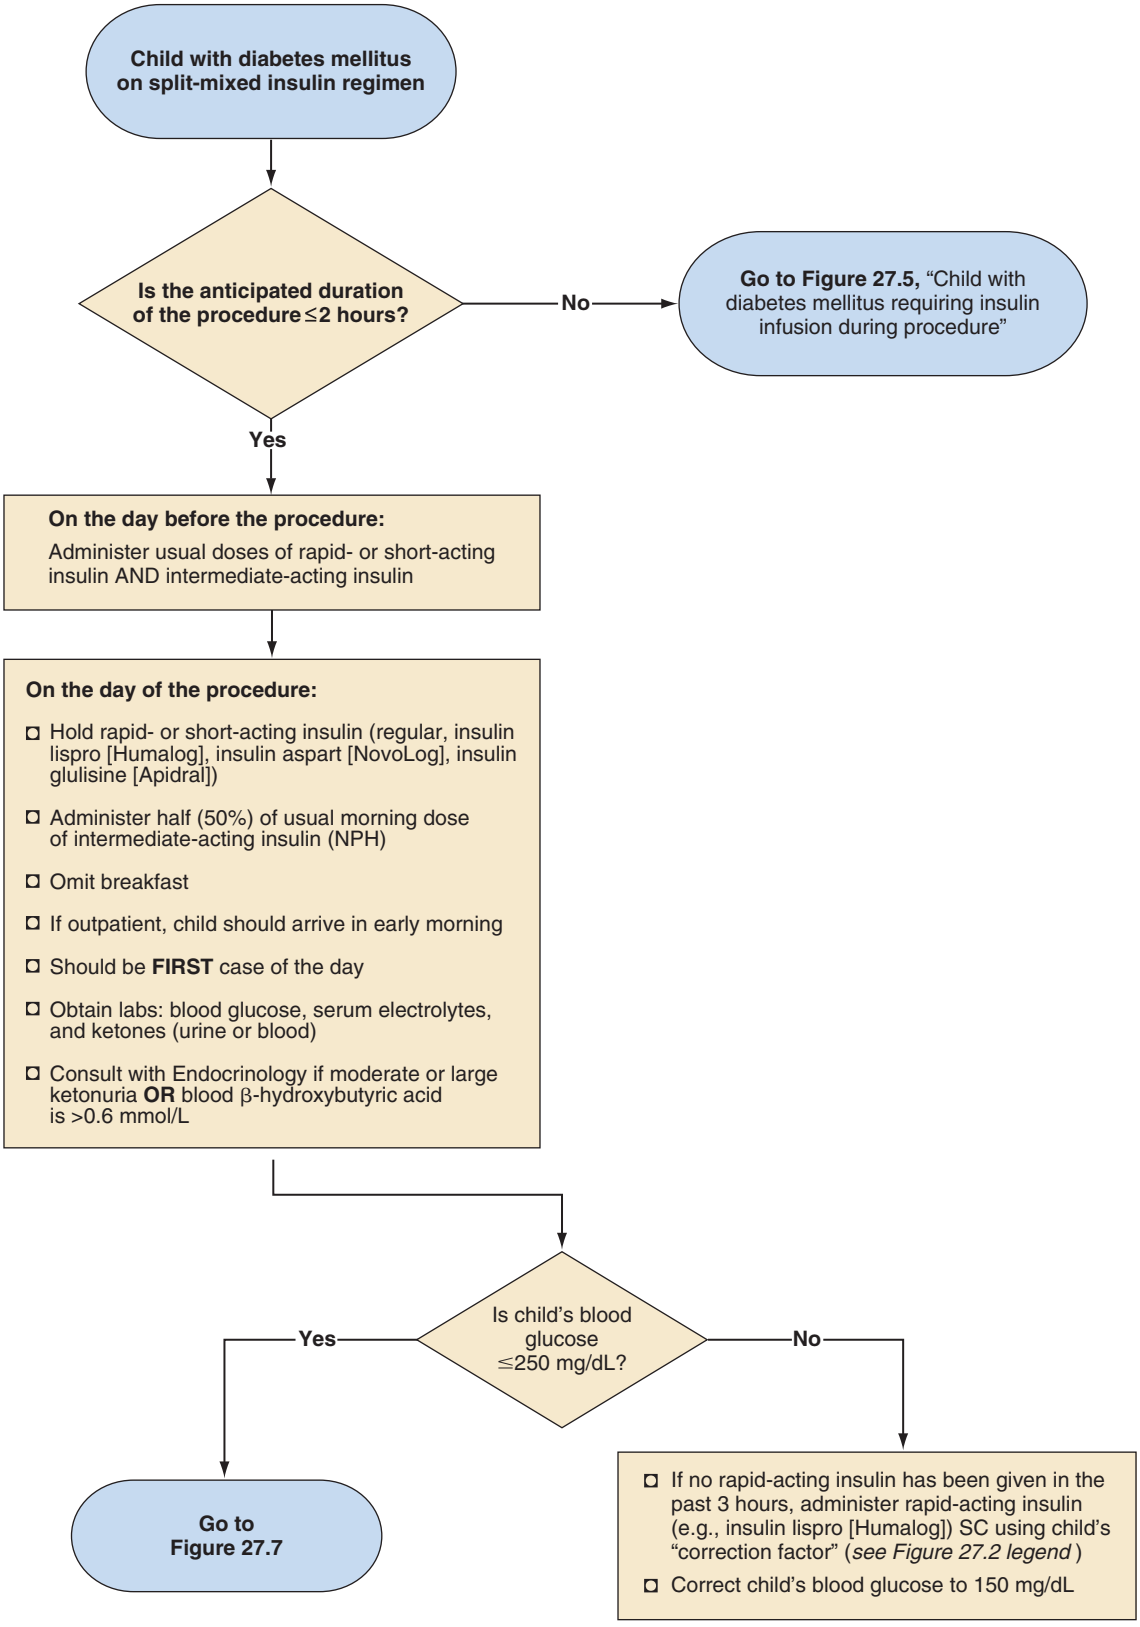

FIGURE 27.2 Preoperative management for children with diabetes mellitus on split-mixed insulin regimens. The calculation for insulin "correction factor" is as follows:

1 Divide 1500 by child's total daily dose (TDD).
2 If daily dose varies (i.e., use of sliding scales), use the *average* daily dose in the past week to determine TDD.
3 Example: If TDD = 50 units, then insulin correction factor is 1 unit insulin lispro (Humalog) to reduce blood glucose by 30 mg/dL.

concentrations should be measured hourly and either insulin or dextrose adjusted, as necessary, to maintain blood glucose in the target range of 100 to 200 mg/dL. If the blood glucose exceeds 250 mg/dL, urine or blood ketones should also be measured (see Fig. 27.7). Either an increase in the rate of continuous insulin infusion or subcutaneous administration of a rapid-acting insulin analog is used to correct intraoperative hyperglycemia. Intraoperative IV bolus of regular insulin is not recommended because this causes a rapid supraphysiologic increase in serum insulin concentration, which, owing to insulin's short half-life (approximately 5 minutes), will have a short-lived effect on blood glucose concentration. In contrast, subcutaneously administered rapid-acting insulin analogs have a typical and reproducible pharmacologic profile.

POSTOPERATIVE MANAGEMENT

As soon as the child is able to resume drinking and eating normally, the usual diabetes regimen, including insulin and/or oral agents, may be reinstituted and the dextrose infusion discontinued (Fig. 27.8). One exception to this approach is for children with type 2 diabetes who take metformin; metformin should be withheld for 48 hours and renal function must be within normal limits before its resumption. IV dextrose and electrolyte solution should be continued until oral intake is restored. An infusion of IV short-acting insulin (regular) or intermittent subcutaneous rapid-acting insulin should be administered, not more frequently than every 3 hours, to maintain blood glucose in the target range of 100 to 200 mg/dL. Frequent blood glucose monitoring and monitoring

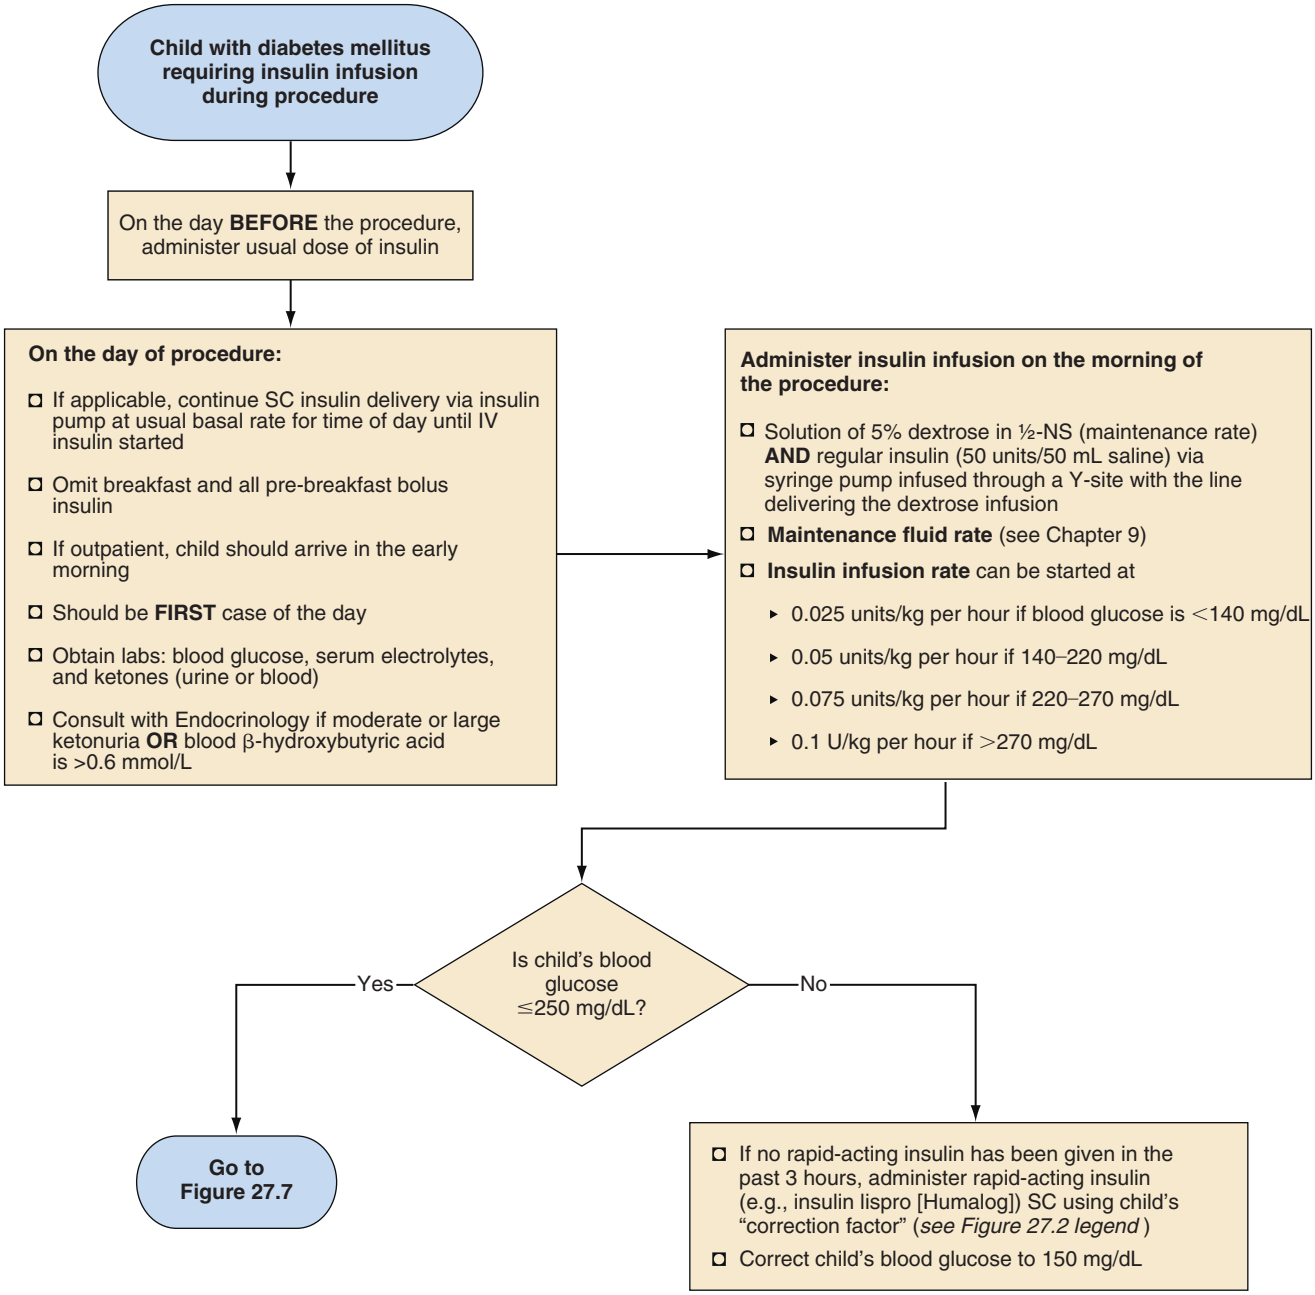

FIGURE 27.5 Preoperative management for children with diabetes mellitus who require insulin infusions during surgery. *IV*, intravenous; *NS*, normal saline; *SC*, subcutaneous. blood or urine ketones is essential because of the variable effects of surgical trauma, inactivity, pain, anxiety, nausea and/or vomiting with poor oral intake, medications, and postoperative infection. At the time of discharge from the hospital, children and their parents or care providers should be given appropriate guidelines regarding these issues. Those who are admitted to the hospital overnight after surgery should be managed in consultation with the endocrinology service, if possible, to coordinate appropriate scheduling and subsequent dosing of insulin.

SPECIAL SURGICAL SITUATIONS

Children with diabetes who need urgent surgery must have a full clinical and biochemical assessment. Frequently, the problem necessitating surgery may have led to metabolic decompensation that must first be corrected and stabilized, unless the need for surgery is immediate. These children are often dehydrated; in addition to administering insulin, rehydration and electrolyte replacement is critical to address their metabolic derangements and restore normal glomerular filtration and renal function. In

most cases, these children require emergent surgery that should be managed with an IV infusion of insulin as described earlier (see Fig. 27.5). Children with diabetic ketoacidosis require close collaboration between the anesthesiology and endocrinology services.

Diabetes Insipidus

Children undergoing neurosurgical procedures for tumors in or near the pituitary gland, especially craniopharyngioma, often require management of diabetes insipidus (DI), as do children with known DI who require anesthesia for surgical or radiologic procedures. The perioperative management of these children requires meticulous attention to fluid and electrolyte balance to prevent either overhydration or underhydration and electrolyte disturbances.

Central DI (also referred to as neurohypophyseal, neurogenic, or vasopressin-sensitive DI) is caused by a deficiency of the antidiuretic hormone, arginine vasopressin, which produces antidiuresis by stimulating V2 receptors on the principal cells of the kidney to promote reabsorption of water.[132] Central DI can be caused by disorders of vasopressin gene structure; accidental or surgical trauma to vasopressin neurons; congenital anatomic hypothalamic or pituitary defects; neoplasms; infiltrative, autoimmune, and infectious diseases affecting vasopressin neurons or fiber tracts; and increased metabolism of vasopressin. The etiology is unknown in approximately 50% of children with central DI.

DIAGNOSIS OF NEUROSURGICAL DIABETES INSIPIDUS: THE TRIPLE-PHASE RESPONSE

It is important to distinguish polyuria (>2 L/m^2 per day) caused by the onset of acute postsurgical central DI from polyuria resulting from diuresis of salt and fluid given during surgery. In both cases, children may have a large volume (exceeding 200 mL/m^2 per hour) of urine. Serum osmolality is increased, associated with inappropriately dilute urine (low urine osmolality), in DI but will be normal in the child excreting excess salt and water. In a solute diuresis, the urine osmolality is usually greater than 300 mOsmol/kg, in contrast to the dilute urine characteristic of DI. A meticulous examination of the intraoperative and postoperative records and careful bedside assessment of volume status (jugular venous distention, capillary refill) helps to distinguish between these two entities.

Of special interest is the triphasic pattern of vasopressin secretion often observed after neurosurgical procedures that interfere with the supraoptic-hypophyseal tract.[133] An initial phase of transient DI may be observed that lasts between 12 hours and 2 days after surgery. This may be explained by local edema that interferes with normal vasopressin secretion. If significant vasopressin-secreting cell damage has occurred, release of stored vasopressin from damaged neurons leads to a second phase that involves water retention. The syndrome of inappropriate antidiuretic hormone secretion (SIADH) may last up to 10 days. Finally, a third phase, permanent neurogenic DI, may follow if more than 90% of vasopressin cells are destroyed. Pronounced SIADH in

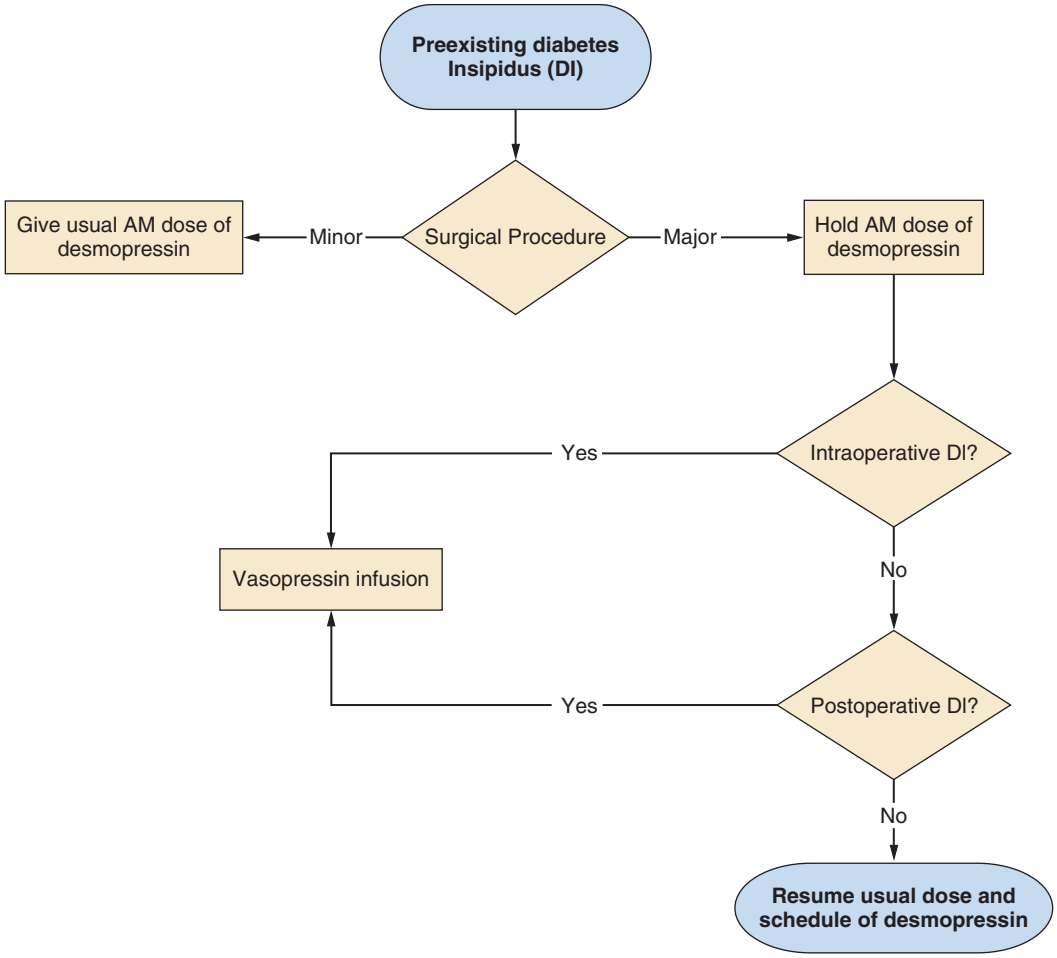

FIGURE 27.9 Perioperative management of diabetes insipidus.

the second phase generally portends permanent DI in the final phase of the triple response. In children with vasopressin and cortisol deficiency (e.g., in combined anterior and posterior hypopituitarism after neurosurgical treatment of craniopharyngioma), symptoms of DI may be masked because cortisol deficiency impairs renal free water clearance. Institution of glucocorticoid therapy may precipitate polyuria, leading to the diagnosis of DI (Fig. 27.9).

PERIOPERATIVE MANAGEMENT OF MINOR PROCEDURES

Children with preexisting DI who are scheduled for a minor procedure—that is, a procedure without significant blood loss and not followed by a period of further fasting or fluid shifts (e.g., myringotomy, radiologic imaging, peripheral orthopedic procedures)—are treated differently from those undergoing a more major procedure associated with blood loss or fluid shifts and delayed postoperative resumption of fluid intake (see Fig. 27.9).

Children undergoing minor procedures with anesthesia should receive their usual morning dose of desmopressin (DDAVP) (Table 27.3). The anesthetic technique is tailored to the procedure (e.g., IV sedation for magnetic resonance imaging [MRI], general endotracheal anesthesia for tonsillectomy). Arterial and urinary catheters are not required, and recovery takes place in the postanesthesia care unit (PACU). Once the morning dose of desmopressin has been administered, intraoperative and postoperative fluids

TABLE 27.3 Medications for Management of Central Diabetes Insipidus

Desmopressin acetate 100-, 200-µg tablets; nasal Rhinal tube 10 µg/0.1 mL; nasal spray 10 µg/0.1 mL can only deliver fixed doses of 10 µg (0.1 mL) per spray	
Oral	Dose: 100–400 µg q8–12 hours
	Oral doses are 10–20 times intranasal doses of desmopressin
	Onset of action: ~1 hour
	Duration: 6–8 hours; dose dependent (0.4 µg has antidiuretic effect up to 12 hours)
Intranasal	Dose: ~10–20 µg/dose q12–24 hours
	Onset of action: within 1 hour
	Duration: 5–21 hours
Vasopressin (Pitressin) (20 units/mL; 0.5-mL, 1-mL, and 10-mL vials). Dilute in normal saline or 5% dextrose in water	
Intravenous	Dose: 1.5 mU/kg per hour; titrate upward in 0.5 mU/kg per-hour increments to target urine output <2 mL/kg per hour
	Onset of action: rapid; maximum effect is achieved within 15 minutes of initiation of continuous infusion
	Duration: action ceases within 20 minutes of stopping intravenous infusion

should be restricted to the rate of 1 L/m^2 per 24 hours (~two-thirds of usual maintenance fluid requirement) to match insensible free water losses and obligatory urine output. Oral fluids may be offered once the child is awake. Although modern PACU policies often no longer require successful fluid intake before discharging the ambulatory patient, discharging the child with DI should be delayed until the child is able to freely take oral fluids without vomiting. Subsequent doses of DDAVP should be administered according to the child's usual preoperative schedule.

PERIOPERATIVE MANAGEMENT OF MAJOR PROCEDURES

A major surgical procedure is defined as an operation associated with the potential for significant blood loss; intraoperative or postoperative hemodynamic, neurologic, or respiratory instability; entry into a body cavity (e.g., craniotomy, abdominal surgery, thoracic surgery); craniofacial or airway surgery; major orthopedic surgery (e.g., spine surgery, tumor resection or amputation, major osteotomies); and/or surgery followed by delayed resumption of unrestricted fluid intake. The child with DI should be scheduled as the first case of the day. On the day before the procedure, the child treated with DDAVP should receive the usual morning dose, but only 50% of the usual evening or bedtime dose (see Fig. 27.9). On the morning of the procedure, DDAVP is withheld. The child undergoing a major procedure should receive general anesthesia with conventional monitoring, as well as insertion of arterial and urinary catheters when appropriate, and after surgery is admitted to a high-care facility (e.g., ICU). A central venous catheter for monitoring central venous pressure, although not indicated solely for the management of DI, is useful in the postoperative period.

At the start of the procedure, an infusion of aqueous vasopressin (available as Pitressin 20 U/mL in a 1-mL vial, diluted to 20 U/1000 mL to yield a final concentration of 20 mU/mL) should be started at 1.5 mU/kg per hour (0.0015 U/kg per hour). IV fluids, using normal saline with 5% dextrose, should total 1 L/m^2 per 24 hours to approximate insensible losses and obligate urine output. Additional IV saline, isotonic fluids, or blood products may be given to replace the blood and surgical fluid loss, to offset the third-space fluid losses, and to maintain hemodynamic stability. Fluid intake and output should be continuously monitored and serum sodium concentration measured frequently to ensure water balance is maintained. Urine output should not routinely be replaced in the child receiving a vasopressin infusion. Accidental overdoses resulting from inadequate dilution of the highly concentrated stock solution result in severe abdominal cramping, diarrhea, vomiting, and pallor owing to action at V1 receptors on smooth muscle in the gastrointestinal tract and blood vessels.

NEW PERIOPERATIVE DIAGNOSIS

The new diagnosis of intraoperative or postoperative DI is based on clinical and laboratory findings, including a serum sodium concentration greater than 145 mmol/L, polyuria (>4 mL/kg per hour) for 30 minutes or more, increased plasma osmolality (>300 mOsm/kg) in association with hypotonic urine (<300 mOsm/kg), and after excluding the presence of glycosuria and diuretic or mannitol administration as possible causes of polyuria.

When DI occurs, an infusion of aqueous vasopressin (20 U/1000 mL) is initiated at 1.5 mU/kg per hour (0.0015 U/kg per hour); because aqueous vasopressin has a brief plasma half-life (approximately 10–20 minutes), the rate of infusion is increased every 30 minutes until urine output decreases to less than 2 mL/kg per hour, indicating that antidiuresis has been achieved. Once a urine output of less than 2 mL/kg per hour is achieved, the vasopressin infusion is maintained at a constant rate.

IV DDAVP should *not* be used in the acute management of postoperative central DI because it offers no advantage over aqueous vasopressin and because its long half-life (8–12 hours) compared with that of vasopressin, increases the risk of water intoxication and precludes dose titration.

POSTOPERATIVE MANAGEMENT

The child with DI should be cared for in an ICU after major surgery. Fluid input and output, serum electrolytes, and osmolality are monitored closely (hourly if necessary) in the intraoperative and postoperative periods. Until stability is achieved, it is important to have a urinary catheter in place to distinguish postoperative urinary retention from oliguria. The vasopressin infusion initiated intraoperatively is continued in the ICU. Fluid administration is *not* adjusted according to urine output; however, fluid deficits are replaced and blood pressure supported until antidiuresis (urine output <2 mL/kg per hour) is clearly established. In the patient with maximum antidiuresis, total (oral and IV) maintenance fluids should not exceed insensible plus obligatory urinary losses (i.e., approximately 1 L/m^2 per 24 hours). In the postoperative period, appropriate maintenance fluid is generally 5% dextrose in half-normal saline solution with 0 to 40 mEq/L of potassium chloride (depending on the serum potassium concentration). Blood loss should be replaced with normal saline solution, 5% albumin, or blood products, as appropriate.

Aqueous vasopressin in a dose of 1.5 mU/kg per hour results in a supranormal blood vasopressin concentration of approximately 10 pg/mL, twice that needed for full antidiuretic activity.[134] The effect of vasopressin is maximal within 2 hours after starting an infusion.[134]

After hypothalamic, but not transsphenoidal surgery, greater initial concentrations of vasopressin are occasionally required to treat acute DI. This may be attributed to the release of a substance related to vasopressin from the damaged hypothalamo-neurohypophyseal system, which acts as an antagonist to normal vasopressin activity.[135] Much greater rates of vasopressin infusions, resulting in plasma concentrations greater than 1000 pg/mL, should be avoided because they may cause cutaneous necrosis,[136] rhabdomyolysis,[136,137] and cardiac rhythm disturbances.[137]

POST–INTENSIVE CARE UNIT MANAGEMENT

Children treated with vasopressin for postneurosurgical DI should be switched from IV to oral fluid intake at the earliest opportunity. With an intact thirst mechanism and access to free water, the patient will better regulate blood osmolality. Once oral intake has been resumed without nausea and vomiting (often by the morning of the day after surgery), the vasopressin infusion should be stopped; all IV infusions should be stopped to avoid iatrogenic fluid overload, and oral fluids are permitted freely. DDAVP is then reinstituted (nasally or orally) in the child with preexisting DI or begun in the child who has new-onset DI (see Table 27.3).

Syndrome of Inappropriate Antidiuretic Hormone Secretion

SIADH is caused by the inability to excrete free water and is characterized by hyponatremia, plasma hypoosmolality (<275 mOsm/kg), inappropriately concentrated urine (>100 mOsm/kg), natriuresis in the absence of edema and volume depletion, and normal renal

and adrenal function.[138–140] The dilutional hyponatremia of SIADH develops secondary to inappropriately increased levels of plasma antidiuretic hormone (ADH, also known as arginine vasopressin) relative to plasma osmolality.[140]

The major causes of SIADH are neurologic and psychiatric diseases, pulmonary disorders and interventions, malignancies, surgery, and medications (Table 27.4).[139–141] Medications that cause SIADH can act by stimulating the release of ADH, by enhancing the effect of ADH, or by acting as an ADH analog.[139] Although ADH secretion impairs water excretion, the other mechanisms that regulate fluid volume and sodium balance (renin-angiotensin-aldosterone system and atrial natriuretic peptide) are intact. Volume expansion activates natriuretic mechanisms (decreased proximal sodium reabsorption and decreased aldosterone production), resulting in sodium and water excretion and the restoration of near-euvolemia. With chronic SIADH, sodium loss is a more prominent feature than is water retention. Severe hyponatremia increases cell size because of entry of water into the cell along its osmotic gradient and may be associated with loss of intracellular potassium and other solutes in an attempt to restore cell volume.

TABLE 27.4 Causes of Syndrome of Inappropriate Antidiuretic Hormone Secretion

Central Nervous System Disturbances
Head trauma
Brain tumor
Hydrocephalus
Subarachnoid hemorrhage
Stroke
Infection (meningitis, encephalitis, brain abscess, AIDS)
Acute psychosis
Drugs
Vasopressin, desmopressin
Carbamazepine, oxcarbamazepine
Cyclophosphamide
Vincristine or vinblastine
Cisplatin
Phenothiazines
Serotonin uptake inhibitors
Tricyclic antidepressants
Monoamine oxidase inhibitors
Methylenedioxymethamphetamine ("ecstasy")
Nicotine
Major Surgery
Major abdominal or thoracic surgery
Pituitary surgery
Pain
Severe nausea
Pulmonary Disease
Pneumonia, tuberculosis
Asthma
Atelectasis
Pneumothorax
Acute respiratory failure
Positive-pressure ventilation
Neoplasia
Carcinoma of lung, gastrointestinal tract or genitourinary tract
Thymoma
Leukemia
Lymphoma
Sarcoma
Other tumors
Miscellaneous
Idiopathic
Hereditary SIADH
Gain-of-function mutation in the gene encoding vasopressin-2 receptor

Hyponatremia caused by SIADH can lead to clinical symptoms. Inappropriate infusion of hypotonic fluids in the postoperative period can exacerbate the hyponatremia caused by SIADH.[142,143] The clinical manifestations of symptomatic hyponatremia are principally neurologic. Early symptoms include headache, nausea, vomiting, weakness, confusion, altered consciousness, and lethargy. Late symptoms include seizures, coma, decorticate posturing, and death.[144] The severity of symptoms is related to both the absolute serum sodium concentration (most patients with serum sodium levels >125 mEq/L are asymptomatic) and its rate of decrease, especially if greater than 0.5 mEq/L per hour. Children are at greater risk than adults for developing hyponatremic encephalopathy because of a larger brain/skull size ratio, which limits room for brain expansion.[144,145]

PERIOPERATIVE MANAGEMENT

Many of the causes of SIADH are transient and resolve spontaneously once the underlying condition is corrected. Treatment of SIADH consists mainly of water restriction (i.e., maintaining a daily water intake that is less than daily water losses). If dilutional hyponatremia is mild and asymptomatic, therapy may not be required. In adults, both moderate and severe hyponatremia (serum sodium ≤130 mEq/L) are associated with increased mortality.[146,147]

Hyponatremic encephalopathy should be treated immediately with hypertonic (3%) saline solution. For mild to moderate symptoms with a low risk of herniation, treatment consists of 3% saline at a rate of 0.5 to 2 mL/kg per hour.[148] For severe symptoms, treatment consists of a bolus of 2 mL/kg 3% saline (to a maximum of 100 mL) over 10 minutes.[144,145,148] This may be repeated 1 or 2 times until symptoms improve, with a goal of increasing serum sodium concentration of 5 to 6 mEq/L in the first 1 to 2 hours.[144,145,148] The greater the duration of hyponatremia and the lower the serum sodium concentration, the greater the concern for brain injury secondary to overcorrection of hyponatremia. Overcorrection of chronic hyponatremia can lead to serious, permanent, and even fatal neurologic complications from osmotic demyelination (central pontine myelinolysis).[144,145,149] Recommended safe limits for the rate of hyponatremia correction vary from 6 to 15 mEq/L per 24 hours.[145,148,150–152] The hypertonic saline infusion should stop when the absolute concentration of serum sodium reaches 120 to 125 mEq/L. Hypertonic saline solution is usually combined with furosemide to limit treatment-induced expansion of the extracellular fluid volume.[151] Thereafter, treatment should consist of fluid restriction.

Thyroid Disorders

Thyroid hormones play an important role in metabolic processes, growth, and development in children.[153] The thyroid gland develops

from the embryonic pharyngeal floor and descends along the thyroglossal duct to its final position in the anterior neck. Thyroid hormone production is controlled by the hypothalamic-pituitary-thyroid axis. Two principal thyroid hormones are produced, thyroxine (T_4) and triiodothyronine (T_3). Although T_4 is the predominant circulating thyroid hormone, T_3, which is primarily formed by peripheral conversion from T_4, is the major physiologically active thyroid hormone. Serum T_4 and T_3 concentrations in turn regulate hypothalamic thyrotropin-releasing hormone (TRH) and anterior pituitary thyroid-stimulating hormone (TSH) secretion via a negative feedback loop. Thyroid hormones are transported in the blood by carrier proteins, including thyroxine-binding globulin (80% of binding), prealbumin (10%–15% of binding), and albumin (5%–10% of binding). Protein-bound T_4 and T_3 are not biologically active. Only 0.03% of circulating T_4 and 0.3% of T_3 are unbound and active.[154]

HYPOTHYROIDISM

Classification and Epidemiology

Hypothyroidism, the most common thyroid disorder in children, can range from subclinical to overt disease. Subclinical hypothyroidism is characterized by a mildly elevated TSH with normal concentrations of T_4 and T_3.[155] It is usually a self-limiting problem with a low rate of progression to overt hypothyroidism, although consensus on the treatment of subclinical hypothyroidism is still a matter of debate.[156–158] Iodine deficiency continues to be the foremost cause of hypothyroidism worldwide.[159] However, the most common causes of primary hypothyroidism in the United States and other regions where iodine intake is adequate are congenital hypothyroidism and Hashimoto thyroiditis.[153] Other less frequent causes of primary hypothyroidism include sick euthyroid syndrome, hypothyroidism secondary to medications (thionamides, lithium, amiodarone), and radiation or surgery to the thyroid or neck.[153] Hypothyroidism can also be caused by disorders of the pituitary gland or the hypothalamus.

