Notices

Knowledge and best practice in this field are constantly changing. As new research and experience broaden our understanding, changes in research methods, professional practices, or medical treatment may become necessary.

Practitioners and researchers must always rely on their own experience and knowledge in evaluating and using any information, methods, compounds, or experiments described herein. In using such information or methods they should be mindful of their own safety and the safety of others, including parties for whom they have a professional responsibility.

With respect to any drug or pharmaceutical products identified, readers are advised to check the most current information provided (i) on procedures featured or (ii) by the manufacturer of each product to be administered, to verify the recommended dose or formula, the method and duration of administration, and contraindications. It is the responsibility of practitioners, relying on their own experience and knowledge of their patients, to make diagnoses, to determine dosages and the best treatment for each individual patient, and to take all appropriate safety precautions.

To the fullest extent of the law, neither the Publisher nor the authors, contributors, or editors, assume any liability for any injury and/or damage to persons or property as a matter of products liability, negligence or otherwise, or from any use or operation of any methods, products, instructions, or ideas contained in the material herein.

ELSEVIER Book Aid International Working together to grow libraries in developing countries
www.elsevier.com • www.bookaid.org

We dedicate the sixth edition of A Practice of Anesthesia for Infants and Children *to physicians around the world who have the pleasure and responsibility of caring for children in the operating room, ICU, and other venues where anesthesia services are vital such as radiology, cardiac catheterization laboratory, and sedation services such as oncology. In particular, we acknowledge those practitioners who take care of children and deliver the best possible care with limited resources and at times with antiquated equipment, limited drugs, electricity, and even the availability of oxygen. Our specialty has grown exponentially in the past 30 years and as a result of new licensing laws, medications are now more thoroughly investigated before they are released for use in children. Ultrasound technology has made regional anesthesia and invasive line insertion far safer than in the past. The quality of airway devices continues to improve. Noninvasive continuous cardiac output devices may provide the next generation of monitors to safeguard the care of our children. Depth of anesthesia monitors also continue to evolve, but still remain unreliable in younger children; we hope that advances will ensure greater reliability in the infant and young child to assess the depth of anesthesia as well as to enable differentiation of moderate from deep sedation and deep sedation from general anesthesia.*

We also dedicate this book to the children to whom we provide anesthesia daily and to their parents/guardians to assure them that their children will receive the highest standard of care and will be as safe as possible from harm. Our specialty continues to investigate the possible adverse effects of anesthetics on the developing brain to determine whether the findings in newborn animals are simply laboratory curiosities or are in fact translatable and potentially harmful to infants and children. Evidence at this time neither confirms nor refutes significant injury to the developing human brain. The challenge we face in our daily work is to reassure parents that anesthesia and the drugs we use are safe (to the best of our current knowledge) and that they do not pose real and substantive risks for their children.

This edition of A Practice of Anesthesia for Infants and Children *highlights key advances and questions in our specialty that we hope will continue to inspire anesthesiologists worldwide through the text, the web-based videos and illustrations, and the pocket shortcut card and phone app (Pedi Anesth).*

PREFACE

A Practice of Anesthesia for Infants and Children, Sixth Edition, has continued to evolve from its humble beginnings in 1986 with only 304 pages in the 1st edition to more than 1200 pages in the current edition. Founding coeditors of this text Dr. John Ryan and Dr. Nishan Goudsouzian retired, and Dr. I. David Todres succumbed to lymphoma. Dr. Jerrold Lerman joined as a coeditor for the 4th edition, and Dr. Brian J. Anderson joined for the 5th edition; the addition of Dr. Anderson broadened the clarity and insight into basic pharmacology in all chapters.

The current edition includes 109 authors from five continents, 22 of whom are new contributors. The book continues to be a highly respected, evidence-based synopsis of the practice of pediatric anesthesia reflecting a broad perspective from a host of international experts. As was the case in past editions, many of the authors are board-certified in pediatrics and anesthesiology, surgery, and a number of pediatric subspecialties, enhancing the basic understanding of hematology, pulmonology, cardiology, nephrology, hepatology, and neurology. As in the last edition, the book is divided into 10 color-coded sections: Introduction, Drug and Fluid Therapy, The Chest, The Heart, The Brain and Glands, The Abdomen, Other Surgeries, Emergencies, Pain, and Special Topics. This format allows the reader to find chapters and topics of interest easily and quickly. We have shifted all but a few selected references for each chapter to the accompanying Expert Consult website with hypertext links to the original publications in an effort to contain the size of the book. Color illustrations, photographs, and graphics maximize clarity and enhance visual appeal; many new video clips, figures, tables, and appendices are also available online.

In keeping with our mission to create a comprehensive text, we have again sought contributions from a number of pediatric subspecialists who share their perspectives and insights into basic pediatric physiology and the pathophysiologic implications of disease in children. In each case, the specialists have been paired with a pediatric anesthesiologist to ensure that the basic science is intertwined with a practical clinical perspective. These are the "Essentials" chapters.

Maintaining the past tradition, the largest chapter of the book is the pharmacology chapter, which now includes more than 2000 references. The chapter is written by all three editors, reflecting their different perspectives in pediatric pharmacology. We have maintained discussion of older and less frequently used medications to address the wide range of practices globally. The pediatric airway chapter includes an extensive discussion of supraglottic devices as well as emergency airway management strategies and equipment currently available for use in infants and children. There are many online videos illustrating their use.

All chapters on specialized topics, such as thoracic anesthesia, orthopedics, plastic surgery, general and urologic surgery, ophthalmology, otorhinolaryngology, burns, and cardiac topics, including physiology, cardiac surgery, cardiopulmonary bypass, medications for hemostasis, cardiac assist devices, and cardiac catheterization laboratory, have been updated.

The chapter on anesthesia in the developing brain has been substantively redacted to reflect the current state of knowledge on this subject and includes a comprehensive table of all published studies on this topic at the time of publication. Thus, readers are provided with ready access to the most important publications in this area. Chapters concerning anesthesia for extremely premature infants, the ex-utero intrapartum treatment procedure, trauma, and infectious diseases have also undergone significant revision.

Three new chapters focus on pharmacogenomics and the implications regarding drug interactions and drug metabolism, total intravenous anesthesia (TIVA), and on the perioperative management of oncology patients. The pharmacogenomic chapter underscores genetic implications of predicting drug effects and illustrates genetic variants that result in complications that are increasingly important in the day-to-day clinical management of patients. TIVA is becoming an increasingly popular technique as programmable pumps for drug delivery become more accessible.

The last 13 chapters of the book include management of trauma, cardiopulmonary resuscitation, malignant hyperthermia, ultrasound-guided regional anesthesia, management of acute and chronic pain, anesthesia outside the operating room, PACU, sedation for diagnostic and therapeutic procedures, vascular access, infectious disease, medical simulation, and the exceedingly important topic of pediatric anesthesia in developing countries.

It should be noted that our text is accompanied by a website that contains many supplemental pictures, tables, figures, and video clips that will enhance the readers' experiences. The pocket reference card that provides general recommendations for doses of commonly used medications by weight and other useful guides such as LMA sizes, ETT sizes, and other quick references has now been expanded to include a phone-based application for both Android and iPhones that can be found with the search words "Pedi Anesth" that was sponsored by the Starship Children's Hospital in Auckland New Zealand. The phone application provides immediate weight-based dosing of all commonly used medications and other helpful algorithms. Additionally, the expanded version of the phone application contains color illustrations of common congenital heart lesions courtesy of Elsevier, as well as many additional tables and treatment algorithms.

As with all previous editions, this revision involved quite a journey reflecting a microcosm of the world and life in general. Many contributors again experienced various challenges such as loss of loved ones, personal crises, illness, and others during the writing of their chapters. Despite all these obstacles the authors have succeeded in crafting masterful chapters to create what we hope you will agree is an up-to-date, state-of-the-art text in pediatric anesthesia.

Once again, while assembling this new edition, the editors spent many days, evenings, and weekends debating controversial issues and crafting the language of the chapters such that all chapters were edited and reviewed by all three editors and common

ground reached. This is an especially useful exercise since it improves the readability of the text and represents a fusion of the USA, Canadian, and New Zealand approaches to and understanding of pediatric anesthesia, which combines our global experience and understanding.

We believe that *A Practice of Anesthesia for Infants and Children*, Sixth Edition, continues to provide the framework for residency and fellowship training in pediatric anesthesia globally and will continue to be a valuable resource for passing the subspecialty boards in pediatric anesthesiology, as well as a resource for practicing pediatric anesthesiologists and other pediatric care providers around the world.

Charles J. Coté
Jerrold Lerman
Brian J. Anderson

ACKNOWLEDGMENTS

We wish to thank our wives, husbands, significant others, children, friends, secretaries, and staff members who lent their support to this wonderful international family of experts that has come together to produce *A Practice of Anesthesia for Infants and Children*, Sixth Edition. In particular, we wish to thank the departments of anesthesiology, pediatrics, surgery, and internal medicine around the world who supported the academic endeavors of their staff and thus made it possible for them to contribute to the sixth edition. We thank Elsevier for their continued support of international education in less medically advanced countries by providing a variety of textbooks, including *A Practice of Anesthesia for Infants and Children,* to Fellows of the World Federation of Societies of Anesthesiologists as well as other fledgling programs, particularly those in sub-Saharan Africa. It is through such international endeavors that we ensure the global availability of the most recent advances in our specialty.

The editors wish to dedicate this edition of the book to honor the passing of Richard J. Kitz, MD, the chairperson who gave Dr. Coté the editorship of this book in 1982. Without his foresight, encouragement, and support, this book may never have been created.

Summary

IN THIS CHAPTER, WE outline the basis of our collective practice of pediatric anesthesia. These basic principles of practice can be applied regardless of the circumstances; they provide the foundation for safe anesthesia.

Preoperative Evaluation and Management

PARENTS AND CHILD

Anesthesiologists must assume an active role in the preoperative assessment of children. Ideally, the same anesthesiologist who performs the preoperative evaluation will anesthetize the child. The preoperative evaluation should include a complete review of the birth, medical, surgical and family histories; a review of the medical record; evaluation and review of laboratory, radiologic, and other investigations; and physical examination of every child who is to be anesthetized (see Chapter 4). When appropriate, the child should receive preoperative medical therapy to optimize his or her medical conditions (e.g., a child with reactive airway disease) before receiving anesthesia. In addition, the emotional state of the child and family must be considered and appropriate psychological and, if necessary, pharmacologic support provided. The anesthesia team, working in concert with surgical colleagues, nursing, and child-life specialists (e.g., the use of iPad, movies, play therapy, or games) should find appropriate and creative techniques to prepare the child and family for the surgical experience (e.g., using videotapes, booklets, hospital tours, and/or trained paramedical personnel). The marked increase in the number of outpatient surgical procedures has reduced the time available for the anesthesiologist to interact with the family and the child preoperatively. Despite the reduced contact time, these support strategies should continue to be included in the preoperative assessment.

Familiarity with a child's clinical and psychological status as well as the parental concerns is essential to delivering quality anesthesia care. To achieve the very best outcome for each child, it is essential to meet with the child and the parents (or caregiver or legal guardian) together and establish rapport preoperatively. If the family speaks a different language than the anesthesiologist, then a medical interpreter should be sought.

Many developmental issues are related to the hospital experience. For example, toddlers fear separation from their parents, younger children fear mutilation from their surgery, and teenagers fear loss of control, awareness, and pain (see Chapter 3). When conducting the preoperative interview, speak directly to the child (who is old enough to understand [usually age 5 years and older]) and explain what anesthesia involves and what will transpire when they enter the operating room in terms that are age appropriate. Children at the age of reason have the same fears as adults but may have greater difficulty articulating them. For example, identify the key elements that distinguish "sleep" from anesthesia medicine from the sleep they experience at home. Explain that even if children undergo anesthesia for hours, they will feel as if they were unconscious for only a few minutes. Children should be reassured that unlike sleep at home, *the anesthetic prevents them from feeling anything during surgery, that they will not wake up during the procedure, and that they will awaken after the surgery.*

How anesthesia will be induced should be explained to the child in terms that are appropriate for the child's developmental

level. For young children, one can describe that he/she will breathe "laughing gas" through a flavored mask, with a flavor that he/she chooses. Older children can be given the option to receive anesthesia either intravenously (IV) with nitrous oxide by mask, topical local anesthesia cream (e.g., eutectic mixture of local anesthetics [EMLA]) or vapocoolant such as Pain Ease (Gebauer Chemicals, Cleveland, OH) to establish IV access painlessly; or if they are afraid of needles, they may choose to receive anesthesia by an inhalational induction. Child-life specialists can be particularly helpful in demonstrating the anesthesia mask and circuit, illustrating that an IV is just a plastic tubing and not a needle and even decorating the mask with stickers and picking flavored scents.