Biochemical Tests of Thyroid Function

In general, measurement of serum TSH, T_4, and unbound or free T_4 is sufficient for initial assessment of thyroid function. Free T_4 is preferable to total T_4 since it eliminates the effects of variation in protein binding. TSH is a sensitive test for diagnosing primary thyroid disorders and generally precedes noticeable changes in total T_4 and T_3 levels. In primary hypothyroidism, serum TSH is increased, whereas total T_4 and free T_4 are decreased. If the total T_4 level is reduced but free T_4 and TSH values are unchanged, thyroxine-binding globulin (TBG) deficiency is the most likely diagnosis. No treatment is required for TBG deficiency since these individuals have normal concentrations of free T_4 and are clinically euthyroid. If the hypothalamic-pituitary axis is not intact, such as in cases of secondary or tertiary (central) hypothyroidism, diagnosis and treatment is based on serum T_4 levels and clinical signs and symptoms.

Clinical Manifestations

Since thyroid hormone affects all metabolically active cells, hormone deficiency leads to a wide array of systemic abnormalities. Classic signs and symptoms of hypothyroidism in children include short stature, fatigue, weight gain, dry skin, hair loss, coarse facial features, hoarse voice, and constipation. Myxedema coma is a severe manifestation of hypothyroidism that can occur in profoundly hypothyroid individuals exposed to an external stress, such as infection, trauma, anesthesia, or cold temperature.[160] Myxedema coma can result in severe life-threatening hypoxemia and hemodynamic instability.[160–163] Myxedema coma is rare in adults and even more uncommon in children, with only two reported cases.[163,164]

Neonatal Hypothyroidism

Congenital hypothyroidism remains the most frequent preventable cause of intellectual disability with an increased risk in neonates weighing less than 2 kg or more than 4.5 kg.[153,165] Thyroid dysgenesis or agenesis accounts for the majority of cases, whereas a smaller percentage results from thyroid dyshormonogenesis and secondary or tertiary hypothyroidism.[153,166] Since most neonates do not exhibit the classic signs or symptoms of hypothyroidism during the perinatal period owing to the transplacental passage of maternal thyroid hormones, testing via the neonatal screen is necessary to diagnose congenital hypothyroidism.[153] Screening programs may measure T_4, TSH, or both. Early detection and implementation of thyroid replacement are essential to avoid permanent neurologic sequelae. The classic syndrome of congenital hypothyroidism that develops in the first 3 months of life occurs in countries with no screening programs. The typical findings include macrosomia, enlarged fontanel, macroglossia, coarse facial features, hoarse cry, umbilical hernia, constipation, hypothermia, decreased activity, and neonatal jaundice (Fig. 27.10).[153] In general, affected children who receive adequate thyroid replacement starting early in the neonatal period lead normal lives.[167]

Treatment

The goal of thyroid replacement is to normalize T_4 within 1 to 2 weeks and TSH within 4 weeks,[168] reversing the metabolic derangements caused by hypothyroidism. In general, daily levothyroxine (LT_4) replacement normalizes T_4 concentrations within a week but normalizes TSH levels more slowly, over 4 to

FIGURE 27.10 An infant with congenital hypothyroidism. ("Congenital hypothyroidism." Wikipedia: The Free Encyclopedia. Wikimedia Foundation, Inc., February 24, 2012, accessed March 31, 2012, http://en.wikipedia.org/wiki/Congenital_hypothyroidism.)

6 weeks.[169] The appropriate starting LT_4 dose varies with age and disease state. For neonates, the starting dose is 10 to 15 μg/kg per day,[153,168] which is much greater than the conventional replacement dose of 2 to 6 μg/kg per day in older children and adolescents.[153] In healthy children with acute hypothyroidism (e.g., after thyroidectomy), full LT_4 replacement can be started immediately. In children with severe, chronic hypothyroidism, smaller doses of LT_4 titrated slowly every few weeks are recommended, since these children are at risk of developing adverse effects (headaches, insomnia, hyperactivity, pseudotumor cerebri) when given a full thyroxine dose.[153,170] After stabilization of the dose, children and adolescents should continue to have regular clinical examinations and TSH monitoring owing to increased dose requirements during puberty and pregnancy.[171,172] Thyroid replacement can be given parenterally if needed. The IV dose of LT_4 is approximately half of the oral dose and should be given once daily.

Preoperative Management

Because thyroid hormones play a critical role in regulating metabolism, children should be clinically and biochemically euthyroid before undergoing elective surgery. Children with known hypothyroidism should have documented normal thyroid function tests before surgery. A detailed history should be obtained regarding previous thyroid disorders, head and neck radiation, radioiodine therapy, thyroid surgery, and family history of thyroid disease.[173] The majority of reported complications have occurred in patients with unrecognized hypothyroidism.[174] In addition, children with autoimmune disorders, such as type 1 diabetes mellitus and celiac disease, and children with genetic syndromes, such as trisomy 21 and Turner syndrome, are at increased risk for developing primary hypothyroidism and should be screened if symptomatic.[153,175–177]

Children with subclinical or mild hypothyroidism often must undergo urgent surgery without delay. Thyroid replacement can be started and continued with the same regimen as described in the outpatient setting. Perioperative risk in this group of children is minimally increased, but preoperative sedation should be minimized as these patients can be very sensitive to opioids and benzodiazepines.[178,179] For children with moderate to severe hypothyroidism, surgery should be postponed when possible, until thyroid hormone concentrations normalize on replacement therapy. In these children, there is concern for decreased cardiac function, abnormal response to hypercapnia and hypoxia, delayed gastric emptying, hypothermia, and increased sensitivity to anesthetics.[174,178–181] When urgent surgery is required, perioperative treatment with IV LT_4 should be given to minimize complications.[117,173,179] Since these children may also have adrenal insufficiency and because thyroid replacement may precipitate an adrenal crisis, glucocorticoids should also be administered.[174,179] An exception to this strategy applies to the child presenting for cardiovascular surgery or cardiac catheterization because of the concern that a rapid increase in thyroid function would increase myocardial oxygen demand, thereby precipitating or worsening unstable coronary syndromes. Several studies in adults have reported no adverse outcomes in cardiac patients undergoing surgery without thyroid replacement.[117,173,182] Therefore thyroid replacement could be initiated postoperatively in children with cardiovascular disease; however, many endocrinologists recommend starting with a minimal dose of T_4 in consultation with the cardiologist.[179]

Sick Euthyroid Syndrome

In sick euthyroid syndrome, abnormal thyroid test results occur in the setting of a nonthyroid illness, such as a critical illness. During times of stress or illness, increased conversion of T_3 to a metabolically inactive form (reverse T_3) occurs. With more severe illness, T_4 and free T_4 levels may be reduced. TSH levels may also be reduced because of hypothalamic-pituitary axis dysfunction.[153] Individuals are considered euthyroid if the TSH values are not increased. Controversy exists regarding possible benefits of using T_4 or T_3 therapy to treat sick euthyroid syndrome.[153,183–185]

HYPERTHYROIDISM

Classification and Epidemiology

Hyperthyroidism is a condition caused by excess circulating thyroid hormones that increases metabolic activity in the peripheral tissues. Almost all children with hyperthyroidism have suppressed serum TSH concentrations resulting from negative feedback by the increased concentrations of T_4 and T_3. Overt hyperthyroidism is characterized by both biochemical and clinical manifestations of the disease. A child with subclinical hyperthyroidism has reduced TSH concentrations but is typically asymptomatic.[186,187]

In children, hyperthyroidism occurs less frequently than hypothyroidism and is nearly always caused by Graves disease. Other causes of childhood thyrotoxicosis include autoimmune thyroiditis (Hashimoto thyroiditis), autonomously functioning thyroid nodules, infections of the thyroid gland, iodine-induced hyperthyroidism, TSH-secreting pituitary adenomas, and thyroid hormone ingestion.[188–190] Hyperthyroidism can be associated with McCune-Albright syndrome (triad of fibrous dysplasia of bone, café-au-lait skin spots, and precocious puberty).[190,191] A rare thyroid disorder that mimics the increased levels of T_4 and T_3 in hyperthyroidism is thyroid hormone resistance. However, unlike other causes of childhood thyrotoxicosis, thyroid hormone resistance should not be treated with antithyroid medications.[192,193]

Graves Disease

Graves disease is the most common cause of childhood hyperthyroidism. The pathogenesis of Graves disease is unclear but is believed to result from a complex interaction of genetic, immune, and environmental factors.[189,194] Graves disease is more frequent in children with other autoimmune diseases or with a condition associated with autoimmunity, as in Turner syndrome, trisomy 21, or DiGeorge syndrome.[195] In Graves disease, the immune system produces antibodies to the TSH receptor. These antibodies bind to and stimulate the TSH receptors found on the thyroid follicular cells, causing excessive synthesis and secretion of thyroid hormone. Most children with Graves disease have a smooth, diffusely enlarged goiter, ocular signs, as well as the systemic signs and symptoms associated with thyrotoxicosis.[189] Because few children with Graves disease enter spontaneous remission, treatment of hyperthyroidism is required. Current treatment options include antithyroid medications, radioactive iodine therapy, or surgical removal of the thyroid gland.[189,194,196] Although virtually all children enter remission during therapy with antithyroid drugs, adverse effects are relatively common (see later discussion) and the majority of children treated for 2 to 3 years relapse shortly after discontinuation of therapy.[197,198] Radioactive ablation is usually definitive and carries less risk than surgery.[199]

Thyroiditis

The term *thyroiditis* is used to describe a heterogeneous group of disorders that result in inflammation of the thyroid gland with subsequent release of preformed thyroid hormone. Hashimoto thyroiditis is the most common form of thyroiditis in children.[190] Transient hyperthyroidism can result from the initial inflammatory

process, but symptoms generally last up to about 8 weeks, until preformed stored thyroid hormone is depleted. Thus the majority of children with Hashimoto thyroiditis present with a goiter but are asymptomatic.[153] In some children, antibodies that stimulate the TSH receptors on the thyroid follicular cells are present, prolonging the hyperthyroid phase by continued oversecretion of thyroid hormone.[200] In children that are symptomatic during the transient hyperthyroid phase, β-blockers should be used to control symptoms. In children with stimulating TSH receptor antibodies, antithyroid drugs are needed in addition to the β-blockers since thyroid hormone is being produced.[200] Some children develop hypothyroidism after the recovery phase because of lymphocytic infiltration of the thyroid gland and destruction of thyroid tissue.

Thyroiditis can also manifest as painful inflammation of the gland and fever secondary to bacterial or viral infection. *Haemophilus influenzae*, group A streptococci, and *Staphylococcus* are the most frequent causes of acute infectious thyroiditis, which can be complicated by thyroid gland cutaneous fistulae.[201] Viral infections of the thyroid gland are less severe. Owing to the difficulty in distinguishing bacterial from viral infections, all cases of infectious thyroiditis are treated with antibiotics. Treatment with antithyroid drugs is not indicated, but if the child is symptomatic, β-blockers should be used.

Clinical Manifestations

Most of the symptoms that children experience are the same regardless of the cause of hyperthyroidism. Classic signs and symptoms of hyperthyroidism include goiter, tachycardia, palpitations, dyspnea, fatigue, proximal muscle weakness, tremor, brisk reflexes, heat intolerance, insomnia, nervousness, increased frequency of bowel movements, and weight loss despite a normal or increased appetite.[189,194] Many children with hyperthyroidism have an inability to concentrate, resulting in poor school performance, and may be initially mistaken to have attention deficit hyperactivity disorder. Other medical conditions associated with long-standing hyperthyroidism include growth acceleration and advancement in epiphyseal maturation, delay in onset of puberty, and irregular menses.[189,202]

Children with Graves disease may develop additional autoimmune manifestations, such as ophthalmopathy. Pretibial myxedema and dermopathy are rare in children.[195] Ocular involvement in Graves disease is characterized by inflammation and edema of the retro-orbital tissue and extraocular muscles, resulting in proptosis and impaired ocular muscle function. Children with Graves ophthalmopathy often complain of eye irritation or ocular dryness because of lid retraction, which is due to increased adrenergic tone of the ocular muscles resulting in a prominent stare (Fig. 27.11). If left untreated, corneal ulceration may develop and lead to irreversible eye damage, including blindness. Once hyperthyroidism is treated, the lid retraction and "adrenergic stare" resolve quickly, but proptosis from Graves ophthalmopathy usually persists or regresses only slightly.[189,196,203]

FIGURE 27.11 Proptosis of the eyes in a child with Graves disease.

Treatment

Since antithyroid medications are the least invasive of the treatment options for Graves disease, they remain the first line of treatment for children, even though only 25% to 40% of children with Graves disease will enter remission with treatment.[189,195] Favorable predictors of remission in Graves disease after treatment include a small thyroid gland and milder disease at time of diagnosis, older age, postpubertal status, decrease in stimulating TSH receptor antibodies over time, presence of other autoimmune diseases, and duration of treatment greater than 2 years.[189,194] Methimazole is the drug of choice for children with Graves disease. Minor adverse effects occur in 14% to 25% of children treated with thioamides and include nausea, skin rash, arthralgias, myalgias, gastrointestinal problems, and neutropenia. Serious adverse effects occur in less than 2% of children and include agranulocytosis, hepatitis, liver failure, vasculitis with a lupus-like syndrome and Stevens-Johnson syndrome. Propylthiouracil is no longer recommended for treatment of Graves disease in children because of the unacceptable risk of hepatotoxicity and liver failure.[189,195]

Radioactive iodine therapy is used for adolescents who are not in remission or relapse after treatment with antithyroid medications or for those who have developed a serious adverse reaction to the medications or are noncompliant with medication use. It is also used for children who require immediate definitive therapy. Several longitudinal studies have shown that children are not at increased risk for developing thyroid cancer if appropriate ablative doses of radioiodine are used.[189,195]

Thyroidectomy is reserved for children and adolescents with a large thyroid gland, a history of failed drug therapy, severe ocular disease, or poor response to radioactive iodine therapy. Surgeons with expertise performing thyroidectomies in children should undertake the surgery because of the potential for serious complications, including hemorrhage, transient or permanent hypoparathyroidism, and vocal cord paralysis.[189,195]

Perioperative Management

Children should be euthyroid or slightly hypothyroid before surgery to minimize complications and avoid precipitation of thyroid storm. The possibility of airway compromise related to a large goiter should be considered and carefully evaluated.

In children with uncontrolled hyperthyroidism, surgery should be postponed until thyroid hormone concentrations normalize with therapy. If presenting for emergency surgery, careful preparation of the patient is essential and may include administration of antithyroid drugs, iodine, β-blockers, and corticosteroids.[179,204] Uncontrolled hyperthyroidism can be ameliorated by administering oral iodine (Lugol solution or saturated solution of potassium iodine) to block further release of thyroid hormone from the

TABLE 27.5 Management of Hyperthyroid Crisis

Drug Class	Recommended Drug	Starting Dose	Mechanism of Action
Iodine	Potassium iodide (SSKI)	3–5 drops by mouth q6 hours	Blocks release of thyroid hormone from gland
	Lugol solution	4–8 drops by mouth q6–8 hours	Blocks release of thyroid hormone from gland
β-Blockers	Propranolol	Infant: 2 mg/kg per day by mouth divided q8–12 hours Child: 10–40 mg by mouth q6–8 hours	β-adrenergic blockade; decreased T_4 to T_3 conversion
	Esmolol	100–200 µg/kg per minute IV infusion	β-adrenergic blockade; decreased T_4 to T_3 conversion
Thioamide	Methimazole	0.4 mg/kg per day by mouth divided q8–12 hours	Inhibits new hormone synthesis
	Propylthiouracil	5–10 mg/kg per day by mouth divided q8 hours	Inhibits new hormone synthesis; decreases T_4 to T_3 conversion
Supportive treatment	Intravenous fluid	20–40 mL/kg normal saline	Replacement of increased insensible losses resulting from fever, diaphoresis, vomiting, and diarrhea
	Cooling blankets, ice packs	Reduce fever	
	Acetaminophen	Children 2–12 years: 15 mg/kg q6 hours or 12.5 mg/kg q4 hours; maximum daily dose: 75 mg/kg per day (≤4 g/day) Adolescents >12 years: <50 kg: 15 mg/kg q6 hours or 12.5 mg/kg q4 hours; maximum single dose: 750 mg/dose; maximum daily dose: 75 mg/kg per day (≤4 g/day) ≥50 kg: 1000 mg q6 hours or 650 mg q4 hours; maximum single dose: 1000 mg/dose; maximum daily dose: 4 g/day	Reduce fever
	Hydrocortisone	2 mg/kg IV q8 hours (maximum dose 100 mg)	Decreases T_4 to T_3 conversion; enhances vasomotor stability

SSKI, saturated solution of potassium iodide.

thyroid gland.[179,205] Excess iodine transiently inhibits thyroid hormone release (the Wolff-Chaikoff effect).[205] Iodine should not be administered before methimazole treatment as it may initially increase the amount of thyroid hormone released.[179,205]

Rarely untreated or undertreated hyperthyroidism can lead to thyroid storm, which has a reported incidence of 0.1 to 3 per 100,000 hospitalized patients.[206] Thyroid storm is usually precipitated by a second superimposed insult, such as infection, trauma, surgery, or diabetic ketoacidosis.[205] Thyroid storm may be difficult to differentiate from an acute malignant hyperthermia (MH) reaction.[207,208] However, in contrast to MH, thyroid storm has a more variable onset (usually an insidious onset 6 to 18 hours postoperatively, although it can develop precipitously during surgery), it induces a less severe metabolic acidosis than MH, and the serum creatine phosphokinase (CPK) remains unchanged. Since the serum CPK peaks at 12 to 18 hours after an MH reaction, it is a late sign to differentiate thyrotoxicosis from MH. If the presentation proves difficult to distinguish from MH (both diseases may present with tachycardia, rigidity, and fever), it is prudent to administer dantrolene sodium 2.5 mg/kg IV.[209] However, if the hypermetabolic signs abate after dantrolene, one cannot conclude that the reaction was MH, since dantrolene attenuates the hypermetabolic signs of thyroid storm as well.[208] The differential diagnosis also includes neuroleptic malignant syndrome and pheochromocytoma.[179]

Thyroid storm is an endocrine emergency and immediate, aggressive management is essential to avoid death.[161,188,207] Untreated, the mortality rate from thyroid storm is 10% to 30%.[177,210] The recommended treatment for thyroid storm remains a multidrug approach to (1) block production and release of thyroid hormone, (2) prevent conversion of T_4 to T_3, (3) antagonize the peripheral (adrenergic) effects of thyroid hormone, and (4) control systemic disturbances with supportive therapy (Table 27.5).[162,196,205,211–215] Pharmacologic treatment includes administration of parenteral β-blockers, methimazole or propylthiouracil, glucocorticoids (which decrease conversion of T4 to T3 and prevents relative adrenal insufficiency), and antipyretics (acetaminophen).[179,204,207]

Parathyroid and Calcium Disorders

PHYSIOLOGY OF CALCIUM HOMEOSTASIS

The four parathyroid glands are usually present in two pairs on the posterior aspect of the superior and inferior poles of the thyroid gland, with the inferior pair occasionally ectopic elsewhere in the neck or chest. Parathyroid hormone (PTH) is released from secretory granules in response to a decrease in serum ionized calcium. Its secretion is inhibited by hyperphosphatemia, profound hypomagnesemia or hypermagnesemia, or increased 1,25-dihydroxyvitamin D (calcitriol). The calcium-sensing receptor in the parathyroid mediates PTH release. PTH has three primary modes of increasing serum calcium: (1) increased renal tubular reabsorption of calcium as well as decreased reabsorption of phosphate; (2) upregulation of osteoclast-mediated calcium and phosphate release from bone; and (3) renal conversion of 25-hydroxyvitamin D to the active metabolite, calcitriol. In turn, calcitriol increases absorption of calcium and phosphate from the gastrointestinal tract and has

direct calcium-releasing effects on bone. Calcitonin is secreted by the thyroid C cells and has calcium-reducing properties via its own G protein–coupled receptor.

HYPOCALCEMIA

Neonatal Hypocalcemia

Neonatal hypocalcemia owing to prematurity, perinatal stress/asphyxia, and maternal diabetes is common but is typically transient.[216,217] Less common causes include maternal hyperparathyroidism, transient neonatal hypoparathyroidism, vitamin D deficiency, excessive diuretic use or phosphate load, and congenital hypoparathyroidism.[217] Maternal vitamin D deficiency remains a cause of infant hypocalcemia in the United States, regardless of the infant's dietary intake.[218,219]

The most common cause of congenital hypoparathyroidism is the DiGeorge sequence (also known as velocardiofacial syndrome or 22q11.2 deletion).[216,217] The degree of parathyroid hypoplasia in the DiGeorge sequence is variable, so hypocalcemia may present during infancy, childhood, or periods of stress.[216] Other causes of congenital hypoparathyroidism include isolated hypoparathyroidism, hypercalciuric hypocalcemia, mitochondrial disorders (Kearns-Sayre syndrome, mitochondrial encephalopathy) and metabolic syndromes (Kenny-Caffey syndrome).[216,217,220] Reduced PTH or PTH resistance (pseudohypoparathyroidism) cause hyperphosphatemia beyond the already increased normal range in neonates, whereas vitamin D deficiency or resistance is associated with low to normal serum phosphate concentrations.

Childhood Hypocalcemia

Etiologies for hypocalcemia in children include hypoparathyroidism (congenital and acquired), insensitivity to PTH (pseudohypoparathyroidism), disorders of vitamin D supply or metabolism, and calcium/phosphorus/magnesium disorders.[216,221,222] Acquired hypoparathyroidism may be due to infiltrative disease of the parathyroid gland (hemochromatosis, Wilson disease, granulomatous disease, or metastatic cancer), autoimmune hypoparathyroidism (polyglandular autoimmune disease type1), or postsurgical complications of thyroid or parathyroid surgery.

In polyglandular autoimmune disease type 1, the principal features are mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency.[216,221,223] Ectodermal dystrophy of the nails is often present, leading to an alternative name for this syndrome, autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED).[221,223]

Persistent hypocalcemia in infants and children can have many manifestations, including poor feeding, circumoral numbness, paresthesias, laryngospasm, tetany, seizures, myocardial dysfunction, and myopathy.[222] Initial evaluation of hypocalcemia, regardless of age, includes measurement of serum calcium, phosphate, magnesium, alkaline phosphatase, creatinine, PTH, 25-hydroxyvitamin D, and 1,25-dihydroxyvitamin D, plus urine calcium, phosphate, and creatinine. Therapy for acute hypocalcemia includes parenteral calcium, followed by oral calcium supplementation and 25-hydroxyvitamin D if reduced,[219] and calcitriol instead of synthetic PTH. The use of PTH was initially contraindicated in children because of a potential risk of developing osteosarcoma.[224] PTH is now used as an alternative to calcitriol because extensive use in adults and studies in children have not shown an increased risk.[221,224–226]

Perioperative Management

Hypocalcemia is usually managed by IV infusion of calcium in the form of calcium chloride or calcium gluconate, with frequent measurement of serum ionized calcium concentrations to guide therapy (see Chapter 12). Calcium salts release free calcium ions and should be given via a central venous catheter because their hypertonicity and the increased concentration of ionized calcium causes intense local vasoconstriction that may lead to necrosis of the skin and subcutaneous tissues and possibly gangrene of the affected limb if administered via a peripheral IV cannula that becomes interstitial. In the postoperative period after the child is tolerating oral intake, IV calcium supplementation may be converted to oral supplementation.

HYPERCALCEMIA

Hypercalcemia is an uncommon finding in children.[227,228] Parathyroid causes of hypercalcemia include neonatal hyperparathyroidism (HPT), primary HPT, parathyroid hyperplasia, familial hypocalciuric hypercalcemia (familial benign hypercalcemia), and rarely, parathyroid carcinoma.[229] Neonatal HPT is usually an adaptation to maternal hypocalcemia. In children and adolescents, 65% of HPT may be attributed to a single parathyroid adenoma that is unresponsive to increases in serum calcium level.[227]

Parathyroid hyperplasia occurs in familial forms of hyperparathyroidism, including multiple endocrine neoplasia type 1 (MEN 1), in which HPT is the presenting manifestation the majority of the time.[227,230,231] MEN 1 is also associated with pancreatic and pituitary tumors.[230,231] HPT is a less common manifestation of MEN 2A, in which medullary thyroid carcinoma and pheochromocytoma occur.[232] Mutations in the calcium-sensing receptor gene result in a greater serum calcium set point in familial hypocalciuric hypercalcemia (familial benign hypercalcemia), an incidental diagnosis that is benign.[233,234] Mutations in this calcium-sensing receptor gene can also lead to a life-threatening form of neonatal severe HPT.[227] Secondary HPT with relatively normal calcium levels is a common pediatric phenomenon that accompanies renal failure, renal tubular acidosis, and hypophosphatemic rickets.[235]

When hypercalcemia is present, the differential diagnosis includes Williams syndrome (associated with hypercalcemia in 15% cases), vitamin A intoxication, vitamin D intoxication, hypophosphatasia, granulomatous disorders, subcutaneous fat necrosis, immobility, and medications (thiazide diuretics, lithium, theophylline).[227,236] Solid tumors may secrete increased concentrations of parathyroid hormone–related protein (PTHrP). Tumors, such as leukemias, lymphomas, and others, may release excess cytokines and osteoclast-activating factors, with the hypercalcemia leading to the tumor diagnosis.[237,238]

Signs and symptoms of hypercalcemia are usually nonspecific, such as nausea and vomiting, failure to thrive, irritability, polyuria, constipation, and fatigue. Initial laboratory evaluation of hypercalcemia is similar to the evaluation for hypocalcemia given earlier.[239]

Evaluation of unexplained hypercalcemia includes additional hormone or genetic testing for MEN syndromes, measurement of PTHrP for malignancy, blood for tumor markers, bone marrow biopsy, and relevant imaging. When HPT is found, ultrasonography is helpful to assess the parathyroid glands, but MRI or technetium-sestamibi scan is more precise, especially at locating ectopic tissue.[240]

Perioperative Management

Management of acute hypercalcemia begins with discontinuing or minimizing all sources of calcium (enteral/parenteral feeds, total parenteral nutrition). Children should be aggressively hydrated with isotonic fluids. The administration of a loop diuretic, such

as furosemide, increases urinary calcium excretion.[241] Calcitonin, which inhibits bone resorption, decreases the calcium concentration, although tachyphylaxis may occur within 1 or 2 days.[227] Bisphosphonates, such as pamidronate, are potent inhibitors of bone resorption. Pamidronate is preferred in children; a single dose can rapidly reduce the serum calcium concentrations with an effect that lasts 2 to 4 weeks.[227,241] Glucocorticoids may also be useful since they inhibit synthesis of 1,25-dihydroxyvitamin D_3. Definitive therapy for primary HPT is parathyroidectomy.[227,240–242] Acute management after parathyroidectomy requires careful monitoring and replacement of calcium and possibly the use of calcitriol for persistent hypocalcemia. In isolated parathyroid hyperplasia, MEN, or secondary HPT, surgeons may elect to leave a portion of one gland in the forearm to avoid permanent hypoparathyroidism, which is challenging to manage.

Adrenal Disorders

PHYSIOLOGY

Adrenal steroidogenesis begins with cholesterol as a precursor and results in three types of steroids: mineralocorticoids, glucocorticoids, and sex steroids (androgen precursors).[243] Most of the enzymes involved in adrenal (or gonadal) steroidogenesis are cytochrome P450s. The adrenal cortex consists of three zones: the outer zona glomerulosa exclusively synthesizes mineralocorticoids owing to localized expression of CYP11B2, whereas the zona fasciculata and reticularis synthesize glucocorticoid and androgens owing to localized expression of CYP17.[244] Cortisol, the end product of the glucocorticoid pathway, is the primary regulator of the hypothalamic-pituitary-adrenal axis, in which hypothalamic corticotropin-releasing hormone regulates pituitary adrenocorticotropic hormone (ACTH) secretion and downstream adrenal production of all three categories of steroid. ACTH release follows a diurnal pattern with a peak at 0400 to 0800 hours and, most importantly, markedly increases in response to trauma, acute illness, high fever, and hypoglycemia.

Mineralocorticoid production is primarily controlled by the renin-angiotensin system, in which angiotensinogen secreted by the liver is cleaved by renin to angiotensin I, which is then converted to angiotensin II.[245] The mineralocorticoid pathway is also responsive to ACTH, as demonstrated by an increase in all mineralocorticoid precursors and the end product aldosterone within minutes of exogenous ACTH stimulation. However, hypopituitarism does not lead to mineralocorticoid deficiency because an intact renin-angiotensin system independently stimulates aldosterone synthesis. Nevertheless, patients with ACTH deficiency may present with hyponatremia (glucocorticoids are required for free water excretion) and hypotension. The latter consequence of failure of the adrenal to release an adequate amount of glucocorticoid may be attributable to the role of cortisol in enhancing vascular responsiveness to catecholamines and inotropic activity.[246] This essential aspect of glucocorticoid activity is the most lethal potential consequence of both primary adrenal insufficiency and hypothalamic-pituitary deficiency and requires the utmost caution on the part of pediatrician, endocrinologist, surgeon, or anesthesiologist. When any question regarding adequacy of the hypothalamic-pituitary-adrenal axis arises, it is prudent to provide exogenous glucocorticoid, particularly perioperatively.[247]

CAUSES OF ADRENAL INSUFFICIENCY

Primary adrenal insufficiency is suspected from features such as weight loss, nausea and vomiting, poor appetite, and, specifically, the characteristic skin hyperpigmentation that is secondary to melanocyte-stimulating hormone receptor cross-stimulation by ACTH (which is present in extraordinarily large concentrations).[248] Primary adrenal insufficiency is uncommon in countries with advanced health care systems now that infectious diseases such as tuberculosis are less prevalent, but adrenal hemorrhage still causes adrenal failure.[249] Autoimmune adrenal insufficiency, sometimes as part of a polyendocrinopathy syndrome, is now the most common cause and includes both glucocorticoid and mineralocorticoid deficiency. Glucocorticoid deficiency with or without mineralocorticoid loss is characteristic of congenital adrenal hyperplasia.[250] Rare disorders causing adrenal insufficiency include adrenoleukodystrophy,[251] congenital adrenal hypoplasia, X-linked adrenal hypoplasia congenita, and ACTH receptor defects.[252]

Congenital or acquired lesions of the hypothalamus or pituitary may lead to ACTH deficiency. In general, these lesions cause other pituitary deficiencies, particularly growth hormone or TSH deficiency; isolated ACTH deficiency is rare. Both growth hormone and ACTH deficiency may cause hypoglycemia in infancy. Central nervous system malformations leading to ACTH deficiency are usually detectable by MRI. A notable central nervous system anomaly with hypopituitarism is septo-optic dysplasia,[31,253–255] which may be associated with an assortment of midline defects, such as an absent or underdeveloped septum pellucidum and optic nerve hypoplasia, but isolated pituitary agenesis or hypoplasia is more common. Acquired lesions leading to hypopituitarism include hydrocephalus, meningitis, infiltrative disorders,[256] and tumors such as craniopharyngioma or histiocytosis X.[257] Tumor resection, especially craniopharyngioma, cranial irradiation, and chemotherapy, can lead to multiple pituitary deficiencies, often evolving over many years.[168]

TESTING FOR ADRENAL INSUFFICIENCY

Serum cortisol concentrations follow a diurnal pattern, with concentrations peaking during an ACTH surge in the early morning and waning later in the day. Although a morning serum cortisol concentration of less than 5 μg/dL is less than normal and suggestive of adrenal insufficiency, it may be difficult to interpret the significance of a random cortisol concentration. A reduced concentration at any other time of day is uninformative and should not be used to test for adrenal function. In contrast, laboratory confirmation of primary mineralocorticoid deficiency by obtaining a random serum sample shows a low aldosterone concentration despite markedly increased plasma renin activity.

Primary adrenal insufficiency may be effectively assessed in two ways[258]: either by simultaneous measurement of serum cortisol and plasma ACTH concentrations or by stimulating the adrenal with exogenous ACTH (cosyntropin [Cortrosyn], the biologically active fragment of ACTH containing the first 24 amino acids). A markedly increased random plasma ACTH concentration is definitive evidence of primary adrenal insufficiency, but concentrations can be moderately increased by the stress of phlebotomy itself. Therefore blood for plasma ACTH concentrations should be obtained from an indwelling catheter to avoid false-positive values.

Hypothalamic-pituitary insufficiency is more difficult to assess. The complete absence of ACTH levels, as in the obvious case of pituitary ablation or destruction, leads eventually to adrenal atrophy and complete unresponsiveness to cosyntropin stimulation, a finding that necessitates maintenance glucocorticoid replacement. However, an "adequate" response to cosyntropin implies only tonic ACTH secretion and does not guarantee the ability to generate

a normal surge of ACTH during stress. As a consequence, any patient with a central nervous system lesion that might cause hypothalamic-pituitary-adrenal axis deficiency should receive stress doses of glucocorticoid (see later discussion). In practical terms, a post–cosyntropin-treatment cortisol value of 10 to 20 µg/dL in an at-risk child suggests the need for stress coverage, whereas a value less than 10 µg/dL indicates long-term replacement.[258,259]

PERIOPERATIVE MANAGEMENT OF ADRENAL INSUFFICIENCY

Glucocorticoid Dosing

Endogenous cortisol secretion is 6 to 8 mg/m^2 per day. Because a fraction of oral cortisol is degraded by the liver, the typical oral replacement dose is 10 to 12 mg/m^2 per day. A replacement dose of hydrocortisone depends on age and body size but generally is 5.0 to 7.5 mg two to three times a day orally for an adolescent with chronic adrenal insufficiency. No dose monitoring is required, but the child's growth rate should be tracked according to age. With concomitant or isolated mineralocorticoid deficiency, replacement uses fludrocortisone (Florinef) at an approximate dose of 0.1 mg orally per day, independent of body size, with intermittent monitoring of blood pressure and plasma renin activity. When the primary goal of glucocorticoid therapy is not replacement but suppression of ACTH secretion, as in congenital adrenal hyperplasia, the daily hydrocortisone dose is generally 15 to 20 mg/m^2, guided by monitoring of the serum concentration of 17-hydroxyprogesterone, androstenedione, dehydroepiandrosterone sulfate, and testosterone. Alternatives to hydrocortisone include prednisone, which is four to five times more potent than hydrocortisone. Dexamethasone is 30 to 40 times more potent than hydrocortisone, but it has no mineralocorticoid activity and carries much more significant risk of adverse effects, such as osteopenia and aseptic necrosis of the femoral head, and so should not be used for long-term routine replacement therapy. Single-dose use of dexamethasone has not been associated with aseptic necrosis of the femoral head.