If the parents will be present at induction of anesthesia, it is preferable that they attend a preoperative instructional session during which a typical induction is described along with the child's responses, perhaps complemented by a video of an induction. The parents should be instructed on how they might assuage their child's concerns, and questions from the parents should be answered. It is challenging to expect parents to cope with their child's induction without providing any preoperative instruction and teaching. Specific changes that might be observed in their child during anesthetic induction can be addressed as follows:

1. As your child is anesthetized, his or her eyes may roll up: "You might see your child's eyes roll up and this might be disturbing to you, but this is completely normal and expected; it happens to all of us when we fall asleep; it is just that we are not looking for it."
2. "As children fall asleep the structures in the neck relax so they may snore or make other noises from their throat; if your child does this, it is completely normal."
3. "As the anesthetic reaches the brain, the brain sometimes gets excited and causes movements of the arms and legs that are without purpose, or it may cause them to turn their head from side to side. This means the anesthetic is having its effect and even though your child appears to be partly awake, he or she has received enough anesthesia to ensure that he or she does not remember this."
4. "If your child becomes frightened, we will increase the amount of the anesthesia medicine rapidly and calm your child as quickly as possible."
5. If anesthesia is induced intravenously, the parents should be informed that their child might suddenly become limp, stop moving and breathing, and appear pale. These are all normal reactions.

At the same time, parents should not be pressured to be present for induction of anesthesia. If the parents are present at induction, it must be clear that they may be asked to leave the operating room if a new or additional risk to the child surfaces during the induction. Parents should be informed that their presence at induction is for their child's benefit and that their presence is a privilege, not a right. Moreover, in some circumstances it may not be in the child's best interest for parents to be present at induction, such as when the health care team could be distracted when everyone's attention should be focused on the child.

A simple explanation of the monitors to be used during anesthesia can be interesting to children and reassuring to parents. For example, the pulse oximeter can be described as a *"Band-Aid–like device"* that lights up red and measures the oxygen in the bloodstream during anesthesia and recovery. It is very helpful as an early warning indicator of low oxygen levels in the perioperative period. The blood pressure cuff can be characterized as an *"arm hugger"* or *"muscle tester";* and the electrocardiogram leads can be called *"little sticky things that let us watch your heart beat but don't hurt at all."* Simple descriptions of the measurements may also be soothing. For example, *"We measure the amount of oxygen you (your child) are (is) breathing, we measure the amount of the anesthesia medicines you (your child) are (is) breathing, and we measure the carbon dioxide you (your child) are (is) breathing out to ensure that your (your child's) breathing is just right throughout the anesthesia."* Sometimes asking teenagers if they have studied carbon dioxide in school science class helps them to better understand the monitors and provides reassurance, as well as making it more interesting.

These preemptive discussions are meant to attenuate the parents' anxiety at a time when we need to focus on the child. It is common for parents to decline to be present during induction after hearing these explanations.

To prepare children for recovery from anesthesia, it is useful to describe our strategies to minimize emesis and pain after surgery. In emetogenic surgery and in children who are prone to emesis, prophylactic antiemetic therapy will be administered during anesthesia. If pain is anticipated during recovery, analgesics will be administered during anesthesia either in the form of a regional block and/or parenteral analgesics and supplemented in the recovery room should the child experience further pain. Anesthesiologists can provide valuable assistance in this respect because of their knowledge of the pharmacology of sedative and opioid medications (see Chapter 7), as well as their ability to perform neuraxial and peripheral nerve blocks (see Chapters 42 to 44). If special monitoring is required in the operating room or postoperatively, this should be explained and the child assured that the IV catheters, airway devices, and all invasive monitoring devices will be placed after induction of anesthesia to avoid causing discomfort and will be removed as soon as the child's postoperative condition permits. The possible need for postoperative intensive care, including assisted ventilation, should be anticipated and fully discussed with the parents and child (if the child is of an appropriate age) in circumstances that warrant such discussion.

The anesthesiologist who sits down with the family, who speaks slowly and clearly while answering questions, and who is neither distracted nor in a rush to leave, presents a much more sincere and caring impression to both the child and parents than the anesthesiologist who stands tapping his or her toes while interviewing the family, who speaks quickly, and whose body language points toward the door as if he or she is looking to exit the interview as quickly as possible. The detail with which this information is presented will vary from child to child and family to family, as well as with the anesthesiologist's understanding of the needs of the child and family. The anesthetic prescription should not be recited in a cold and technical manner, but rather with communication that addresses the parents' and the child's questions and concerns. This dialogue is frequently afforded too little time, leaving the parents and child insecure and apprehensive, their questions unanswered. Body language is especially important during this preoperative interview. But by the end of the interview, the child and parents should understand that you will be providing the quality of care that ensures the child's safety during anesthesia, thus reducing the child's and parents' anxiety.

THE ANESTHESIOLOGIST

Anesthesiologists must fully understand the proposed surgical, medical, or investigative procedure to facilitate the planning of an appropriate level of monitoring and selection of anesthetic drugs and technique. They must anticipate the needs of the

surgeon or proceduralist in terms of positioning the child, the need for or avoidance of muscle relaxants, considerations regarding specific procedures (e.g., the surgeon's need to monitor motor and sensory evoked potentials may influence choices of anesthetic technique), IV fluids and blood products (see Chapters 9 and 12), as well as the need to alleviate perioperative anxiety and pain. For complex cases, the anesthesiologist and surgeon should formulate a plan and convey it to the parents and child preoperatively. Any important medical issues that require clarification should be investigated during the preoperative evaluation by consulting appropriate medical consultants as indicated. Consultant recommendations must be carefully reviewed and should reflect the consultant's understanding of the anesthesia process and what you require regarding the child's medical condition to assist you in the delivery of anesthesia (see Chapters 11, 13, 16, 24, 27, 28, and 30).

All children should fast preoperatively. Infants must receive special consideration; prolonged abstinence may lead to dehydration or hypoglycemia (see Chapters 4 and 9). Children may surreptitiously circumvent the preoperative fasting orders, especially if the period of fasting is prolonged or other children in the vicinity have food. One must always be prepared for the possibility of a full stomach and its sequelae. For example, the risk of pulmonary aspiration of gastric contents is increased in some children (e.g., those who ate a meal just before a trauma, those who had previous esophageal surgery, or those with a hiatus hernia). In these children, the anesthetic management should be modified to minimize the risk of regurgitation and aspiration. Preoperative consideration must be given to proper psychological support, appropriate premedication, and the timing of the premedication (see Chapters 3 and 4). Psychological support of the child and parents must never be neglected, no matter how calm they might appear. Premedication may be administered on the ward or in the waiting area; however, in children at risk for desaturation or cardiorespiratory compromise, the child may require monitoring and/or close observation. Critically ill children must be accompanied by skilled staff who will ensure continued infusions of vasoactive medications and who are skilled in the management of any emergencies that could arise during transport (see Chapter 39). In some, premedication may be omitted because of the critical nature of a child's illness or because a child is especially cooperative.

Informed Consent

The benefits and risks of the anesthetic procedure must be presented in clear, easily understood terms. At the same time, it is important not to present this information in a manner that unduly frightens the child or parents. The details of such a presentation will depend, in part, on the severity of the underlying medical and surgical conditions and how these affect anesthetic management and the planned procedure. Thus, risk can be presented in general terms, such as the following:

- "The risks of anesthesia depend on the health of the child. For example, if a child has a heart, lung, or kidney disorder, or so on, then the risk from anesthesia is increased. In your child's case, these are our concerns" (and then elaborate the particular patient's issues, such as reactive airway disease, apnea of prematurity, etc.). "Knowing these problems ahead of time makes it easier for us and reduces the anesthetic risk for your child because we can modify our anesthetic prescription according to your child's specific needs. However, there is always the possibility of allergic or unusual responses to anesthetic medications that we cannot predict even if your child has had anesthesia before, and that is why we shall carefully observe and monitor your child throughout the anesthetic as I have described."

We are designing the "anesthetic prescription" specifically for the particular needs of their child, and this notion should be described exactly this way to the parents. We are physicians and not technicians, and just as the pediatrician writes a prescription for antibiotics, anesthesiologists write the treatment prescription for anesthesia and administer it.

If a child is critically ill or has a disease process that is an immediate threat to his or her life, then this must be explained to the family. If a parent asks about the mortality risk, then all one can say is that the mortality related to anesthesia in most advanced countries is very small–less risky than crossing a busy thoroughfare on foot. Statistically, the incidence varies from one in several hundred thousand for healthy children undergoing routine procedures to a much greater rate for those who are critically ill. Nonetheless, the mortality for any specific child cannot be predicted with certainty. Recent concerns regarding possible anesthetic agent–induced neurotoxicity in young children (see Chapter 25) have been expressed by parents of young children during the preoperative visit. We should remind parents that the decision to proceed with anesthesia and surgery is a balance of the benefits and risks of both anesthesia and surgery and that the absence of substantive human data that anesthetics cause harm to young children combined with the sensitivity of our monitors to detect untoward events and our experience should allay their concerns.

Operating Room and Monitoring

For the anesthesiologist to successfully carry out a proposed anesthetic plan, the child's medical record must be examined for pertinent information before induction of anesthesia. For children who have already been assessed preoperatively, the record should be reviewed again for new information that may have been added since the initial evaluation. It is most important that the child's identification bracelet is checked, especially if the anesthetizing team is different from the preoperative evaluation team. A "time-out" and checklist for nurses, surgeon, and anesthesiologist to confirm the child's name, the planned surgical procedure, and the site of the surgical procedure (right or left side or bilateral); airway concerns; the need for prophylactic antibiotics; allergies and anaphylaxis; and availability of special equipment and large bore IV access are also reviewed. It is also important to confirm whether antibiotics were administered on the ward or in the ICU to avoid double-dosing of antibiotics. This review constitutes a vital safety net in the operating room (Fig. 1.1). All equipment for induction and maintenance of anesthesia, including suction and all necessary monitoring devices, must be checked by the anesthetic team and operational before induction of anesthesia (see Chapters 4 and 52).