Conventional stress glucocorticoid coverage is 3 to 10 times the patient's usual replacement dose, depending on the severity of illness or trauma, although this practice is not evidence based.[260] There is little risk associated with the transient use of excess glucocorticoid. We recommend exogenous glucocorticoid replacement for children who are receiving oral replacement therapy with 3 to 5 times the patient's usual oral maintenance dose for intercurrent illness or fever (>101°F) and 5 to 10 times the oral maintenance dose for major surgery, during critical illness, or in major emergencies. For children who require stress glucocorticoid coverage but who do not take outpatient steroids, or who are unable to take medications by mouth, we recommend using parenteral cortisol (Solu-Cortef) at a dose of 0.5 mg/kg per every 12 hours for illness associated with nausea, vomiting, diarrhea, or fever (>101°F) and 0.5 to 1 mg/kg every 6 hours for perioperative, intensive care, or emergency department indications for up to 72 hours.[261]

Iatrogenic Adrenal Suppression and Tapering

Increased doses of exogenous glucocorticoids are used chronically for control of autoimmune disorders, suppression of transplant rejection, and control of inflammatory processes. Iatrogenic adrenal suppression depends on the duration and dose of glucocorticoid used. Periods of high-dose steroids up to 7 to 10 days do not suppress the hypothalamic-pituitary-adrenal axis. Adrenal suppressive treatments lasting 3 to 6 weeks require a taper over 1 to 2 weeks to allow recovery of the hypothalamic-pituitary-adrenal axis. Long-term high-dose treatment may require up to 6 to 9 months for complete return of hypothalamic-pituitary-adrenal function and necessitates a taper during that period. At the termination of the taper, a repeat cosyntropin stimulation test should be performed to confirm recovery of function, and any repeat trauma or illness during the period of taper requires short-term stress coverage.

The glucocorticoid taper has two meanings. The tempo of therapeutic tapers of prednisone by gastroenterologists, rheumatologists, nephrologists, and oncologists, and of dexamethasone by surgeons, depends entirely on their assessment of the immune or inflammatory process. As long as the glucocorticoid dose is in excess of the replacement dose, and regardless of the dose, the hypothalamic-pituitary-adrenal axis continues to be suppressed. It is only when the steroid dose is tapered down to the daily replacement dose (approximately 10 mg/m^2 hydrocortisone, 2 mg/m^2 prednisone, or <0.5 mg/m^2 dexamethasone) that the endocrine taper begins. At that point, the prednisone should be switched to hydrocortisone for ease of starting a gradual taper from replacement therapy to reduced doses while function of the hypothalamic-pituitary-adrenal axis is reestablished. In the perioperative period, steroid coverage should be administered if there is any concern about the integrity of the hypothalamic-pituitary-adrenal axis during a steroid taper (Table 27.6).

TABLE 27.6 Steroid Equivalency Ratios and Doses

Steroid	Relative Antiinflammatory Potency	Relative Mineralocorticoid Potency	Daily Replacement (mg/m^2)
Hydrocortisone	1	2	10
Cortisone	0.8	2	12
Prednisone	4	1	2.5
Prednisolone	5	1	2
Dexamethasone	20–30	0	<0.5

HYPERCORTISOLISM (CUSHING SYNDROME)

Excess cortisol, whether exogenous or endogenous, results in muscle wasting, truncal obesity, moon facies, hypertension, hyperglycemia, osteopenia, and growth deceleration.[262,263] Iatrogenic hypercortisolism is common in pediatrics,[264] whereas Cushing disease or syndrome is rare.[265] Cushing disease refers to an ACTH-secreting pituitary adenoma. Cushing syndrome refers to other conditions of excess glucocorticoid, including ectopic ACTH-secreting tumors[266] and adrenal tumors that secrete cortisol.[267] An adrenal tumor (adenoma or carcinoma) is the most likely cause of hypercortisolism in a young child. These tumors can secrete any combination of steroids and commonly cosecrete androgens, resulting in virilization.[268] A unilateral glucocorticoid-secreting tumor typically causes hypothalamic-pituitary-adrenal axis suppression, requiring careful tapering of hydrocortisone replacement after resection to reestablish normal cortisol production in the contralateral adrenal gland.[269]

In a child with signs of hypercortisolism (and not simply obesity), screening tests include an overnight small dose dexamethasone suppression test, measurement of 24-hour urinary free cortisol and creatinine, and measurement of nocturnal salivary cortisol concentrations.[270] If screening tests suggest a diagnosis of hypercortisolism, additional adrenal steroids should be measured

and an adrenal computed tomographic scan or MRI obtained. In an adolescent with pure glucocorticoid effects and suspicious results of a corticotropin-releasing hormone stimulation test or longer dexamethasone suppression test[271] suggestive of a pituitary ACTH-secreting adenoma (Cushing disease), pituitary MRI is warranted.[272] Because pituitary adenomas can be very small, bilateral inferior petrosal sinus sampling may be necessary to locate the adenoma.[273]

PERIOPERATIVE MANAGEMENT OF HYPERCORTISOLISM

Therapy for Cushing disease and Cushing syndrome is surgical.[274,275] There are no specific anesthetic considerations except the supportive management of secondary manifestations, such as obesity and its attendant airway concerns, hypertension, and skin and bone fragility.

Pheochromocytoma

Pheochromocytomas and paragangliomas are rare neuroendocrine tumors that arise from neural crest–derived cells. They can occur anywhere from the base of the skull to the pelvis where paraganglia are found.[276,277] Functional tumors produce catecholamines and are known as chromaffin tumors. These tumors derive their name from the dark grey-brown immunostaining of chromogranin A by chromium salts.[278]

ETIOLOGY

Nearly 80% of functional paraganglial tumors occur in the adrenal medulla and are referred to as pheochromocytomas. The other 20% of cases arise from extraadrenal paraganglionic tissue.[276,277] The overall incidence of pheochromocytoma is estimated in the general population at approximately 0.3 cases per million per year.[278] About 10% to 20% of all pheochromocytomas are diagnosed in childhood, with an average age at the time of onset of 11 years.[276,278] In large registries of pediatric paraganglial tumors, there appears to be a male predominance in childhood, whereas during the reproductive years, this shifts to a greater female predominance with the net effect being an equal distribution in the sexes.[279] In contrast to adults, pheochromocytomas in children are more often benign, bilateral, multiple in number, and extraadrenal.[278]

While only 5% to 10% of pediatric paraganglial tumors are malignant, metastases can be widespread and have been found in the bones, lungs, lymph nodes, and liver.[276,277] The European-American Pheochromocytoma-Paraganglioma Registry reports that as many as 80% of patients diagnosed before 18 years of age had a germline mutation in one of the known susceptibility genes.[280] To date, mutations in at least 10 susceptibility genes have been linked with pheochromocytoma-associated cancer syndromes such as von Hippel-Lindau (*VHL*), multiple endocrine neoplasia (*MEN*) type 2, neurofibromatosis 1, paraganglionic syndromes types 1–4, and familial pheochromocytoma syndromes.[280,281] Additionally, tuberous sclerosis and the Carney triad have also been associated with pheochromocytomas.

CLINICAL PRESENTATION

The clinical presentation of paraganglial tumors in children can vary greatly and may be due to catecholamine secretion or from mass effect. Tumors may also be found as incidental radiologic findings or as part of screening for one of the hereditary syndromes.[278] Functional pheochromocytomas and paragangliomas can secrete different catecholamines, including epinephrine, norepinephrine, and dopamine. Norepinephrine is the most predominant hormone secreted, whereas only 10% to 20% of tumors secrete epinephrine and dopamine. However, there is no direct relationship between circulating catecholamine concentrations and overt symptoms.

Hypertension is the most typical presenting symptom in children, but it may be sustained rather than paroxysmal as is often the case in adults,[282] and is usually not associated with tumors that primarily secrete dopamine. Another common presentation in children is regular, intermittent headaches often associated with nausea and vomiting. Other reported findings include weight loss, polyuria, visual disturbances, and anxiety.[283] Although extremely rare, epinephrine-secreting tumors can actually present as circulatory shock owing to decreased intravascular volume and myocardial depression, the result of sustained high concentrations of catecholamines.

DIAGNOSIS

Because of the deleterious consequences of a missed pheochromocytoma diagnosis, testing should be performed for any child who presents with signs suggestive of pheochromocytoma or other paraganglial tumor. Paragangliomas may be mistaken for the more common neuroblastomas because of their similar location and secretion of vanillylmandelic acid and homovanillic acid.[279] Initial screening should include biochemical testing for catecholamine excess, followed by radiologic studies to find the anatomic location of a suspected catecholamine secreting mass. Traditionally catecholamines and their metabolites are typically measured in a 24-hour urine collection; however, this is often difficult in children. Plasma free metanephrines (metanephrine and normetanephrine) are produced and secreted by tumors independent of catecholamine release caused by tumor or sympathetic responses.[284] Liquid chromatography mass spectrometry assays to detect plasma free metanephrine and normetanephrine are now available and have a reported sensitivity of 98%.[285]

Once the biochemical diagnostic tests suggest the presence of a paraganglial tumor or pheochromocytoma, additional imaging to locate the mass is warranted. The most common location in children is in the abdomen, both within and outside the adrenal gland. Both CT and MRI can be used to locate these tumors[286]; considerations such as radiation exposure and possible need for general anesthesia may influence which technique is used, depending on the age of the child. The accuracy of locating a pheochromocytoma with these two techniques is similar,[286] although both have limitations in distinguishing a pheochromocytoma from other intraabdominal lesions less than 1 cm in diameter. Another imagining test, ^{131}I-metaiodobenzylguanidine (MIBG), can be helpful for identifying small tumors outside the adrenal gland as well as metastatic disease.[287]

PREOPERATIVE MANAGEMENT

Once the diagnosis of a pheochromocytoma or paraganglioma has been established, additional workup is often needed as medical therapy is initiated before surgery. A few basic laboratory results can be helpful in detecting remote organ involvement. For example, hypokalemia may be present in the context of hyperaldosteronism, or an abnormal total and ionized calcium level may indicate parathyroid gland involvement, suggestive of MEN 2 syndrome. Excess catecholamines can also increase fasting glucose concentrations or cause an abnormal glucose tolerance test result. Long-term exposure to increased circulating catecholamine concentrations not only causes vasoconstriction and relative hypovolemia, but it can also lead to cardiomyopathy, congestive heart failure, and

arrhythmias. Therefore a preoperative electrocardiogram and echocardiogram should be obtained as part of the preoperative assessment.[286]

Surgical resection of pheochromocytoma should almost always be done on an elective basis after the child's medical status has been properly investigated, medical conditions stabilized, the location of the tumor(s) determined, and therapeutic α-adrenergic receptor blockade has been established. Preoperative α-adrenergic blockade is critical to success and has reduced perioperative complications during pheochromocytoma resection from 60% to 3%.[288] Effective blockade is evidenced by normalization of blood pressures for age and resolution of other symptoms, such as palpitations and headache. It must be emphasized that β-adrenergic blockade should *never* be introduced until α-adrenergic blockade has been well established; otherwise, this could result in unopposed paroxysmal systemic hypertension, leading to acute congestive heart failure, an acute coronary event, stroke, and even death. β-Adrenergic blockade to control reflex tachycardia or arrhythmias should only be started once α-adrenergic receptor blockade has been well established.[278]

Preoperative preparation is most commonly achieved with the noncompetitive α-adrenergic blocker, phenoxybenzamine. Phenoxybenzamine irreversibly alkylates α-adrenergic receptors, reducing the risk of an α-adrenergic–mediated increase in blood pressure during surgery. Phenoxybenzamine may be administered either orally or intravenously.[281] The effective oral dose usually ranges between 0.25 and 1.0 mg/kg per day and is given in divided doses. After the initial starting dose, increases should be titrated up every 2 to 3 days (owing to the drug's long half-life) until effective α-adrenergic blockade is achieved with normalized systolic blood pressure for the child's age.[276] This may require doses as large as 2 mg/kg per day and take several weeks of therapy to establish the correct dose.[278,281]

Oral bioavailability of phenoxybenzamine is only 20% to 30% with a 24-hour onset of action.[281] Alternatively, IV phenoxybenzamine has been used to more rapidly and reliably block α_1-receptors, although this requires close monitoring for peripheral vasodilatation and decreases in blood pressure, especially in the setting of relative hypovolemia. The action of phenoxybenzamine is terminated only by synthesizing new α-adrenergic receptors. The disadvantage of irreversibly blocking α-adrenergic receptors, as conferred by phenoxybenzamine, is that reactive hypotension may follow removal of the tumor, with resistance to interventions that are intended to increase the peripheral vascular resistance. One alternative, phentolamine, has been used because it has a much shorter half-life than phenoxybenzamine and is reversible. Calcium channel blockers may also aid in normalizing blood pressure with fewer orthostatic changes, although this is more common in adults.

ANESTHETIC CONSIDERATIONS

Resection of a catecholamine-secreting tumor is one of the most challenging and rare cases in anesthetic practice. The surgical approach may be open or laparoscopic depending on the tumor location, size, and surgeon's preference. The primary goal and challenge is maintaining stable hemodynamics both before tumor removal and immediately after. This requires careful planning preoperatively and anticipating intraoperative changes. Given the high-risk nature of these patients, surgical resection ideally should be done in a center with experience in such cases.[289]

Ensuring adequate α-adrenergic receptor blockade before entering the operating room is key for both normalizing blood pressure and expanding the contracted intravascular volume.[289] Anxiolysis prior to placement of invasive monitors or induction is important to maintain circulatory homeostasis and mitigate any stressor that may trigger a catecholamine surge. If feasible, invasive monitors such as arterial catheters are placed before induction of general anesthesia. A central venous catheter is always indicated for fluid management monitoring and delivering vasoactive infusions, including both vasodilators and vasoconstrictors. In patients with evidence of myocardial dysfunction, noninvasive continuous cardiac output assessments, a pulmonary artery catheter, or transesophageal echocardiography are essential to tailor the intraoperative management.

The goal during general anesthesia induction and intubation is to limit hemodynamic stress. Depending on the age of the patient, this can be accomplished with either IV or inhalational agents. Medications that may cause histamine release and sympathomimetics, such as ketamine, morphine, curariform neuromuscular blockers, and meperidine, should be avoided. Some have suggested succinylcholine may trigger a sympathetic response via stimulation of the sympathetic ganglia or fasciculations and thus should also generally be avoided, although succinylcholine is now rarely administered in pediatric anesthesiology for other reasons.[290] Airway instrumentation should be attempted only after adequate depth of anesthesia is established, and adjuncts such as IV lidocaine may be of benefit.[289] Vecuronium or rocuronium are the preferred neuromuscular blockers owing to their lack of autonomic effects and histamine release.[291]

Hypertension can occur during the surgery, especially during manipulation of the tumor, despite α-adrenergic blockade. Measures to control the blood pressure include increasing the inspired concentration of inhalational anesthetic, sodium nitroprusside infusion, IV magnesium sulfate,[290] and in refractory cases of hypertension, nicardipine and fenoldopam have been used successfully.[292] Tachycardia may also occur; the preferred β-adrenergic blocker to control heart rate is esmolol because of its very brief duration of action.

Sudden hypotension may also occur once the tumor has been ligated as a result of the sudden removal of the source of catecholamines and irreversible α-adrenergic blockade by phenoxybenzamine. These factors, in conjunction with a contracted plasma volume, blood loss, and anesthetic agents, may lead to profound and persistent hypotension.[289] Hypotension may continue for several days postoperatively until new α-adrenergic receptors are synthesized. Supportive treatment with volume expansion and vasopressors such as epinephrine, norepinephrine, and vasopressin may be needed.[289,290] Postoperative management in an ICU is required.

Finally, reactive hypoglycemia may occur on removal of the source of catecholamines and the coexisting relative excess plasma insulin levels; thus blood glucose concentrations should be measured frequently until stabilized. Consultation with an endocrinologist and steroid replacement should be initiated if bilateral adrenalectomy has been performed.[289]

Baylis PH. The syndrome of inappropriate antidiuretic hormone secretion. *Int J Biochem Cell Biol.* 2003;35:1495-1499.

The author reviews the cardinal diagnostic criteria, clinical features, and pathophysiology of SIADH, which develops because of persistent detectable or elevated plasma arginine vasopressin concentrations in the presence of continued fluid intake. Inappropriate infusion of hypotonic fluids in the postoperative state is a

common cause. For symptomatic patients with chronic SIADH, the mainstay of therapy is fluid restriction.

A concise review article on the presentation and management of extreme thyroid disorders, myxedema coma, and thyrotoxic storm.

Seckl JR, Dunger DB, Lightman SL. Neurohypophyseal peptide function during early postoperative diabetes insipidus. *Brain*. 1987;110:737-746.

Neurohypophyseal function, including serial measurements of plasma and urinary arginine vasopressin (AVP) and the AVP prohormone/carrier peptide neurophysin I concentrations, was investigated in 11 children undergoing pituitary or suprasellar surgery. The authors conclude that early postoperative diabetes insipidus is not a result of decreased levels of circulating AVP but may be related to the release of biologically inactive precursors from the damaged neurohypophysis. These may lead to renal refractoriness to AVP.

Silverstein J, Klingensmith G, Copeland K, et al. Care of children and adolescents with type 1 diabetes: a statement of the American Diabetes Association. *Diabetes Care*. 2005;28:186-212.

This statement provides a comprehensive review of the diagnosis of diabetes, management of type 1 diabetes, and acute and chronic complications of type 1 diabetes.

Sterns RH, Riggs JE, Schochet SS Jr. Osmotic demyelination syndrome following correction of hyponatremia. *N Engl J Med*. 1986;314:1535-1542.

This is a description of eight patients who developed a neurologic syndrome with clinical or pathologic findings typical of central pontine myelinolysis, which developed after they presented with severe hyponatremia. Each patient's condition worsened after relatively rapid correction of hyponatremia (>12 mmol of sodium per liter per day). The data suggest that the neurologic sequelae were associated with correction of hyponatremia by more than 12 mmol/L per day. When correction proceeded more slowly, patients had uneventful recoveries. Osmotic demyelination syndrome is a preventable complication of overly rapid correction of chronic hyponatremia.

TODAY Study Group, Zeitler P, Hirst K, et al. A clinical trial to maintain glycemic control in youth with type 2 diabetes. *N Engl J Med*. 2012;366(24):2247-2256.

This is the primary report of the TODAY Study, a randomized trial of 699 adolescents with type 2 diabetes. The study found that monotherapy with metformin was associated with durable glycemic control in approximately half of children and adolescents with type 2 diabetes. The addition of rosiglitazone, but not an intensive lifestyle intervention, was superior to metformin alone.

Wolfsdorf JI, Allgrove J, Craig ME, et al. ISPAD Clinical Practice Consensus Guidelines 2014. Diabetic ketoacidosis and hyperglycemic hyperosmolar state. *Pediatr Diabetes*. 2014;15(suppl 20):154-179.

The authors review the pathophysiology of diabetic ketoacidosis in childhood and discuss currently recommended treatment protocols. Current concepts regarding cerebral edema are presented, as are strategies for prediction and prevention of diabetic ketoacidosis.

Postoperative Concerns

THE ANESTHESIA PRACTITIONER IS OFTEN FACED with a child who has acute kidney injury (AKI) or renal failure. Renal disease requires the practitioner to be vigilant about fluid homeostasis, acid-base balance, electrolyte management, choice of anesthetics, and potential complications. This requires a thorough understanding of the excretory and fluid homeostatic functions of the kidney, particularly in the neonate and younger child. If not managed assiduously, perioperative renal dysfunction can deteriorate into renal failure or multiorgan system failure resulting in significant morbidity or mortality. The anesthesia provider must understand renal physiology, appropriate preoperative preparation, intraoperative management, and postoperative care of the child with renal disease.

Renal Physiology

The basic functions of the kidney are to maintain fluid and electrolyte homeostasis and metabolism. The first step in this tightly controlled process is the production of the glomerular filtrate from the renal plasma. The glomerular filtration rate (GFR) depends on renal blood flow (RBF), which depends on the systolic blood pressure and circulating blood volume. The kidneys are the best perfused organs per gram of weight in the body. They receive 20% to 30% of the cardiac output maintained over a wide range of blood pressures through changes in renal vascular resistance. Numerous hormones play a role in this autoregulation, including vasodilators (i.e., prostaglandins E and I_2, dopamine, and nitric oxide) and vasoconstrictors (i.e., angiotensin II, thromboxane, adrenergic stimulation, and endothelin). Congestive heart failure and volume contraction severely limit the ability of the kidney to maintain autoregulation.

When adjusted for body surface area (BSA) or scaled using allometric theory (see Chapter 7), both RBF and GFR double in the first 2 weeks of postnatal life and both continue to increase steadily, reaching adult values by 2 years of age (see Figs. 7.11 and 7.12).[1,2] The increases in RBF over time parallel similar increases in cardiac output and decreases in renal vascular resistance. The initial GFR and the rate of increase during the first few years correlate with the neonate's postmenstrual age at birth. For example, the GFR (corrected using BSA or allometry) of a neonate born at 28 weeks gestation is one-half of that of a full-term infant (see Figs. 7.11 and 7.12).[3] GFR may be estimated from the serum creatinine concentration and the height of the child according to the following formula[4,5]:

$$\text{GFR (mL/min/1.73 m}^2\text{)} = \text{height (cm)} \times k/\text{serum creatinine}$$

In the equation, k is a constant that varies with age; 0.413 for infants, 0.55 for children, and 0.7 for adolescent boys. The serum creatinine concentration, especially in the first days of life, reflects the maternal serum creatinine concentration and therefore cannot be used to predict neonatal renal function until at least 2 days after birth.[6]

FLUIDS AND ELECTROLYTES

The kidney regulates the total body sodium balance and maintains normal extracellular and circulating volumes.[7] The adult kidney

filters 25,000 mEq of sodium per day, but it excretes less than 1% through extremely efficient resorption mechanisms along the nephron. The proximal tubule resorbs 50% to 70%, the ascending limb of the loop of Henle resorbs about 25%, and the distal nephron accounts for 10% of the filtered sodium load. Several hormones, including renin, angiotensin II, aldosterone, and atrial natriuretic peptide (ANP), and changes in circulating blood volume contribute to maintaining the sodium balance.[8]

Serum osmolality is tightly regulated through changes in arginine vasopressin (AVP) release and thirst.[9–11] AVP, also called *antidiuretic hormone,* is synthesized in the hypothalamus and stored in the posterior pituitary, where it is released in response to an increasing plasma osmolality. AVP is also released in response to decreases in the circulating blood volume and hypotension, including responses to nausea, vomiting, opioids, inflammation, and surgery. AVP binds to receptors in the collecting duct, increasing the permeability of the tubules to water and leading to increased water resorption and concentrated urine. Neonates are much less able to conserve or excrete water compared with older children, rendering the fluid management and volume issues important tasks for the anesthesiologist in this young age group.[12]

The regulation of serum potassium is managed by the kidney and depends on the concentration of plasma aldosterone. Aldosterone binds to receptors on cells in the distal nephron, increasing the secretion of potassium in the urine. Neonates are much less efficient at excreting potassium loads compared with adults, and the normal range of serum potassium concentrations is therefore greater in neonates; Table 28.1 provides the normal values.[13] Potassium regulation is affected by the acid-base status; excretion of potassium increases in the presence of alkalosis and decreases in the presence of acidosis. Causes of hyperkalemia and hypokalemia are presented in Tables 28.2 and 28.3, respectively.

ACID-BASE BALANCE

The kidney is involved in the regulation of acid-base balance and the response to the stress of illness. The kidney reclaims virtually all of the filtered bicarbonate in the proximal tubule and regenerates bicarbonate (HCO_3^-) lost in the neutralization of acid generated by the normal combustion of food, especially protein, and the formation of bone. New bicarbonate is the product of cells in the distal nephron that decompose the carbonic acid (H_2CO_3) formed from water (H_2O) and carbon dioxide (CO_2) by carbonic anhydrase. The protons (H^+) that are generated from this process are pumped into the lumen of the collecting duct, where they combine with hydrogen phosphate (HPO_4^{2-}) or ammonia (NH_3) generated by the catabolism of amino acids, mainly glutamine, in the tubule cells.

Infants, especially neonates, maintain a slightly acidotic blood (pH = 7.37) and decreased plasma bicarbonate concentration (22 mEq/L) compared with older children and adults (pH = 7.39; plasma bicarbonate = 24 to 28 mEq/L).[14] The reduced plasma concentration of HCO_3^- is the result of a reduced threshold or the plasma concentration at which HCO_3^- is incompletely resorbed by the kidney. Neonates maintain acid-base homeostasis but are limited in their ability to respond to an acid load.[15] This is especially true for preterm infants.

Disease States

The causes of and differences in renal diseases between children and adults are substantive. Depending on the cause of the renal disease, management may be different. Adult renal disease usually results from long-standing diabetes mellitus or hypertension with an associated compromise in cardiovascular function. Children may also have renal failure owing to diseases such as sickle cell disease or systemic lupus erythematosus, but cardiovascular function is far less commonly compromised.

ACUTE RENAL FAILURE AND ACUTE KIDNEY INJURY

Acute renal failure (ARF) or acute renal insufficiency is defined as an abrupt deterioration in the ability of the kidneys to clear nitrogenous wastes, such as urea and creatinine. Concomitantly, there is a loss of ability to excrete other solutes and maintain a normal water balance. This leads to the clinical presentation of acute renal insufficiency: edema, hypertension, hyperkalemia, and uremia.

Acute kidney injury (AKI) has almost replaced the traditional term *acute renal failure (ARF)*, which was used in reference to the subset of patients who had an acute need for dialysis. With the recognition that even modest increases in serum creatinine are associated with a dramatic increase in mortality, the clinical spectrum of acute decline in GFR is broader. Minor deterioration in GFR and kidney injury are captured in a working clinical definition of kidney damage that allows early detection and intervention and uses AKI in place of ARF. The term ARF is preferably restricted to those with AKI who also require renal replacement therapy.[16] The prognosis of AKI is assessed in part by the use of the RIFLE criteria, which include three severity categories (i.e., **R**isk, **I**njury, and **F**ailure) and two clinical outcome categories (**L**oss and **E**nd-stage renal disease) (Table 28.4).

The term ARF has often been incorrectly used interchangeably with *acute tubular necrosis (ATN)*, which usually refers to a rapid deterioration in renal function occurring minutes to days after an ischemic or nephrotoxic event. Although acute tubular necrosis is an important cause of ARF, it is not the sole cause, and the terms are not synonymous. For the purposes of this chapter, AKI refers to the disease formerly called ARF.

TABLE 28.4 RIFLE Classification of Renal Failure and Kidney Injury

RIFLE Factors	GFR Criteria	Urine Output Criteria	
Risk	Increased Cr × 1.5 or decreased GFR >25%	UOP <0.5 mL/kg per hour > 6 hours	High sensitivity
Injury	Increased Cr × 2 or GFR decrease >50%	UOP <0.5 mL/kg per hour > 12 hours	
Failure	Increased Cr × 3 or GFR decrease of 75% or Cr ≥4 mg/dL Acute rise ≥0.5 mg/dL	UOP <0.3 mL/kg per hour > 24 hours or Anuria > 12 hours	
Loss	Persistent ARF: complete loss of kidney function > 4 weeks		High specificity
ESKD	End-stage kidney disease (> 3 months)		

Modified from Bellomo R, Ronco C, Kellum JA, Mehta RL, Palevsky P. Acute Dialysis Quality Initiative Workgroup. Acute renal failure—definition, outcome measures, animal models, fluid therapy and information technology needs: the Second International Consensus Conference of the Acute Dialysis Quality Initiative (ADQI) Group. *Crit Care.* 2004;8:R204–R212.

ARF, acute renal failure; *Cr*, creatinine; *ESKD*, end-stage kidney disease; *GFR*, glomerular filtration rate; *RIFLE*, Risk of renal dysfunction, Injury to the kidney, Failure of kidney function, Loss of kidney function, and End-stage kidney disease; *UOP*, urine output.

Etiology and Pathophysiology

AKI is often multifactorial in origin or the result of several distinct insults. To treat AKI, it is important to understand its causes and pathophysiology. The etiologies of AKI are varied, but can be broadly classified as follows (Table 28.5):

- *Prerenal*, implying poor renal perfusion as the cause
- *Renal*, implying intrinsic renal disease or damage as the cause
- *Postrenal*, implying an obstruction to the excretion of urine as the cause

Prerenal insults comprise the majority (up to 70%) of cases of AKI. They usually result from massive losses of extracellular fluid, such as in gastroenteritis, burns, hemorrhage, or excessive diuresis, as well as in cardiac failure and sepsis. The common feature of this condition is diminished renal perfusion. In response to the reduction in RBF, there is a compensatory increase in afferent tone, which decreases the GFR and increases the retention of salt and water. The net effect of these events is a drastic reduction in urine volume, often leading to oliguria and/or anuria. If the underlying problem is recognized early and treated aggressively, progressive renal insufficiency may be averted. Nonsteroidal antiinflammatory drugs, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor blockers can aggravate prerenal azotemia by further reducing glomerular capillary pressure and the GFR.[17]

Parenchymal disease or injury accounts for 20% to 30% of the cases of abrupt onset of AKI. In infants, the common causes include birth asphyxia, sepsis, and cardiac surgery. In older children, the important causes of AKI include trauma, sepsis, and hemolytic uremic syndrome. Prolonged prerenal azotemia may result in overt renal injury. Similarly, intrarenal obstruction to blood flow from thrombi or vasculitis may cause renal failure. Drugs such as aminoglycosides or amphotericin B or other nephrotoxins, including radiocontrast agents, may induce AKI through tubular or interstitial injury as a result of allergic reactions, as can be seen with penicillins. Acute glomerulonephritis is another cause of AKI in children; rarely, pyelonephritis can lead to AKI.

The remaining causes of AKI result from the obstruction to urine flow. These conditions account for less than 10% of all cases of AKI and may involve obstruction of both kidneys. Sudden anuria suggests a postrenal cause for the AKI. The obstruction can occur within the collecting system of the kidney (intrarenal), in the ureter, or in the urethra (extrarenal). Intrarenal obstruction may occur with the tumor lysis syndrome with the deposition of uric acid crystals, from myoglobinuria, hemoglobinuria, or from medications such as acyclovir and cidofovir. Extrarenal obstruction can be caused by stones inspissated in the ureters or from external compression by lymph nodes or a tumor. As with other forms of AKI, prompt recognition and appropriate intervention to relieve the obstruction may facilitate full recovery of renal function and obviate a permanent reduction in renal function.

The exact pathophysiology of AKI remains unclear, but several factors have been identified.[18] In the initial phase of AKI, profound renovascular vasoconstriction reduces GFR (Fig. 28.1). Factors known to increase renal vasoconstriction include increased activity of the renin-angiotensin and the adrenergic systems and endothelial dysfunction with increased endothelin release and decreased nitric

TABLE 28.5 Causes of Acute Renal Failure

Prerenal Failure	Renal Failure	Postrenal Failure
Hypovolemia Volume loss Gastrointestinal, renal losses Sequestration (burns, postoperative)	Acute glomerulonephritis Postinfectious Membranoproliferative glomerulonephritis Rapidly progressive glomerulonephritis Glomerulonephritis due to systemic disease (e.g., HUS, DIC, SLE)	Obstruction Intrinsic (papillary necrosis due to diabetes, sickle cell disease, or analgesic nephropathy) Intrarenal abnormalities, ureteral obstruction, obstruction of the bladder or urethra Extrinsic (tumor compression, lymphadenopathy)
Hypotension Shock Vasodilators	Acute interstitial nephritis Drug-induced hypersensitivity (penicillin) Infections	
Decreased effective blood flow Low cardiac output Cirrhosis Nephrotic syndrome	Tubular disease ATN (ischemic, nephrotoxic) Intratubular obstruction (uric acid, oxalate)

oxide synthesis. However, therapeutic interventions to vasodilate the intrarenal vasculature, such as prostaglandin and dopamine infusions, ACE inhibitors, calcium channel blockers, and endothelin receptor antagonists, have not significantly reversed established AKI.[19]

Another factor in the pathogenesis of AKI is renal tubule cell injury, the direct result of a nephrotoxic agent or from an ischemic insult (Fig. 28.2). Cellular injury leads to sloughing of the brush border, swelling, mitochondrial condensation, disruption of cellular architecture, and loss of adhesion to the basement membrane with shedding of cells into the tubular lumen.[20] These changes, which occur within minutes of an ischemic event, contribute to the decreased GFR by obstructing the lumen of the tubule.[21] These cellular changes allow the filtrate to leak back into the peritubular blood, reducing the excretion of solutes and the effective GFR.

Some of the cellular derangements in AKI, such as a reduction in ATP concentrations,[21] cell membrane injury by reactive oxygen molecules,[22] and increased intracellular calcium concentrations from changes in membrane phospholipid metabolism, lead to cell death. Reactive oxygen molecules also stimulate the production of cytokines and chemokines that play a role in cell injury and vasoconstriction.

Neutrophils that are recruited during reperfusion injury after renal ischemia mediate parenchymal renal damage.[23] Reperfusion injury increases intracellular adhesion molecule 1 (ICAM-1) on endothelial cells promoting the adhesion of circulating neutrophils and their eventual infiltration into the parenchyma. Neutrophils then release reactive oxygen molecules, elastases, proteases, and other enzymes that lead to further tissue injury.

Diagnostic Procedures

A thorough history and physical examination can yield important insight into the likely causes of AKI. The initial laboratory assessment of a child with AKI should include the measurement of serum urea, creatinine, electrolytes, and a urinalysis. Prerenal azotemia is typically associated with a ratio of blood urea nitrogen (BUN) to creatinine that exceeds 20. In cases of renal parenchymal dysfunction, this ratio is closer to 10. Hematuria and proteinuria are consistently present in AKI, independent of the cause, although the presence of cellular casts, especially red blood cell casts, in the urinary sediment is suggestive of glomerulonephritis. Granular casts are associated with prerenal azotemia.

One test to distinguish prerenal azotemia from established renal failure from ischemia or nephrotoxins is the fractional excretion of sodium (FE_{Na}). The FE_{Na} is calculated using the following equation:

$$FE_{Na} = \frac{U_{Na} \times S_{Cr}}{S_{Na} \times U_{Cr}} \times 100\%$$

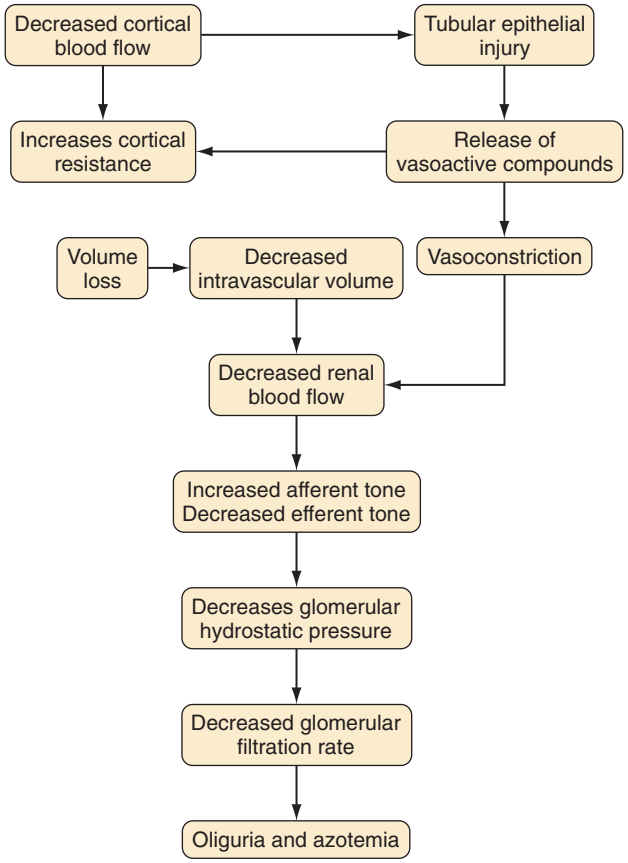

FIGURE 28.1 Hemodynamic factors in the pathogenesis of acute renal failure.