Monitoring should be appropriate for the child's clinical condition and the surgical procedure. In every situation, basic monitoring is essential; to this are added special monitoring devices as they become necessary. The basic monitors are the anesthesiologist's eyes, ears, and hands, which confer the ability to observe a child's color and chest movements, to listen for heart tones and breath sounds, and to palpate the arterial pulse and temperature of the skin. A precordial or esophageal stethoscope is

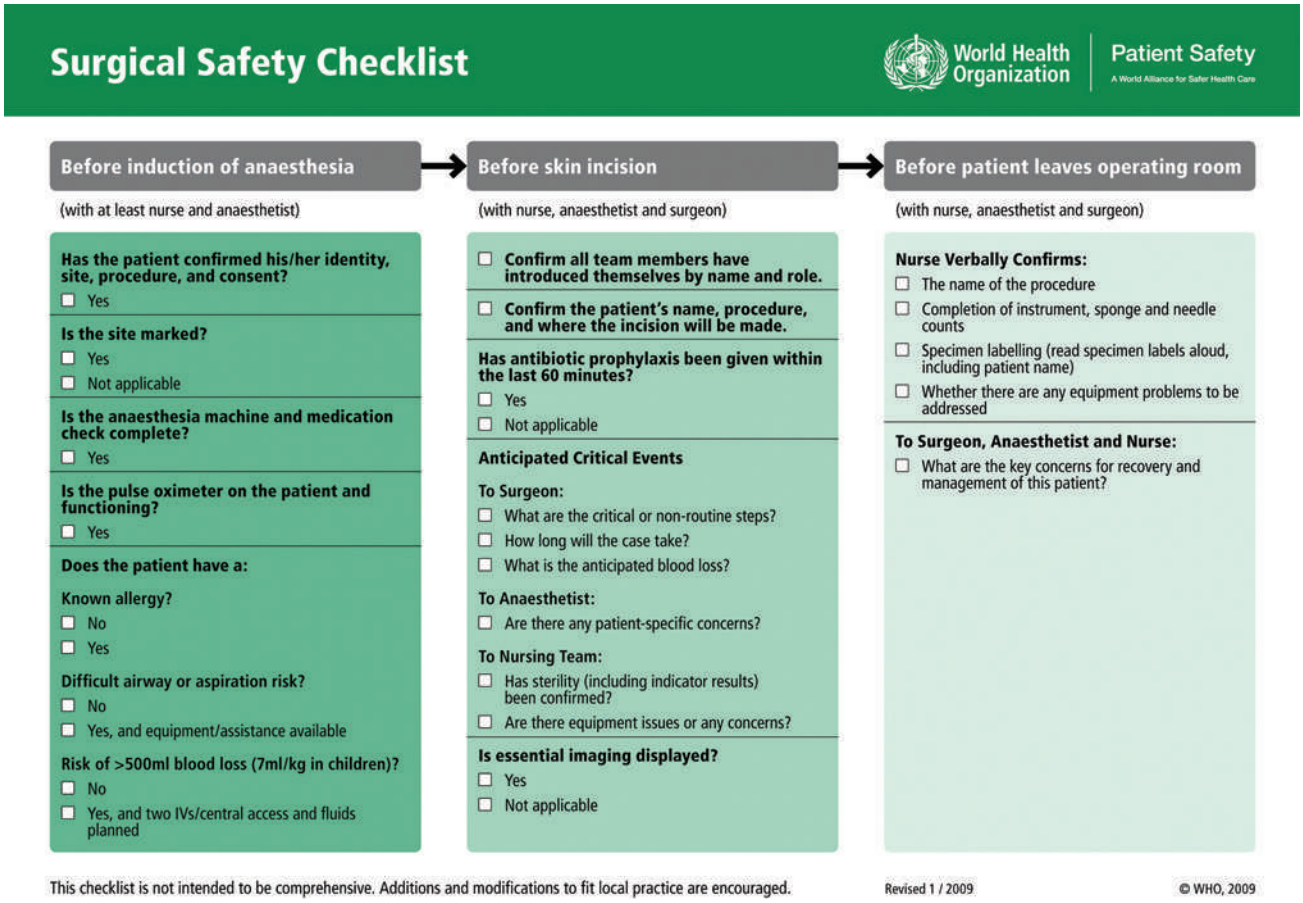

FIGURE 1.1 WHO Surgical Safety Checklist. (From World Health Organization, Geneva, 2009. Available from: http://www.who.int/patientsafety/safesurgery/en/.)

a very useful and simple device to monitor heart sounds and the quality of breath sounds, even when our attention is focused away from physiologic monitors. All children, except those undergoing the briefest noninvasive procedures, should have IV access to allow for fluid administration and to provide a route for rapid and predictable drug administration. If IV access is already in place, its patency should be checked preoperatively. The size of the catheter should be confirmed in case a larger cannula is required to administer large volumes of fluid or blood during surgery. If so, the new catheter should be placed after induction of anesthesia. A balanced salt solution is an appropriate fluid to infuse in most children undergoing elective surgery, although glucose-containing solutions may be preferred in specific circumstances (see Chapter 9). Continuous monitoring of the electrocardiogram, temperature, inspired oxygen concentration, oxygen saturation, expired carbon dioxide, and serial blood pressure determination are considered routine. Expired carbon dioxide monitors (especially those that display the waveform) and pulse oximetry are extremely important in the early detection of potential anesthetic-related events that, if undetected, could result in serious morbidity or mortality. Identifying the anesthetic agent and monitoring its concentration breath by breath is also helpful but not mandatory. The role of wakefulness-monitoring devices in children remains unestablished, especially in children younger than 2 years of age (see Chapters 7 and 52). Near-infrared spectroscopy is being used increasingly during cardiac surgery; it provides a useful monitor of cerebral (i.e., organ) oxygenation. The routine use of noninvasive continuous cardiac output monitors will likely provide the next generation of operating room monitoring (see Chapter 52), providing an early warning of evolving adverse hemodynamic events and the response to corrective measures (e.g., the administration of blood, crystalloid, vasopressor, vagolytic).

Invasive hemodynamic monitoring (e.g., direct arterial blood pressure, central venous pressure) may be required for major surgery if extensive blood loss or major fluid shifts are anticipated, or if a child is medically unstable. Urine output provides indirect data of the intravascular volume and organ perfusion in the presence of normal renal function. Monitoring urinary output is particularly useful for prolonged operations, for procedures involving major blood loss, when there is the potential for rapid or massive blood loss, when wide variations in blood pressure and fluid balance can be anticipated, or during induced hypotensive anesthesia. *In general, if a particular variable would be monitored in an adult, then the same approach should be adopted for a child.*

Invasive monitors are sometimes forsaken in a child because the pediatric anesthesiologist considers that the risk/benefit ratio does not justify their use. However, when the benefits outweigh the risks, these monitors provide an accurate estimate of blood pressure, cardiac output, filling pressures, and cardiac and pulmonary function. In turn, they provide a safe mechanism for

assessing the response to pharmacologic interventions, as well as the responses to administration of blood products, fluids, and vasoactive medications (see Chapter 52).

A cautionary note: As monitoring has become more sophisticated, anesthesiologists have become more distanced than ever from their patients. Relying totally on monitoring devices to detect clinical abnormalities is dangerous. *The focus must always be on the child and the surgical field. Electronic monitors may fail, and if the anesthesiologist focuses too much attention on the monitor in an effort to interpret it, rather than attending directly to the child, the child may suffer.* This is the reason a precordial stethoscope is so useful; strong heart sounds in the face of failed monitors provide some degree of assurance that the child is not in severe trouble. The tone of the pulse oximeter should be audible by everyone in the operating room to identify a decreasing oxygen saturation. *Silencing the monitor and its alarms for an extended period of time is a serious breach of safety and practice standards.* One of the editors is aware of a child for whom all monitor alarms and sounds were disabled during anesthesia who was discovered dead at the conclusion of the procedure after an unrecognized, unintended tracheal extubation. All monitors should be functioning and their alarms audible at all times during anesthesia of infants and children.

Induction and Maintenance of Anesthesia

Significant differences in the physiology, pharmacology, and development of a child mandate that the anesthesiologist not consider the child simply a small adult. In an infant, the rate of uptake of inhalation anesthetic agents is more rapid than in an adult. Similarly, protein binding, volume of distribution, and effect-site time constants for some drugs in infants may be less than in adults, resulting in more rapid responses to a given dose. Thus, if changes need to be made, the inspired concentration of an inhalation agent should be adjusted more gradually and the doses of medication diluted and titrated more carefully than in older children and adults (see Chapter 7).

In principle, the approach to an anesthetic procedure in a child is similar to that in an adult. However, in practice it is often advisable to modify the sequence of applying the monitors. In a relatively stable child, induction of anesthesia may proceed with only a pulse oximeter and possibly a precordial stethoscope; the remaining monitors are applied after induction. This sequence often avoids a prolonged preinduction phase during which a child may have more time to become anxious and distressed. In a struggling, upset child, some monitors may display accurate values before induction of anesthesia, whereas others may not. For example, the pulse oximeter may not provide reliable values in a struggling child until the finger or toe is motionless. In critically ill children, however, omitting some monitors to avoid upsetting them is imprudent, especially if it compromises the child's well-being during anesthesia. Thus, the management of the child during induction of anesthesia should be tailored to the child's behavior and illness severity.

Clinical Monitors

In children as in adults, monitoring begins with the basic observations of a child's general condition: the heart rate, blood pressure, respirations, and temperature. The most important aspect of basic monitoring consists of using the senses of sight, hearing, and touch to integrate all the data provided by patient observations and the monitors.

SIGHT

Observing a child's chest excursions (depth and symmetry), the color of the nail beds, oral mucosa, and capillary refill provides vital information regarding the adequacy of ventilation and perfusion. Observation of the surgical field provides an immediate indication of the extent of fluid shifts and blood loss, the color of the blood in the surgical field, evidence of muscle relaxation, depth of anesthesia, and various physiologic problems that may occur during the surgery (e.g., surgical retraction causing venous obstruction).

HEARING

Listening to the pitch of the pulse oximeter as well as the heart tones and breath sounds through a precordial or esophageal stethoscope provides instant and continuous feedback about oxygenation (pulse oximeter), heart rate and rhythm, an impression of the cardiac output (changes in intensity of heart sounds), and the adequacy of ventilation (wheezing, stridor, laryngeal spasm, no air exchange). This information is particularly helpful in diagnosing arrhythmias, hypovolemia, anesthetic overdose, and airway obstruction. It may also be helpful to listen to the sounds of surgery, such as the sudden change in the noise of the suction device with rapid blood loss or the surgeon's comments regarding technical difficulties with the procedure.

TOUCH

Intermittently examining a child—especially palpating peripheral pulses and the skin—provides information that may confirm the auditory input about heart rate, cardiac output, blood pressure, perfusion, and temperature.

Airway and Ventilation

The most important consideration in the safe practice of pediatric anesthesia is to ensure a patent airway. Airway obstruction occurs readily because of the unique characteristics of the infant and child airway (see Chapter 14). Thus, the anesthesiologist must be constantly vigilant of the airway to ensure that it remains patent at all times, particularly during mask anesthesia. In this case, the expired carbon dioxide tension may underestimate the true carbon dioxide tension because of a poor mask fit and/or air leaks combined with an obstructed airway. Airway obstruction may lead to hypoventilation, although the causes of hypoventilation may be central (opioids or inhalation agents) or peripheral (muscle relaxants) in origin. The capnogram is usually very accurate during mask anesthesia with a circle breathing circuit. Failure to detect an appropriate end-tidal carbon dioxide tension suggests inadequate ventilation, a mask leak, or reduced pulmonary blood flow, with the result that the child's condition may deteriorate from lack of an adequate airway or dilution of the anesthetic gas concentrations.

Although it is desirable to optimize ventilation by maintaining an arterial carbon dioxide pressure within the normal range (35 to 45 mm Hg), most healthy infants and children are not harmed by mild to moderate hypoventilation provided arterial oxygenation is maintained; however, severe overventilation has the capacity to reduce cerebral perfusion.

Constant monitoring of the inspired concentration of oxygen, the expired concentration of carbon dioxide, and the oxygen saturation is a valuable adjunct to the senses of sight, hearing, and touch. *Failure to ventilate adequately is probably the most important factor in the morbidity and mortality of children undergoing anesthesia.*

Fluids and Perfusion

Appropriate intraoperative fluid management is especially important in infants and children. Because of the relatively small blood volumes of infants and children, hypovolemia may develop rapidly after what may appear to be a trivial amount of blood loss. Fluid shifts may occur in infants because they fasted for a prolonged period. Replacement of lost blood and basic fluid administration must be carefully titrated (using rate-limiting devices) because overhydration readily occurs. The anesthesiologist should have a clear plan for the type and volume of fluid for perioperative administration. Preoperative calculation of maintenance, deficit, and potential third-space losses helps in formulating this fluid management plan, although for children older than 1 year of age, the fluid replacement strategy has been greatly simplified. A well-planned outline results in a rational and safe approach to both fluid maintenance and correction of fluid deficit and losses (see Chapters 9 and 12). The anesthesiologist should have immediate access to indwelling IV cannulae; line obstructions, loose connections, disconnections, or interstitial cannulae result in children not receiving the intended fluid therapy or medications or infusing them into the subcutaneous space, sometimes with disastrous consequences.

Conduct of the Anesthesia Team

The anesthesiologist must concentrate exclusively on the child and the monitors throughout the procedure. The child's safety is in his or her hands, and any inattention may place the child's life in jeopardy. Should members of the anesthesia team need to replace each other during the anesthetic, it is essential that the "baton of responsibility" be passed by communicating all of the relevant aspects of the child's health, as well as of the anesthetic and surgery that have occurred up to that time. All drugs on the anesthesia machine must be clearly labeled by name and dosage; the use of bar code scanners and automatic labeling devices with color coding are particularly useful. For infants, dilution of drugs or the use of tuberculin syringes may improve the safety of drug administration by limiting the amount of drug in each syringe and allowing more accurate dose administration, although a disproportionate amount of the small volumes of a drug–as in the case of undiluted drugs administered from a tuberculin syringe–may be trapped in the dead space of claves and/or stopcocks, resulting in an underdosing of the drug.

Ongoing communication between the anesthesiologist and surgeon is important if the anesthesiologist is to anticipate potential changes in a child's physiologic status resulting from surgical manipulations and deal with them immediately, appropriately, and effectively.

The conclusion of an anesthetic procedure is fraught with potential problems. The anesthesiologist should not be left alone in the operating room without a nurse or other physician, nor should he or she relax vigilance while a child is awakening and during transport to the recovery room or intensive care unit. It is during this stage that airway obstruction, desaturation, vomiting and aspiration, and emergence delirium are likely to occur.

Records of an anesthetic procedure must be accurate and complete; however, anesthesiologists must avoid the compulsion to complete these during the procedure if a child's condition warrants his or her full attention. The increasing availability of anesthesia information management systems (AIMS) provides an accurate history of physiologic parameters and frees the anesthesiologist to focus on the patient; however, filling in "required" check boxes can be a distraction, particularly at the conclusion of anesthesia.

The Postanesthesia Care Unit

In most jurisdictions, the department of anesthesiology is responsible for the postanesthesia care unit (PACU). Accordingly, the anesthesiologist's responsibility to a child continues into the PACU. Transport to the PACU must be carried out with appropriate monitoring, attention to a clear airway and adequate ventilation, oxygenation, and perfusion. If necessary, battery-powered infusion pumps should be used to maintain accurate infusions of vasoactive drugs. If needed, oxygen should be administered by face mask. Oxygen saturation may be monitored during transport; administering oxygen while monitoring pulse oximetry renders the oximeter a poor reflection of ventilation. Nevertheless, oxygen should be provided during transport to children who have not fully awakened. These children should be transported in the "tonsil position" or "recovery position" (lateral decubitus position) for two major reasons: (1) the dimensions of the upper airway are greater in this position than supine and (2) should vomiting occur, the regurgitant material will flow out of the mouth, away from the larynx and will be identified immediately. This position also allows head extension. The mask should be observed for condensation with each breath to assess the respiratory rate as well as gas movement with respiration.

On arrival in the PACU, a summary of the medical and surgical problems of the child, important intraoperative events–including the timing of antibiotics, analgesics, local anesthetics, or nerve blocks–and details of the anesthetic prescription are given to the PACU personnel. Appropriate social and family histories (marital status) should also be provided to the PACU staff (e.g., nervous parents, history of child abuse or neglect) to help ease social issues that may occur in PACU. The PACU must be equipped with age- and size-appropriate monitoring and resuscitation equipment. Vital signs (oxygen saturation, heart rate, blood pressure, respirations, temperature, and pain score) should be recorded on admission to the PACU and serially during the PACU stay (see Chapter 47). If appropriate, specific instructions should be given relating to oxygen requirements, ongoing fluid management, laboratory tests (e.g., hematocrit, blood gases, electrolytes, and coagulation profile) and radiographs. Once the anesthesiologist confirms that the child's vital signs are stable and has completed the information handover, it is important to take even a brief moment to meet with the parents to confirm that their child is recovering from the anesthetic without (if true) issues or difficulties. They would be interested in knowing how their child tolerated the anesthetic and what they might expect when they visit their child in the recovery room. If the child requires special attention (airway issues, hypotension, possible ongoing blood loss, obstructive sleep apnea, and so on) in the PACU, then the anesthesiologist should reassess the child personally while reassuring the parents before the child is discharged or make appropriate arrangements for postoperative monitoring.

Postoperative Visit

For children who had ambulatory surgery, it is helpful for a member from the anesthesia team to call the family at home on postoperative day one or two to determine their level of satisfaction and identify any complications that may have occurred. Children who were admitted to the hospital overnight should be visited before

discharge to assess the postanesthetic clinical course and discuss the child's reaction to the anesthetic. A note documenting the visit should also be included in the child's record. These visits help the public understand the role of anesthesiology in the operating room and beyond as a vital medical specialty.

Summary

This introductory chapter presents fundamental aspects for the safe practice of pediatric anesthesia. The chapters that follow elaborate on these principles with our collective experience used to guide the practicing anesthesiologists as well as those in training. Key principles for the safe practice of pediatric anesthesia are repeated throughout the book to emphasize their importance and are supplemented with a range of perspectives on clinical and controversial issues.

Interactions With the External World During Growth and Development

GROWTH IS A COMPLEX succession of phenomena that starts with the fusion of two cells and matures by 9 months into a complex organism known as a fetus. This phenomenally complex process not only produces a human being, it also traces the history of species with each and every fetus through embryology. Development is more than a simple increase in the number of cells; it includes interactions between the cells and interactions between the fetus and the environment, effects that are modulated by intracellular and intercellular signaling.[1]

It is incumbent upon the physician to understand the developmental changes that occur to the fetus and infant over time, and how these changes affect both responses to diseases and to drug pharmacokinetics and pharmacodynamics.

Normal and Abnormal Growth and Maturation

Growth is the quantitative increase in physical development of the body, whereas maturation is the genetic, biologic, and physical development of the child; both phenomena occur during pregnancy and continue after birth. Prenatal growth is the most important phase in development, comprising organogenesis in the first 8 weeks (embryonic growth), followed by the functional development of organ systems and maturation of the fetus (fetal growth). Rapid growth occurs particularly in the second trimester; a major increase in weight from subcutaneous tissue and muscle mass occurs in the third trimester. The duration of gestation and the weight of an infant are important correlates that vary with ethnicity, maternal environment, and pathology (Table 2.1).

By convention, the term *prematurity* has been applied to neonates who weigh less than 2500 g at birth. However, the designation *preterm neonate* may be more appropriate, defined as an infant born before 37 completed weeks of gestation. A *term or full-term neonate* is an infant born between 37 and 42 completed weeks of gestation. *A postterm neonate* is one born after 42 completed weeks of gestation.

Preterm neonates are further classified according to their actual birth weight. A low–birth-weight (LBW) neonate weighs less than 2500 g regardless of the duration of the pregnancy. A very low–birth-weight (VLBW) neonate weighs less than 1500 g, and an extremely low–birth-weight neonate weighs less than 1000 g. More recently, neonates that weigh less than 750 g at birth are referred to as "*micropremies*"; very limited information has been published regarding the anesthetic management of this vulnerable subpopulation of neonates (see Chapter 37). Common neonatal problems as they relate to age and birth weight are presented in Table 2.2.

After birth, physical growth continues at a rapid pace during the first 6 months of extrauterine life but slows by about 2 years of age. Physical growth accelerates a second time during the pubertal period. A simple way to remember how rapidly infants grow is that birth weight doubles by 6 months of age and triples by 1 year. Length doubles by 4 years of age. This scale, however, does not consistently affect all organs or organ functions. It is important to correctly and precisely assess the stage of development of the

TABLE 2.1 The Relationship of Gestational Age to Weight

Gestation (weeks)	Mean Weight (g)
28	1165 ± 109
32	1760 ± 128
36	2621 ± 274
40 (full term)	3351 ± 448

Moro reflex	Complete but exhaustible (>32 weeks)	Complete
Sucking reflex	Weak	Strong, synchronous with swallowing

child because any substantial deviations warrant an investigation of the cause. For example, height and weight are important metrics of maturity, although other factors may also impact maturity.[2] including those that cause excessive weight gain or prevent normal weight gain (Figs. 2.1 and 2.2).

Gestational Age Assessment

The gestational age of an infant may be assessed in one of three ways. The most accurate means of assessing gestational age is by measuring the crown-rump length of the fetus during a first-trimester ultrasonographic examination. A second method involves calculating gestational age from the first day of the mother's last menstrual period, but this is commonly inaccurate and can result in errors. Alternately, the Dubowitz scoring system is a well-accepted method that combines neurologic and physical criteria of the neonate to provide an accurate assessment of gestational age.[3,4] A summary of the significant neurologic and physical signs of maturity is presented in Table 2.3.

WEIGHT AND LENGTH

Growth is assessed by changes in weight, length, and head circumference. Percentile charts are valuable for monitoring the child's growth and development. Deviations in growth from the past percentile are more significant than any single measurement (Figs. 2.3 and 2.4). Weight is a more sensitive index of well-being,

TABLE 2.2 Common Neonatal Problems With Respect to Weight and Gestation

illness, or poor nutrition than length or head circumference and is the most commonly used measurement of growth. Changes in weight reflect changes in muscle mass, adipose tissue, skeleton, and body water; as a result, weight is a nonspecific metric of growth. Measurement of length provides the best indicator of skeletal growth because it is not affected by changes in adipose tissue or water content.

Term neonates may lose 5% to 10% of their body weight during the first 24 to 72 hours after birth from loss of body water. However, by 7 to 10 postnatal days, they have returned to their birth weight. An average daily increase of 30 g (210 g/week) is expected during the first 3 months after birth, after which an increase of 70 g each week is expected for the subsequent 10 to 12 months (Table 2.4).

When graphing the weight of a preterm neonate on a growth chart, it is common to use the neonate's corrected gestational age (postmenstrual age; postconception age is taken from conception and is approximately 2 weeks less) instead of his or her chronologic age (postnatal age [i.e., from birth]) during the first 2 years of the infant's life to correct for prematurity.

Weight and length are important metrics of growth, although other changes affect the composition of the body itself, especially the total body water, which decreases at the expense of the extracellular compartment during infancy. Adult proportions are achieved by approximately 1 year of age (see Fig. 7.8).[5,6] These changes in the distribution of water throughout the body have important implications for drug dosing and distribution in the neonate and infant. Males have a greater percentage of water, whereas females have a slightly greater percentage of fat. The percentage decrease in extracellular water is greater than the decrease in total body water because of the simultaneous increase in intracellular water (Table 2.5).[7]

TABLE 2.4 Approximate Relationship of Age to Weight

Age (years)	Weight (kg)
1	10
3	15
5	19
7	23

Corresponding equation for 18 months to 8 years of age is: Wt (kg) = 2 × Age (years) + 9.
For age >8 years: Wt (kg) = 3 × Age (years).

TABLE 2.5 Relationship of Age to Body Water

Age	Body Water (%)	Extracellular	Intracellular
Fetus	90	60	25
Preterm	80	55	30
Full-term	70	50	35
6-12 months	60	30	40

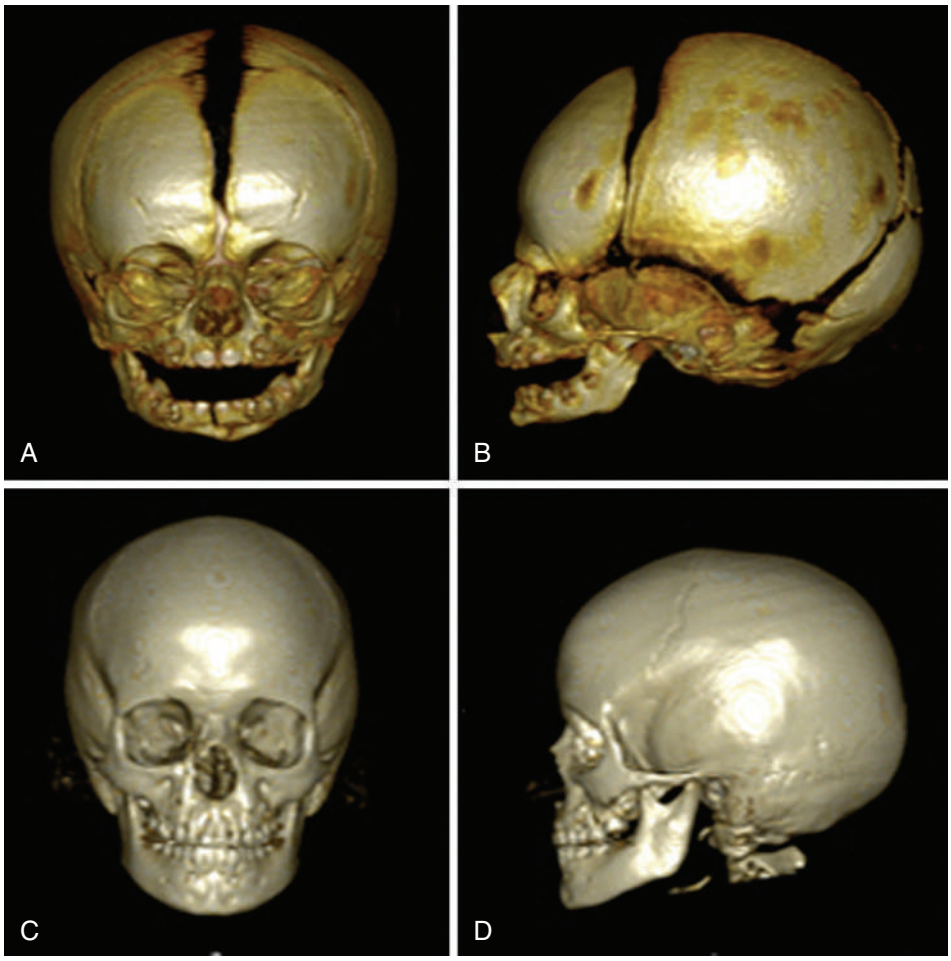

FIGURE 2.5 Cranial Development. **A** and **B** depict the skull of a neonate with wide-open suture. **C** and **D** depict the skull of a 7-year-old boy with fused sutures.