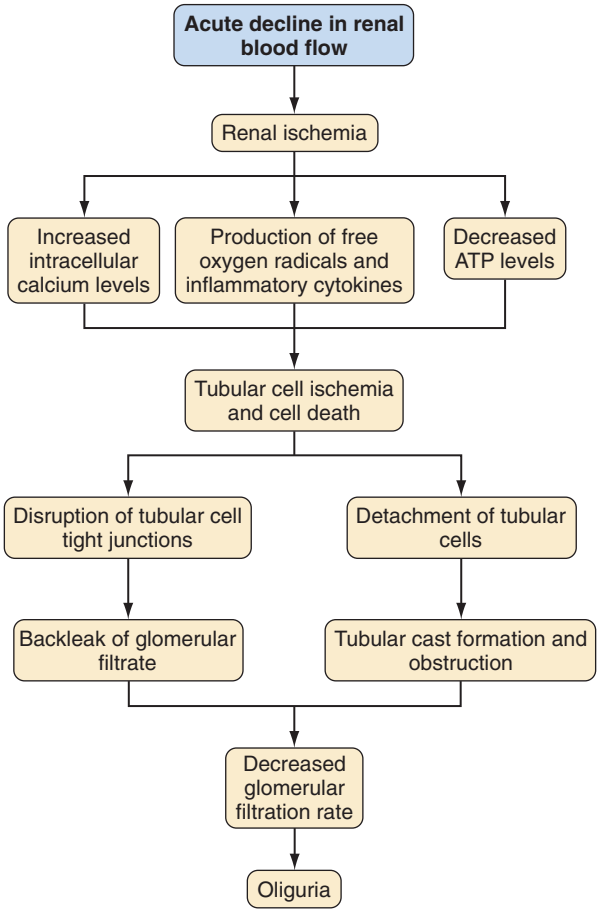

FIGURE 28.2 Influences of specific injuries on the nephron in the pathogenesis of acute renal failure. *ATP*, adenosine triphosphate.

U_{Na} and S_{Na} are urine and serum sodium concentrations, and U_{Cr} and S_{Cr} are the urine and serum creatinine concentrations, respectively. In prerenal azotemia, the FE_{Na} is usually less than 1% for adults and children and less than 2.5% for infants. In established AKI from ischemia and nephrotoxins, but not acute glomerulonephritis, the FE_{Na} usually exceeds 1%. Administration of diuretics may confound the interpretation of this test.

The initial radiologic assessment of children with AKI is ultrasonography. Renal ultrasound does not depend on renal function and can define the renal anatomy, changes in parenchymal density, and possible outlet obstruction by demonstrating dilation of the urinary tract. Doppler interrogation of the renal vessels provides information on vascular flow. Further radiographic studies, such as voiding cystourethrography, nuclear renal flow scanning, dynamic functional MRI, and abdominal computed tomography (CT), may be indicated in select children and conditions.

Therapeutic Interventions

Therapeutic interventions in children with AKI should be aimed at the underlying cause and at improving renal function and urine flow. Children with AKI caused by hypovolemia should be fluid resuscitated with at least 20 mL/kg over 30 to 60 minutes with normal saline solution or a balanced salt solution. For children with significant hypotension, an alternative choice is a colloid-containing solution. Children with oliguria caused by hypovolemia usually respond within 4 to 6 hours with increased urine output. Anecdotal reports have supported the use of low-dose dopamine in AKI. A recent clinical trial has demonstrated benefit from dopamine in improving urine output in very low–birth-weight neonates.[24]

Diuretics have been commonly used to treat oliguric AKI. There are several theoretical reasons why mannitol, furosemide, and other loop diuretics may ameliorate AKI. First, diuretics may convert oliguric AKI to nonoliguric AKI. Second, loop diuretics decrease energy-driven transport in the loop of Henle, and this may protect cells in regions of hypoperfusion. However, neither mannitol nor loop diuretics can predictably convert an oliguric patient with AKI to a polyuric patient. Diuretics have not been shown in clinical studies to influence renal recovery, need for dialysis, or survival in patients with AKI.[25,26] Diuretics should be used only after the circulating volume has been adequately restored and should be stopped if there is no early response.

Dopamine has been widely used to prevent and manage AKI. In low doses (0.5–2.0 μg/kg per minute), dopamine increases renal plasma flow, GFR, and renal sodium excretion by activating dopaminergic receptors. Infusion rates in excess of 3 μg/kg per minute stimulate α-adrenergic receptors on systemic arterial resistance vasculature, causing vasoconstriction; cardiac β_1-adrenergic receptors, increasing cardiac contractility, heart rate, and cardiac index; and β_2-adrenergic receptors on systemic arterial resistance vasculature, causing vasodilatation. In a meta-analysis of 24 studies and 854 adult patients, dopamine did not prevent renal failure, alter the need for dialysis, or change the mortality rate. In a randomized clinical trial of low-dose dopamine in 328

critically ill adult patients, dopamine did not change the duration or severity of the renal failure, need for dialysis, or mortality.[27] From these data, the routine use of low-dose dopamine in patients with AKI cannot be supported.

Several other agents that were useful in experimental models of AKI have been investigated but have not shown clinical success. ANP increases GFR in animal models of AKI by increasing renal perfusion pressure and sodium excretion. An initial study demonstrated some benefit with ANP in patients with AKI,[28] especially in those with oliguric AKI,[29] although a subsequent study of 222 adult patients with oliguric AKI failed to detect a difference between patients treated with ANP and placebo in terms of the need for dialysis or mortality.[30] Insulin-like growth factor 1 has been beneficial in animal models of AKI, presumably by potentiating cell regeneration. However, in a multicenter, placebo-controlled trial in adult patients with AKI, insulin-like growth factor 1 failed to speed the recovery, decrease the need for dialysis, or alter mortality.[31] Thyroxine abbreviates the course of experimental AKI but had no effect on the duration of renal failure and actually increased mortality threefold (by suppression of thyroid-stimulating hormone).[32]

In patients with severe AKI, renal replacement therapy through dialysis is life sustaining. The indications for initiation of dialytic therapy are persistent hyperkalemia, volume overload refractory to diuretics, severe metabolic acidosis, and overt signs and symptoms of uremia such as pericarditis and encephalopathy. Many nephrologists recommend dialysis if the BUN value approaches 100 mg/dL or even earlier, especially in the oliguric patient, although this has not proved to alter outcome. A retrospective study that compared early (BUN <60 mg/dL) versus late (BUN >60 mg/dL) initiation of dialysis in adult patients suggested that early initiation improved survival.[33] However, the timing of the initiation of dialysis remains an unresolved question.

Three strategies are available to replace renal function in critically ill children and adults: hemodialysis, peritoneal dialysis, and a variation of continuous replacement therapies, such as continuous venovenous hemofiltration (CVVH), continuous venovenous hemodialysis (CVVHD), and continuous venovenous hemodiafiltration (CVVHDF). None of these strategies has been proven superior to the others. However, in the individual child, one strategy may be more practical than the others. Hemodialysis is technically more difficult than peritoneal dialysis in an infant and hemodynamically unstable children. Continuous replacement therapies appear to cause less hemodynamic instability compared with hemodialysis and offer more predictable solute and fluid removal than peritoneal dialysis. Hemodialysis and continuous replacement therapies require large-bore vascular access to achieve the large blood flows that are necessary to support these strategies.

Although these three strategies differ technically, they share similar principles (Fig. 28.3). All three strategies remove nitrogenous wastes (i.e., urea), excess fluid, and excess solutes, especially potassium. This is achieved by circulating the child's blood over a semipermeable membrane that separates the blood from a salt solution (i.e., dialysate) on the contralateral surface. The movement of solutes across the membranes occurs by diffusion (i.e., solutes move across the membrane along their concentration gradients) and ultrafiltration (i.e., osmotic or hydrostatic pressures). The rate of removal of water and solute waste depends on the characteristics of the membrane (i.e., pore size and selectivity), diffusion, and ultrafiltration.[34]

The permeability characteristics and surface areas for the membranes are known for specific dialyzers used in hemodialysis and hemofiltration. The peritoneum serves as the dialysis membrane in peritoneal dialysis and remains physically unalterable, but changes in dialysate composition and length of time the dialysate is exposed to the peritoneal membrane changes the amount of solute and water removed. In all forms of renal replacement therapy, the therapeutic prescription is individualized for the child.

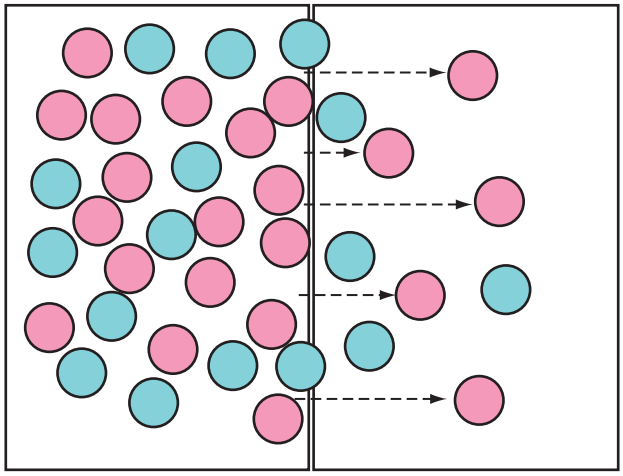

FIGURE 28.3 Principles of dialysis. Solute *(pink circles)* moves from the blood to the dialysate *(broken arrows)* in response to a concentration gradient (i.e., diffusion). The obligate passive movement of water *(blue circles)* attempts to maintain appropriate osmolarity. This flux of solute and water (i.e., ultrafiltration) may be enhanced by increased osmotic pressure (i.e., glucose in peritoneal dialysis fluid) or by increased hydrostatic pressure, which is created mechanically as transmembrane pressure in hemodialysis.

Hemodialysis

Hemodialysis is very effective for AKI, being the best modality for the rapid removal of toxins, such as drug overdoses or other ingestions or metabolic toxins resulting from poisoning or inborn errors. Hemodialysis is very efficient, reducing the BUN by 60% to 70%, normalizing the serum potassium concentration, and removing fluid equal to 5% to 10% of the body weight within 3 to 4 hours. To accomplish this, large-vessel venous access is required to provide rapid blood flows (5-10 mL/kg per minute). In infants, this is achieved by inserting a double-lumen catheter into the subclavian, internal jugular, or femoral vein. In small infants, two single-lumen catheters placed in different sites may be necessary to access and return the blood. Rarely, a single-lumen catheter may be used for both outflow and return of blood. Modern hemodialysis machines have microprocessors that can accurately measure the amount of fluid removed and this should be summarized for the anesthesiologist.

Hemodialysis usually requires systemic anticoagulation with heparin, the effectiveness of which can be monitored by the activated clotting time (ACT). Hemodialysis can be undertaken without an anticoagulant in children who are at significant risk for bleeding by using a rapid blood flow rate and by frequently rinsing the blood circuit with saline. However, clotting commonly forms within the circuit with subsequent loss of the extracorporeal blood.

In addition to the risk of bleeding, hemodialysis is associated with several other adverse effects, the most common of which is hypotension. This usually results from overly aggressive removal of fluid, although it can also result from sepsis or the release of cytokines and autokines from blood passing over the surface of

the hemodialysis filter. Muscle cramps, headache, nausea, and vomiting are also commonly reported. A more serious complication of hemodialysis is the disequilibrium syndrome that is related to the rapid removal of solute from the bloodstream with slow equilibration with the tissues, particularly the brain. This can cause cerebral edema, manifested by headache, obtundation, seizures, or coma. The disequilibrium syndrome is usually reported in children undergoing dialysis for the first time. This can be obviated by dialyzing for brief but frequent sessions initially, especially if the BUN concentration is increased substantially. Infection of the dialysis catheter is another common problem that can be minimized by using sterile central line techniques.

Peritoneal Dialysis

Peritoneal dialysis has a long history as renal replacement therapy in children.[35] It is relatively simple and easy to perform, even in small infants, and there is usually no hemodynamic instability. Although not as efficient as hemodialysis, optimal results are obtained if it is performed continuously to control solute and water balance. Peritoneal dialysis involves instilling dialysate fluid into the peritoneum for a set period and then draining the fluid and replacing it with fresh dialysate. This cycling removes waste products by diffusion and water by ultrafiltration as a consequence of a high glucose concentration in the dialysate. The efficacy of peritoneal dialysis depends on the volume of dialysate instilled per cycle and the number of cycles per day. Most children with acute renal failure are managed with 1- to 2-hour cycles of 5- to 30-mL/kg dwell volumes. Children with chronic renal failure are managed with greater cycle times and larger dwell volumes. The amount of fluid removed can be controlled by changing the concentration of the glucose in the dialysate. Short-term peritoneal dialysis can be accomplished with a nontunneled catheter, but should dialysis be required beyond 3 to 5 days, a subcutaneously tunneled cuffed catheter is preferred to minimize the risk of peritonitis.

The principal complications of peritoneal dialysis are infection and mechanical problems related to the catheter. It is common to find poor drainage from the catheter, usually the result of fibrin occlusion of the catheter or from omentum or bowel covering the inlet holes. The catheter may leak at its point of insertion. Hernias, especially inguinal hernias in boys, may develop as a consequence of the increased abdominal pressure from the infused dialysate. Mild hyponatremia may develop in infants because of the relatively low sodium concentration (130 mEq/L) in commercial dialysate. Less common but serious complications include bowel injury and intraabdominal hemorrhage from catheter insertion and peritonitis.

CHRONIC RENAL FAILURE

The loss of functioning renal mass results in a compensatory increase in filtration by the remaining renal tissue.[36] For example, within the first 48 hours after a unilateral nephrectomy, there is a demonstrable increase in the GFR and evidence of contralateral renal hypertrophy. By 2 to 4 weeks, the GFR has returned to 80% of normal, and there is no clinical evidence of renal dysfunction. With the loss of 50% to 75% of renal mass, there is an increase in the residual function to 50% to 80% of normal and often little evidence of clinical renal insufficiency. When the residual renal function decreases to 30% to 50% of normal, the term *chronic renal insufficiency* applies. At this point, acute illness and other stress states may result in acidosis, hyperkalemia, and dehydration. It is only when the residual function decreases to less than 30% of normal that the term *chronic renal failure* is used. At this point, electrolyte abnormalities begin to appear, and more importantly, there is limited ability of the kidney to adjust to perturbations in volume status and electrolyte concentrations. The term *uremia* refers to the symptoms of anorexia, nausea, lethargy, and somnolence that develop as a result of chronic renal failure. Uremia ultimately leads to death unless dialysis therapy or renal transplantation is performed. Initiating dialysis or transplanting a kidney is referred to as end-stage renal disease care.

Chronic renal insufficiency and chronic renal failure are both categories within the larger schema of chronic kidney disease (CKD). Although the stages are defined by categorizing continuous measures of function (i.e., GFR) and therefore are somewhat arbitrary, they do provide a context for the evaluation and management of kidney disease. There are six stages of CKD:

Stage I: The GFR is normal (>90 mL/minute per 1.73 m^2), but there may be evidence of chronic renal disease, including an abnormal urinalysis, hypertension, or abnormal renal ultrasound.

Stage II: A GFR of 60 to 89 mL/minute per 1.73 m^2 indicates mild kidney damage and mild decrease in GFR.

Stage III: A GFR of 30 to 59 mL/minute per 1.73 m^2 is a moderate decrease in the GFR.

Stage IV: A GFR of 15 to 29 mL/minute per 1.73 m^2 is a severe decrease in the GFR, often accompanied by electrolyte or metabolic derangements.

Stage V: A GFR <15 mL/minute per 1.73 m^2 indicates kidney failure that requires renal replacement therapy.

Stage VI: Patients are undergoing dialysis or are transplant recipients.

Despite losses of up to 90% of renal function, sodium homeostasis usually is well maintained in chronic renal failure. With large decreases in the GFR, the kidney maintains normal serum sodium by increasing the FE_{Na} from less than 1% up to 25% to 30%, largely through decreases in distal tubular resorption. Some of the hormonal factors associated with this adaptation include aldosterone, ANP, and a poorly characterized natriuretic hormone that inhibits Na^+/K^+-ATPase. With chronic renal failure, the kidney loses its ability to handle a wide range of sodium intake, from 1 to 250 mEq/m^2 per day. Instead, the kidney may only be able to handle a narrow range of sodium intake of 50 to 100 mEq/m^2 per day. It may be possible to decrease this obligatory excretion of sodium to 5 to 20 mEq/m^2 per day, although it may occur only after weeks of decreasing the sodium intake slowly. Certain children with renal disease, especially those with obstructive uropathy or tubulointerstitial disease, may be unable to adjust to a decreased sodium intake and display a salt-losing nephropathy. These children are prone to dehydration with salt restriction and may need supplemental salt to ensure normal growth. In others, a regular diet may lead to sodium retention, volume overload, and hypertension; sodium intake must be individualized to fit the limitations of each child.

Water balance is also affected by chronic renal failure. There is an obligatory total osmolar excretion that limits the ability of the kidney to excrete free water. The concentrating ability of the kidney is affected, limiting its ability to make a maximally concentrated or dilute urine. These limitations may result in water retention and hyponatremia or dehydration if water is administered in amounts exceeding the kidney's capabilities. These limitations must be considered when treating children with chronic renal failure, particularly before surgery when free access to water is restricted.

In those with chronic renal failure, the serum potassium concentrations usually remain normal until the GFR is less than 10% of normal. Potassium excretion normally occurs in the distal nephron. However, in response to an increase in potassium intake

or loss of renal mass, Na^+/K^+-ATPase increases in the remaining collecting tubules; this is responsible, in part, for the augmented excretion of potassium per nephron. In uremic animals, potassium is excreted from the renal tubules sixfold faster than in nonuremic animals and 1.5 times the filtered potassium load. Partial adaptation can occur in the absence of aldosterone, but aldosterone plays an important role in the maintenance of normal potassium homeostasis. This is demonstrated by the presence of hyperkalemia in children with hyporeninemic hypoaldosteronism or in those treated with the aldosterone antagonist spironolactone.

Approximately 13% of dietary potassium is excreted via the colon. This can increase to 50% by the activation of colonic Na^+/K^+-ATPase via aldosterone. An additional mechanism that plays an essential role in the adaptation to an acute potassium load is the redistribution of potassium from the extracellular to the intracellular compartment, which depends on insulin, β-adrenergic catecholamines, aldosterone, and pH. Despite the presence of total body potassium depletion in uremia, the uptake of potassium into the cells is impaired. This contributes to the intolerance to an acute potassium load in uremia despite the ability to excrete a potassium load.

Hyperkalemia is a major problem in chronic renal failure.[37] Hyperkalemia can result from an extrinsic potassium load, but it may also be caused by fasting or acidosis, in which case the source of the potassium is the intracellular compartment. This can be a particular problem when a child has fasted before surgery and can be ameliorated by an infusion of glucose and insulin. Drugs that can cause hyperkalemia in renal failure include spironolactone, β-adrenergic blockers, and ACE inhibitors. When clinically significant hyperkalemia develops in a child with chronic renal failure, the first-line therapy is to stabilize the myocardium with exogenous calcium and then to redistribute the potassium into the intracellular compartment with insulin and glucose. To deliver the same dose of ionized calcium, the dose of calcium gluconate (in milligrams per kilogram) should be three times that of calcium chloride. All doses of calcium are optimally delivered through a central venous access line because calcium infusions are irritating to peripheral veins and can cause necrosis of the skin if extravasation occurs. More definitive correction of hyperkalemia is accomplished by removing potassium from the body using dialysis or sodium polystyrene sulfonate (Kayexalate). At eight times the usual asthma dose, nebulized albuterol has been effective in redistributing potassium intracellularly, whereas sodium bicarbonate ($NaHCO_3$) administration has not been effective (Table 28.6). In contrast, significant hypokalemia is unusual in the absence of potassium restriction, alkalosis, or diuretic therapy.

Metabolic acidosis is common in those with chronic renal failure.[38] In moderate renal insufficiency, the type of metabolic acidosis is a non–anion gap acidosis, but in severe renal insufficiency, the metabolic acidosis is an anion gap acidosis, because of the presence of excess phosphate, sulfate, and organic acids. The primary cause of metabolic acidosis in chronic renal failure is the inability of the remaining proximal renal tubules to increase ammonium formation to keep pace with the loss of renal mass. The kidney becomes unable to generate the 1 to 3 mEq/kg per day of new bicarbonate that is necessary to compensate for the bicarbonate lost to buffering endogenous acids. Previous studies have suggested a major role for decreased resorption of bicarbonate by the proximal renal tubule in chronic renal failure. Although this may occur in the presence of volume overload, severe secondary hyperparathyroidism, and disorders such as Fanconi syndrome, it is not a major cause of acidosis in chronic renal failure. Except for severe phosphate depletion, decreased excretion of phosphate as a titratable acid normally does not contribute to metabolic acidosis.

TABLE 28.6 Treatment of Hyperkalemia

Treatment	Dosage
Stabilization of Myocardium	
Calcium and bicarbonate	Calcium gluconate: 10% 30–100 mg/kg IV *or* Calcium chloride: 10% 10–33 mg/kg IV Sodium bicarbonate: 1 mEq/kg IV if acidotic
Shifting of Potassium to Intracellular Space	
Hyperventilation	
Insulin and glucose	Insulin: 0.10–0.3 unit/kg *or* 0.1 U/kg per hour infusion Glucose: D_{50} 1–2 mL/kg *or* D_{25} 2–4 mL/kg IV *or* D_5 1–2 mL/kg per hour
Albuterol	Albuterol: 2.5–5 mg/mL nebulization
Decreasing Total Body Potassium	
Sodium polystyrene sulfonate (Kayexalate)	1 g/kg up to 40 g every 4 hours PO or PR
Furosemide (diuretic)	0.5 mg/kg up to 40 mg

D, dextrose; *IV*, intravenous; *PO*, per os (oral); *PR*, per rectum (suppository).

One of the earliest manifestations of chronic renal failure is secondary hyperparathyroidism.[39] Secondary hyperparathyroidism, which results from inadequate formation of 1,25-$(OH)_2$ vitamin D (i.e., 1,25-dihydroxyvitamin D_3 or calcitriol), develops in moderate renal insufficiency in the presence of normal serum concentrations of calcium and phosphorus. As the renal insufficiency becomes more severe, overt hypocalcemia and hyperphosphatemia often develop. Hypocalcemia is caused by decreased calcium absorption from the gastrointestinal tract as a result of a true deficiency of 1,25-$(OH)_2$ vitamin D. Diminished release of calcium from bone occurs as a result of resistance to the action of parathyroid hormone. Calcium and phosphate may be deposited in soft tissues as a consequence of hyperphosphatemia.

The kidney plays a key role in the maintenance of phosphate homeostasis by regulating its excretion. In the presence of a normal GFR, the kidney excretes 5% to 15% of the filtered load of phosphate, whereas in chronic renal failure, the kidney can increase its fractional excretion of phosphate to 60% to 80%. Through this adaptation, the kidneys are able to maintain a phosphate balance in chronic renal failure, but they do so at an increased serum phosphate concentration. More importantly, the failing kidneys have no reserve with which to increase phosphate excretion in response to a phosphate load. In children with chronic renal failure, a large phosphate load, such as can occur with the administration of a phosphate-containing enema, can lead to life-threatening hyperphosphatemia and hypocalcemia.

Hematologic Problems

One of the most common manifestations of chronic renal failure is anemia. The anemia of chronic renal failure is the result of impaired erythropoiesis, hemolysis, and bleeding. Of these, impaired erythropoiesis is most important and usually the result of a deficiency of erythropoietin production. Erythropoietin is

synthesized and secreted by the peritubular cells in the renal cortex in response to decreased tissue oxygenation. It acts on receptors on the erythroid burst-forming units and erythroid colony-forming units. With loss of renal mass, erythropoietin secretion does not respond adequately to hypoxia, and anemia ensues. Children with chronic renal failure are now treated with recombinant erythropoietin (50–150 U/kg by intravenous [IV] injection three times per week) when their hematocrit decreases to less than 30%.[40,41] When the hematocrit increases to 36%, the dose is maintained at approximately 75 U/kg with the same frequency. Erythropoietin may also be administered subcutaneously only once weekly, obviating the need for IV injections. Doses of erythropoietin in excess of 150 U/kg increase the hematocrit faster than smaller doses, but both therapies take 4 to 8 weeks to reach the target hematocrit of 33% to 36%. Children who are scheduled for erythropoietin therapy should begin oral iron, vitamin C (a cofactor for iron absorption from the gastrointestinal tract), and folic acid 2 to 3 weeks in advance to ensure adequate iron and folic acid stores to facilitate erythropoiesis. The most common cause for failure of erythropoietin, and therefore erythropoiesis, is concurrent iron deficiency. Current recommendations are aimed at maintaining serum ferritin concentrations in excess of 250 ng/mL and a transferrin saturation greater than 25%. Other causes for the failure of erythropoietin to increase or maintain the hematocrit are occult infections, hemolysis, aluminum overload, severe hyperparathyroidism, and occult bleeding. Complications of erythropoietin therapy include worsening of hypertension and a possible increased incidence of thrombosis of polytetrafluoroethylene vascular grafts.

The other major hematologic problem in chronic renal failure is bleeding. This classic and lethal complication in children with terminal uremia results from platelet dysfunction in the presence of a normal coagulation profile and normal platelet counts. The best indicator of platelet dysfunction in children with chronic renal failure is a prolonged bleeding time. The platelet dysfunction is the result of poorly described abnormalities attributed to the uremic environment, rendering platelet transfusions ineffective. Dialysis improves platelet dysfunction, as does improvement in the hematocrit with transfusions or erythropoietin therapy. Preoperative IV desmopressin acetate (1-deamino-8-D-arginine vasopressin, DDAVP) (0.3 μg/kg) improves the bleeding time in children with uremia.

Cardiovascular Complications

Hypertension is one of the most common complications of chronic renal failure and contributes significantly to the morbidity and mortality of these children. The cause is multifactorial and includes volume overload and hormonal abnormalities, such as increased secretion of renin, that result from the underlying renal disorder. In children who are undergoing dialysis, volume overload is the result of inadequate removal of volume during dialysis. The goal of ultrafiltration is to remove sufficient salt and water to achieve the dry weight that is appropriate for each child. The *dry weight* is the weight at which the child has no signs of volume overload but below which the child has hypotension. The initial response to volume overload is to increase the cardiac output. Later, the cardiac output returns to normal, but the peripheral resistance increases because of peripheral vasoconstriction, resulting in hypertension. These children may have no other signs of volume overload, such as edema, but with a reduction in total body salt and water content, the blood pressure can be controlled with little or no antihypertensive medication.

In other children, intrinsic renal abnormalities play a primary role in hypertension. Oral antihypertensive agents are often effective in controlling the severe refractory hypertension, although in some, bilateral nephrectomies may be required to control the hypertension. Of the mechanisms that cause hypertension in these children, increased renin secretion is the best understood. Renin activates the formation of angiotensin I, which is then converted to angiotensin II, a powerful vasoconstrictor. Children with renin-dependent hypertension respond poorly to control of blood pressure by salt and water removal alone but respond well to ACE inhibitors such as captopril.

Cardiovascular disease is the most common cause of death in patients undergoing long-term dialysis, including children.[42] Children with chronic renal failure can have abnormalities of the pericardium, myocardium, cardiac valves, and coronary arteries. Pericarditis was once considered a sign of the terminal phase of uremia, but it occurs in 15% of children who are undergoing dialysis and can be symptomatic or clinically silent. In uremic patients with pericarditis who are not undergoing dialysis, intensive dialysis often results in its resolution within ~2 weeks. Some children require surgical procedures such as pericardiocentesis, pericardial drainage with a catheter or through a pericardial window, or pericardiectomy.

Left ventricular failure is also a common complication of chronic renal failure. In older patients, coronary artery disease may lead to myocardial dysfunction, severely limiting cardiac output. Volume overload and hypertension, which increase preload and afterload, respectively, are important causes of heart failure. With proper fluid management and antihypertensive medication, these abnormalities can be controlled. Anemia is another contributing factor that can be controlled with the use of erythropoietin. An array of metabolic abnormalities associated with chronic renal failure, such as secondary hyperparathyroidism, electrolyte and acid-base imbalances, and the accumulation of nonspecific uremic toxins, contribute to abnormal myocardial function.

Causes of Chronic Renal Failure

The causes of chronic renal insufficiency and failure can be correlated with age (Table 28.7). The chronic renal failure that is commonly encountered in early infancy results largely from congenital anomalies or perinatal asphyxia. Later in childhood, renal failure may result from dysplasia, or acquired lesions, whereas those affected in adolescence may have deterioration of function related to acquired disease, manifestation of inherited disease, or secondary lesions resulting from other illnesses (e.g., systemic lupus erythematosus, sickle cell disease) or their treatments.

Preoperative Preparation of the Child With Renal Dysfunction

Renal disease in children is a significant cause of perioperative morbidity and mortality and thus influences the approach to general anesthesia.[43–45] The preoperative preparation of these children depends largely on the stage of the renal dysfunction and the level of severity. Whether the child has CKD, AKI, has undergone a kidney transplant, or is susceptible to an intraoperative renal insult, the approach to the preoperative and perioperative anesthesia care will change.

CKD is a multisystem disease that requires a thorough and comprehensive preoperative assessment. These children may be oliguric and at risk of fluid overload or polyuric and vulnerable

TABLE 28.7 Causes of Chronic Renal Failure and Associated Syndromes

Infancy (Congenital Anomalies)	Childhood	Adolescence
Prune-belly syndrome	Dysplasia	Focal segmental glomerulosclerosis
Congenital obstruction	Agenesis	Membranoproliferative glomerulonephritis
Posterior urethral valves	Autosomal dominant PKD	Secondary glomerulonephritis
Multicystic dysplasia	Reflux nephropathy	Systemic lupus erythematosus
Agenesis	Obstruction	Sickle cell disease
Autosomal recessive PKD	Focal segmental glomerulosclerosis	HIV-associated nephropathy
Reflux nephropathy	Membranoproliferative glomerulonephritis	Diabetes mellitus Vasculitis Hemolytic uremic syndrome Henoch-Schönlein purpura Interstitial nephritis Malignancy

HIV, human immunodeficiency virus; *PKD*, polycystic kidney disease.

to dehydration. Electrolyte and acid-base disturbances are predictably common. Alterations in compartment volumes and protein binding change drug pharmacokinetics. Hypertension may be present owing to fluid overload, exacerbated by renin excretion from the failing kidney or from an autonomic hyperactivity common in CKD. Typically these children have a normocytic normochromic anemia (from reduced erythropoietin levels) and platelet dysfunction by uremia. Ascites, common in end-stage renal disease, increases the risk of aspiration and pulmonary atelectasis in the perioperative period. Children may be encephalopathic secondary to increased blood concentrations of urea and may have seizure disorders. Finally, the CKD may be part of a syndrome, with other important implications for anesthesia. Therefore careful delineation of the type of renal disease and its comorbidities should be reviewed at the time of the preoperative visit to anticipate potential problems during the anesthetic.

Perioperative renal dysfunction may also occur in any child with normal renal function who is subjected to perioperative insults. AKI after cardiopulmonary bypass (CPB) is a well-known cause of morbidity and mortality. The pathogenesis is not simply a consequence of hypoperfusion but a complex interplay of CPB-related injury, oxidative stress, and activation of a systemic inflammatory reaction.[46] Preexisting renal insufficiency compounds this risk, necessitating precautions to preserve renal perfusion. Associated risk factors include hypovolemia that leads to vasoconstriction, the administration of nephrotoxic agents such as contrast media, embolic events in cases involving arterial vessel cross-clamping, renal ischemia, and inflammation.

Consideration of associated risks is important because perioperative renal failure is associated with mortality rates of 60%–90%. It is therefore vital to avoid factors that may augment preexisting renal dysfunction.[47,48] In adult patients, 1% developed postoperative AKI after general surgical procedures [49]; those at greatest risk were older men (≥56 years old). Although these data may not be directly applicable to children, children with congestive heart failure, hypertension, preoperative renal insufficiency, or ascites may also be at increased risk for AKI. Identification of those at risk is not a trivial exercise because postoperative AKI will increase postoperative morbidity and mortality.

PREOPERATIVE LABORATORY EVALUATION

Routine preoperative blood testing in children has become unpopular in the past few years.[50] However, several preoperative laboratory tests should be assessed in children with renal insufficiency. This allows the practitioner to determine the severity of the presenting disease and provides a baseline that may be compared with intraoperative and postoperative laboratory values to ensure proper protective renal care.

As a broad standard, a complete blood cell count, BUN, electrolytes, creatinine, and coagulation panel should be performed preoperatively. An electrocardiogram should be obtained if there is a history of hypertension and an echocardiogram if there is the suspicion of a pericardial effusion and/or cardiomyopathy.

Children with known renal failure, especially those with a significant reduction in renal function and those undergoing dialysis, require preoperative serum electrolyte analysis. Abnormal serum potassium concentrations often occur in children with renal failure; acceptable limits depend on the local laboratory standards, the child's acid-base status, and trends in the potassium concentration over time. Chronic hypokalemic or hyperkalemic states are less likely to cause cardiac manifestations than acute changes. Acute hypokalemia reduces the arrhythmia threshold and increases cardiac excitability; acute hyperkalemia may result in life-threatening arrhythmias. A child with chronic renal failure whose serum potassium concentrations are chronically 5.5 to 6.0 mEq/L does not need correction of the hyperkalemia, whereas a child with an acute increase to a potassium concentration greater than 5.5 mEq/L often requires intervention before the surgical procedure and anesthesia. Existing acidosis must be taken into consideration in determining total body potassium concentrations, understanding that acute acidosis promotes extracellular hyperkalemia at a rate of 0.5 mEq/L for every decrease in pH of 0.1 unit. There are several approaches to treating hyperkalemia and were discussed earlier (see Table 28.6). Ideally, correction of hyperkalemia is accomplished by removing potassium from the body using dialysis or sodium polystyrene sulfonate (Kayexalate). Urgent management in the operating room will include hyperventilation, nebulized albuterol and calcium, in addition to a glucose and insulin infusion.

Hypomagnesemia likewise predisposes a child to the risks of supraventricular and ventricular arrhythmias and should be corrected preoperatively. Hypermagnesemia or hypophosphatemia may cause muscle weakness and potentiate the action of neuromuscular blocking drugs (NMBDs). Administration of calcium is helpful in treating hyperkalemia or hypermagnesemia.

Hemoglobin, hematocrit, and platelet counts should be part of the preoperative evaluation. Hemoglobin levels should be measured within 24 hours of the procedure and on the morning of the procedure if the hemoglobin is labile. Morbidity and mortality in adult patients with renal failure are increased at hemoglobin concentrations less than 11 g/dL.[43,51] These were likely the effect of anemia on the incidence of left ventricular hypertrophy; in children, this relationship may not hold true. Recombinant erythropoietin reduces the risks of cardiac compromise from left ventricular hypertrophy by increasing the hemoglobin to normal values.[52,53] Blood transfusion is generally not indicated if the hematocrit is more than 25%.

The platelet count, although typically normal in children with renal failure, does not portend platelet dysfunction. The best metric to assess platelet dysfunction in children with chronic renal failure is a prolonged bleeding time. Signs of coagulopathy such as petechiae should alert the practitioner of platelet dysfunction. Platelet dysfunction does not necessarily improve with platelet transfusion. Dialysis, red blood cell transfusion, and erythropoietin improve platelet dysfunction. Desmopressin (0.3 μg/kg given by IV infusion over 15-20 minutes) can improve the bleeding time in children with uremia and can minimize hypotension when given 1 hour before surgery. It releases endothelial von Willebrand factor/factor VIII complex and improves platelet function for 6 to 12 hours.