Another, more precise metric to assess development is to calculate the body surface area (BSA).[8] BSA can also be described using an allometric equation with an exponent of ⅔ (see Chapter 7):

$$BSA \propto weight^{2/3}$$

HEAD CIRCUMFERENCE

Head size reflects the growth of the brain and correlates with intracranial volume and brain weight. Changing head circumference reflects head growth and is a part of the total body growth process; it may or may not indicate underlying involvement of the brain. An abnormally large or small head may indicate abnormal brain development, which must alert the anesthesiologist to possible underlying neurologic problems. A large head may indicate a normal variation, familial feature, or pathologic condition (e.g., hydrocephalus or increased intracranial pressure), whereas a small head may indicate a normal variant, familial feature, or pathologic condition such as craniosynostosis or abnormal brain development.

During the first year of life, head circumference normally increases 10 cm, and in the second year increases 2.5 cm. By 9 months of age, head circumference reaches 50% of adult size, and by 2 years it is 75%. Head circumference is closely followed on standard percentile growth curves. As with weight, deviations in the growth of the head from its past percentile are more significant than a single measurement.

The anterior fontanel should be palpated to assess whether it is sunken (dehydration) or bulging abnormally (suggesting increased intracranial pressure as in hydrocephalus, infection, hemorrhage, or increased partial pressure of carbon dioxide in the arterial blood [$PaCO_2$]). If it is bulging, the sutures should be palpated for abnormal separation as a result of increased intracranial pressure. The anterior fontanel closes between 9 and 18 months of age; the posterior fontanel closes by 2 to 4 months of age (Fig. 2.5). Cranial molding occurs particularly in LBW neonates and is usually of no clinical importance.

FACE

Although the cranial vault increases rapidly in size, the face and base of the skull develop at a slower rate. At birth, the mandible is small; but as a child develops, forward growth occurs, reducing the obliquity of the mandibular angle. Failure of prenatal development of the mandible may be associated with severe congenital defects (e.g., Pierre Robin sequence, Treacher Collins, or Goldenhar syndromes). These syndromes often have other associated anomalies. After 2 years of age, the cranial vault increases only marginally in size, whereas the facial configuration undergoes substantive changes. The maxilla grows rapidly to accommodate the developing teeth. In addition, the frontal sinuses develop by 2 to 6 years of age, and the maxillary, ethmoidal, and sphenoidal sinuses appear after 6 years of age.

TEETH

The first tooth, usually a lower incisor, erupts at approximately 6 months after birth (deciduous dentition). Thereafter, one tooth usually erupts each month until all 20 primary deciduous teeth are present by 28 months of age. Preterm infants may show severe enamel hypoplasia in their primary dentition.[9,10]

Permanent teeth begin to appear by 6 years, with the shedding of the deciduous teeth; this process continues over the next 6 to 8 years. Some hereditary disorders such as Down syndrome, as well as others including cerebral palsy, medications (e.g., tetracycline), and nutritional defects can lead to abnormally developed teeth.

Airway and Respiratory System

Airway development includes a large number of structures, including the cranial vault and base, craniovertebral development, face, branchial apparatus, larynx, and oral cavity.

These structures are involved not only in the respiratory function (to provide enough oxygen and to remove carbon dioxide) but also in separating the circulation of air from the swallowing of liquid and food. A variety of processes, including ventilation, perfusion, and diffusion, are involved in fulfilling these functions. Specifically, the anesthesiologist has to consider these developmental changes because of their implications in airway management and ventilation.

UPPER AIRWAY DEVELOPMENT

During development, the upper airway of the infant undergoes major anatomic modifications that include changes in size, shape, and interrelationships; this is particularly prominent during the first few years of life.

The face and the nasal chamber, the oropharynx with the tongue, and the laryngotracheal lumen are the three main components of the upper airway. Development of the neurocranium leads to maturation of the cranial vault and skull base, whereas development of the viscerocranium leads to the skeletal portions of the face. The primordial areas involved in forming the covering of the tongue appear early in the second month of development.

The skull base grows rapidly until age 6 years, with relatively slower growth thereafter. The cranial base flexes postnatally in a rapid growth trajectory that is complete by 2 years of age.

The depth of the nasopharynx increases as a result of remodeling of the palate as well as changes in the angulation of the skull base. During childhood, the soft tissues of the pharyngeal structures surrounding the upper airway increase proportionally to the skeletal structures. After birth, the dimensions of the nasal cavity increase very rapidly. During the first year of life, the total minimal cross-sectional area increases by 67% and the volume of the anterior 4 cm of the nasal airways by 36%.[11,12]

The volume of the oral cavity in the neonate is proportionally less than that in the adult, primarily because of the shorter mandibular ramus. The volume of the oral cavity greatly increases during the first 12 months because of rapid growth in the height of the mandibular ramus.

In the neonate, the tongue contains considerably less fat and soft tissue compared with that in the adult, but it is large relative to the dimensions of the mouth, with relatively larger extrinsic musculature and a less developed superior longitudinal muscle, resulting in a flat dorsal surface with poor lateral mobility (see also Chapter 14).

The larynx is developed embryologically from ectodermal, endodermal, and mesodermal tissues that are derived from the third, fourth, and sixth branchial arch and pouch apparatus. The development of the larynx and airway in the neonate is outlined in detail in Chapter 14. The laryngeal opening (epiglottis and vocal cords) in a neonate and 2-year-old boy are shown in Fig. 2.6. Note the long, omega-shaped epiglottis and the pearly white vocal cords in the neonate.

RESPIRATORY SYSTEM DEVELOPMENT

The development of the respiratory system begins during week 4 of gestation. Three "laws" that describe the temporal development of the airways, alveoli, and pulmonary vessels govern normal lung growth.

Airways: The bronchial tree down to and including the terminal bronchioles forms by week 16 of gestation. The acinus, consisting of all the airway structures distal to the terminal bronchiole and the entire gas-exchanging apparatus, develops throughout the remainder of gestation.

Alveoli: Alveoli develop mainly after birth, increasing in number until approximately 8 years of life and in size until growth of the chest wall ceases.

Pulmonary vessels: Arteries and veins accompanying the bronchial tree form by week 16 of gestation. Those vessels lying within the acinus follow the development of the alveoli. Both the appearance and growth of arterial smooth muscle lag behind the sprouting of new vessels and are not completed until late adolescence.

TRANSITION TO AIR BREATHING

Fetal breathing movements have been detected as early as 11 weeks of gestational age; they are interspersed with long periods of apnea and produce little tidal movement of lung fluid.[13,14] The critical event in the change from placental to pulmonary gas exchange is the first inspiration, which initiates pulmonary ventilation, promotes the clearance of lung fluid, and triggers the change from the fetal to the neonatal pattern of circulation.

The first breath is a gasp that generates a transpulmonary distending pressure of 40 to 80 cm H_2O.[15] This moves the tracheal fluid (100 times more viscous than air), overcomes surface forces that develop as the air–fluid interface reaches the small airways, and overcomes tissue resistance. In some neonates, the removal of lung fluid may be delayed, producing the syndrome called *transient tachypnea of the newborn*.[16,17] Tachypnea lasts for 24 to 72 hours and is associated with a characteristic chest radiographic appearance consisting of increased perihilar markings, fluid in the interlobar fissures, and streaky linear opacities in the parenchyma.

With the onset of pulmonary ventilation, pulmonary blood flow sharply increases. Decreased pulmonary vascular resistance (PVR) and increased peripheral systemic vascular resistance (loss of the umbilical circulation) are the two crucial events involved in the immediate transition from the fetal circulation to the normal postnatal pattern. The increase in systemic afterload causes an immediate closure of the flap valve mechanism of the foramen ovale and reverses the direction of shunt through the ductus arteriosus. Until these fetal shunt pathways close anatomically, the pattern of circulation is unstable. Increased pulmonary vascular reactivity in response to hypoxia and acidosis may precipitate a reversal to right-to-left shunting ("flip-flop" circulation) (see also Chapter 18).

In the first few minutes after birth, a state of "normal" asphyxia exists as a result of the impaired placental blood flow during

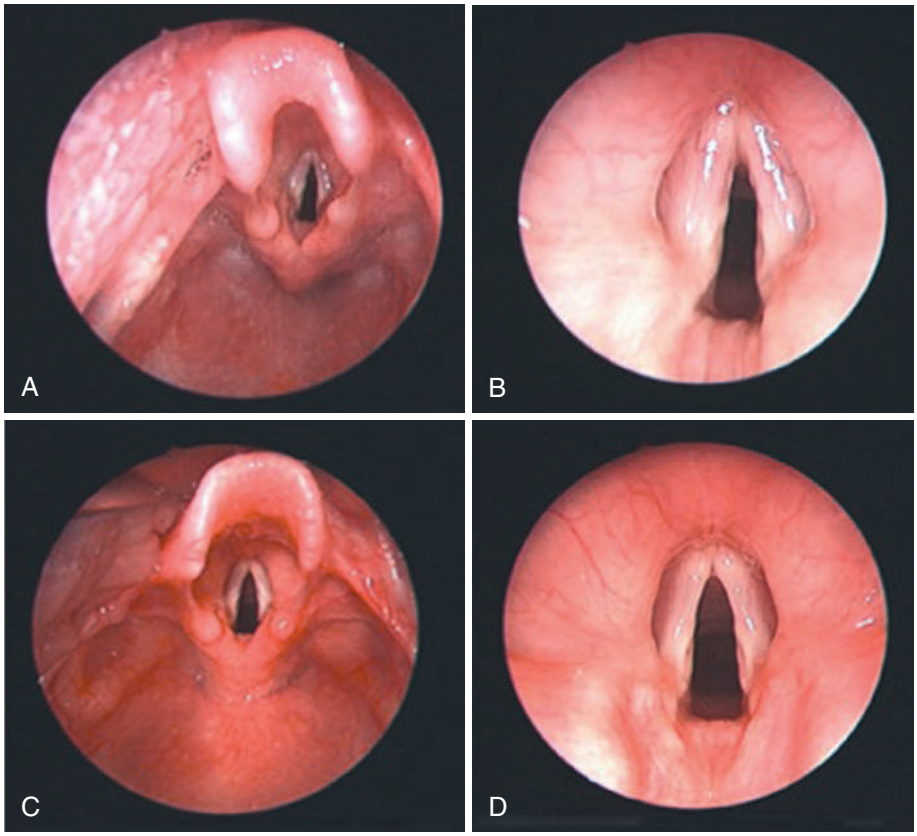

FIGURE 2.6 Larynx Development From Neonate to 2 Years Old. The larynx in the neonate (**A** and **B**), with the long epiglottis (**A**) and the vocal cords (**B**, close-up). The larynx in a 2-year-old (**C** and **D**) with a shorter epiglottis (**C**) and the vocal cords (**D**, close-up).

labor. The partial pressure of oxygen in arterial blood (PaO_2) and pH are reduced, whereas the $PaCO_2$ is increased immediately after birth, but these partial pressures change rapidly in the first hours after birth. Extrapulmonary shunting through fetal channels and intrapulmonary shunting, probably through unexpanded regions of the lung, persist for some time after birth, so that in neonates the physiologic right-to-left shunt is about three times that in adults.[18]

MECHANICS OF BREATHING

Chest Wall and Respiratory Muscles

The accessory muscles of inspiration are relatively ineffective in infants because of an unfavorable configuration of the rib cage. In infancy, the ribs extend horizontally from the vertebral column, moving little with inspiration.[19] Hence, the cross-sectional area of the thoracic cage remains fairly constant throughout the breathing cycle. In fact, inspiration depends almost exclusively on the descent of the diaphragm. These factors increase the workload on the diaphragm, rendering it at risk for fatigue, particularly in the preterm infant.