Depending on the degree of renal failure and suspected cardiac involvement, additional testing may include an electrocardiogram, a chest radiograph, and an echocardiogram. These tests can assist the practitioner in determining evidence of left ventricular hypertrophy, arrhythmias, and the presence or absence of pericardial effusions.

Measures of renal function essentially indicate the GFR and tubular function (diluting capacity) of the kidneys. Urea and creatinine are traditional indicators of renal function, with plasma urea being a very simplistic marker of global renal function. Creatinine, being relatively constantly produced by the muscles, can be used as a guide to GFR, but lacks sensitivity and specificity. Recently, other endogenous [cystatin C, β-trace protein (BTP)] and exogenous (inulin, iohexol) biomarkers have been used to diagnose AKI after an intraoperative insult. New molecules, such as neutrophil gelatinase-associated lipocalin (NGAL), kidney injury molecule-1 (KIM-1), and netrin-1, are a few of the many new promising biomarkers that await validation in the clinical setting.[54–57]

Increasingly in the adult literature, there is evidence that specific biomarkers (such as endogenous ouabain, an adrenal stress hormone) can predict AKI in cardiac surgical patients, although to date, similar data in children have not been forthcoming.[58]

PERIOPERATIVE DIALYSIS

In the child with renal failure, dialysis prevents hyperkalemia and removes excess water. However, excessive or overly aggressive dialysis may lead to electrolyte abnormalities and hypovolemia. Accordingly, the timing of this therapy or need for the therapy should be discussed with the child's nephrologist. Ideally, children with renal failure who undergo *intermittent* hemodialysis should have dialysis on the day before surgery rather than on the day of surgery to optimize their fluid and electrolyte status and minimize problems with acute fluid shifts with hypotension, hypokalemia, and anticoagulation. To limit any effects of residual heparin, the interval between dialysis and surgery should be 4 to 6 hours. Hemodialysis can be performed without heparin if is required urgently.

Children who require peritoneal dialysis can undergo dialysis up until the day of surgery. Peritoneal dialysis should be resumed with the consideration that the child's pulmonary function must be able to tolerate the increased abdominal distention. Consultation with the child's nephrologist is recommended to optimize the child's clinical status before the procedure and to arrange the appropriate timing of the peritoneal dialysis.

MEDICATIONS

Children with renal failure may require their medications to be adjusted in the perioperative period. These medications typically include antihypertensives, and although proceeding with elective surgery with moderate hypertension may be acceptable, severe or labile hypertension should ideally be controlled before surgery. Induction of anesthesia may cause hypotension in children with chronic hypertension, although preloading with balanced salt solution may attenuate this effect. There is a temporal relationship between adults who take ACE inhibitors for blood pressure control on the day of surgery and hypotension at induction of anesthesia and cardiac arrest.[59] Moderate hypotension was significantly more frequent in those who discontinued their ACE inhibitor within 10 hours of induction of anesthesia compared with those who had not taken their medication for more than 10 hours before induction.[59] Additional studies in adults and opinion leaders recommend that ACE inhibitors should be stopped on the day before surgery to prevent hypotension after induction of anesthesia, although the hypotension can be easily managed, especially during total IV anesthesia.[60–62] All other antihypertensives, immunosuppressives, and steroids should be continued. Most other medications can be safely held until they can be resumed postoperatively. Antacid prophylaxis may be indicated for those with gastroesophageal reflux. Premedication with a benzodiazepine such as midazolam may be valuable.

Finally, a knowledge of the child's daily fluid status including output and input is important to appreciate. If and when dialysis was last performed–and therefore the child's dry weight and actual weight–should be recorded on the day of surgery. Tubular disorders, obstructive uropathy, or hypoplastic/dysplastic kidneys may have fixed polyuria and are at risk for dehydration if oral intake is restricted (NPO) for long periods. Standard fasting intervals may be followed, including clear fluids until 2 hours before the procedure, to help prevent dehydration and alleviate anxiety. Alternatively, for the inpatient, maintenance IV fluids should be continued while the child is NPO.

Intraoperative Management

STRATEGIES FOR RENAL PROTECTION

Children with chronic renal failure frequently present with serious medical problems that complicate anesthesia.[63,64] These problems stem mainly from fluid and electrolyte abnormalities, complications of chronic renal failure such as anemia and hypertension, and differences in the pharmacokinetics of anesthetic agents in children with renal failure. The most important strategies for preserving renal function are optimization of hemodynamics and intravascular volume and the avoidance or cautious use of drugs that are nephrotoxic (such as certain antibiotics, contrast agents, and nonsteroidal antiinflammatory drugs). Both the administration of isotonic saline (as compared with hypotonic saline) and, more recently, IV sodium bicarbonate before the injection of contrast agents are protective against contrast induced nephropathy.[65,66]

Strict glycemic control by titrating insulin during cardiac and vascular surgery has been associated in adults with a reduction in the incidence of AKI requiring renal replacement therapy.[65] This may not be true in children, in whom hyperinsulinemic hypoglycemia is more concerning in the critically ill child and hyperglycemia is actually better tolerated.[67]

Dopamine has long been considered renally protective, but conventional wisdom now would suggest that its actual effect is variable and difficult to predict. Fenoldopam, a selective dopamine 1–receptor agonist, increases GFR without the hypertension associated with the use of dopamine. It produces a more significant reduction in creatinine than dopamine and may therefore have a role in renoprotection. Although several empirical measures

have been recommended for renal protection in the perioperative period, a Cochrane review concluded that no interventions, whether pharmacologic or otherwise, protected the kidney in the perioperative period.[68]

In a child with AKI and low urine output, it is tempting to administer diuretics to increase RBF and flush the renal tubules. However, the use of diuretics in a child with renal disease may worsen the renal failure by causing hypovolemia and decreasing renal perfusion.[69]

VASCULAR ACCESS

In addition to routine monitoring, the absolute need for arterial access should be cautiously considered because it may affect future shunt sites. Arterial access is useful to monitor blood pressure that may be labile during the perioperative period and to measure blood gases and electrolytes. However, central venous access may achieve these same goals as well as monitor volume status (as urine output is a poor metric for renal perfusion in these children), secure IV access, and ensure the safe and reliable delivery of vasoactive medications including calcium, and avoid compromising future arterial access. Serum potassium concentrations must be monitored and corrected to avoid arrhythmias or conduction problems.

ENVIRONMENT

Careful positioning of children with renal osteodystrophy and careful antiseptic techniques for vascular line placements are essential. Strategies to maintain normothermia, including increasing the room temperature and application of a forced-air warming blanket. should be considered to avoid hypothermia.

FLUIDS AND BLOOD PRODUCTS

In the child with renal insufficiency, fluid management requires a balanced approach. The child must receive adequate hydration to prevent further renal deterioration in an otherwise injured kidney. Children with renal failure and a history of hypertension are at risk for both hypotension and hypertension and require some degree of fluid resuscitation for stability. However, they also may have hypoalbuminemia with low oncotic pressure that puts them at risk for pulmonary edema. Ideally, if the child is euvolemic, standard fluid therapy based on typical surgical fluid management is preferred. Fluid overload must be avoided in all anuric children and in outpatients. Although common sense and years of practice suggest that normal saline solution is preferable to lactated Ringer's solution because of the potassium load in the latter, a series of adults who underwent kidney transplantation showed that 19% of those who received IV saline had potassium concentrations of 6 mEq/L, and 31% had a metabolic acidosis that required treatment compared with none for both the potassium concentration and metabolic acidosis in those who received lactated Ringer's solution.[70] Lactated Ringer's solution or similar balanced salt solutions should be considered for children with renal failure.

The debate over colloids versus crystalloids continues with renal function being an important endpoint. While albumin can be used in children with renal disease, it confers little advantage over saline. Hexaethyl starch, on the other hand, may cause a coagulopathy as well as renal dysfunction. In a 2013 Cochrane review, researchers found no evidence that colloids conferred any advantage over clear fluids.[71]

Children with significant renal failure are at a greater risk for bleeding in the perioperative period. As a consequence, the hemoglobin concentration should be monitored closely. This is a classic and lethal complication in children with terminal uremia that results from platelet dysfunction in the presence of a normal coagulation profile and normal platelet counts. Blood and component therapy may be used in accordance with surgical losses and to maintain the hemoglobin concentration greater than 11 g/dL. Other components that may be effective to alleviate surgical oozing or occult bleeding should be given based on the clinical need because coagulation studies may not be true indexes of the coagulation status in children with platelet dysfunction.

ANESTHETIC AGENTS

The pharmacokinetics and pharmacodynamics of anesthetic agents and perioperative medications may be altered in children with renal failure. The medications most likely to be affected are those that depend on renal excretion, such as the hydrophilic, highly ionized agents. Repeated doses of medications that depend primarily on renal excretion for elimination should be administered at greater intervals or in smaller doses than they are given otherwise. Examples of commonly used perioperative medications that primarily depend on renal elimination are penicillins, cephalosporins, aminoglycosides, vancomycin, and digoxin.

Anesthetic agents should be tailored according to the circumstances and child. For example, the duration of action of medications delivered as a single bolus depends more on redistribution than on elimination. If the volume of distribution of the medication is unchanged, the single bolus dose should be unchanged. Medications that depend only in part on renal elimination (e.g., rocuronium or vecuronium) have a normal duration of action when delivered as a bolus or short-term infusion. Many anesthetics depend in part on renal elimination, including pancuronium, vecuronium, rocuronium, atropine, glycopyrrolate, and neostigmine.

Induction of anesthesia may be carried out safely as long as the child is euvolemic and the pharmacokinetics and pharmacodynamics of the induction agent are understood and accounted for. Anesthetic agents may be affected by the presence of anemia, acidosis, and altered drug binding owing to hypoproteinemia in children with renal disease. Antihypertensives such as ACE inhibitors, particularly in combination with diuretics, may lead to profound hypotension at induction of anesthesia.[72]

The dose of propofol to induce anesthesia using the bispectral index and clinical signs to indicate the state of hypnosis in adult patients with renal failure were significantly greater than in those without renal disease.[73] This has been attributed to a larger volume of distribution in patients with renal failure, consistent with previous studies of thiopental.[74] Anemia is another contributing factor. It may indirectly cause a greater plasma volume and greater cardiac output. When propofol is delivered as an infusion, no significant differences in pharmacokinetic (principally clearance) or pharmacodynamic parameters have been observed.[75] There is also some evidence to suggest that propofol, when compared with sevoflurane, may be renoprotective as a result of its ability to attenuate the perioperative increase in proinflammatory mediators.[46]

There are insufficient data regarding the use of inhalational anesthetics for induction in children with renal impairment. For maintenance of anesthesia in adults, desflurane and isoflurane do not further impair renal function in those with preexisting renal disease.[76] Sevoflurane at low flows is associated with increased circuit concentrations of compound A, which is nephrotoxic in rats but not in humans.[77–79] In adults with normal renal function, low-flow sevoflurane anesthesia has been associated with mild, transient proteinuria but no changes in BUN, creatinine level, or creatinine clearance.[79] In adults with renal insufficiency, low-flow

sevoflurane is as safe as low-flow isoflurane in terms of kidney function.[78] Overall, sevoflurane is considered safe in patients with renal disease, but low flows are best avoided. Because desflurane is minimally metabolized (rate of 0.2%) in vivo, it may be preferred even at very low flows (1 L/minute).

NMBDs have evolved over the years to provide a choice of relaxants for use in children with renal disease. Children with chronic renal failure may have existing autonomic neuropathy and associated delayed gastric emptying that puts them at risk for aspiration. Along with renal implications, aspiration should be anticipated when choosing an NMBD for airway management. Succinylcholine is often avoided in children with renal failure because of its well-known propensity for increasing serum potassium. However, succinylcholine does not increase the plasma potassium concentration in patients with renal failure any more than in patients with normal renal function (0.5–0.8 mEq/L of potassium) unless a peripheral neuropathy is present.[80,81] The plasma concentration of potassium is chronically increased in renal failure, which implies that the intracellular and extracellular potassium concentrations are in equilibrium. As a result, the usual 0.5- to 1-mEq/L increase in serum potassium after succinylcholine causes no clinical manifestations, despite the large absolute concentration of potassium. This contrasts with patients with acute hyperkalemia in whom the intracellular and extracellular potassium concentrations are in disequilibrium, which predisposes these children to ventricular arrhythmias after succinylcholine. In the latter case, succinylcholine is relatively contraindicated, whereas in the former case, it is not contraindicated.

The pharmacodynamics of NMBDs in children with renal insufficiency merit consideration. The onset time of rocuronium in children with renal failure (>2 minutes) was significantly greater than in the control children (1.5 minutes). This difference was attributed to a greater volume of distribution, decreased serum albumin concentrations, and possibly to a reduced cardiac output in children with renal failure who were taking antihypertensives. The slower onset time of rocuronium in children with renal failure must be considered when a rapid-sequence intubation is required and succinylcholine is contraindicated. On the other hand, the duration of action of rocuronium in children with normal renal function and end-stage renal disease is similar[82]; the time to recover a train-of-four ratio of 70% was 29 minutes in both groups with a 0.3-mg/kg dose. This is not surprising because elimination of rocuronium is predominantly biliary and not via the kidneys.

NMBDs such as atracurium and cisatracurium are ideal choices for children with renal insufficiency because their elimination is completely independent of the kidney. Despite the fact that both agents undergo spontaneous degradation by plasma esterase and Hofmann elimination, neuromuscular blockade should still be monitored.[83] Therefore with appropriate monitoring and dosing, atracurium, cisatracurium, vecuronium, and rocuronium are all acceptable NMBDs in children with renal disease and provide reliable durations of action after a single bolus dose.

If a prolonged neuromuscular blockade occurs, hypermagnesemia should be ruled out. In this case, calcium may be administered to help antagonize the blockade. The elimination of neostigmine may be delayed beyond elimination of atropine or glycopyrrolate, and muscarinic effects such as bradycardia, increased secretions, or bronchospasm may theoretically occur postoperatively after antagonism.

Sugammadex is a binding agent selective for aminosteroidal NMBDs such as rocuronium and vecuronium. It is entirely renally excreted with an elimination half-life of approximately 100 minutes. As discussed elsewhere, rocuronium is metabolized almost entirely in the liver but when it is bound to sugammadex, it is both inactivated and effectively removed from the circulation; the rocuronium-sugammadex complex is eliminated by the kidney. Special consideration should therefore be given to patients with renal failure.[84] Suggamadex dosing in mild to moderate renal dysfunction is the same as in patients with normal renal function; it is not recommended for those with severe renal failure.[85] In a patient with normal renal function, rocuronium can be redosed in about 25 minutes after sugammadex administration. Because there is currently no redosing data for patients with renal failure, the use of sugammadex should be carefully considered.

Remifentanil may be a preferred choice for a maintenance opioid in the intraoperative period in children with renal insufficiency because of its rapid metabolism by nonspecific blood and tissue esterases. The pharmacokinetics and pharmacodynamics of remifentanil are not altered in patients with renal disease, but the principal metabolite of remifentanil has reduced elimination,[86,87] which is not clinically relevant. Doses of other opioids should be reduced by 30% to 50% to avoid respiratory depression in children with chronic renal failure. Active metabolites of morphine and meperidine (no longer recommended for children other than to treat shivering) can likewise accumulate in patients with renal failure, whereas those of fentanyl and sufentanil do not. Dialysis may be required to eliminate these active metabolites.[88] Hence, the latter opioids are preferred when remifentanil is not indicated.[89–93] Prolonged antagonism of opioid effects with naloxone can be expected in renal failure patients.

Dexmedetomidine, an α_2-adrenoceptor agonist, has diuretic properties via its suppression of vasopressin secretion. GFR and renal blood flow are enhanced, thereby increasing urine output. Some advocate its use in protecting against contrast-induced nephropathy, but it has also been shown to have an antiinflammatory effect. It has been shown to reduce levels of harmful inflammatory molecules such as tumor necrosis factor-α (TNF-α) and increase proteins such as bone morphogenetic protein-7 (BMP-7), thought to be protective against sepsis-induced AKI.[94] The clinical efficacy of this has yet to be established, but dexmedetomidine has been associated with improved short-term mortality in adult patients with sepsis and children after surgery for congenital heart disease. While it is metabolized in the liver, none of the renally excreted metabolites are thought to be active. The renoprotective effect of dexmedetomidine therefore may make it a logical sedation and anesthetic choice in children who are vulnerable to AKI, thereby further increasing its appeal for use in children with renal disease.[95,96]

Delayed emergence, vomiting and aspiration, hypertension, respiratory depression, and pulmonary edema are potential problems that should be anticipated with anesthetic emergence. Hyperkalemia as a consequence of tissue injury, catabolism, blood transfusion, and acidosis is common. Children with chronic renal failure usually have chronic metabolic acidosis with limited buffer reserve. Modest hypercapnia with emergence may lead to significant acidosis and hyperkalemia. Careful attention should be given to the fluid needs of the child postoperatively to minimize volume overload and pulmonary edema.

Regional anesthesia is a viable alternative to general anesthesia or an adjunct in many cases. The anesthesia team must pay particular attention to coagulation studies and signs of coagulopathy before embarking on any central block because abnormal platelet function puts the renal failure patient at risk for an epidural hematoma.

POSTOPERATIVE CONCERNS

The postoperative care of the child with renal disease must take into account the level of renal function, anemia, and preexistence of hypertension. In the child with limited ability to excrete a salt and water load, care must be given to the rate and amount of postoperative fluids administered, with consideration of the volume given during the procedure and operative losses. In children with renal insufficiency, nephrotic syndrome, or tubular disorders (especially those with concentration impairments), it is common to administer fluid volumes that approximate anticipated output and insensible needs. This volume needs to be adjusted for third spacing, ongoing losses, and the administration of blood and blood products.

For children with known renal disease, care must be taken to identify medications that need to be resumed in the immediate postoperative period. Children who have been on chronic antihypertensive medications may be able to resume oral medications when awake. It may be necessary to treat isolated hypertensive episodes with IV medications during the postoperative period. It is important to assess the contribution of pain and anxiety to increased blood pressures to avoid overtreatment.

Because of ischemic tissue injury, it is possible that preexisting metabolic acidosis and hyperkalemia may worsen in the postoperative period. In children who have renal failure, careful monitoring of electrolytes during and after the procedure may prevent untoward emergencies. When clinically significant hyperkalemia develops in a child with chronic renal failure, treatment is imperative (see Table 28.6).

Acute hypertension can be treated with a variety of IV and oral medications (Table 28.8).[97] The therapy for acute symptomatic hypertension should be directed toward rapid normalization of blood pressure. Prompt and effective therapy must be initiated, often before the cause has been discerned. The rate of change of blood pressure can be just as important as its absolute level in the pathogenesis of hypertensive emergencies. Blood pressure itself may be a poor determinant of the severity of the clinical situation and the need for aggressive parenteral therapy. The decision to use aggressive parenteral therapy should be based on an absolute number and on clinical findings that define the situation as emergent. The drugs most often chosen are potent vasodilators, such as hydralazine, diazoxide, or nitroprusside, although nitroprusside is infrequently used today. In its stead, nicardipine and labetolol have been adopted as first-line therapies for acute hypertension in children; these drugs have the advantages of IV administration, safety, and rapid onset of action.

Hemodialysis or peritoneal dialysis can be safely resumed on the first postoperative day, with the exception of children who have operative placement of a dialysis access port for more emergent therapy. In these children, the timing of renal replacement therapy must be individualized in consultation with the child's nephrologist.

Uremic encephalopathy may occur and should be considered in any child who exhibits confusion or prolonged sedation in the postanesthesia care unit. These children should be transferred to an intensive care setting for monitoring, stabilization, and airway management during further workup.

With a careful preoperative assessment and review of preexisting disease, many postoperative complications can be anticipated and avoided. Hypervigilance during the entire perioperative period allows children with renal disease to be managed in a safe manner.

TABLE 28.8 Management of Acute Malignant Hypertension

Drug	Dose	Side Effects
Sodium nitroprusside	1–10 µg/kg per minute IV	Possible cyanide and thiocyanate toxicity, acute hypotension
Enalaprilat[a]	0.01–0.06 mg/kg IV 6 hourly	Onset 15 minutes in neonates; hypotension, angioedema, anaphylactoid reaction, and increase serum creatinine; avoid with increased plasma renin levels, AKI, and CKD
Labetalol	0.1–0.4 mg/kg per hour *or* 0.2–1 mg/kg IV every 10 minutes (maximum 40 mg)	Bradycardia; caution in children with head injuries at risk for hypotension
Nicardipine	0.5–5 µg/kg per minute IV (maximum 20 mg/hour)	Acute hypotension; possible superficial thrombophlebitis if administered through a peripheral IV.
Hydralazine	0.1–0.5 mg/kg IV or IM, not to exceed 2 mg IV 6 hourly	
Esmolol	100–500 µg/kg IV over 2 minutes LOAD 50–100 up to 300 µg/kg per minute IV infusion	Bradycardia, acute hypotension

[a]Intravenous angiotensin-converting enzyme inhibitor.
AKI, acute kidney injury; *CKD,* chronic kidney disease

ABDOMINAL SURGERY AND UROLOGIC interventions make up a large fraction of anesthetic practice for the pediatric anesthesiologist. The field is rapidly evolving, with increased use of laparoscopic surgery, including robot-assisted procedures.[1] This chapter focuses on the specific issues related to abdominal and urologic surgery, particularly in young children. The management of infants for pyloromyotomy and other neonatal abdominal procedures is discussed in Chapter 37.

General Principles of Abdominal Surgery

"THE FULL STOMACH": THE RISK FOR PULMONARY ASPIRATION OF GASTRIC CONTENTS

Many abdominal surgeries are emergent procedures that require a rapid induction of anesthesia and protection of the airway to prevent regurgitation and pulmonary aspiration. Adhering to fasting guidelines for elective surgery does not ensure that the stomachs of children with acute abdomens are empty of liquids and solids. The only metric that has been associated with gastric emptying after an acute emergency in children is the time interval between the last food ingested and the occurrence of the pathologic event or trauma.[2] However, there is no firm fasting interval after a trauma that predicts a zero risk of regurgitation and aspiration. The presence or absence of bowel sounds is also not predictive of gastric emptying or of the risk of regurgitation. Preoperatively, some children with acute abdomens are administered oral contrast agent before abdominal ultrasonography and/or computed tomography (CT) to visualize the stomach contents and to estimate their volumes. However, these radiologic tools may not provide reliable estimates of the volume of the gastric contents.[3,4] Indeed, the absence of gastric contents in these scans does not eliminate the risk of vomiting and regurgitation. Consequently, there is no evidence that delaying the surgical procedure for the express purpose of emptying the stomach will reduce the risk of regurgitation; postponing may actually increase the risk of complications by delaying the urgently needed surgical attention to the acute abdomen.

RAPID-SEQUENCE INDUCTION

Rapid-sequence induction (RSI) is recommended for children with a full stomach to quickly secure the airway. This approach is intended to minimize the risk of aspiration, although it is not evidence-based. The strategy is to predetermine the drug doses for the child and have all the required airway equipment (age- and

size-appropriate) ready to use. The predetermined drug doses are administered in a rapid sequence and when muscle relaxation has been achieved, the trachea is intubated and the cuff (if used) inflated. Many clinicians apply cricoid pressure to occlude the esophageal lumen during RSI, although not a single randomized trial has compared the frequency of regurgitation and aspiration with cricoid pressure during RSI with that with an inhalational or slow IV induction in either children or adults as summarized in a recent Cochrane review.[5] Recently, the presence of microaspirates in the tracheas of 95 adults at risk for regurgitation (obese, those with diabetes, and those with gastroesophageal reflux) was compared with and without cricoid pressure during induction of elective surgery. There was no difference in the frequency of microaspirates in the two groups.[6] This lack of evidence, combined with both theoretical and actual complications associated with RSI and cricoid pressure in children, has led to great skepticism regarding their roles in preventing pulmonary aspiration in children who are at risk, although large population-based studies are lacking.[7] Only 74% of anesthesiologists in Northern Ireland perform RSI for children scheduled for appendectomy, 78% in the United States use it for pyloromyotomy, and 83% in England use it for forearm fractures within 2 hours of eating and after recent opioid administration.[8–10] In two surveys, 16% and 28% of anesthesiologists in the United States and United Kingdom, respectively, reported that a number of children with full stomachs had experienced gastric regurgitation despite using RSI with cricoid pressure; several of them progressed to serious harm and even death.[9,11]

Despite the lack of evidence supporting the effectiveness of RSI in children with full stomachs, we continue to recommend this approach for the majority of children at risk. Whether cricoid pressure during RSI contributes substantively to preventing regurgitation performed remains unclear. Based on evidence from non-randomized controlled studies (RCTs), a recent Cochrane review concluded that cricoid pressure may not be necessary to safely achieve RSI.[5] The authors assert that well-designed and properly conducted RCTs should be encouraged to assess the safety and effectiveness of cricoid pressure in infants and children; however, because the frequency of pulmonary aspiration is so small, it would take many thousands of cases to establish a substantive outcome and likely would not be readily approved by an institutional review board.[5]

Complications of RSI, for the most part, relate to improperly performed RSI (e.g., excessive cricoid pressure distorting the anatomy of the airway,[12] causing difficulty in securing the airway) or poor selection of patients (those with a known difficult airway, where a more measured approach must take precedence over concerns for possible aspiration).

RSI in infants and children requires more planning than in older children and adults for several reasons. First, the induction drugs should be flushed into the child's veins using a separate flush syringe to ensure a rapid bolus administration of the drugs. Succinylcholine remains useful for rapid-sequence tracheal intubation for brief procedures. The introduction of intermediate-acting neuromuscular blocking drugs (NMBDs) with rapid onset, coupled with concerns about the risk of hyperkalemia after succinylcholine in children with undiagnosed neuromuscular diseases (especially males <8 years of age), has dramatically reduced the use of succinylcholine in elective surgery. With the shift from succinylcholine to nondepolarizing NMBDs for rapid paralysis in young children, inability to intubate and prolonged paralysis may present serious, possible life-threatening problems. However, with the availability of sugammadex, the use of rocuronium (1.2 mg/kg) represents a safe alternative to succinylcholine.[13–15] Second, preoxygenation is often difficult in infants and children because they commonly resist the tight application of the face mask needed to fully denitrogenate the lungs. Failure to ventilate the lungs after induction and before tracheal intubation may result in desaturation more rapidly in young infants and children than older children, and in those with upper respiratory tract infections or other causes of a limited oxygen reserve.[16,17] During laryngoscopy and intubation, mask ventilation with 100% oxygen should begin when the saturation reaches 95%, to attenuate the nadir in oxygen saturation that follows.[16] Third, the force needed to occlude the esophagus when applying cricoid pressure to infants and children is poorly understood and poorly applied, can distort the view of the larynx during laryngoscopy, may not occlude the lumen of the esophagus, and may actually deform the lumen of the trachea if excessive force is applied.[7,12,18] For example, as little as 10-N force will distort the shape of the cricoid ring and reduce the lumen by 50% in children younger than 5 years of age.[12] Effective cricoid pressure that occludes the esophagus in children and permits bag-and-mask ventilation with up to 40 cm H_2O peak inspiratory pressure without gastric insufflation[19] is known as a modified RSI. Thus, if the first attempt at tracheal intubation fails or the child desaturates during laryngoscopy, properly maintained cricoid pressure allows bag-and-mask ventilation to restore oxygenation, without increasing the risk of regurgitation. A third technique that uses low insufflation pressures, known as the controlled RSI technique, has also been proposed.[20,21] In the United Kingdom, a recent survey of adult anesthetists that documented a large variability in how the RSI was performed[22] has prompted calls for evidence-based guidelines for RSI in infants and children.

INDICATIONS FOR PREOPERATIVE NASOGASTRIC TUBE PLACEMENT

Although there are no published guidelines for placing nasogastric tubes preoperatively, it is reasonable to insert a tube preoperatively to allow drainage of gastrointestinal fluids in cases of documented bowel obstruction (e.g., ileus, strangulated bowel, pyloric obstruction) or in other situations in which the risk of aspiration is judged to be substantial. The child may experience discomfort when a nasogastric tube is inserted preoperatively, but this must be balanced against the need to decompress the stomach and reduce the risk of regurgitation during induction of anesthesia. For every other indication, the nasogastric tube may be placed after tracheal intubation. It should be noted that the presence of a nasogastric tube may decrease lower esophageal sphincter tone, increase the risk for reflux, and reduce the ability to clear refluxed gastric contents from the distal esophagus.[23,24] Thus the anesthesiologist is faced with the dilemma of whether or not to remove the nasogastric tube that was placed before induction of anesthesia. It may be reasonable to apply suction to the nasogastric tube, evacuate all of the gastric contents, and then remove the nasogastric tube before inducing anesthesia because it is unclear whether cricoid pressure, even if properly applied, prevents wicking of gastric contents along the path created by the nasogastric tube. It should be further noted that even with a well-placed nasogastric tube, one can never guarantee that the stomach has been completely emptied.

FLUID BALANCE

Many acute abdominal emergencies are associated with pronounced and significant shifts in fluids, mainly in the form of dehydration,

electrolyte losses, third-space fluid shifts, and hypovolemia. In most instances, correction of these derangements is mandatory before proceeding with anesthesia and surgery. However, when a large fraction of the bowel becomes strangulated and ischemic, large volumes of fluid may be sequestered in the bowel. In these cases, hypovolemia should be suspected and resuscitation initiated as anesthesia is rapidly induced. In some elective cases (e.g., bowel resection because of inflammatory bowel disease), fluid and electrolyte resuscitation should routinely be a focus of special interest, because the child may not be fully compensated at the time of surgery.

To date, published studies have suggested that resuscitation with crystalloid fluids and colloids have equipoise.[25] In children, initial resuscitation is usually undertaken with balanced salt solutions. A recent Cochrane review concluded that the use of isotonic intravenous (IV) fluids with sodium concentrations similar to that of plasma reduces the risk of hyponatremia.[26] Although colloids may result in less tissue edema and less volume infused, the expense may not justify their routine use. In fact, some have even questioned the use of colloids in patients with sepsis.[27]

POTENTIAL FOR STRANGULATED OR ISCHEMIC BOWEL AND SEPSIS

The need for anesthesia and surgery becomes more urgent when the bowel is potentially ischemic and/or necrotic. For example, if a volvulus is suspected, immediate action is necessary; otherwise the child is at risk for massive bowel necrosis necessitating resection of dead bowel with subsequent short bowel syndrome, a condition associated with serious lifelong medical problems or even death. Even if the child is far from optimally resuscitated, anesthesia must be induced and maintained, preferably with anesthetics that maintain circulatory homeostasis, while simultaneously correcting the dehydration (or hypovolemia) and electrolyte imbalance. The situation is somewhat less critical in the child with an incarcerated inguinal hernia, although delay of even this surgery should be minimized.

Ischemic bowel may release a host of mediators that can cause severe hemodynamic instability. Children with acute intraabdominal disease should always be regarded as being at risk for bacterial translocation and possible septicemia. Those with overt sepsis are usually easy to identify and may have already been admitted to the pediatric intensive care unit. However, children with incipient or early sepsis may not exhibit overt signs. Accordingly, the signs of sepsis should be actively sought. If septicemia is present or suspected, appropriate IV antibiotics should be administered without delay, preferably before anesthesia and surgery. Children with sepsis or presepsis can be extremely unstable and may require inotropic and/or vasoactive drugs. Immediately after induction of anesthesia vascular sympathetic tone may be attenuated, leading to sudden hemodynamic instability. Thus, when a substantial segment of the bowel becomes ischemic, the anesthesiologist must maintain anesthesia without depressing the circulation excessively, acutely resuscitate the child with appropriate fluids, correct electrolyte imbalances, particularly potential hyperkalemia, and consider the use of inotropic and/or vasoactive medications as needed. It should be noted that hemodynamic instability might acutely worsen when ischemic bowel is suddenly reperfused or immediately after the abdominal cavity is opened. In such cases, close communication with the surgeon is paramount. Furthermore, the presence of sepsis-induced acute lung injury may reduce pulmonary compliance. Thus the anesthesiologist needs to prepare for invasive monitoring (arterial and central venous pressures) and an intraoperative ventilator that is capable of delivering high positive end-expiratory pressure (PEEP).

PRESENCE OF ABDOMINAL COMPARTMENT SYNDROME

Acute intraabdominal disease processes may lead to a critically increased intraabdominal pressure (IAP).[28] If the IAP increases above the capillary perfusion pressure of the intraabdominal organs, an abdominal compartment syndrome can develop. Organ perfusion will become compromised and ischemia and/or necrosis may develop. The most commonly affected organs in this situation are the bowels, kidneys, and liver. Abdominal compartment syndrome occurs less frequently in children than in adults.[29] Causes of abdominal compartment syndrome include burns, extracorporeal membrane oxygenation,[30] closure of gastroschisis or omphalocele (see Chapter 37),[31] abdominal trauma,[32,33] abdominal surgery,[34] and a host of other intraabdominal pathologies, including necrotizing enterocolitis, Hirschsprung enterocolitis, perforated bowel, diaphragmatic hernia, and Wilms tumor.[30,35,36] Insufficient perfusion of the bowel may cause an ileus, translocation of bacteria, lactate accumulation, and production of mediators that cause hemodynamic instability. Increased IAP can reduce liver blood flow, which will reduce hepatic function,[37] mainly manifested as an inability to metabolize lactate, impaired drug metabolism,[37,38] and, in severe cases, impaired synthesis of coagulation factors. Because the pressure is also transmitted to the retroperitoneal space, renal function may become impaired, resulting in oliguria or anuria and reduced excretion of drugs.[35] In addition, cranial displacement of the abdominal contents and splinting of the diaphragm may seriously compromise ventilation.[39]

If acute intraabdominal compartment syndrome is suspected, then the IAP should be monitored to prevent the pressures from exceeding the critical threshold of 20 to 25 mm Hg. IAP can be measured indirectly by transducing a nasogastric tube or bladder catheter.[40] Some define compartment syndrome when the vesicular (bladder) pressure exceeds 10 to 12 mm Hg.[41,42] The diagnosis of intraabdominal compartment syndrome should be suspected when the triad of (1) massive abdominal distention, (2) increased bladder pressures and increased peak inspiratory airway pressures, and (3) evidence of hepatic, renal, and/or cardiac dysfunction are present.[36,43,44]

Children with acute intraabdominal compartment syndrome are often hemodynamically unstable. Although decompression of the abdomen by a laparotomy will immediately normalize the IAP, reperfusion of the ischemic tissues almost always releases a host of biologically active substances that cause profound hypotension. These substances may also precipitate acute renal failure and lead to a disseminated intravascular coagulopathy. As in the case of sepsis, the anesthesiologist must be fully prepared to address these challenges by ensuring that blood products are present in the operating room and vasopressors are drawn up and available before induction of anesthesia. Some children will require a patch abdominoplasty as a temporizing measure to protect abdominal organs that require delayed primary closure of the anterior abdominal wall.[36,43]

PREOPERATIVE LABORATORY TESTING AND INVESTIGATIONS

Most minor elective cases (e.g., umbilical or inguinal hernia repair) do not require any preoperative workup beyond a basic history and physical examination. Many centers require a preoperative urine (or hemoglobin) screen for pregnancy in females who have reached menarche (see Chapter 4).[45] More complex elective cases

may warrant additional laboratory testing, including basic hematology screening and electrolyte profile.