The chest wall of a neonate is floppy because it consists of noncalcified cartilage, its musculature is poorly developed, and the ribs are incompletely calcified.[20,21] As the work of breathing increases, diaphragmatic displacement must also increase to overcome these deficiencies and maintain the tidal volume. The increased workload may lead to diaphragmatic fatigue and respiratory failure or apnea, especially in preterm infants.[22,23]

Muscle strength depends on the presence of an adequate number of type I (slow twitch, high oxidative capacity) muscle fibers to respond to an increased workload. The diaphragm of the neonate and more critically, the preterm infant, has limited number type I (slow twitch, high oxidative capacity) muscle fibers (see Fig. 14.11). This compounds the risk for respiratory failure in the developing infant.

Elastic Properties of the Lung

Changes in the static pressure–volume relationship of the lungs during growth are caused by increases in volume and changes in the elastic properties of lung tissue. Volume is the principal factor that determines lung compliance, which increases throughout childhood. Specific lung compliance remains relatively constant throughout childhood.[24,25] In contrast, specific compliance of the chest wall declines throughout childhood and adolescence, reflecting the progressive calcification of the ribs and the increasing bulk of the thoracic muscles.

Static Lung Volumes

A detailed description of static lung volumes based on body weight is presented in Table 2.6.

Total Lung Capacity

Adults have a much greater total lung capacity (TLC) than infants (Fig. 2.7). This difference reflects the fact that TLC is an effort-dependent variable, dependent on the strength and efficiency of

TABLE 2.6 Age-Dependent Respiratory Variables

	Newborn	6 months	12 months	3 years	5 years	12 years	Adult
F (breaths/minute)	50 ± 1	30 ± 5	24 ± 6	24 ± 6	23 ± 5	18 ± 5	12 ± 3

(mL/kg)	63						82
pH	7.3–7.4		7.35–7.45				7.35–7.45
Pa_{O_2} (mm Hg)	60–90		80–100				80–100
Pa_{CO_2} (mm Hg)	30–35		30–40				37–42

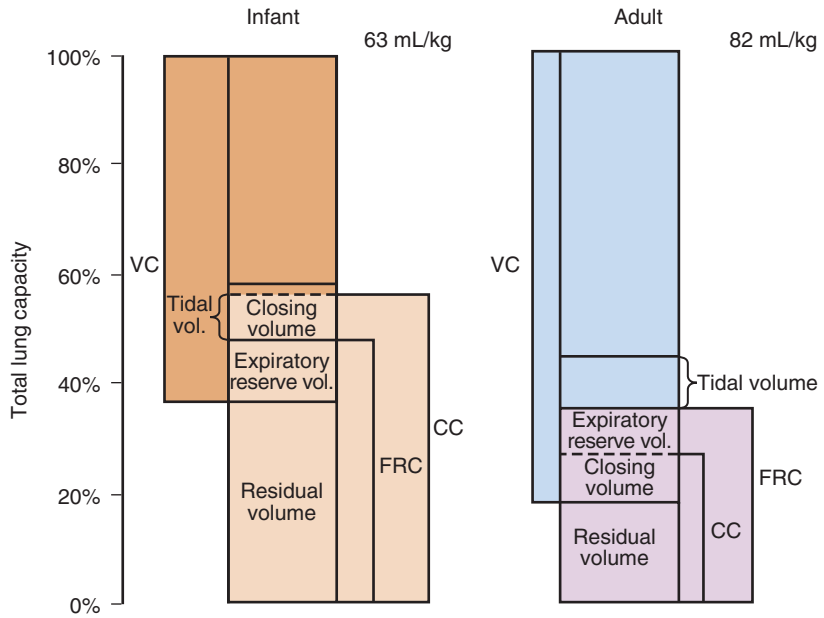

FIGURE 2.7 Lung Volumes in Infants and Adults. Note that in infants, tidal volume breathing occurs at the same volume as closing volume. *CC,* Closing capacity; *FRC,* functional residual capacity; *VC,* vital capacity. (Modified from Nelson NM. Respiration and circulation after birth. In: Smith CA, Nelson NM, eds. *The Physiology of the Newborn Infant.* Springfield, IL: Charles C Thomas; 1976; 207.)

the inspiratory muscles, which can be estimated by the maximum inspiratory pressure at functional residual capacity (FRC). An adult can generate negative pressures in excess of 100 cm H_2O; a neonate can generate pressures as great as 70 cm H_2O, a surprisingly large value considering the weaknesses cited above. This has been attributed to the small radius of curvature of the infant's rib cage, which by the Laplace relationship converts a small tension into a large pressure gradient.[26]

Functional Residual Capacity

FRC normalized to weight (per kilogram) is constant throughout development, although the mechanical factors on which it is based differ in infants and adults.[27] FRC is the volume of gas within the lungs at end of expiration, when the outward forces of the chest wall are balanced against the inward, elastic recoil of the lungs (Fig. 2.8). In the supine neonate, FRC is small, in part because the weak outward forces of the compliant chest wall are

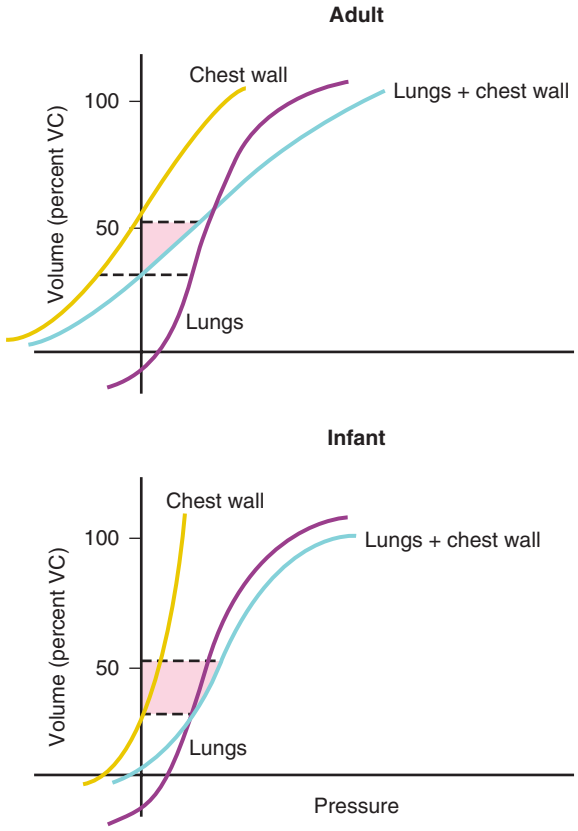

FIGURE 2.8 Compliance curves for the chest wall (yellow), lungs (purple), and thorax (combination of chest wall and lungs [blue]) in infants and adults. (Modified and reproduced with permission from Pérez Fontán JJ, Haddad GG. Respiratory physiology. In: Behrman RE, Kliegman RM, Jenson HB, eds. *Nelson Textbook of Pediatrics*. 17th ed. Philadelphia: WB Saunders; 2003:1363.)

more than offset by the elastic recoil of the lungs. In addition, the large abdomen pushes the diaphragm upward. The neonate may increase the FRC by exhaling against a closed glottis.

An important clinical implication of the dynamic control of FRC is that an apneic infant has a disproportionately smaller reserve of intrapulmonary oxygen on which to draw than a similarly affected adult. This, combined with their increased metabolic rate, contributes to the rapid development of hypoxemia if the airway becomes compromised in the anesthetized infant.

Closing Capacity

As exhalation proceeds to completion, small airways in dependent regions of the lung close, leading to air trapping in the affected areas. Closing capacity is closely related to age, decreasing throughout childhood and adolescence and increasing thereafter throughout adult life (see Fig. 2.7). This pattern of change has been related to the development and deterioration of lung elastic tissue and its effect on recoil pressure. The latter is the principal determinant of transmural pressure and therefore patency of the smallest airways, which lack intrinsic stability because they contain no cartilage.

Closing volume is within the range of tidal breathing in many older adults and some children younger than 10 years (see Fig. 2.7). It is not possible to measure closing volume in children younger than 5 years, but because the elastic recoil pressure is small in infancy (see Fig. 2.8), some airways likely remain closed throughout tidal breathing. This notion is supported by the finding that infants have a large "trapped gas volume" that is not in free communication with the conducting airways. Age-related changes in PaO_2, which parallel the changes in the difference between FRC and closing volume, may also be related to airway closure.[28]

AIRWAY DYNAMICS

Resistance and Conductance

Airway resistance decreases markedly with growth from 19 to 28 cm H_2O/L per second in neonates to less than 2 cm H_2O/L per second in adults.[27,28] Airway resistance is greater in preterm than in full-term infants. On the other hand, specific airway conductance (reciprocal of resistance) is greater in preterm infants but decreases steadily during the first 5 years of life.[29,30]

Distribution of Resistance

The distribution of airway resistance changes markedly at approximately 5 years of age. Airway resistance per gram of lung tissue is constant at all ages in the "central airways" (trachea to the twelfth to fifteenth bronchial generation), whereas it decreases markedly at approximately 5 years of age in the "peripheral airways" (i.e., distal to the twelfth to fifteenth generation to the alveoli).

Inspiratory and Expiratory Flow Limitation

Tracheal compliance in neonates is twice that of adults; it is even greater in preterm infants and appears to be a consequence of cartilaginous immaturity. The functional importance of this finding is that dynamic collapse of the trachea may occur with inspiration and expiration (see Fig. 14.10).

Regulation of Breathing

In neonates as in adults, PaO_2, $PaCO_2$, and pH control ventilation, with PaO_2 acting mainly through peripheral chemoreceptors in the carotid and aortic bodies and $PaCO_2$ and pH acting on central chemoreceptors in the medulla. In contrast to the adult, an infant's response to hypercapnia is not potentiated by hypoxia, but the latter may actually depress the hypercapnic ventilatory response in term and preterm infants.[31,32]

High concentrations of oxygen depress respiration in the neonate, whereas low concentrations stimulate it. The hypoxic response, however, is not consistent. Initially, hypoxia restores respiration to baseline but thereafter it depresses it. This pattern of response persists in normal term infants throughout the first week of life but may persist longer in preterm neonates. After this initial period, the response to persistent hypoxia gradually transitions to the adult response, which is a sustained increase in ventilation.[33,34]

Periodic breathing commonly occurs in neonates. This should be distinguished from clinical apnea, which occurs in as many as 25% of all preterm infants, especially in the most severely preterm infant. Apnea of prematurity may be a life-threatening condition. In this situation, the apneas may be prolonged and associated with desaturation of arterial oxygen, bradycardia, and loss of muscle tone. The frequency of these apneas increases in the presence of other organ pathology such as intraventricular hemorrhage.