Preoperative laboratory testing is strongly advised in more critically ill children. Liver and renal function tests, coagulation profile, and serum albumin concentration should be assessed and blood typed and crossmatched. In children with sepsis or who have an acute intraabdominal compartment syndrome, a preoperative chest radiograph may indicate the severity of pulmonary involvement. An echocardiogram may be needed to assess myocardial contractility and volume status if cardiac dysfunction is suspected.

MONITORING REQUIREMENTS

Routine elective cases rarely require more than standard monitoring equipment. In children undergoing major intraabdominal procedures, invasive arterial and central venous blood pressure monitoring may be indicated. A multiple-lumen central venous line inserted at the beginning of the procedure will facilitate administration of inotropic and/or vasoactive drugs, in addition to measuring central venous pressure; ultrasound-guided insertion is strongly recommended.[46] These lines are of great value in the immediate postoperative period for blood sampling, drug administration, ongoing assessment of intravascular volume status, and parenteral nutrition. Transesophageal echocardiographic, transesophageal Doppler, or continuous noninvasive cardiac output (CO)[47] evaluation may provide valuable intraoperative and postoperative information regarding the child's volume status, as well as cardiac contractility (see also Chapter 52).[48–58]

A urinary catheter with a pediatric urometer (i.e., a graduated collection receptacle), which provides an accurate measure of urine output, is a useful monitor for most intraabdominal procedures. Maintaining a stable hourly urine output may safeguard against the development of hypovolemia and possibly prerenal azotemia (see the section "Laparoscopic Surgery" for discussion of changes in urine output with increased IAP).

Monitoring IAP is important during laparoscopic surgery, although it is of minimal value in omphalocele and gastroschisis surgeries, as long as the abdomen remains open. Once the abdomen is closed, however, IAP provides useful prognostic information regarding intraabdominal organ (e.g., renal) blood flow, circulatory stability, and respiratory embarrassment (see Chapter 37).[39]

CHOICE OF ANESTHETIC

The anesthesiologist may use his or her personal preference of anesthetic technique for the management of both elective and emergency intraabdominal surgery in children. However, airway management associated with intraabdominal surgery requires careful consideration. Even when the child is not at increased risk for regurgitation and aspiration, the risk of regurgitation can be increased if the surgeon positions the child in the Trendelenburg position and/or insufflates the peritoneal cavity with carbon dioxide (CO_2) during laparoscopic surgery. A particular concern arises when the surgeon decides to decompress distended bowel by creating an enterotomy and directly draining the fluid, or by "milking" or "stripping" the bowel in a retrograde direction until the contents can be vented with a nasogastric tube. The latter method can cause massive intestinal regurgitation that exceeds the capacity of the nasogastric tube causing pulmonary aspiration.[59] It is for this reason and others that a laryngeal mask airway (LMA) should not be used during intraabdominal surgery; we strongly recommend that the trachea should be intubated with a cuffed tube as standard practice in these cases.

Regional anesthetic techniques may be useful adjuncts in children undergoing both minor and major abdominal surgery. Those who have had open abdominal procedures will require IV opioids or the use of a continuous epidural infusion of local anesthetics with or without opioids for perioperative pain management (see Chapter 44). Analgesia is commonly supplemented with parenteral nonsteroidal antiinflammatory drugs and/or acetaminophen. In most children who have had laparoscopic surgery, adequate postoperative analgesia may be achieved by infiltrating local anesthetics at the port insertion sites. However, referred shoulder pain, the result of accumulated air under the diaphragm, may require IV opioids.[60] In critically unstable children or those with sepsis, the use of neuroaxial anesthesia is not recommended because sympathetic blockade may further exacerbate the hemodynamic instability and the catheter could provide a nidus for infection.

General Principles of Urologic Surgery

With the exception of acute drainage of urinary obstruction (i.e., ultrasound-guided nephrostomy or cystostomy procedures) and torsion of the testis, most pediatric urologic surgeries are elective. In the vast majority of cases, these children are otherwise healthy or have stable medical conditions that do not require more than a careful history, physical examination, and review of the child's medical record. Children who undergo urologic procedures may be suffering from emotional disturbance because of repeated interventions and sensitivity of the surgical site. This mandates special psychological attention before and after anesthesia.

Worldwide, the prevalence of latex allergy has recently been estimated to be 9.7%, 7.2%, and 4.3% among health care workers, susceptible patients, and the general population, respectively.[61] In the 1990s, the prevalence of latex allergy in children with spinal dysraphism exceeded 70%, several years later, it had decreased to less than 17%, and most recently evidence suggests the prevalence may be as small as 3% in those with dysraphism in a nonlatex environment.[62] Indeed, latex anaphylaxis is of particular concern in children with chronic urologic disorders.[63–66] In the past, children with spina bifida were prone to developing latex allergy much more often than those without spina bifida[67–70] because the former were repeatedly exposed to latex urinary catheters beginning early after birth. All children with congenital malformations of the urinary tract who were repeatedly exposed to latex via their mucous membranes beginning in the neonatal period were at significant risk for developing latex hypersensitivity until recently.[71,72] However, a widespread shift in practice to avoid exposure to all latex products in these children has been extremely (but not 100%) effective in attenuating the prevalence of this allergy.[62] The exceptions usually occur when someone unfamiliar with the child's latex allergy introduces a latex product and sensitizes the child or triggers a reaction. Thus latex-free management is highly recommended in this population.[62,73–75]

REDUCED RENAL FUNCTION

Children with chronic renal disease have impaired renal function, which may affect drug dosing and disposition, as well as cause secondary effects on the cardiovascular system. In the most severe cases, the child may require dialysis to balance fluids and electrolytes. In children with renal disease, it is essential to determine the degree of renal impairment by consulting the child's nephrologist and reviewing the serum creatinine, blood urea nitrogen, sodium, and potassium concentrations (see also Chapter 28).

Because renal impairment may also affect clotting, a coagulation profile, including platelet count, should be reviewed preoperatively if substantial blood loss is anticipated. These children are prone to fluid overload, particularly those who are anuric and dialysis dependent. Apart from clinical signs associated with fluid overload, measuring the child's weight and comparing it with their normal weight is a simple means to assess the child's current volume status. If cardiac function or volume status remains in doubt, an echocardiogram should be obtained. Children with chronic renal insufficiency often have impaired left ventricular function even before they require dialysis, so a preoperative echocardiogram may be indicated[76–80]; pericardial effusion is also a concern.[77,81,82]

For children undergoing dialysis, the most recent date of dialysis should be documented. Overhydration and/or hypervolemia and hyperkalemia should be corrected preoperatively with dialysis. Although dialysis corrects these abnormalities, and may transiently improve platelet function (peritoneal dialysis yielding more consistent improvement than hemodialysis), it is best to avoid dialysis within 12 hours of anesthesia to preclude a relative hypovolemia and to allow sufficient time for body fluids to reequilibrate (see Chapter 28).[83,84] Postdialysis laboratory indexes of serum electrolytes (particularly potassium), hemoglobin or hematocrit, renal function (creatinine and blood urea nitrogen), and the child's weight loss should be assessed. For children who undergo hemodialysis, IV access and blood pressure measurements should not be obtained in the extremity ipsilateral to the arteriovenous fistula.

SYSTEMIC ARTERIAL HYPERTENSION

Systemic hypertension is common in renal insufficiency in adults but is far less common in children. Nonetheless, some children with urologic disorders develop systemic hypertension associated with disturbances in the renin-angiotensin system.[85–88] As in adults, it is important to control systemic hypertension before induction to avoid wide swings in blood pressure. In contrast to adults, however, hypervolemia is an important cause of hypertension in children with renal insufficiency that should be considered and treated preoperatively. Children and adults are often treated with similar antihypertensive medications (see Chapter 28).[87,88] All medications should be continued up to and including the morning of surgery to maintain intraoperative and postoperative hemodynamic stability with the exception of angiotensin-converting enzyme (ACE) inhibitors. The latter drugs should be stopped 1 day before surgery to avoid intraoperative hypotension[89–91]; however, withholding this medication may also lead to rebound hypertension postoperatively. If these medications are not withheld, vasopressors may be required during anesthesia to stabilize the blood pressure.[92] Because therapy-resistant renal hypertension is an indication for nephrectomy, one should anticipate and be prepared to treat wide fluctuations in blood pressure, including severe hypertension during the first stage of the operation and profound hypotension when the responsible kidney is removed. Therefore, long-acting antihypertensive agents are best avoided during the early stages of a nephrectomy in a child.

CORTICOSTEROID MEDICATIONS

Children with renal disease may be chronically treated with corticosteroids as part of their medical management (e.g., children with proteinuria or who have undergone previous renal transplant surgery). In such cases, a stress dose of parenteral corticosteroids during surgery is indicated, with continued supplementation until the child resumes his or her normal corticosteroid medication by the enteral route. In more complex situations, consultation with a pediatric nephrologist or endocrinologist is warranted to optimize corticosteroid supplementation, although in more straightforward cases, a dose of 2.5 mg/kg of IV hydrocortisone two to three times each day is usually adequate (see Chapter 27).

INFECTION OR SEPSIS

Obstructive urinary tract disease or chronic renal insufficiency increases the risk for urinary tract infections. If treated properly, the infection should not interfere with anesthesia. However, in children with overt signs of systemic illness or septicemia, the anesthetic and postoperative courses may be difficult.

MONITORING REQUIREMENTS

Standard noninvasive monitoring is adequate for the vast majority of urologic procedures, as they are of minor or moderate magnitude (e.g., circumcision, orchiopexy, pyeloplasty, and ureter neoimplantation). The anesthetic care required for infants and children undergoing penile surgery is routine, including a forced-air heating mattress to prevent hypothermia for surgeries lasting longer than 1 hour. However, recognizing the minimal amount of skin that is exposed during this type of surgery, the child's temperature often increases, necessitating close monitoring of the child's temperature to avoid overheating.

Invasive monitors (i.e., arterial and central venous access for pressure monitoring and administration of vasoactive drugs) may be indicated in major surgical interventions, and in cases with concomitant problems (e.g., decreased renal function, significant hypertension, associated cardiac dysfunction, sepsis). If central venous access is deemed necessary, the coagulation status of the child should be evaluated because platelet function may be substantially compromised. Ultrasound guidance improves safety while securing central venous access in cases in which a coagulopathy is present or suspected on clinical grounds (see Chapter 49). In the unstable child, even more complex monitoring (e.g., esophageal Doppler monitoring, transesophageal echocardiography, or continuous noninvasive CO)[47] should be considered (see Chapter 52).

It is important to monitor urine output, although the volume of urine may not reflect renal function. During surgery that involves the bladder or in children who are anuric, urine output will not be available for part or all of the surgery. Hence, other indexes of fluid status and perfusion must be used. Heart rate and systolic blood pressure are reliable indexes of volume status and perfusion in most children, although as stated earlier central venous pressure and invasive arterial pressure measurement may be indicated in special cases. Surgeons may be heartened to observe urine flowing into the bladder after reimplantation of ureters and kidney transplantation in place of measuring it. Preloading with a balanced salt solution may be useful in such circumstances; occasionally a loop diuretic is requested.

Laparoscopic Surgery

BACKGROUND

Although laparoscopic surgery was introduced more than 80 years ago, its role in pediatric surgery has become notable only in the past 10 to 15 years. To a large extent, this has been due to improved technology in optics and miniaturization of the instruments. An increasing number of general and urologic surgical procedures (including appendectomy, cholecystectomy, and splenectomy, as well as those to treat inguinal hernia and undescended testicles) are performed either laparoscopically or using robotic techniques in children of all ages (Figs. 29.1 to 29.4).[93–101] More sophisticated

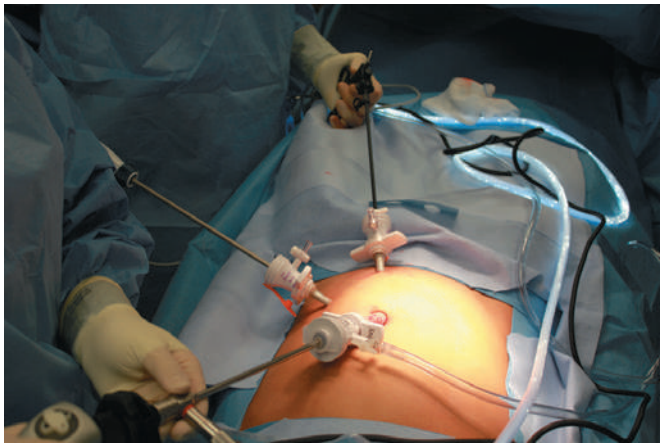

FIGURE 29.1 A child undergoing laparoscopic appendectomy, presented as a paradigm for the surgical setup for any multiple-trocar laparoscopic surgery. Three incisions were made, two in the anterior abdominal wall and the third in the umbilicus. The first two trocars carry instruments to manipulate the appendix, while the third holds the camera for viewing by all personnel in the operating room. All cables swing widely off the surgical field.

FIGURE 29.2 Wide-angle view of the operating room with surgeon and scrub nurse viewing the appendix being held by the grasper, shown on the overhead monitor.

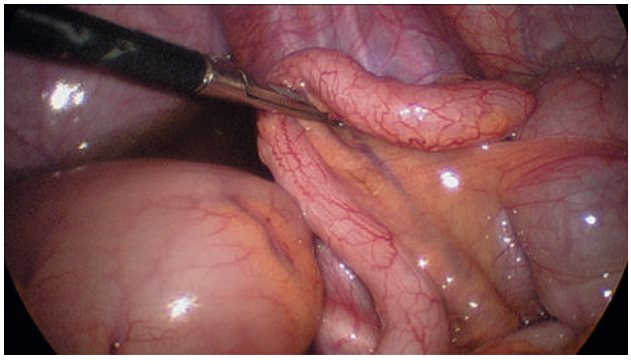

FIGURE 29.3 Inside the abdominal cavity with a view of the inflamed appendix that has been mobilized. The peritoneal attachments must be peeled off the appendix before it is ligated and removed.

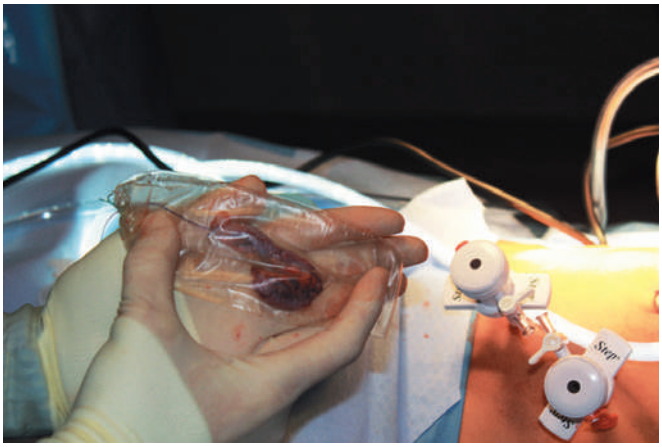

FIGURE 29.4 The appendix is ligated, inserted into a plastic container, and withdrawn, usually through the trocar or incision site without contaminating adjacent tissues. The appendix is shown in the surgeon's hand after removal.

laparoscopic techniques have enabled the performance of complex surgical procedures, including Nissen fundoplication, colectomy, pyeloplasty, bowel pull-through, and removal of large organs, including the kidney and spleen.[99,102–105] Technological advances now permit laparoscopic surgery in neonates and small infants, including those with hypoplastic left heart syndrome after stage 1 or 2 repair.[101,106–108] It must be noted, however, that laparoscopic surgery in children with cyanotic heart disease carries with it a substantial risk that exceeds most other populations having this form of surgery. Although several reports suggest that infants and children of all ages, at all stages of palliative repair of their cyanotic heart disease, tolerate laparoscopic surgery,[108–110] the risk for those with Fontan physiology undergoing laparoscopic surgery is substantial. It is essential to understand that in Fontan physiology, pulmonary blood flow is passive, and decreases in venous return (whether from increases in intrathoracic pressure or head-up positioning) or increases in pulmonary vascular resistance (because of increased CO_2 partial pressures or decreased minute ventilation) could severely reduce CO.[111] Creating a pneumoperitoneum for laparoscopic surgery and extreme positions increase IAP and arterial CO_2 tensions (increasing pulmonary artery pressure) reduces venous return and increases the risk of reducing the CO in children with Fontan physiology (see later discussion). Successful management of these children during laparoscopic surgery requires a multidisciplinary team that functions in concert to enhance the child's outcome (1) by optimizing the child's condition preoperatively and identifying any cardiac issues, (2) by recruiting surgeons who can complete the surgery quickly and efficiently, (3) by maintaining the children in the supine position throughout the surgery, (4) by maintaining normocapnia, (5) by monitoring the child with a transesophageal echo probe as needed, as well as with an arterial invasive pressure monitor for blood gas analysis, and (6) by insufflating the abdomen to the minimal (<8 mm Hg) IAP that is surgically feasible. Larger studies are required before children with cyanotic heart disease, particularly those with Fontan physiology, can routinely undergo laparoscopic surgery in any center except those with specialized teams to manage these children.

Laparoscopic surgery offers a number of advantages over open surgery, including more rapid emergence from anesthesia, faster ambulation, earlier discharge from the hospital, and reduced perioperative complications.[112–115]

Because laparoscopic surgery involves the insufflation of gas into the abdominal cavity to visualize the intraabdominal organs, the stomach should be decompressed using a nasogastric or orogastric tube for upper abdominal surgery, whereas the bladder should be emptied using a urinary catheter for lower abdominal surgery. Surgical access to the peritoneal cavity is achieved with trocars introduced through one to three small (3 to 10 mm in diameter) incisions; the laparoscopic instruments and a camera are then passed through the trocars. Laparo-endoscopic single-site (LESS), single-port, single-incision laparoscopic surgery (SILS), single-incision multiport laparoscopy (SIMPL), or "belly button" surgery has been developed, in which all instruments pass through a single incision and a single large trocar (often in the umbilicus) (E-Figs. 29.1-29.3).[116–120]

Pneumoperitoneal pressure is a major concern for all laparoscopic approaches. Experimental evidence in adult and newborn pigs demonstrated that the risks of cardiorespiratory consequences and potentially fatal emboli were directly related to the peak pneumoperitoneal pressure.[121,122] In infants and children, the optimal pneumoperitoneal pressure is the least pressure that enables adequate surgical access. CO_2 should be insufflated through one of the trocars until the IAP reaches 6 to 15 mm Hg; most surgeons currently limit the IAP in neonates and young infants to 6 to 8 mm Hg and in children to 10 to 12 mm Hg.[123] The IAP is maintained throughout the surgery by intermittently insufflating additional CO_2. Although CO_2 is most commonly used, a number of gases have been investigated (see later discussion).[124] CO_2 is the preferred gas because it does not support combustion, is rapidly cleared from the peritoneal cavity at the end of surgery, and does not expand into bubbles or spaces.[103,125,126]

Adverse Effects of Pneumoperitoneum

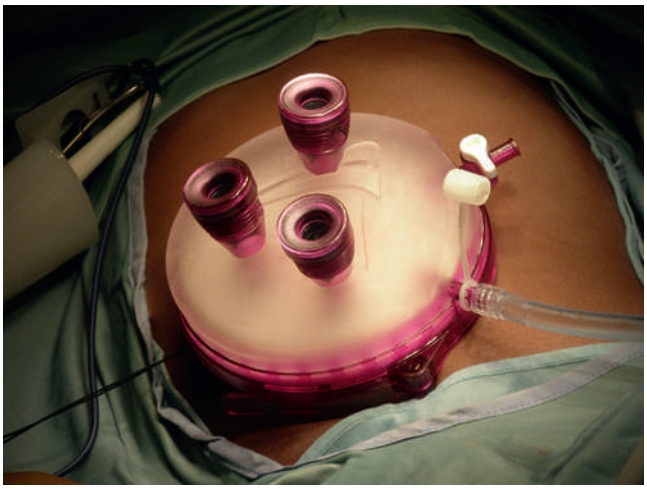
The increased IAP during laparoscopic surgery may cause a number of physiochemical side effects, including cardiorespiratory depression, hypothermia as the result of dry gas leakage, pneumothorax or subcutaneous emphysema, endobronchial intubation resulting from the upward shift of tracheal bifurcation, or injury resulting from paracentesis.

Carbon Dioxide

The major disadvantage of using CO_2 to insufflate the peritoneum arises from its rapid absorption from the peritoneum, with the absorption and washout of CO_2 more rapid and the peak end-tidal partial pressure of CO_2 ($PETCO_2$) greater in infants than in older children.[127,128] The inverse relationship between age and the rate of CO_2 absorption from the abdomen has been attributed to the thinner peritoneum and the reduced peritoneal fat deposits in the abdomen of infants compared with older children.[128,129] Because CO_2 is so readily absorbed, particularly in infants, both the $PETCO_2$ and $PaCO_2$ may increase 20% to 50% above baseline.[104,123,125,127,130] The resultant hypercapnia, which occurs more commonly in surgery lasting longer than 1 hour, particularly in neonates,[131] necessitates an increase in minute ventilation (from 50% to 100%) to maintain a physiologic pH.[103,132] The difference between the partial pressures of arterial and end-tidal CO_2 ($PaCO_2$–$PETCO_2$) often increases during insufflation of CO_2.[130,132] In one report, the $PaCO_2$–$PETCO_2$ gradient before and after pneumoperitoneum increased from a mean of 5.7 mm Hg to 13.4 mm Hg.[133] It should be noted that in neonates and in children with cyanotic congenital heart disease, the $PETCO_2$ may not reliably track the $PaCO_2$ during CO_2 insufflation, leading some to recommend arterial blood gas monitoring to validate the $PETCO_2$ measurements.[130,133,134]

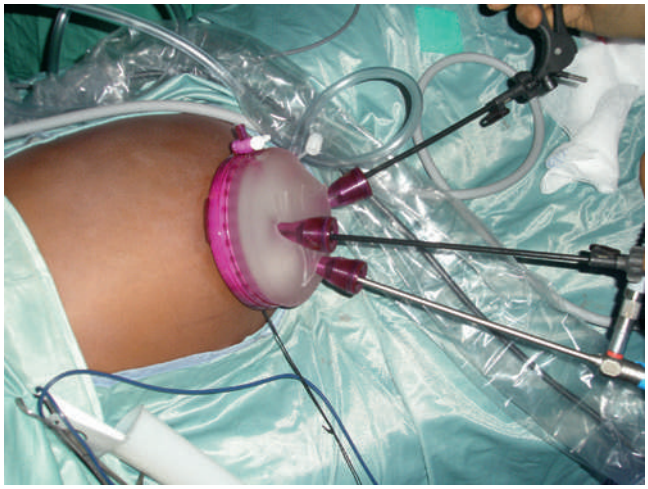
Increased $PaCO_2$ may also trigger spontaneous respiratory efforts that could interfere with surgery. In addition, it may initiate a sympathetic response, including increases in the heart rate, blood pressure, and cerebral blood flow, as well as precipitate ventricular arrhythmias, although this occurs rarely with sevoflurane. A sudden increase in $PETCO_2$ may also suggest a diagnosis of malignant hyperthermia if accompanied with sudden onset of tachycardia.[135–137] If this diagnosis proves to be difficult to confirm or reject (in malignant hyperthermia expect venous PvO_2 <40 mm Hg; see Chapter 41), it may be necessary to desufflate the abdomen and determine if the clinical and laboratory findings suggestive of malignant hyperthermia resolve.[129,138]

Gas Emboli



Gas emboli have been reported in several laparoscopic studies, most of which were interesting curiosities of no clinical consequence, although in several, the result was profound cardiovascular collapse.[139–141] Most consider the emboli to be intravascular CO_2 bubbles, although there is evidence to suggest that some emboli contain nitrogen or air.[142] Intravascular embolization of CO_2 may occur when the insufflation pressure exceeds the venous pressure, forcing CO_2 bubbles into the venous circulation, resulting in sudden cardiovascular collapse.[140] Continuous precordial Doppler or expired CO_2 partial pressure are effective in detecting a gas embolus, although the Doppler may be overly sensitive, with numerous false-positive results. It has been suggested that many episodes of subclinical gas embolism are unrecognized because the symptoms are mild and nonspecific.[143] However, children with right-to-left shunts or potential right-to-left shunts, such as a patent foramen ovale, are vulnerable to the systemic effects of these emboli. Although CO_2 is soluble in blood and rapidly buffered, CO_2 emboli dissolve slowly in blood, taking 2 to 3 minutes to disappear.[144] Hence, large emboli may block blood flow in the heart for several minutes or more before they dissolve. The minimum rate of infusion of CO_2 into blood that triggers cardiovascular collapse in pigs is 1.2 mL/kg per minute[144]; comparable data in humans are lacking. Anesthesiologists should be aware of the high-risk conditions that predispose to CO_2 emboli (e.g., increased abdominal insufflation pressure, hypovolemia and reduced venous pressure, spontaneous respirations, and resection of vessel-rich parenchymatous organs) and communicate closely with the surgeons at all times.

Some investigators suggest that clinically important gas emboli are actually nitrogen, not CO_2 gas emboli.[140] Whereas transient emboli are thought to be composed of CO_2, emboli that persist may be nitrogen gas.[140] Nitrogen is insoluble in blood (blood/gas partition coefficient of 0.014), which explains its persistence as an embolus in blood. These emboli may arise from air, either present in or entrained by the trocar during insufflation of the peritoneum, that is forced into a transected blood vessel while the carboperitoneum is pressurized.[140] This mechanism is a rare source for gas in the circulation, which may explain, in part, why the emboli that occur during laparoscopy very rarely result in cardiovascular instability and arrest.



In contrast to CO_2, insufflation with oxygen, air, and nitrous oxide for laparoscopic surgery has been eschewed because they all support combustion. However, repeat desufflations of the pneumoperitoneal gas during laparoscopy in pigs whose lungs were ventilated with 66% nitrous oxide in oxygen prevents the concentration of nitrous oxide from exceeding 10% in the pneumoperitoneal cavity.[145] Nitrous oxide is still avoided for both insufflation and as an adjunctive anesthetic gas during laparoscopy,

E-FIGURE 29.1 The "poor man's" single incision multiport laparoscopy (SIMPL) device. Through a flap lifted in the umbilicus, a collapsible sheath is passed into the peritoneal cavity that opens once inside the abdomen to stabilize the sheath. On the skin surface, a ring stabilizes the sheath, over which a surgical glove is affixed. A fingertip on the glove is nicked and the gas insufflator (carbon dioxide feed) is inserted. The peritoneal cavity is then inflated to the desired pressure. Through adjacent finger tips, the camera and operating instruments are passed to perform the surgery. (Courtesy Dr. K. Vali, Pediatric Surgery, Women and Children's Hospital of Buffalo, Buffalo, NY.)

The ports and gas insufflator are mounted on the outside. For more information, see Chandler NM, Danielson PD. Single-incision laparoscopic cholecystectomy in children: a retrospective comparison with traditional laparoscopic cholecystectomy. *J Pediatric Surg*. 2011;46(9):1695–1699. (Courtesy Dr. K. Vali, Pediatric Surgery, Women and Children's Hospital of Buffalo, Buffalo, NY.)

E-FIGURE 29.3 A commercially available single incision multiport laparoscopy (SIMPL) device in a child through which the camera and two laparoscopic instruments have access to the abdominal cavity. This is achieved through the umbilicus with one surgical incision. For more information, see Chandler NM, Danielson PD. Single-incision laparoscopic cholecystectomy in children: a retrospective comparison with traditional laparoscopic cholecystectomy. *J Pediatric Surg*. 2011;46(9):1695–1699. (Courtesy Dr. K. Vali, Pediatric Surgery, Women and Children's Hospital of Buffalo, Buffalo, NY.)

because it also expands into gas-filled cavities should gas emboli appear in the circulation.[125] Its use during laparoscopic surgery may distend the bowel in bowel obstruction and obscure the surgeon's view, as well as expand any CO_2 emboli that develop.

The inert gases argon and helium were also candidate gases for insufflation to create a pneumoperitoneum as they cannot be oxidized (and therefore ignited), although they are much more expensive than CO_2. When argon was used to create a pneumoperitoneum in pigs, embolization occurred more frequently than with CO_2.[146] In theory, both argon and helium can cause serious sequelae if embolized into the vascular system because they are insoluble in blood (blood/gas solubility of helium is 0.007 and argon is 0.029) and therefore likely to persist.[103,125,126,146]

RESPIRATORY EFFECTS

As the pressure within the peritoneal cavity increases, the frequency of adverse respiratory effects also increases, particularly at IAP greater than 15 cm H_2O. The respiratory manifestations of increased IAP include cephalad displacement of the diaphragm, decreased excursion of the diaphragm, and decreases in pulmonary and thoracic compliance, vital capacity, functional residual capacity, and closing volume.[147] Cephalad displacement of the diaphragm shifts ventilation to the nondependent parts of the lungs, creating a ventilation-perfusion mismatch. With a small functional residual capacity in children, cephalad displacement of the diaphragm further compresses the lungs, causing collapse of the small airways, ventilation-perfusion mismatch, and possibly hypoxemia. Other adverse pulmonary mechanics after insufflation include increased peak inspiratory pressures up to 27% and decreased compliance as much as 39%.[148] These physiologic changes are compounded by the extreme body tilting (i.e., extreme head-up or head-down positions) often requested by surgeons.[125,149] Positioning the child head down (i.e., Trendelenburg position) first decreases compliance by 17%, and second, adding a pneumoperitoneum decreases compliance by an additional 27%, requiring increases in peak inflation pressures of 19% and 32%, respectively.[150] In a recent study in which the pneumoperitoneum was created before Trendelenburg positioning in children whose lungs were ventilated using pressure control and 5 cm H_2O PEEP, a pneumoperitoneum of 12 cm H_2O decreased both dynamic compliance and tidal volume by 42%.[151] The addition of 20 degrees of Trendelenburg positioning only decreased these values by an additional 10%. All of these changes in pulmonary function can be offset by increasing minute ventilation (rate and peak inflation pressure) by as much as 50% to 100%. Pulmonary function appears to be restored more readily after laparoscopic than open surgery.[103]

Another respiratory concern is that the pneumoperitoneum and the extreme Trendelenburg position can shift the tracheal tube in a rostral direction, as far as 1.2 to 2.7 cm, possibly having an impact on the carina or passing into a bronchus.[152] With these changes, inspired oxygen concentrations in excess of 30% may be required, along with PEEP to restore adequate oxygenation. A persistent 5% decrease in oxygen saturation has been associated with partial or intermittent endobronchial intubation.[153]

Securing the airway for laparoscopic surgery requires particular attention. Cuffed tracheal tubes are preferred over uncuffed tubes to ensure effective alveolar ventilation despite the conditions described above,[134] although LMAs and ProSeal supraglottic airways (Teleflex Medical Inc.; Research Triangle Park, NC) have been used for brief procedures during laparoscopic surgery without complications.[126,154] If the child has a mature tracheotomy, the air leak around the tracheotomy must be assessed before surgery and if the leak is excessive, the tracheotomy should be replaced with a cuffed tracheotomy, a cuffed tube, or an armored (cuffed) tracheal tube. If the air leak around the tracheotomy is insignificant, then ventilation should be adequate even in the presence of increased IAP during laparoscopic surgery.

Excessive IAP may cause gas to track across the diaphragm, causing a pneumomediastinum or pneumothorax.[126] This is more common in hiatus hernia surgery and Nissen fundoplication, during which dissection of the esophagus may create passages for gas to traverse the diaphragm. Pneumomediastinum should be suspected if subcutaneous emphysema appears. If surgery creates a transdiaphragmatic passage for CO_2 to accumulate in the pleural space, the resulting pneumothorax may produce cardiorespiratory manifestations. A chest radiograph should be obtained if subcutaneous emphysema appears during or after surgery, or if there is a high index of suspicion that a pneumothorax has formed. Both pressure- and volume-controlled ventilation have been used during laparoscopic abdominal surgery in infants and children. In a single randomized study, both ventilation strategies with 5 mm Hg PEEP maintained effective ventilation and gas exchange.[155]

To avoid the cardiorespiratory compromise of a pneumoperitoneum, a gasless laparoscopic approach has been described. This requires lifting the anterior abdominal wall to create an intra-abdominal tent.[126,156] Implementation of the gasless approach in pediatric medicine has been rather slow, presumably because of technical difficulties and the scarcity of instruments for infants and children.

CARDIOVASCULAR EFFECTS

Three major factors may contribute to adverse cardiovascular responses during pneumoperitoneum: (1) IAP, (2) position (i.e., steep head-up or reverse Trendelenburg), and (3) release of neurohumoral vasoactive substances.[126,147,156] Increased IAP exerts a biphasic effect on venous return and CO. In neonatal pigs, the cardiac index (CI) decreased 55% when IAP exceeded 20 mm Hg.[126] In the animal model, the magnitude of the increase in IAP determined the degree to which the circulation was depressed.[134,157] For example, at IAP 15 mm Hg or less, blood is compressed out of the splanchnic circulation, increasing venous return, which either increases or results in no change in CO. In contrast, at IAP greater than 15 mm Hg, the inferior vena cava is compressed, reducing venous return and therefore CO. Studies in children yielded similar results; when the IAP exceeded 12 mm Hg, myocardial contractility[158] and venous return[125] decreased. In both infants and children, CO_2 insufflation to IAP 10 to 13 mm Hg decreased CI approximately 13%.[159–161] In studies in infants and children in which the CI decreased during increased IAP (10-12 mm Hg), the CI returned to preinsufflation values when the abdomen was desufflated.[158–160] Left ventricular systolic function was diminished, and septal wall motion abnormalities have been reported with an IAP of 10 to 12 mm Hg in children with a CO_2 pneumoperitoneum.[158,159] No significant changes in echocardiographic indexes of left ventricular work, preload or afterload, have been noted if the IAP is 10 mm Hg or lower during the pneumoperitoneum.[123] When standard indexes of hemodynamics were measured in infants and young children during laparoscopic Nissen fundoplication, IAP of 10 mm Hg or less yielded no significant changes in heart rate and blood pressure but a slight increase in CI.[162,163] If IAP is maintained at 10 mm Hg or less, then the impact on hemodynamics (particularly CO) should be clinically insignificant, because venous return may be enhanced as a result of displacement of blood from the splanchnic bed, and afterload is not increased.[125,134,162] Most importantly, if

the IAP is less than 5 mm Hg, CI is maintained in infants during a CO_2 pneumoperitoneum[162]; these low insufflation pressures are those often used to examine the contralateral side of a hernia defect during surgery.

Body position during laparoscopic surgery may exaggerate cardiovascular changes. For Nissen fundoplication, a steep head-up position (>20-degree incline) has been used, which reduces venous return.[149] In adult pigs, laparoscopic surgery for Nissen fundoplication increased pleural and mediastinal pressures that, in turn, reduced CO episodically at an IAP of 15 mm Hg.[164] These decreases in CO were manifested by episodes of hypotension and hypoxia. When children were positioned in the steep head-up position, they developed transient hypotension and bradycardia that were reversed immediately with fluid loading and atropine.[165]

It is imperative to continuously monitor IAP to minimize the cardiorespiratory effects of laparoscopic surgery and to avoid excessive insufflation pressures. In adults, induction of anesthesia, insufflating the IAP to 14 mm Hg and a 10-degree head-up tilt decrease the CI more than 50%.[166] Some clinicians recommend a maximum IAP during laparoscopy in children of 6 to 8 mm Hg to limit the cardiorespiratory effects,[167] although most studies favor pressures of 10 to 12 mm Hg.[151,157,159,168] In neonates and infants, the maximum IAP should not exceed 6 to 8 mm Hg to minimize cardiorespiratory effects. Based on the current literature, the net cardiovascular effects of insufflating the abdomen to pressures of 12 mm Hg or less, combined with the head-up position, are likely to be well tolerated if adequate hydration is maintained and bradycardia is avoided.[165]

CENTRAL NERVOUS SYSTEM EFFECTS

Laparoscopic surgery must be carefully evaluated if planned for a child with increased intracranial pressure (ICP) or in the presence of a ventriculoperitoneal shunt. The combination of increased IAP, increased systemic vascular resistance, increased $PaCO_2$ tension, and Trendelenburg position (as in lower abdominal surgery) may dramatically increase ICP. In adults during extreme head-down position (40 degrees) for prolonged periods, such as in robot-assisted surgery in the pelvis, cerebral tissue oxygen saturation is well maintained, as evidenced by near-infrared spectroscopy.[169] Under similar surgical conditions, intraocular pressure increased 100%, and scleral edema and blurred vision may develop.[170] In anesthetized children during laparoscopic surgery, intraocular pressure increased 30% after insufflation (<15 mm Hg IAP) compared with laparotomy surgery.[171]

Patency of a VP shunt should be evaluated before the procedure to prevent sudden increases in ICP during the procedure. Children with reduced brain ventricular system compliance may sustain dramatic increases in ICP if the IAP is sufficient to attenuate the drainage of cerebrospinal fluid into the abdominal cavity. In these children, laparoscopic surgery may be relatively contraindicated.[149] The risks should be thoroughly explored and discussed with the neurosurgeon, general surgeon, anesthesiologist, and the family. Children with VP shunts have shown a range of responses to laparoscopy from dramatic increases in ICP to no change at all.[147,172,173] Accordingly, a variety of approaches have been suggested. Some advocate externalizing the shunt and clamping the distal (intraabdominal) end of the shunt before surgery to prevent CO_2 from passing retrograde up the shunt or from the laparoscopic pressure disrupting the shunt valve, although these valves are stable with an IAP up to 80 mm Hg.[174] Another approach has been to temporarily isolate the tip of the VP shunt in an Endopouch bag (Ethicon, Somerville, NJ) while insufflating pressures to 12 mm Hg and then removing the bag at the end of the procedure.[175] Others discourage externalizing the shunt as sequelae have been reported, and instead recommend monitoring the ICP to prevent and detect increases in ICP and further recommend retraction of abdominal tissue during the laparoscopic surgery.[174] For the surgeon, using a SILS approach to laparoscopic surgery in these children reduces the risk of both traumatizing and infecting the VP shunt.[176] One retrospective review reported that laparoscopy in children with VP shunts was not associated with an increased risk of shunt infection compared with open procedures.[174] No single strategy can provide the optimal management for every child with a VP shunt undergoing laparoscopic surgery.

RENAL EFFECTS AND FLUID REQUIREMENTS

Increased IAP decreases renal blood flow, renal function (creatinine clearance and glomerular filtration rate), and urine output.[134,147,177] One study examined renal oxygenation with near-infrared spectroscopy and found no evidence of renal hypoxemia when age-appropriate IAPs were used (<6 mm Hg in neonates, <8 mm Hg in 2- to 12-month old infants, <10 mm Hg 1 to 2 years of age, <12 mm Hg 2–8 years of age). At the same time, they reported increasing cerebral oxygen saturation (likely from increased cerebral blood flow from increased arterial CO_2), heart rate, and mean arterial pressure.[178] The overall effects of IAP on renal function and renal filtration are poorly understood. Decreases in urine output during laparoscopic surgery in children vary, in part, with the age of the child: oliguria occurs in older children and anuria in infants younger than 1 year of age.[147,149,179] The etiology of the renal dysfunction and oliguria is multifactorial but includes direct and indirect effects of IAP on renal perfusion, antidiuretic hormone (ADH), endothelin, and nitric oxide (NO).[147,180] ADH concentrations increase as a result of reduced renal blood flow, resorbing water, and decreasing urine output. IAP increases renal endothelin (endothelin-1), resulting in renal venoconstriction, which reduces renal blood flow and urine output.[147,180] Inhibiting endogenous NO exacerbates the renal dysfunction during pneumoperitoneum through several mechanisms, including reduced renal perfusion and increased salt and water resorption (e.g., oliguria).[180] In theory, pretreating patients with a NO donor (such as L-arginine or nondepressor doses of nitroglycerin) may attenuate the detrimental effects of a pneumoperitoneum on renal function.[180] Renal tubular injury does not contribute to the renal dysfunction associated with increased IAP.[181] In adult donor nephrectomy patients, an overnight infusion of fluids followed by a colloid bolus immediately before the pneumoperitoneum attenuated the adverse hemodynamic effects and reduced the magnitude of changes in creatinine clearance associated with increased IAP.[182] Comparable data in children have not been forthcoming.

Fluid administration during laparoscopic surgery should be carefully monitored. Open abdominal surgery may require 10 to 15 mL/kg per hour of balanced salt solution to offset third-space fluid losses from extensive bowel manipulation. Although the existence of and manipulation of a real "third space" are debated, the conceptual fluid shift is real. During laparoscopic surgery, however, these fluid requirements are reduced because little fluid is lost and the bowels are minimally manipulated. In fact, care must be taken to avoid fluid overload. Urine output is often used as an index of preload in children undergoing abdominal surgery, but 88% of infants and 33% of children develop anuria or oliguria during laparoscopic surgery. Because these issues completely resolve within several hours of desufflation, fluid challenge is not necessary

in these children as fluid overload is a real possibility.[179] Transient oliguria in children after laparoscopic surgery should not be viewed as an early indicator of impending renal dysfunction.

PAIN MANAGEMENT

Postoperative pain after open general and urologic surgery primarily results from the skin and muscle incisions. With the small incisions used during laparoscopic surgery, perioperative pain is less than with open surgery.[183–185] A systematic review of pain after laparoscopic antireflux surgery in children reported mild to moderate pain in ~20% of children and severe pain in 4%.[186] Intraperitoneal administration of local anesthetic has also been evaluated as a strategy to attenuate pain after laparoscopic surgery. A recent systematic review of this strategy in children concluded that there is some benefit from this approach although the dose of local anesthetic is limited by the child's weight. Additional studies are needed to fully assess the effectiveness of this approach.[187] To date, there have been a dearth of studies investigating pain after laparoscopic surgery in children.

Pain after laparoscopic surgery arises from several sources, including the incision sites, residual gas in the abdomen, referred pain from the diaphragm, and stretch on nerves from peculiar patient positions. A long-acting local anesthetic should be infiltrated around the incision sites at the end of laparoscopic surgery to prevent postoperative incisional pain. Some children develop pain after laparoscopic surgery, including back and shoulder tip pain. In these instances, multimodal pain therapy including acetaminophen, nonsteroidal antiinflammatory agents, and (less commonly) opioids are effective.[104,105,126] Recent evidence suggests that SIMPL for appendectomy causes less pain than surgery with a multiport system.[188]

Robot-Assisted Surgery

Robot-assisted surgery is relatively new to pediatric surgery and urology, with only limited published experience, although it has been used extensively in adults since the late 1990s to facilitate minimally invasive endoscopic surgery. Enhanced with three-dimensional magnifying views and feedback-controlled enhanced motions of human hands, robot-assisted surgery enables very fine manipulation of surgical instruments while eliminating natural human tremors. It has great potential as the future direction for pediatric surgery and urology.[1,169,189–194]

Robotic surgery was initially introduced as a tool for remote battlefield surgery. It is now available to assist pediatric surgeons in performing complex surgery, with less tissue and organ damage on extremely small surgical targets. Most of the information currently available is limited to one product (da Vinci Surgical System, Intuitive Surgical, Sunnyvale, CA) and to adult urologic procedures. However, rapid innovation and miniaturization of equipment has resulted in several pediatric centers undertaking robot-assisted laparoscopic surgery, with excellent outcomes (Videos 29.1 and 29.2). Concerns from the anesthesiologist's perspective regarding this relatively new approach are summarized in Table 29.1. Most of the perceived problems relate to the extended duration of procedures and the steep Trendelenburg position used, although numerous surgeries have been performed without this position.[169,189] Published evidence with robot-assisted surgery has yielded outcomes comparable to laparoscopic surgery in children, prompting many to question whether this new and expensive surgical venture is justified.[195–197] However, rapidly advancing technology offers enormous opportunities for robot-assisted surgery in children in the very near future, for very fine and technical dissection in small and constrained spaces.[198]

TABLE 29.1 Issues Regarding Current Robotic-Assisted Procedures From the Anesthetist's Perspective

Dependence on Extreme Body Position, Such as Extreme Trendelenburg Position (Because of Absence of Adequate Surgical Assistance for Surgical Field Exposure), May Lead to:
Increased intracranial pressure, ocular pressure, and impairment of cerebral perfusion
Optic nerve or retinal morbidity
Cerebrofacial congestion, airway edema, vocal cord palsy, delayed awakening
Possible overstretching of nerves passing through the axilla and nerve plexus damage
Extended lithotomy leading to compartment syndrome in the lower legs
Tendency to apply greater intraabdominal pressure
Circulatory depression and respiratory depression
Carbon dioxide insufflation related complications
Absence of Touch, Traction, and Compression Sensations of Holding Instruments or Tissues:
All the manipulations are dependent exclusively on the visual sense
Inability to know the events occurring in an invisible place, overt tissue damage
Possibility of overlooking overt bleeding or tissue damage
Absence of Robot Legs and Easy Movability:
Once fixed, it is hard to change the position of the robot or the child's position
Difficulty in checking IV access sites and the airway
Unlimited and unexpected surgical approaches
Exploration of new surgical approaches and complex tasks at awkward angles
Greater surgical and setup times, hypothermia, and pressure sores
Unpredictable movement of robot and camera arms
Hitting or compressing the child's face
Organization of all tubing and cables, including intravenous tubing and breathing hoses.
Need for Emergency Undocking of the Robot in Case of Mechanical Failure or Critical Events

Specific General Surgical and Urologic Conditions

NISSEN FUNDOPLICATION

This surgery is indicated for children with documented gastric fluid reflux for whom medical management failed. It involves mobilizing the muscles around the esophagus and suturing them tightly around the esophagus at the level of the lower esophageal sphincter. This surgery requires general anesthesia and tracheal intubation and is usually performed laparoscopically, with increasing application of robot-assisted technology.[199]

Children who require a Nissen fundoplication often have a neurologic injury (i.e., cerebral palsy) that causes esophageal dysmotility. This dysmotility heralds esophageal reflux that, if

severe, may result in recurrent aspiration pneumonia. If medical and gastric tube therapies fail, a Nissen fundoplication may be considered. The anesthetic considerations are few because surgery is not associated with postoperative pain, large fluid shifts, or large blood loss. Positioning a bougie within the esophagus during surgery allows the surgeons to gauge how tight to tie the muscles around the esophagus; without a bougie, the muscles around the esophagus may be overtightened, causing an esophageal obstruction. Care must be taken to avoid dislodging the tracheal tube while manipulating the bougie. At the end of the procedure, it is common for the surgeon to request that 50 to 60 mL of air be insufflated into the stomach via the gastric tube to ensure there are no anastomotic leaks. In general, surgery is completed in less than 1 hour in experienced hands, with a complication rate of about 10% and an average hospital stay of about 1.6 days. Postoperative pain is usually easily managed; however, open procedures usually require continuous analgesia for 2 to 3 days.[200,201]

PECTUS EXCAVATUM

Although this is a deformity of the chest wall, pediatric surgeons most often carry out the corrective procedure. The classic approach to correcting a pectus excavatum involves an open procedure with fracture of the sternum, removal of multiple costal cartilages, and elevating the sternum with fixation, using one or two stainless steel bars. The Nuss procedure is a less invasive technique,[202,203] whereby a U-shaped bar is blindly passed through the thorax hugging the undersurface of the sternum. Once across the chest, the bar is flipped, through which process the sternum is pushed anteriorly without fracturing it, thus avoiding the creation of a flail chest by the removal of the costal cartilages. This procedure has since been modified, whereby the bar is passed through the thorax under direct vision, using thoracoscopy to reduce possible perforation of major structures (e.g., the heart or lungs).[204–206] Although the risk of this complication is reduced when the Nuss procedure is performed under direct vision, it may still occur.[207–209] Both blind and thoracoscopic approaches cause significant postoperative pain, which may be treated with patient-controlled analgesia, a thoracic epidural catheter, or a lumbar epidural catheter and epidural morphine (see Chapters 42-45).[210–212] Because these procedures are generally performed in teenagers, the thoracic epidural is preferably placed with the teenager awake but sedated. Compliance with inserting the epidural catheter while awake may be difficult in less mature teenagers. It is unclear whether the thoracic epidural provides improved analgesia compared with standard patient-controlled analgesia for this procedure.[213] It should be noted that these children will return for removal of the pectus bar after several years. Occasionally, the bar has become adherent to the pericardium or lung, resulting in a severe, sudden, and catastrophic rupture of a major vessel or chamber in the heart when the pectus bar is removed.[214] It would be prudent to establish ample IV access to provide the means to rapidly transfuse fluids and blood should a catastrophic blood loss occur.

CIRCUMCISION

Globally, the prevalence of male circumcision is 40%, with half of these surgeries performed for religious or cultural reasons.[215] Circumcision is performed in neonates, infants, children, and adults with local, regional, or general anesthesia. The indications for circumcision include phimosis, recurrent balanitis, religious beliefs, and parental preference. Inhalational anesthesia supplemented by a regional block is preferred. Classic circumcision involves cutting the foreskin and cauterizing and suturing the skin edges. The duration of surgery is usually less than 1 hour. The type of anesthetic and airway management do not significantly affect perioperative outcomes. The most common complication arising from circumcision is bleeding.

In infants and children, circumcision is performed with the patient under general anesthesia. Multimodal pain therapy includes acetaminophen (e.g., 10–15 mg/kg orally or 30–40 mg/kg rectally before starting surgery) or 10 to 15 mg/kg IV, parenteral opioids (i.e., morphine 0.05–0.1 mg/kg), and/or local anesthetic without epinephrine (dorsal penile block, caudal block, subcutaneous ring block, and topical lidocaine-prilocaine [eutectic mixture of local anesthetics (EMLA)]) (see Chapter 42).[216] In a comparative study, suprapubic penile block provided better analgesia than subcutaneous ring block of the penis.[217] When a caudal block was compared with penile blocks and parenteral analgesics, a Cochrane review concluded that both rescue analgesia and nausea and vomiting were comparable with all three techniques, although the analysis was limited because of small numbers and poor methodology.[218,219]

HYPOSPADIAS AND CHORDEE

This congenital malformation occurs in 1 of 250 liveborn males. It often occurs in isolation, without other congenital anomalies. *Hypospadias* refers to a malposition of the meatus of the urethra: rather than opening at the distal tip of the penis, the urethra opens along the undersurface of the penis anywhere from just proximal to the glans to the scrotum (Fig. 29.5). The majority of hypospadias defects are distal, occurring near or at the glans of the penis. Between 15% and 50% instances of hypospadias have an associated chordee, whereas 8% have an undescended testis. A small number of children with hypospadias have urethral

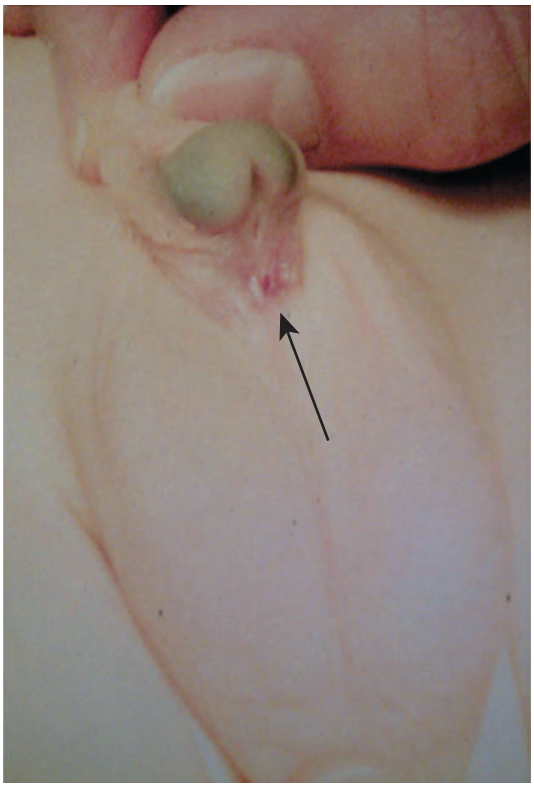
openings remote from the glans of the penis, including the scrotum (Fig. 29.6; E-Figs. 29.4 and 29.5).

Surgery is undertaken with an expected duration of between 1 and 4 hours depending on the severity of the hypospadias. It is important to establish an understanding with the urologist of the type of regional block that will suit the extent of surgery: those requiring a minor hypospadias repair (single-stage procedure—that is, meatal advancement and glanuloplasty technique [MAGPI]) or Mathieu repair may be managed with a face mask, LMA, or tracheal tube. The anesthetic prescription is at the discretion of the anesthesiologist; the children are outpatients and receive either a penile block or a single-shot caudal block. Those with more extensive hypospadias who require longer surgery will require either an LMA or a tracheal tube. They may be admitted to a hospital for one to two nights and need a strategy for continuous postoperative analgesia. For the latter, either a caudal or a lumbar epidural catheter may be inserted after induction to reduce the anesthetic requirements and provide postoperative analgesia. If opioids are avoided, a caudal-epidural block consisting of only local anesthetic (e.g., bupivacaine 0.125–0.175% plain) does not delay micturition after the urinary catheter has been removed.[220]



CRYPTORCHIDISM AND HERNIAS: INGUINAL AND UMBILICAL

These surgeries, together with hydrocele repair, are common outpatient procedures. *Orchiopexy* refers to mobilizing the undescended testis that is either in the inguinal canal or, less commonly, within the abdominal cavity (Fig. 29.7), and securing it firmly in the scrotum. Approximately 33% of preterm infant males are born with one undescended testis, whereas only 3% of full-term males are similarly affected. Although the incidence of undescended testis decreases to 1% by 3 months of age, the incidence remains at 1% thereafter. Cryptorchidism usually occurs in isolation, although it is associated with a number of conditions, including Prader-Willi syndrome, Noonan syndrome, and cloacal exstrophy.

Undescended testes are categorized, based on physical examination, to include testes that are truly undescended, those that are ectopic, and those that are retracted. The retracted ones are not true undescended testes because they can be massaged into the scrotum and require no further treatment. In the case of true undescended testes, the testes must be located, mobilized, and then fixed within the scrotal sac to ensure viability. Failure to mobilize the testes out of the inguinal canal or abdomen may result in atrophy, torsion, testicular cancer, or hernias.

An *inguinal hernia* in a child is a congenital failure of the processus vaginalis to obliterate. In this case, a loop of bowel protrudes beyond the internal ring, causing a bulge in the inguinal region or scrotum. These protuberances may appear periodically, with complete resolution in the interim. On occasion, a small sac of fluid is present in the scrotum, known as a *hydrocele*, and is confused for a loop of bowel in the scrotum (E-Fig. 29.6). Hydroceles are removed electively with the same approach as for an inguinal hernia. On occasion, the loop of bowel does not reduce spontaneously from the hernia and remains trapped in the canal, necessitating a visit to the emergency department. A surgeon is often required to manually reduce the trapped bowel. In these cases, the hernia repair is then scheduled as an urgent or elective surgery, depending on whether there is suspicion of persistent or potential recurrent ischemia to the bowel. In some cases, the entrapped bowel cannot be reduced and an incarcerated hernia or obstructed bowel is diagnosed. Incarcerated hernias and bowel obstructions are surgical emergencies that require general anesthesia and muscle relaxation to reduce the strangulated bowel. The emergency nature of the surgery requires careful questioning regarding the time interval between the last meal and the onset of abdominal pain and strangulated bowel. It is usually assumed that these children have a full stomach. At the time of open reduction, if the bowel does not appear to have adequate perfusion, a segment of the ischemic or necrotic bowel may have to be resected.

Management of cryptorchidism and inguinal hernia requires general anesthesia (face mask, LMA, or tracheal tube) and a pain management strategy. When the surgeon pulls on the foreskin, hernia sac, or testis during surgery, laryngospasm may occur if the depth of anesthesia is inadequate. Anesthesia can be deepened most rapidly by an IV bolus of propofol; increasing the inspired concentration of inhalational anesthetic may also deepen the anesthetic provided gas can be exchanged. Multimodal pain therapy, as described earlier, may be used together with a regional block.

E-FIGURE 29.6 Right hydrocele in the scrotum, evidenced by the swollen right sac. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, NY.)

Regional blocks (ilioinguinal, iliohypogastric, scrotal block; caudal-epidural block; or transversus abdominis plane block) are used for both orchiopexy and inguinal hernia surgery, using either a landmark-based or ultrasound-guided method (see Chapters 42 and 43).[221]

An *umbilical hernia* is a 1- to 5-cm defect in the anterior abdominal wall (usually halfway between the umbilicus and the xiphisternal junction), with intermittent protuberance of bowel through the defect. This defect occurs in 15% of children, more commonly in children of African rather than European descent, and equally in both sexes. It also occurs frequently in preterm and low–birth-weight infants. Many resolve spontaneously in the first year of life, but those that persist require surgical closure. If the defect is small, then an LMA may be sufficient, provided a deep level of anesthesia is maintained when the suture needles pass through each side of the rectus muscle. If the defect is large, tracheal intubation and, depending on the surgeon, muscle relaxation may be required. A deep level of anesthesia with an inhalational anesthetic or an IV bolus of propofol (1–2 mg/kg) while the defect is closed usually provides sufficient relaxation to reduce the defect in most cases.

TORSION OF THE TESTIS

Presentation of a male with sudden onset of acute scrotal pain in the absence of trauma requires immediate investigation and possible surgery to preserve a potentially viable testis. The differential diagnosis of acute onset of torsion of the testis (Fig. 29.8) includes torsion of the testicular appendix, torsion of the spermatic cord, epididymitis, and incarcerated hernia. The majority of testes can be saved if surgery is performed within 6 hours of the onset of pain if the diagnosis is confirmed by Doppler ultrasonography or suspected on clinical grounds.[222] The salvage rate for the testis decreases to 50% if surgery is undertaken 6 to 12 hours after the onset of pain. Children with suspected acute testicular torsion should be considered "an acute abdomen" and assumed to have a full stomach and require RSI and tracheal intubation. Although pain at the time of induction of anesthesia may be intense, when the torsion is relieved, the pain abates. Hence, at the conclusion of surgery many of these children no longer have substantive pain that warrants aggressive treatment.

POSTERIOR URETHRAL VALVES

Posterior urethral valves (PUV) is a spectrum of urethral obstruction that varies from mild to severe. The diagnosis is often made antenatally (preferably by 24 weeks gestation) by ultrasound identification of bladder distention, megaureters, and hydronephrosis. When PUV is diagnosed antenatally, the severity of the disease tends to be greater.[223] Decompression of the urogenital system may be achieved by a vesicoamniotic shunt in utero. Although some recommend that an intervention should be undertaken as quickly as possible to minimize the impact on renal function, evidence suggests that early intervention does not affect the outcome, because renal damage may have already occurred in utero.[224,225]

Postnatally, a lack of or decrease in urine output, urinary retention, or a poor urine stream may be the only indications of the presence of these valves.[226] Affected children can have associated renal insufficiency resulting from congenital renal dysplasia and urethral valve obstruction. Because the renal concentrating mechanism is often impaired, these infants commonly present with greater than normal urine output. Consequently, careful monitoring of urine output and balanced salt solution infusion rate is necessary. Primary valve ablation is required to decompress the urogenital system.

Several indexes have been postulated as predictors of poor long-term renal function in infants with PUV, including a creatinine value of 0.8 mg/dL or greater at birth, antenatal diagnosis, proteinuria, moderate or severe hydronephrosis, and renal dysplasia.[223,227] One study indicated that a nadir creatinine greater than 1 mg/dL and bladder dysfunction were the only independent predictors of long-term renal dysfunction.[228] Children with PUV are scheduled for elective surgery. A general anesthetic is required, with the specific management left to the discretion of the anesthesiologist; there are few special considerations needed.

PRUNE-BELLY SYNDROME

Prune-belly syndrome is a disorder that occurs predominantly (97% of the time) in males, with an incidence of 1 in 40,000 births. Affected infants present with a range of findings, from stillborn to a full-term neonate, with a host of possible organ and chromosomal abnormalities.[227,229] Affected organs may involve orthopedic in 50% (congenital hip dislocation and scoliosis), gastrointestinal in 30% (malrotation and volvulus), congenital heart disease in 10% (tetralogy of Fallot and ventricular septal defect), and chromosomal defects (trisomy 18 and trisomy 21).[227]

In utero, the child's abdomen often swells with fluid (in the presence of oligohydramnios) that is resorbed by birth, leaving the characteristic wrinkled redundant abdominal wall (Fig. 29.9 and E-Fig. 29.7). The pathophysiology of this syndrome is unclear, but it has been suggested that a urethral obstruction in utero leads to dilatation of the urethra (megaurethra is a common finding), which, combined with bladder distention and ascites, causes distention of the abdomen in utero. This ultimately leads to vesicoureteral reflux and ureteral dilatation in 80% of affected children.

Abdominal overdistention in utero causes weak rectus abdominis muscles that undermine the child's ability to exhale forcefully and to generate a strong cough to clear secretions. As a result, chronic aspiration pneumonia may contribute to an early demise. Some have suggested that aggressive intervention to correct the weak rectus muscles by plication and muscle transfer may improve

E-FIGURE 29.7 View of the distended, weak-muscled abdomen in a child with prune-belly syndrome. The muscle wall is so thin that bowel peristalsis may be visualized on the abdominal surface. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, NY.)

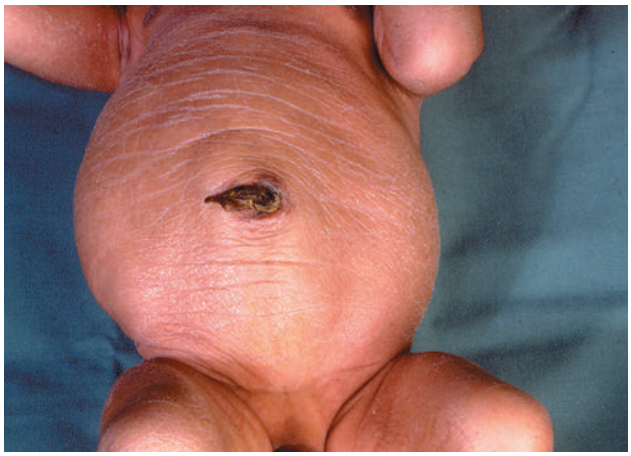

FIGURE 29.9 Prune-belly syndrome. View of the distended, weak muscled abdomen; the muscle wall is so thin that the abdominal surface is bulging in front of the bowels. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, NY.)

respiratory function,[230,231] reduce back strain and pain, decrease bladder volume, and arrest scoliosis.[232] However, this view is not shared by others who prefer to observe the child for signs of regurgitation and aspiration before intervening.[233] Controlling the type of feeds, preventing gastrointestinal reflux disease and constipation, and using antibiotics to treat pneumonia permit the child to grow. Pneumonia must be aggressively treated and completely resolved before entertaining surgery. Percutaneous endoscopic gastroscopy tubes are generally eschewed in these children when feeding is a problem, as abdominal wall surgery is difficult. These children often require urologic surgery to correct vesicoureteral reflux and orchiopexy. Urethral obstruction may be due to the angulation of the urethra within the prostate.

Trisomy 18, the second most common autosomal trisomy, occurs in 1 in approximately 7000 live births and is associated with prune-belly syndrome. In contrast to the simple prune-belly syndrome, 60% to 80% of these infants are female. Trisomy 18 is characterized by severe neurologic developmental problems (including microcephaly), micrognathia and/or retrognathia, microstomia, auricular abnormalities, and others. In fact, 95% die in utero, with only 5% to 10% surviving 1 year and only 1% reaching 10 years of age. Mortality results from cardiac anomalies (90% of affected children have a ventricular septal defect, valvular heart defect, atrial septal defect, hypoplastic left heart syndrome, tetralogy of Fallot, or other cardiac defect), renal anomalies, failure to thrive, and apnea.[234,235] Additional findings include pulmonary hypoplasia and gastrointestinal anomalies (including omphalocele, ileal atresia, and esophageal atresia).

General anesthesia with tracheal intubation is required for most surgeries in children with prune-belly syndrome. Controlled ventilation is recommended because of the variability in the strength of the abdominal muscles. It is prudent to suction the lungs once the trachea has been intubated to assess the severity of secretions. As little muscle relaxant as possible should be used during the surgery, with preferably no neuromuscular blocking drugs administered during the last hour, to ensure the child's muscles have had time to recover to maintain an adequate tidal volume after extubation. Opioids should be used cautiously to limit respiratory depression; regional anesthesia may be preferred in view of their difficulty with clearing secretions from the tracheobronchial tree.[236]

URETERAL REIMPLANTATION

Vesicoureteral reflux, in which urine passes retrograde up the ureter, is a congenital disorder affecting 0.5% to 2% of children.[237] It occurs 10 times more commonly in Caucasian than African American children, is more common in male neonates but 5 to 6 times more common in females younger than 1 year of age, and more commonly occurs in red-haired children.[237] There is a genetic component to this disorder with 34% of siblings affected, although the pattern of inheritance is unknown.[238] Recurrent episodes of pyelonephritis may occur, leading to renal scarring and reduced renal function, depending on the severity of the reflux. The pathology is thought to be an anatomically abnormal insertion of the ureter into the bladder that fails to close tight when the bladder fills and contracts. A voiding cystourethrogram is the definitive test to diagnose reflux and assess its severity. Mild forms of vesicoureteral reflux are managed with daily antibiotics until the child outgrows the reflux. However, more severe forms or those who develop kidney infections despite antibiotic therapy require surgical correction. The classic surgical approach for vesicoureteral reflux is an open procedure in which the affected ureters are reimplanted into the bladder wall, re-creating a normal muscle flap valve.[239] This involves a lower abdominal incision and 2 to 4 hours of surgery. Postoperatively, the pain is often intense, necessitating 2 to 3 days of continuous infusion of local anesthetic via an indwelling caudal or epidural catheter.

More recently, laparoscopic techniques have been developed, with and without robotic control, for reimplantation of the ureters.[239] Preliminary evidence suggests an excellent success rate (>90%) for this approach,[240] although the time for the surgery is more than twice than with the open technique and more complications were identified in children with small bladders.

In the past 20 years, the search for alternatives to surgery has spawned a number of compounds to inject into the terminal submucosal tract of the ureter to prevent reflux. Initially, polytetrafluoroethylene (Teflon; Chemours, Wilmington, DE) was used but more recently a safer, more durable polymer comprised of dextranomer and hyaluronic acid (Deflux; Valeant Pharmaceuticals International, Bridgewater, NJ) supplanted Teflon. In this way, surgeons create a swelling just inferior to the opening of the ureter into the bladder that prevents urine from refluxing (Fig. 29.10, before and after injection of polymer). The technique is successful in 80% to 100% of cases of grade 1-2 reflux after one injection and in 85% of cases of grade 3-4 reflux after two injections (where the grade of reflux was related to the ureterorenal involvement).[241] Although this procedure still requires general anesthesia, its advantages far outweigh its disadvantages in that the duration of the procedure is very brief (usually 15–30 minutes), avoids an abdominal incision, causes no postoperative pain, and it may be performed as ambulatory surgery. However, the results of this injection technique continue to be monitored because long-term outcomes and sequelae have not been determined.

PYELOPLASTY

Ureteropelvic junction obstruction occurs in 0.1% to 0.2% of neonates, approximately twice as frequently in males than females. Pyeloplasty is performed to decompress the renal pelvis either because of intrinsic (congenital) or extrinsic (major vessel)

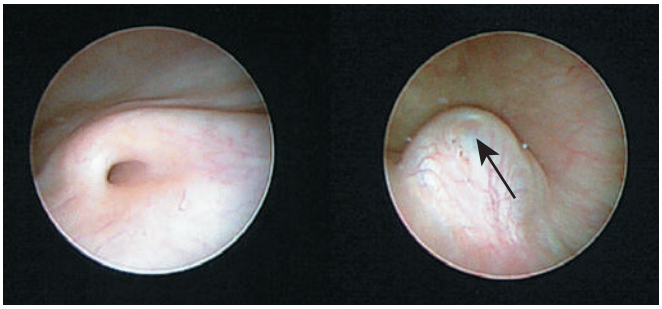

FIGURE 29.10 A child with ureteral reflux. Preinjection (*at left*) with the bladder orifice wide open with no valve to prevent the backwash of urine up the ureter. Polymer was injected into the submucosa of the bladder, raising a mound to seal off the orifice of that ureter. Postinjection (*at right*) with the orifice now appearing as a dimple on the peak of the mound *(arrow)*. (Courtesy Dr. P. Williot, Pediatric Urology, Women and Children's Hospital of Buffalo, Buffalo, NY.)

compression of the ureter. A distended renal pelvis is often diagnosed antenatally and, in some instances, decompressed in utero by percutaneous nephrostomy. The ureteric narrowing often occurs at the ureteropelvic junction, where the ureter exits the renal pelvis. Surgery involves disconnecting the ureter at the renal pelvis, reshaping it, and then reinserting it into the kidney. Such surgery is often performed with the patient in the lateral or prone position, with the table jackknifed. The duration of this surgery is approximately 2 hours and has a success rate of approximately 95%. Dissection is often retroperitoneal, but the incision is placed immediately below the rib cage. This procedure has been performed laparoscopically and with the use of robotics.[115,242]

Anesthetic considerations include the prone or lateral decubitus position (complicated by placing the table in the jackknife position), postoperative pain, and adequate fluid resuscitation. IV access should be established in an upper extremity to maintain adequate atrial filling pressures. If the table is placed in the jackknife position, it is very important to measure the child's blood pressure before and after the table is jackknifed, because venous return may become severely compromised, necessitating reducing the extent of the jackknife and resuscitating the child with fluid. For postoperative pain management, an indwelling high lumbar or low thoracic epidural catheter is placed. We administer lidocaine 2% with 1:200.00 epinephrine immediately after inserting the catheter to set the block before the table is jackknifed. Thereafter a bupivacaine or ropivacaine epidural infusion may be used.

The laparoscopic approach to pyeloplasty in children is relatively new. In renal surgery, CO_2 is insufflated in the retroperitoneal space to provide surgical access.[243] Because of the anatomic differences between the retroperitoneal and intraperitoneal spaces, greater pressures may be required to provide adequate surgical visibility. A mean retroperitoneal pressure of 12 mm Hg increases P_{ETCO_2} and peak inspiratory pressures, and decreases blood pressure.[244] Early evidence indicates that laparoscopic surgery yields outcomes similar to the open approach, although the duration of surgery is approximately one-third greater.[245,246] In part, this has been attributed to the learning curve of this technique. Evidence suggests that the laparoscopic approach decreases the length of hospital stay and may decrease postoperative pain[115,246] (see previous discussion of pain management after laparoscopic surgery).