Prematurity is an important risk factor for life-threatening apnea in neonates and infants undergoing general anesthesia.[35] The risk of postanesthetic respiratory depression is inversely related to gestational age and postconception age at the time of anesthesia (Fig. 4.7 and E-Fig. 4.5).[36] There is a general consensus that infants may be at risk for postoperative apnea up to 60 weeks after conception.[36,37]

The reduced PaO_2 of neonates is compensated by a greater oxygen-carrying capacity as a result of increased hemoglobin concentrations, which decline during the first several weeks of life. At birth, the hemoglobin (Hb) content of the blood is 50% fetal hemoglobin. The position of the oxyhemoglobin dissociation curve depends on the ratio of adult to fetal hemoglobin. At birth, the increased fetal hemoglobin content shifts the curve to the left of the adult curve (from a P_{50} of 27 for Hb A to a P_{50} of 19 for Hb F). During the first week after birth, the curve shifts to the right, reflecting the transition from fetal to adult hemoglobin formation.[24] Normal $PaCO_2$ and pH are somewhat reduced in the neonatal period compared with later infancy (see Table 2.6).

Cardiovascular System

An understanding of cardiovascular development is important for anesthesiologists. This section briefly considers developmental changes in heart rate, blood pressure, cardiac output, and the electrocardiogram; more detailed descriptions are found in Chapters 16 and 18.

HEART RATE

Autonomic control of the heart in utero is mediated predominantly through the parasympathetic nervous system. It is only shortly after birth that sympathetic control begins to appear, although the parasympathetic nervous system continues to dominate in childhood, waning only as adolescence is reached. In neonates, the heart rate may have a wide variation that is within normal limits. The mean heart rate in neonates in the first 24 hours of life is 120 beats per minute. It increases to a mean of 160 beats per minute at 1 month, after which it gradually decreases to 75 beats per minute at adolescence (Table 2.7).[38]

In older children, a significant number of arrhythmias and conduction abnormalities are also encountered, with marked fluctuations in heart rate caused by variations in autonomic tone.

BLOOD PRESSURE

Mean systolic blood pressure in neonates and infants increases from 65 mm Hg in the first 12 hours of life to 75 mm Hg at 4 days and 95 mm Hg at 6 weeks. There is little change in mean systolic pressure between 6 weeks and 1 year of age and even between 1 year and 6 years; thereafter, systolic pressure gradually increases with age.[39,40] These measurements apply to infants and children who are awake and calm. The blood pressure in preterm infants in the first 12 hours is less than that in full-term infants; a gradual increase in blood pressure occurs after birth—68/43 mm Hg on day 1 of life compared with 90/55 mm Hg on day 90 of life (Table 2.8).[41,42] Blood pressure measured in the lower extremity is less than in the upper extremity in children.[43] It has also been noted that infants with birth asphyxia and those who require mechanical ventilation have reduced blood pressures.

Blood pressure in adolescents and adults who were born premature is greater than in those who were born full-term. However, with the slower fetal growth in preterm neonates, LBW was not identified as an independent predictor of this greater blood pressure later in life.[44]

CARDIAC OUTPUT

Determination of cardiac output and blood pressure allows calculation of systemic vascular resistance. It provides important information relating to the left ventricular afterload and allows rational application of vasoactive (e.g., vasoconstrictor, vasodilator) and inotropic drugs. Measurement of cardiac output may be carried out by the Fick method (using oxygen extraction) or thermodilution using a pulmonary artery flow-directed catheter. In neonates, the latter technique is rarely used because shunts at the atrial and ductal levels introduce errors when interpreting the results.

Pulsed Doppler determinations of cardiac output provide reasonable noninvasive estimates of cardiac output for clinical application in neonates. Cardiac output, normalized for body weight, in neonates between 780 and 4740 g at birth, remains fairly constant, changing only 10% over this weight range.[45] The range of cardiac output in both full-term and preterm neonates is 220 to 350 mL/kg per minute, two- to threefold greater than in adults.[45,46] Between birth and the end of the first year, mean cardiac output (normalized for body weight or surface area) remains fairly constant at 204 ± 45 mL/kg per minute.[47] The relatively large cardiac output (in milliliters per minute per kilogram) in neonates reflects their greater metabolic rate (on a weight basis) and oxygen consumption compared with adults. Basal metabolic rate has been shown to increase as size decreases in all species[48] (see Chapter 7).

Pulsed Doppler estimation of cardiac output has also been found useful in assessing left ventricular myocardial dysfunction in neonates after perinatal asphyxia and acidosis, as well as its response to therapy.[49,50] In older children, measurements of cardiac

TABLE 2.7 The Relationship Between Age and Heart Rate[a]

Age	Mean Heart Rate in Beats per Minute (range)
Premature	120–170
0–3 months	100–150
3–6 months	90–120
6–12 months	80–120
1–3 years	70–110
3–6 years	65–110
6–12 years	60–95
>12 years	55–85

1–3 years	90–105	55–70
3–6 years	95–110	60–75
6–12 years	100–120	60–75
>12 years	110–135	65–85

Data from Hartman ME, Cheifetz IM. Pediatric emergencies and resuscitation. In: Kliegman RM, Stanton ST BF, Geme III JW, Schor NF, Behrman RE, eds. *Nelson Textbook of Pediatrics*. 19th ed. Philadelphia: Elsevier; 2011:280.
[a]Note that the blood pressure will be lower during sleep or during anesthesia.

output are necessary in circulatory shock.[51] New noninvasive techniques using changes in impedance hold promise for the future (see Chapter 52; Figs. 52.9 and 52.10).

NORMAL ELECTROCARDIOGRAPHIC FINDINGS

The P wave reflects atrial depolarization and varies little with age. The PR interval increases with age (mean value for the first year is 0.10 sec, increasing to 0.14 sec at 12 to 16 years).[52] The duration of the QRS complex increases with age, but prolongation greater than 0.10 sec is abnormal at any age.

At birth, the QRS axis is right sided, reflecting the predominant right ventricular intrauterine development. It shifts leftward in the first month as left ventricular muscle hypertrophies. Thereafter, the QRS follows a gradual change toward a left-sided axis.

In addition, T waves are upright in all chest leads. Within hours, they become isoelectric or inverted over the left chest; by the seventh day, the T waves are inverted in V_4R (V_4 position under the right clavicle), V_1, and across to V_4. From then on, the T waves remain inverted over the right chest until adolescence, when they become upright over the right side of the chest again. Failure of T waves to become inverted in V_4R and V_1 to V_4 by 7 days may be the earliest electrocardiographic evidence of right ventricular hypertrophy (see also Chapter 16).[53,54]

Renal System

The complex development of the human kidney begins in week 4 of gestation and continues into adulthood. Serious renal malfunction is usually associated with growth retardation.

Urine production begins in utero at 10 to 12 weeks of gestation and is excreted into the amniotic cavity, helping to maintain amniotic fluid volume. The fetus maintains its metabolic homeostasis through the placenta. It is only after birth that the kidney assumes this responsibility. More than 90% of neonates will have voided urine within the first 24 hours after birth. All normal neonates should void by 48 hours after birth; otherwise, they should be investigated for anomalies including posterior urethral valves.[55]

Tubular function begins to develop after 34 weeks of gestation and reaches adult levels by 2 years of age.[56] The number and function of the Na^+/K^+-ATPase transporters are reduced at birth, although their activity increases 5- to 10-fold in the postnatal period. All transporters that rely on the Na^+ gradient are also reduced in function. The renal tubular threshold for resorption of Na^+, glucose, and bicarbonate are decreased in the neonatal period; hence, they are at increased risk for hyponatremia, osmotic polyuria, and metabolic acidosis, respectively.

Nephrogenesis is complete by 36 weeks of gestation. Renal blood flow and glomerular filtration rate (GFR) are reduced and correlate with gestational age. GFR is 20% to 25% of adult rates at term. They increase rapidly in the postnatal period as the result of an increase in cardiac output and a decrease in renal vascular resistance. Adult rates are achieved by approximately 2 years of age[57] (see Fig. 7.12). A reduced GFR significantly affects the ability of the neonate to excrete saline and water loads, as well as drugs. At birth, the serum creatinine concentration reflects the maternal concentration, but this value decreases during the first days after birth. As a result of the rapid growth and increase in muscular mass, normal serum creatinine values increase with age and are greater in males. Creatinine clearance slowly increases in neonates, reaching adult values between 2 and 3 years of age.

In utero, the fetus maintains a mild respiratory acidosis, with a similar plasma bicarbonate concentration, but a greater $PaCO_2$ than its mother. After birth, plasma bicarbonate concentration and $PaCO_2$ are reduced in neonates and infants compared with older children and adults. In addition, the basal acid production in neonates is comparatively greater than in adults and they are less able to respond to an acid load. Endogenous acid production in small children is between 50% and 100% greater per kilogram than adults. This is primarily due to the deposition of Ca^{2+} in bone, a process that produces 0.5 to 1 mEq/ L of acid per day. Bicarbonate absorption from the gastrointestinal tract is an important source of base to neutralize this nonvolatile acid, and in part, explains the tendency of infants to become profoundly acidotic when suffering from gastroenteritis. The neonate or infant is living near its limit of acid compensation and is therefore prone to develop acidosis during the course of an acute illness or starvation.

Neonates and preterm infants are obligate salt losers; they cannot excrete a large salt load or concentrate urine effectively. Immaturity of distal tubular function and relative hypoaldosteronism explain why preterm infants are at increased risk for hyperkalemia.[58]

Digestive and Endocrine System

HEPATIC SYSTEM

Development of the liver and bile ducts begins as an outgrowth of the foregut; by 10 weeks of gestation, the biliary tract has completed its development. The vitelline veins give rise to the portal and hepatic veins. Hepatic sinusoids form the ductus venosus, the bridge between the hepatic vein and the inferior vena cava. Most umbilical venous blood from the placenta passes through the ductus venosus to the inferior vena cava. The remainder passes via the portal vein through the liver to the hepatic veins. The portal venous drainage to the left lobe is less than to the right lobe, leading to a relative underdevelopment of the left lobe. The ductus venosus closes soon after birth.[59]

At 12 weeks of gestation there is evidence of gluconeogenesis and protein synthesis; at 14 weeks, glycogen is found in liver cells. Although by late gestation liver cell morphology is similar to that of adults, the functional development of the liver is immature in neonates and more so in preterm infants. The liver has a major role in metabolism, controlling carbohydrate, protein, and lipid delivery to the tissues. Toward the end of pregnancy, large amounts of glycogen appear in the liver, and, as a result, preterm and small-for-gestational-age (SGA) infants accrue smaller stores of glycogen and are prone to develop hypoglycemia. Bile acid secretion in neonates is reduced, and malabsorption of fat occurs.

The liver is the site for the synthesis of proteins; this process is active in fetal and neonatal life. In fetal life, the main serum protein is alpha-fetoprotein. This protein first appears at 6 weeks of gestation and reaches a peak at 13 weeks. Albumin synthesis starts at 3 to 4 months of gestation and approaches adult values by birth; in preterm infants, the level is reduced. Proteins involved in clotting are also formed in the liver, but their concentrations in preterm and full-term neonates are less than normal for the first few days after birth. Hematopoiesis occurs in the fetal liver, with peak activity at 7 months of gestation. After 6 weeks of age, hematopoiesis is confined to the bone marrow except under pathologic conditions, such as hemolytic anemia (see Chapter 30).

The capacity to enzymatically break down proteins is reduced at birth but matures rapidly throughout the first year, reaching

TABLE 2.9 Causes of Jaundice in Neonates

adult levels by adolescence. This is particularly important in preterm infants, in whom the intake of a large protein load can result in dangerously high levels of serum amino acid concentrations and the subsequent development of a metabolic acidosis. In addition to less effective hepatic metabolism, altered drug binding by serum proteins and immature renal function contribute to the disposition of proteins (see also Chapter 7).