NEPHRECTOMY

Indications for nephrectomy and partial nephrectomy in children include nonfunctioning kidney, dysplastic kidney, urolithiasis, Wilms or other tumor, end-stage renal failure (pretransplantation or to control hypertension), hemolytic uremic syndrome, and polycystic disease. Children who need a nephrectomy require a thorough preoperative assessment in terms of history, physical examination, and laboratory testing, depending on their underlying pathology. These children are often anemic because of chronic disease and possibly decreased erythropoietin concentrations. If the child is being staged for kidney transplant, the nephrologists may prefer to avoid blood transfusions at this time. If time is available and the patient is anemic, oral ferrous sulfate and vitamin C should be commenced 3 to 6 weeks before surgery (vitamin C increases gut absorption of ferrous sulfate) to increase the hemoglobin concentration, particularly if erythropoietin supplementation is planned.[247,248] These children are often small in size and this should be considered when preparing the anesthetic equipment.

Nephrectomies are commonly performed using a retroperitoneal approach with the child in the lateral decubitus position and the table jackknifed. The incision is usually large and located just subcostal to the twelfth rib. If an open approach is planned, an epidural catheter may be placed (see "Pyeloplasty" earlier). If, however, a laparoscopic or robotic-assisted approach is planned,[99] then a neuraxial block is not necessary but the same surgical approach occurs. Outcomes after laparoscopic nephrectomy in children are similar to those after an open procedure, according to the experience from one center,[249] although recent evidence points to less pain and earlier discharge from the hospital.[99]

NEUROBLASTOMA

The adrenal glands are located in the retroperitoneal space, adjacent to the superior pole of the kidneys. Masses that arise in the adrenal gland may be tumors, hemorrhage, infections, or cysts. The tumors in the adrenal glands may arise from the cortex (as in adenoma) or medulla (including the sympathetic chain, as in neuroblastoma or ganglioneuroma) and may be either hyperfunctioning or nonfunctioning.

Neuroblastoma is the most common extracranial solid tumor that presents in childhood, representing 10% of all tumors and 15% of all deaths from tumors.[250] It is the second most common abdominal tumor after Wilms tumor. Its incidence is approximately 1 in 100,000 children in the United States.[251,252] Neuroblastomas arise in the abdomen in 75% of cases and along the sympathetic chain anywhere from the neck to the pelvis in 25%. Only one-third of those that arise in the abdomen arise in the adrenal glands. The median age at presentation is 2 years, with up to 90% occurring in children younger than 5 years with equal sex prevalence. In some series, up to 50% of cases appear in the first month of life, with some diagnosed antenatally; reports of familial neuroblastoma are rare.[250] However, these tumors may be associated with other disorders, including Beckwith-Wiedemann syndrome, neurofibromatosis, Hirschsprung disease, and central hypoventilation syndrome.[250]

Most neuroblastomas are first detected as palpable masses in the abdomen. Symptomatic presentation may present as local pressure on adjacent organs or structures (liver, kidney, or spine), as metastases (lymph nodes, bone marrow, liver, and skin), or with manifestations of excess neurohumoral production (that is, from catecholamines [e.g., systemic hypertension] or vasoactive intestine polypeptides [e.g., diarrhea]).[250] Urinary catecholamines are increased in greater than 90% of children (>1 year of age)

with neuroblastoma. In a minority of instances, the diagnosis is made through incidental examination, either by radiography or ultrasonography.

Staging of these tumors follows two protocols.[251] The International Neuroblastoma Staging System depends on tumor resectability, lymph node involvement, and metastases. However, if patients are not surgical candidates, the staging score holds little relevance. To further stage these tumors, a second scoring system was developed, the International Neuroblastoma Risk Group classification system, which is based on the preoperative radiologic findings only. Survival likelihood depends on a low score, extraabdominal (as opposed to intraabdominal) primary tumor, and younger age. Therapeutic intervention is tailored to the staging of the tumor at presentation and the size of the tumor. Those with favorable tumor biology, no distant metastases, and age younger than 18 months of age are often curable with surgical resection alone. Those with less favorable tumor biology, metastases, and a large tumor size that may present a challenge surgically are ideally treated with a combination of chemotherapy, radiation, and/or bone marrow transplantation to reduce the tumor size first and then with surgical resection. Patients with less favorable biology present a challenge for surgical resection because of local infiltration, large tumor size, and vascular extension. Debulking the tumor has been met with mixed reviews, with great success in low-risk patients but with less success when one of several other therapies in high-risk patients.[253] The most promising treatments for neuroblastomas with poor prognoses include molecular profiling of the tumor.[251] The long-term survival after treating these tumors is 88% for infants and children younger than 18 months, 49% for children 18 months to 12 years, and 10% for those 12 years and older.[254] Preoperative assessment requires a general systems review, with particular focus on the organ systems involved with the tumor. These tumors may present as a large intraabdominal mass that compromises respiration, most commonly manifested as tachypnea. Those with catecholamine-secreting tumors may also present with chronic hypertension. This is mitigated to a large extent if the tumor is shrunk preoperatively, but intraoperative hypertensive episodes still occur in 25% of the children (with urinary catecholamines) during surgery. Children with catecholamine-secreting neuroblastomas should have both α-adrenergic and β-adrenergic blockades established preoperatively (see Chapter 27) to avoid swings in blood pressure during manipulation of the tumor.[255] Less frequently, chronic diarrhea from vasoactive intestine polypeptides may cause chronic dehydration and electrolyte derangements that require correction.

The anesthetic plan depends on the nature and extent of the surgery. A general anesthetic with tracheal intubation and controlled ventilation, as well as standard anesthetic monitors, is required. These should be supplemented with invasive monitoring, including arterial and central venous access for catecholamine secreting tumors, large tumors, and those that are expected to bleed excessively. Anticipation of massive blood loss will necessitate using large-bore upper extremity IV access, blood warmers, and possibly a rapid transfusion device. No specific anesthetic regimen has been recommended for these surgeries.

Although the blood pressure may be controlled with established α-adrenergic blockade, manipulation and squeezing of the tumor during its removal may cause a surge in catecholamine release, necessitating the use of antihypertensive medications intraoperatively (see Chapter 27).[255] Labetalol may be effective in children with hypertension during resection of neuroblastomas[255]; however, it may cause paroxysmal hypertension and heart failure in children who have only β-adrenergic blockade established because of the predominant β-adrenergic blocking action of labetalol.

WILMS TUMOR

Renal tumors represent 2.5% to 7% of tumors in children. Wilms tumor is the most common abdominal tumor, with an incidence of 1 in 100,000 children younger than 15 years of age, and the most common solid renal tumor beyond the first year of life.[252,256] These tumors arise from persistent immature parenchymal renal tissue (referred to as Wilms tumorlet cells), often in the periphery of the kidney (as opposed to the collecting ducts), enclosed by a pseudocapsule. They may achieve a large size before detection, often compressing adjacent renal parenchyma (Fig. 29.11). Histologically, the tumor often includes up to three distinct tissue cell lines: epithelial, blastemal, and stromal cells.[256] The presence of anaplastic cells (in 4% of Wilms tumors) and, more specifically, whether the cells are focal or diffuse in the tumor, and older age at the time of presentation suggest a less favorable response to chemotherapy and less favorable long-term prognosis.[256] With tailored multimodal therapy, the survival from Wilms tumor in the past several decades has increased dramatically, from 30% to ~90%.[257]

Eighty percent of the children with Wilms tumor present between 1 and 5 years of age (peaking at 3–4 years of age) with no gender or racial predominance.[252,256] Presentation of Wilms tumor is similar to that of other intraabdominal tumors in the form of an incidental mass on physical examination; approximately 6% are bilateral. Congenital anomalies coexist with Wilms tumors in 12% of children, notably genitourinary anomalies (5%), hemihypertrophy (2.5%), and aniridia (1%).[256] A number of genetic syndromes are associated with Wilms tumors (e.g., Beckwith-Wiedemann, Fanconi syndrome, and Trisomy 18).[252] Wilms tumors occur twice as frequently in children with horseshoe kidneys than in those with normal kidneys and are also more frequent in those with multicystic dysplastic kidneys.

Preoperatively, most children with Wilms tumors appear well, presenting with constitutional findings including weight loss, loss of appetite, and malaise; a palpable abdominal mass is present in 75% to 90%. Laboratory investigations before nephrectomy include routine complete blood cell count, electrolytes, renal

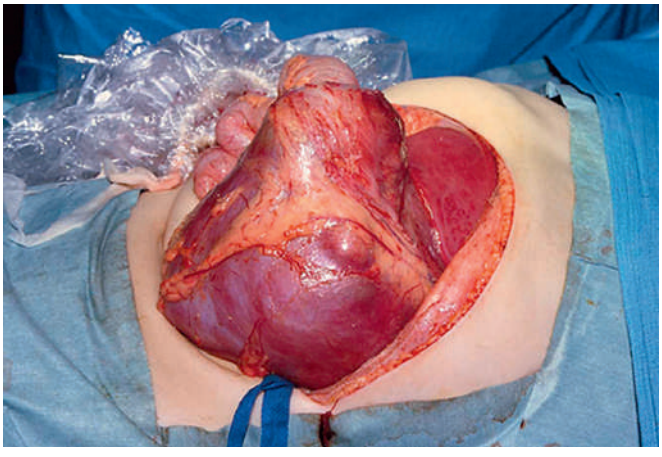

FIGURE 29.11 A Wilms tumor was mobilized and exteriorized from the abdomen. Note that it is encapsulated and contiguous with the left kidney. (Courtesy Daniel P. Doody, MD, Pediatric Surgery, MassGeneral Hospital for Children, Boston.)

function, as well as coagulation indexes. Polycythemia may be present from tumor-induced excess erythropoietin production; acquired von Willebrand disease is present in less than 10%.[252] Microscopic hematuria occurs in 25%, whereas overt hematuria is rare,[256] suggesting tumor invasion of the collecting ducts. Systemic hypertension is present in 25%, presumably as a result of hyperreninemia. Preoperative investigations should include radiography and ultrasonography, the latter highlighting hyperechogenic structures within the kidney. Tumor extension into the ipsilateral renal vein and inferior vena cava must be examined before embarking on surgery, as chemotherapy may lead to involution of these tumors (Fig. 27.12).[252] Magnetic resonance imaging and CT are valuable tools for delimiting the tumor borders within the kidney, as well as metastases in the lungs or other organs.[252] Most recent summaries of the radiologic investigations may determine the need for additional interventions, including echocardiogram and lung scan, to determine the presence of tumor in the heart and lungs, respectively. An echocardiogram may be specifically required to evaluate myocardial function if doxorubicin and other anthracycline chemotherapeutic agents have been administered.[252]

Anesthetic management of children with Wilms tumor is similar to that with neuroblastoma. No specific anesthetic regimen is preferred. The potential for massive and rapid blood loss must be anticipated and appropriate blood products should be immediately available. Invasive monitoring and large-bore IV access (upper extremities should the tumor extend into or compress the inferior vena cava) with adequate blood warming capability is mandatory; a rapid infusion device should be close at hand. Hypertension (precipitated by tumor handling), coagulopathy (acquired von Willebrand disease), extension of the tumor into the proximal inferior vena cava or right atrium, pulmonary tumor emboli, acute right heart failure, and considerations concerning preoperative or previous treatment with chemotherapeutic drugs are anticipated potential complications during anesthesia.[252] These drugs may impair hepatic or hematopoietic function (actinomycin D), cause inappropriate antidiuretic hormone release (vincristine), or myocardial damage (anthracyclines) (see also Chapter 11).[252] Postoperative pain may be controlled using either IV opioids or regional anesthesia, though the risk of a coagulopathy must be ruled out before placing an epidural block.

FIGURE 29.12 Coronal view of the CT scan of a Wilms tumor. Note the massive tumor enveloping the inferior vena cava, as the vena cava is only visible where it enters the liver in the upper midportion of the radiograph (*arrow*). BLADDER AND CLOACAL EXSTROPHY

Bladder exstrophy is a rare congenital anomaly of the genitourinary tract occurring in 1 in 50,000 births with a 2 : 1 male/female ratio, more common in Caucasians than non-Caucasians.[258,259] It occurs as a failure of the abdominal wall to close during fetal development and results in defects of the anterior wall of the bladder and overlying midline abdominal wall. Bladder exstrophy may present with a spectrum of anomalies, including widening of the symphysis pubis, and genital anomalies, such as epispadias, bifid clitoris, and undescended testes (Fig. 29.13). Some regard bladder and cloacal exstrophies as distinct entities, whereas others consider them both extremes in a continuum of antenatal defects.[260] Cloacal exstrophy includes features of bladder exstrophy, plus an omphalocele and spinal defects, and always includes imperforate anus. Because the antenatal diagnosis of bladder exstrophy using ultrasound may be technically difficult, and thus dependent on indirect signs (absence of bladder filling, a low-set umbilicus, widening of the pubic ramus, small external genitalia, or a lower abdominal mass), the diagnosis is usually confirmed at birth when the anterior abdominal wall defect with the exposed bladder mucosa are evident (Fig. 29.13).

Therapy is aimed at the surgical reconstruction of the bladder with preservation of renal function while achieving urinary continence and satisfactory appearance of the external genitalia.[261,262] In a select group of infants, surgical management may be carried out as a single-stage procedure[263]; however the majority require a staged surgical repair directed at closure of the bladder, posterior urethra, and abdominal wall.[264] In addition, a bilateral iliac osteotomy may be performed to facilitate surgical closure, decrease

FIGURE 29.13 Bladder exstrophy in a neonate. Note the open anterior abdominal wall, protuberant bladder, distorted genitalia, and splayed hips.

the stress on the midline soft tissues, and reduce the risk of postoperative wound dehiscence.

Wound dehiscence, bladder prolapse, and multiple attempts at bladder closure are among the risk factors for decreased bladder growth and the inability for the later development of continence.[265] In addition to the immediate postoperative complications, children who have undergone surgical repair of bladder exstrophy carry an increased risk for the development of renal, bladder, and colon adenocarcinoma.[266] Children who require frequent bladder catheterizations or repeat surgeries are at risk for developing latex allergy if latex products are used[66]; fortunately most bladder catheters exclude latex.

Surgical management of the epispadias is usually performed at 6 to 12 months of age, and reconstruction of the bladder neck by 5 years, the latter to allow for bladder training.[264] After the initial surgical repair, children are immobilized for 4 to 6 weeks,[267] with a successful outcome likely when a modified Buck traction with an external fixator or a modified Bryant traction[268] and adequate postoperative analgesia are used.[269]

The preoperative assessment should evaluate the presence and severity of all congenital anomalies, particularly cardiac abnormalities. Signs or symptoms of renal insufficiency and electrolyte imbalance may be present. If the child has renal insufficiency, the dose and frequency of administration of potentially nephrotoxic drugs, as well as the commonly used anesthetic drugs, must be carefully evaluated, particularly water-soluble drugs. Typically, surgery is performed with the child in the supine and lithotomy positions. The duration of surgery is often prolonged, requiring alternating urologic and orthopedic teams for their respective segment of the surgery, and repositioning the child depending on the stage of the surgery, thus requiring judicious management of fluids, blood loss, and temperature control. It is essential to communicate with the surgical teams to ensure an optimal perioperative strategy for balanced salt solutions, colloids, and blood products; a preoperative plan for multimodal perioperative pain management and anticipation of possible postoperative ventilatory support is essential.[264] After applying the standard monitors, anesthesia may be induced either by inhalation or IV; after induction, at least one large-bore peripheral IV line should be placed. A second IV line may be placed, or a central venous catheter and possibly an arterial catheter. In general, if blood loss occurs, it is slow and steady, but if posterior iliac osteotomies are performed, the blood loss may become brisk, requiring aggressive fluid resuscitation and administration of blood products. Beat-to-beat variability of arterial blood pressure and serial laboratory evaluations are valuable during goal-directed resuscitation. Appropriate padding, a fluid warmer, and a forced-air heating system should be standard. The anesthetic prescription varies with the age of the child and whether the surgery is completed in a single or staged repair. Postoperatively, children are transferred directly to the pediatric intensive care unit for recovery.

A general anesthetic in combination with an epidural or caudal continuous infusion technique is often used if there are no associated spine abnormalities and if the catheter can be positioned out of the surgical field.[270]

Maintenance of anesthesia may be achieved using an inhalation anesthetic and small doses of opioids such as a remifentanil infusion; intermittent boluses (0.5–1 mL/kg) or continuous infusions of bupivacaine (0.125%–0.25%) or ropivacaine (0.2%) with or without epinephrine through a lumbar or caudal epidural catheter reduce the need for anesthetic agents. Caudal or epidural analgesia may be provided by advancing the catheter to the appropriate surgical dermatomal level after induction of anesthesia. In neonates, epidural infusions of bupivacaine (0.2 mg/kg per hour) provide excellent analgesia although blood concentrations of bupivacaine steadily increase by 2 days (see later text). The catheter is either secured directly to the skin or tunneled using the epidural insertion needle[271]; a continuous infusion of a local anesthetic may be maintained for several days to provide analgesia and a mild motor blockade that favors immobility. However, care must be taken to avoid systemic toxicity. Neonates are at increased risk for developing local anesthetic toxicity because of their low serum protein concentration and metabolism. Albumin and particularly α1-acid glycoprotein are reduced in this age group,[272] which reduces protein binding and increases the free fraction of bupivacaine and ropivacaine. This free form is metabolized to a lesser extent in the neonate because of immature metabolic pathways and contributes to an increased risk of cardiac and systemic toxicity.[273,274] It is for this reason that the upper limit of infusion of bupivacaine or ropivacaine is limited to 0.2 mg/kg per hour (for 48 hours), which is half that used in children older than 6 months to minimize the risk of local anesthetic toxicity.[275–277] Unfortunately, (free unbound) serum bupivacaine concentrations are difficult to assay and so lidocaine 0.1% (0.8 mg/kg per hour) or chloroprocaine may be preferable (see also Chapters 42 and 44).

The outcome of this complex surgery is determined primarily by the surgical expertise. Urologic incontinence, bladder prolapse, and epispadias revisions require additional urologic surgery. Renal function is usually well maintained throughout; complications of complete repair are reported to be similar to those of the staged repair but usually involve additional soft tissue defects.[278]

Bariatric Surgery in Children

Obesity has become a major threat to public health worldwide (http://www.un.org/en/development/desa/population/pdf/commission/2010/keynote/popkin.pdf). The prevalence of pediatric obesity has increased exponentially, affecting every country over the past few decades. In the United States, the incidence of obesity in children 2 to 19 years old has increased from ~7% in 1980 to ~18% in 2010[279]; one-third of U.S. children are either obese (BMI ≥95th percentile) or overweight (BMI between the 85th and 95th percentiles) (http://www.cdc.gov/obesity/data/childhood.html).[280] The causes of obesity are multifactorial: excess caloric intake, poor nutritional choices, and lack of exercise. However, recent evidence suggests that obese children are obese before the age of 5 years and that the underlying causes may have their provenance in early infancy and childhood.[281] Furthermore, the serious complications from obesity—for example, arterial hypertension, cardiovascular disease, fatty liver, diabetes, asthma, and obstructive sleep apnea (OSA)—are recognized earlier in childhood,[282] often serving as precursors for significant and intractable obesity in adulthood.[283] Multiple studies have reported an increase in medical/surgical complications in hospitalized obese children.[284] Thus the societal burden of obesity is enormous (estimated at $147 billion dollars in yearly health care costs)[285] and mainly driven by a number of associated comorbidities (e.g., diabetes, hypertension, sleep apnea, and depression). If left untreated, obesity may result in earlier mortality.[286,287]

The degree of obesity can be quantified using several metrics, the most common being the body mass index (BMI), defined as the weight (in kilograms) divided by the height squared (in meters squared). In adults, the degree of obesity can be defined by single BMI values (Table 29.2). However, in children the degree of obesity

TABLE 29.2 Obesity Indexes in Adults and Children

Classification of Obesity	Adult (BMI)	Children (Percentile on BMI Growth Chart)
Normal weight	18.5–24.9	5–85
Overweight	25–29.9	85–95
Obesity	30–39.9	>95
Severe obesity	≥40	>120% of the 95th percentile

Based on http://www.cdc.gov/obesity/childhood/basics.html and Pan L, Blanck HM, Sherry B, et al. Trends in the prevalence of extreme obesity among US preschool-aged children living in low-income families, 1998–2010. *JAMA*. 2012:308(24); 2563–2565.[288]

is more difficult to quantify because BMI and other indexes of growth increase nonlinearly with age and gender. As a result, clinicians now define the degree of obesity in children based on growth charts for weight-dependent age and gender (Table 29.2).

To address these worrying statistics, bariatric surgery has emerged as one means to help the most extreme cases of adolescent obesity, especially those who are motivated toward weight loss and are psychologically prepared.[285,289] Bariatric surgery is designed to either bypass part of the small bowel to reduce caloric absorption (Roux-en-Y procedure) or to minimize the size of the stomach (laparoscopic vertical sleeve gastrectomy [LSG]). LSG has replaced the more complex Roux-en-Y gastric bypass surgery as the most commonly performed surgical procedure for obesity in the United States.[290] These surgeries have proven to be safe, cost-effective means of achieving permanent weight loss and providing partial resolution of comorbidities, especially diabetes in adolescents.[291–294]

MULTIDISCIPLINARY APPROACH TO BARIATRIC SURGERY IN ADOLESCENTS

Developing a successful approach to bariatric surgery in children requires a multidisciplinary team with collaboration from many pediatric subspecialists, including bariatric surgeons, anesthesiologists, endocrinologists, gastroenterologists, cardiologists, pulmonologists, psychologists, dietitians, and others.[295,296] Only children who are motivated to lose weight and who exhibit a positive psychological approach to this intensive process should be admitted to these programs.

ANESTHETIC IMPLICATIONS OF OBESITY IN ADOLESCENTS

Obesity is associated with a number of organ disorders including cardiovascular disease (hypertension, dyslipidemias),[297] respiratory (asthma and OSA),[298,299] renal dysfunction,[300] endocrinopathies (diabetes, metabolic syndrome), liver dysfunction (nonalcoholic fatty liver disease, and nonalcoholic steatohepatitis.[301,302] Childhood obesity is associated with early pathologic cardiovascular changes. Hypertension, previously seen most frequently in children with renal disease, is increasingly identified in obese children. The risk of hypertension in obese children is 3-fold and increases as BMI increases. Cardiac risk factors in obese children as young as 5 years of age have been described, including hypercholesterolemia, hypertension, and hyperinsulinemia. LVH has been identified in obese children as young as 10 years of age and is common in adolescents presenting for bariatric surgery. Research is underway to determine if changes in cardiac architecture and function are reversible with weight loss.

Preoperative preparation for bariatric surgery is an involved and prolonged process. A thorough and comprehensive preoperative review and investigation of these organ systems is warranted before proceeding with anesthesia. Once screening is completed, it is essential that the children learn about appropriate nutritional and attitudinal principles for achieving and maintaining weight loss. After evaluating the major organ systems and optimizing organ dysfunction, a preoperative anesthetic interview should be completed. During this evaluation, the anesthesiologist should review the investigations and laboratory results, ensure compliance of all medications and interventions (e.g., continuous positive airway pressure [CPAP] device), and then describe the anesthetic process with the patient and family in detail. Although these children appear large in size, many are psychologically immature and very anxious. Anxiolytic premedication should be offered on the day of surgery. During the interview, the airway should be assessed (see later text) and if a difficult airway is identified, supplementary airway equipment should be available. Children with CPAP devices should be advised to bring them on the day of surgery for possible use postoperatively. Routine fasting instructions and urine pregnancy testing for females who have reached menarche should be ordered or if complete, the results documented. If the child is unable to walk to the operating room, a wheelchair or stretcher rated for the child's weight should be used. The upper extremities should be examined for IV access as this may be difficult in obese patients.[303] A vein finder or ultrasound may be useful to establish venous access. In advance of undertaking bariatric surgery, appropriately sized operating room tables should be present. Operating room tables are rated for the patient's weight; for normal size patients, they may be rated for a maximum of 500 (227 kg) or 600 pounds (272 kg) and for obese patients, 1000 (454 kg) or 1200 pounds (544 kg). In all cases, the children should be strapped to the table to prevent the child from rolling off the table. Unlocking the bed and shifting the table top while the patient is on the table may cause the table to tip, even if the child's weight is within the table rating. This is more likely to occur if the table top is shifted off-center, if the child is placed in reverse orientation, or if a strong force is applied in one direction to the table (http://www.apsf.org/newsletters/html/2013/spring/07_tabletipdanger.htm).

Designing appropriate drug dosing in obese children requires an understanding of the scalars that may be used to estimate the correct dose. Total body weight (TBW) consists of two compartments: fat-free mass (FFM) and the fat mass (FM). In general, the former is the volume into which hydrophilic drugs tend to be distributed, whereas the latter is the volume into which lipophilic drugs are distributed. Because most drugs have both lipophilic and hydrophilic properties, the pharmacology of each drug (or category) must be considered to define its pharmacokinetic properties. Unfortunately, few of the drugs used for anesthesia in obese children have been studied, thus limiting the evidence on which to base drug doses. The FFM, a measure similar to lean body mass, may be considered the sum of the ideal body mass plus the additional mass required to support the physical and metabolic demands of the FM. The latter is derived primarily from an increased muscle mass as well as minor contributions from increased vessel-rich organ mass (heart, liver) and the fluid compartments. As the TBW increases, the FM increases in proportion; FFM increases steadily up to a BMI 40 but then plateaus thereafter.[304]

The ideal body weight (IBW) of a child can be obtained from tables, graphs, or simple equations.[305] Sample equations include

$$\text{IBW} = 2 \times \text{Age (years)} + 9 \text{ for children} \leq 8 \text{ years and}$$
$$3 \times \text{Age (years)} \text{ for} > 8 \text{ years}$$

The lean body weight (LBW) may be estimated using a nomogram[305] or from a simple equation:

$$LBW = IBW + 0.3 \times (TBW - IBW)$$

Dosing is further complicated because the size metric used for a loading dose, which depends on the volume of distribution, may differ from that used for maintenance dosing or infusion rates, which depend on clearance. Most anesthetic drugs are lipophilic and are theoretically distributed in the TBW. However, drug doses for induction of anesthesia are not uniformly based on the TBW.[306] Drugs used to induce anesthesia are distributed into the central compartment and throughout the vessel-rich group of organs (e.g., brain). Even though these drugs are lipophilic, the induction dose is ideally based on the acute volume of distribution (V_d), which is more appropriately based on IBW or LBW.[307] LBW might be a good-sized metric for the dose of propofol for induction of anesthesia,[308] but TBW is better for maintenance/infusion.[309]

Other considerations in obesity include changes in plasma proteins, liver and renal functions, cytochrome enzyme activities,[310] CO, and regional blood flow.[311] Obesity may compromise organ function; dexmedetomidine clearance is reduced in obese adults.[309] The pharmacokinetics of drugs in obesity depend on the physicochemical characteristics of the drugs. For the loading dose of drugs, if the Vd/TBW ratio is reduced in obesity, then the drug is not distributed to the FM and should be based on the LBW or IBW.[304] In contrast, if the Vd/TBW ratio is unchanged or increased in obesity, then the drug is predominantly lipophilic and the dose should be based on TBW.[312,313] For drugs administered for maintenance, the dose should be based on its clearance. If the clearance in obesity is unchanged or decreased, then the dose should be based on LBW or IBW, whereas if the clearance is increased in obesity, then the maintenance dose should be based on the TBW. The use of cerebral function monitors (e.g., bispectral index in teenagers) greatly simplifies propofol infusion dosing by allowing titration of dose to a target effect.

Studies reporting the pharmacokinetics/dynamics of specific anesthetic drugs in obese children are limited.[306,314] Based on the best "available" data, a summary of the doses for induction or maintenance of anesthesia is presented in Table 29.3[315]; as more detailed evidence emerges, the basis for the dose of the drugs continues to evolve.

TABLE 29.3 Dosage of Intravenous Anesthetics in Obese Children

Drug	Induction Dose Based on	Maintenance Dose Based on
Thiopenthal	LBW	
Propofol	LBW	TBW
Synthetic opioids (fentanyl, alfentanil, and sufentanil)	TBW	LBW
Morphine	IBW	IBW
Remifentanil	LBW	LBW
Nondepolarizing neuromuscular blockers	IBW	IBW
Succinylcholine	TBW	
Sugammadex	TBW	

IBW, ideal body weight; *LBW,* lean body weight; *TBW,* total body weight.

Inhalational anesthetic agents with low blood-gas solubility are ideal in this setting. Rapid induction and emergence from anesthesia can be achieved and facilitated in this population with agents such as desflurane or sevoflurane combined with remifentanil.[316] The context-sensitive half-life of desflurane is superior to sevoflurane owing to lower solubility in blood and tissues; thus the former facilitates a more rapid recovery than the latter, particularly for surgeries longer than 2 hours when inhalation anesthetics accumulate in fat.[317] However, desflurane induces more bronchoconstriction than sevoflurane; thus in children with asthma or who smoke cigarettes, sevoflurane's bronchodilatory properties make it preferable to desflurane.

Airway management should take into consideration several basic principles. The presence of increased abdominal girth, shallow tidal volumes, and supine position predispose to rapid desaturation once anesthesia is induced. To preclude desaturation, patients should be preoxygenated in a reverse-Trendelenburg position more than 25 degrees.[318] This provides an adequate reserve of oxygen during laryngoscopy and tracheal intubation, mitigating the risk of desaturation and attenuating atelectasis. To view the glottis aperture, elevation of the head in the sniffing position should be doubled (from normal distance of 7 cm) to ~14 cm. This may be achieved by combining the ramped position with the usual head elevation (7 cm).[319] The quintessential alignment that must be ensured to successfully visualize the larynx in obese children is that the tragus of the ear is at or above the level of the sternal notch in the sniffing position.[320] If the tragus is not elevated above the sternal notch, then the head must be propped up further. An RSI is not usually required in most obese children; those who have gastroesophageal reflux are controlled medically. Gastric fluid volume is increased in obesity, but the fluid pH is not.[321] Therefore the risk of pneumonitis should aspiration occur is no greater than in a nonobese patient.

Ventilation may be a challenge in obese children, particularly during laparoscopic surgery. The pulmonary challenges from laparoscopic surgery are compounded by the large abdominal girth compressing the basal lungs. Increased inspired oxygen concentration may prevent hemoglobin desaturation but may lead to absorption atelectasis. Optimal strategies for ventilation while avoiding barotrauma include low tidal volumes (6–8 mL/kg based on LBW, not TBW), periodic alveolar recruitment maneuvers, PEEP (8–15 mm Hg), a respiratory rate to maintain normocapnia or permissive hypercapnia, particularly during pneumoperitoneum), and a sufficient inspired oxygen concentration to maintain an adequate saturation.[322–324] The ventilation mode has little bearing on the outcomes after anesthesia. At the end of surgery and after extubation, the child should be positioned in the semirecumbent position, administered oxygen by face mask, and monitored en route to the recovery room. Postoperative pain may be managed with either intermittent IV opioids or patient-controlled analgesia.

OSA is common in children who are morbidly obese. Many use nightly CPAP devices, although obese adolescents exhibit poor compliance with these devices.[325] Given the known risks of OSA causing opioid sensitivity, opioids should be administered in reduced doses (⅓–½ the usual doses).[326–328] Intermittent hypoxia commonly complicates the postoperative period. Hence, patients should bring their CPAP or nasal CPAP devices to the hospital for postoperative use. Children may be discharged home after uncomplicated surgery on postoperative day 3.[329–331]

Drug dosing after gastric bypass surgery is poorly understood.[332,333] After gastric bypass surgery, whether Roux-en-Y or

the more popular LSG surgery, rapid weight loss occurs. This often results in the resolution of many comorbidities associated with morbid obesity such as systemic hypertension, diabetes, and so on. However, failure to adjust drug dosing in parallel with the weight loss, reduced gastric residence time, reduced exposure to intestinal cytochrome enzymes (CYP3A4; e.g., increasing atorvastatin blood concentrations), and the resolution of severity of the associated diseases may lead to relative drug overdoses and the associated consequences.[333] For example, after Roux-en-Y gastric surgery, approximately 50% of drugs taken orally have reduced area under the concentration-time curve, whereas 25% have unchanged and 25% have increased area under the concentration-time curve.[334] Oral morphine kinetics after Roux-en-Y showed dramatically increased blood concentrations within the first 2 weeks after surgery that persisted for at least 6 months.[335] The risks of an opioid overdose from the changes in pharmacokinetics not accounting for the effects of comorbidities may be substantial. In one meta-analysis, the range of postoperative to preoperative drug exposure ratio extended from a 10-fold greater ratio for penicillin to a 33% lower ratio for phenytoin and ampicillin.[333] The pharmacokinetics of midazolam after gastric bypass surgery in adults yielded similar bioavailability after oral dosing but greater clearance one year after bypass surgery.[336]

Currently, LSG surgery has eclipsed Roux-en-Y surgery in the United States in popularity, including in the adolescence age group. LSG surgery is not associated with the same extent of gastric dumping as Roux-en-Y surgery, but gastric residence time and absorption with LSG is reduced. Until practice recommendations are forthcoming, it seems prudent to titrate all parenteral drugs to effect during the period of rapid weight loss in particular and to adjust the doses of all oral drugs using therapeutic drug monitoring and individual clinical responses.

Alqahtani A, Elahmedi M, Al Qahtani AR. Laparoscopic sleeve gastrectomy in children younger than 14 years: refuting the concerns. *Ann Surg*. 2016;263(2):312-319.

This retrospective study compared the outcomes after laparoscopic sleeve gastrectomy in children younger than 14 years at the time of surgery with adolescents older than 14 years. The authors concluded that sleeve gastrectomy in children younger than 14 years is both safe and effective.

Kim PH, Patil MB, Kim SS, et al. Early comparison of nephrectomy options in children (open, transperitoneal laparoscopic, laparo-endoscopic single site [LESS], and robotic surgery). *BJU Int*. 2012;109:910-915.

This up-to-date review provides comparative results of both laparoscopic techniques and robotic surgery in children.

Mortensen A, Lenz K, Abildstrøm H, Lauritsen TLB. Anesthetizing the obese child. *Paediatr Anaesth*. 2011;21(6):623-629.

This review presents the epidemiology, pathophysiology, and pharmacology of drugs used in obese children who require anesthesia.

Neira VM, Kovesi T, Guerra L, et al. The impact of pneumoperitoneum and Trendelenburg positioning on respiratory system mechanics during laparoscopic pelvic surgery in children: a prospective observational study. *Can J Anaesth*. 2015;62(7):798-806.

The authors investigated the physiologic impact of 12 mm Hg pneumoperitoneum followed by 20-degree Trendelenburg positioning. They found that both dynamic compliance and tidal volume (normalized to weight) decreased after insufflation of the pneurmoperitoneum (by 42%) but decreased only 10% further after 20-degree Trendelenburg positioning. These changes could be offset by increasing the peak inspiratory pressures during pressure-controlled ventilation with PEEP in children undergoing laparoscopic surgery.

Phillip-Hohne C. Anaesthesia in the obese child. *Best Pract Res Clin Anaesthesiol*. 2011;25(1):53-60.

This review highlights the epidemiology of obesity in children, physiologic changes, and anesthetic considerations.

Walker RW, Ravi R, Haylett K. Effect of cricoid force on airway calibre in children: a bronchoscopic assessment. *Br J Anaesth*. 2010;104(1):71-74.

This investigation documents the magnitude of the external force required to distort the cricoid ring from infants until adolescents. In infants, force as little as 5 N distorts the cricoid rings. The force required to distort the ring increases with age, reaching 15 to 25 N in adolescents.