Physiologic Jaundice

Hyperbilirubinemia (defined as a total serum bilirubin level >5 mg/dL) is a particularly important problem in neonates. About 60% of term and 80% of preterm neonates develop jaundice in the first week of life, with a total bilirubin concentration exceeding 5 mg/dL.[60] Several mechanisms account for the jaundice (Table 2.9).[61,62] In term neonates, the normal total bilirubin concentration is usually less than 5 mg/dL (86 µmol/L) and is rarely greater than 12 mg/dL without a risk factor, peaking on the third to fourth postnatal day. In preterm infants, the bilirubin concentration peaks at 10 to 12 mg/dL on the fifth to seventh postnatal day. After this period, the concentration gradually decreases, reaching adult values (<2 mg/dL) by 1 to 2 months in both term and preterm infants. The concentration of indirect bilirubin is also increased in the first few days after birth. The cause of nonhemolytic physiologic hyperbilirubinemia is excessive bilirubin production from breakdown of red blood cells and increased enterohepatic circulation of bilirubin with deficient hepatic conjugation as a result of decreased uridine 5-diphospho-glucuronyl transferase activity (*UGT1A1*, see Chapters 7 and 30). The relationship between breastfeeding and hyperbilirubinemia has been well documented. It is usually delayed in onset (after the third postnatal day), its cause remains unclear, and it occurs in about 1% of breastfeeding infants. An earlier hypothesis ascribing it to inhibition of UGT activity by 3α, 20β-pregnanediol activity has not been substantiated. In addition, genetic variants may affect bilirubin metabolism.[63,64]

Important pathologic causes of jaundice in neonates are presented in Table 2.10. The relative rarity of cholestasis is in sharp contrast with the very common finding of jaundice during the first weeks of life, and therefore, a false diagnosis of physiologic or breast milk jaundice is easily made. Symptoms indicative of cholestasis such as dark urine and pale stools are often unrecognized.[65]

Once the distinction between physiologic and hemolytic hyperbilirubinemia has been made, the underlying cause can then be treated and efforts can be directed at preventing bilirubin induced encephalopathy (kernicterus) by the use of phototherapy and, in selected cases, exchange transfusions. Phototherapy reduces serum bilirubin concentrations by converting bilirubin through structural photoisomerization and photooxidation into excretable products.[66] There are risks and consequences to phototherapy, particularly in VLBW infants.[67] However, phototherapy is not associated with the development of benign or malignant melanocyte lesions.[68]

Sick preterm infants are especially at risk for kernicterus and are more aggressively treated at reduced bilirubin concentrations than full-term infants. Increasingly common is a form of cholestatic jaundice in LBW infants receiving hyperalimentation for prolonged periods. The mechanism of the jaundice is unclear, although it has been attributed to the inhibition of bile flow by amino acids.[69] Promising therapies for hyperbilirubinemia in LBW infants may include the use of tin-mesoporphyrin, which inhibits the production of bilirubin.[70]

GASTROINTESTINAL TRACT

In an embryo, the digestive tract consists of the developing foregut and hindgut. These rapidly elongate so that a loop of gut is forced into the yolk sac. At 5 to 7 weeks, this loop twists around the axis of the superior mesenteric artery and returns to the abdominal cavity. Maturation occurs gradually from the proximal to the distal end. Blood vessels and nerves (Auerbach and Meissner plexuses) are developed by 13 weeks of gestation and peristalsis begins. The pancreas arises from two outgrowths of the foregut; a diverticulum of the foregut gives rise to the liver.

Enzyme levels of enterokinase and lipase increase with gestational age but are reduced at birth compared with older children. Full-term neonates and preterm neonates handle protein loads reasonably well, although preterm neonates may have difficulty with large loads. Fat digestion is limited, particularly in preterm neonates, who absorb only 65% of adult levels. Neonatal duodenal motility undergoes marked maturational changes between 29 and 32 weeks of gestation. This is one factor limiting tolerance of enteral feeding before 29 to 30 weeks of gestation. Central nervous system abnormalities will delay these maturational changes.[71]

Swallowing is a complex process under central and peripheral control. The reflex is initiated in the medulla, through cranial nerves to the muscles that control the passage of food through the pharyngoesophageal sphincter. In the process, the tongue, soft palate, pharynx, and larynx all are smoothly coordinated. Any pathologic condition of these structures can interfere with normal swallowing. Neuromuscular incoordination, however, is more likely to be responsible for any dysfunction. This is particularly evident when the central nervous system has sustained damage either before or during delivery.

Lower esophageal sphincter pressures are reduced at birth but increase steadily, reaching adult values by 3 to 6 weeks postnatal age. Daily vomiting or "spitting up" is reported in half of all infants between 0 and 3 months of age and in up to two-thirds of infants 4 to 6 months of age.[72] Most of these infants suffer no ill effect ("happy spitters") and grow normally.[73] This condition usually begins in the first weeks after birth and resolves spontaneously by 9 to 24 months of age as solid food is introduced and

the child assumes the upright position. Between 1:300 and 1:1000 infants have gastroesophageal reflux significant enough to warrant treatment to prevent complications.[74]

Meconium is the material contained in the intestinal tract before birth. It consists of desquamated epithelial cells from the intestinal tract, bile, pancreatic and intestinal secretions, and water (70%). Meconium is usually passed in the first few hours after birth; virtually all term neonates pass their first stool by 48 hours. However, passage of the first stool is usually delayed in LBW neonates, possibly because of immaturity of bowel motility and lack of gut hormones as a result of delayed enteral feeding. Meconium ileus occurs in cystic fibrosis or Hirschsprung disease.

The gastrointestinal transit time in the neonate is less than that in the adult but increases with age. The normal physiologic range of stool frequency varies greatly (from 10 times per day to 1–2 times per week)[75] and more often in breastfed infants. The frequency of bowel movements gradually decreases during the first years of life, reaching adult habits at about 4 years of age.

Necrotizing enterocolitis (NEC) is an acquired gastrointestinal disease associated with significant morbidity and mortality in prematurely born neonates. The disease affects about 10% of preterm neonates weighing less than 1500 g or 1% to 5% of all neonatal intensive care unit admissions (see also Chapter 37).

PANCREAS

The placenta is impermeable to both insulin and glucagon. The islets of Langerhans in the fetal pancreas, however, secrete insulin from week 11 of fetal life; the amount of insulin secretion increases with age. After birth, the insulin response is related to gestational and postnatal ages and is more mature in term infants.

Maternal hyperglycemia, particularly when uncontrolled, results in hypertrophy and hyperplasia of the fetal islets of Langerhans. This leads to increased levels of insulin in the fetus, affecting lipid metabolism and giving rise to a large, overweight neonate characteristic of a mother with diabetes (infant of a diabetic mother, IDM). Hyperglycemia alone is not instrumental in this effect; an IDM may also be the result of an increase in serum amino acids in diabetic mothers. Hyperinsulinemia of the fetus persists after birth and may lead to rapid development of serious hypoglycemia. In addition to severe hypoglycemia, the incidence of congenital anomalies is increased in these neonates.

Neonates who are SGA are frequently hypoglycemic, possibly as a result of malnutrition in utero. In addition, hepatic glycogen stores are inadequate, and deficient gluconeogenesis exists. Preterm neonates may be hypoglycemic without demonstrable symptoms, necessitating close monitoring of blood glucose levels.

Full-term neonates undergo a metabolic adjustment postnatally with regard to glucose. Studies have defined values abnormal glucose concentrations as follows: plasma glucose concentrations less than 35 mg/dL in the first 3 hours after birth; less than 40 mg/dL between 3 and 24 hours; and less than 45 mg/dL after 24 hours.[76] It is important to recognize that neonates may develop serious hypoglycemia that could lead to irreversible central nervous system damage, even though they may demonstrate few or no signs and symptoms. Other neonates may present with seizures, but signs may also be subtle (e.g., lethargy, somnolence, and jitteriness).

Hyperglycemia (plasma glucose ≥150 mg/dL) occurs in stressed neonates, particularly in LBW neonates receiving glucose-containing solutions. Hyperglycemia commonly occurs in neonates and infants during elective surgery under general anesthesia; infusion of glucose-containing solutions may increase the risk of hyperglycemia. Thus it is advisable that intraoperative glucose concentrations be monitored. A study in infants undergoing surgery under general anesthesia showed that postsurgical plasma glucose values were significantly greater than postinduction values; insulin changes, however, were minimal.[77] The risk of hyperglycemia is considerably greater in infants weighing less than 1000 g compared with infants 2000 g or greater.[78] Hyperglycemia may also lead to osmotic diuresis and dehydration and has been associated with an increased incidence of intraventricular hemorrhage and a neurologic handicap. It is recommended that intraoperative glucose-containing solutions be administered with an infusion pump and only run at basal rates (see also Chapter 9).

Hematopoietic and Immunologic System

The blood volume in a full-term neonate depends on the time of cord clamping, which modifies the volume of placental transfusion. The blood volume is 93 mL/kg when cord clamping is delayed after delivery, compared with 82 mL/kg with immediate cord clamping.[79] Within the first 4 hours after delivery, however, fluid is lost from the blood and the plasma volume contracts by as much as 25%. The larger the placental transfusion, the greater the loss of fluid in the first few hours after birth, resulting in hemoconcentration. The blood volume in preterm infants is greater (90 to 105 mL/kg) than in full-term neonates because of increased plasma volume.

HEMOGLOBIN

The normal range of hemoglobin in the neonate is 14 to 20 g/dL. The site of sampling must be considered when interpreting these values for the diagnosis of neonatal anemia or hyperviscosity syndrome. Capillary sampling (e.g., heel stick) generally overestimates the true hemoglobin concentration because of stasis in peripheral vessels that decreases the volume of plasma and causes hemoconcentration. The net effect may be an increase in hemoglobin concentration by as much as 6 g/dL; venipuncture is preferred over capillary sampling. In 1% of infants, fetal-maternal transfusion before the umbilical cord is cut may explain many of the "lower normal" hemoglobin values reported.

Erythropoietic activity from the bone marrow decreases immediately after birth in both full-term and preterm infants. The cord blood reticulocyte counts of 5% persist for a few days and decline below 1% by 1 week. This is followed by a slight increase to 1% to 2% by the 12th week, where it remains throughout childhood. Preterm infants have greater reticulocyte counts (up to 10%) at birth. Abnormal reticulocyte values generally reflect hemorrhage or hemolysis.

In term neonates, the hemoglobin concentration decreases during the 9th to 12th weeks to reach a nadir of 10 to 11 g/dL (hematocrit 30% to 33%) but increases thereafter. This decrease in hemoglobin concentration is the result of a decrease in erythropoiesis and, to some extent, to a shortened life span of the red blood cells. In preterm infants, the decrease in the hemoglobin concentration is greater and directly related to the degree of prematurity; also, the nadir is reached earlier (4 to 8 weeks).[80] In infants weighing 800 to 1000 g, the decrement may reach a very small concentration, 8 g/dL. This "anemia" (physiologic anemia of the newborn) is a normal physiologic adjustment to extrauterine life. Despite the reduction in hemoglobin, the oxygen delivery to the tissues may not be compromised because of a shift of the oxygen-hemoglobin dissociation curve (to the right), secondary to an increase of 2,3-diphosphoglycerate.[81] In addition, fetal

hemoglobin is replaced by adult hemoglobin, which also results in a shift in the same direction. In neonates, especially preterm neonates, reduced hemoglobin concentrations may be associated with apnea and tachycardia.[82] Vitamin E administration does not prevent anemia of prematurity; no significant difference was noted between vitamin E–supplemented and unsupplemented groups in terms of hemoglobin concentration, reticulocyte and platelet counts, or erythrocyte morphology in infants at 6 weeks of age.[83] Infants with anemia of prematurity have an inadequate production of erythropoietin (the primary regulator in erythropoiesis). Some centers now use recombinant human erythropoietin in VLBW infants to stimulate erythropoiesis and decrease the need for transfusions.[44,84]

After the third month, the hemoglobin concentration stabilizes at 11.5 to 12 g/dL until about 2 years of age. The hemoglobin concentration in full-term and preterm infants is comparable after the first year. Thereafter, there is a gradual increase in the hemoglobin concentration to mean values at puberty of 14 g/dL for females and 15.5 g/dL for males (see also Chapter 10).

LEUKOCYTE AND IMMUNOLOGY

The white blood cell count may normally reach 21,000/mm^3 in the first 24 hours of life and 12,000/mm^3 at the end of the first week, with the number of neutrophils equaling the number of lymphocytes. The white blood cell count then decreases gradually, reaching adult values by puberty. At birth, neutrophil granulocytes predominate but rapidly decrease in number so that from the first week of life through 4 years of age, the lymphocyte is the predominant cell. After the fourth year, the values approximate adult values. Neonates have an increased susceptibility to bacterial infection, which is related in part to immaturity of leukocyte function. Sepsis may be associated with a minimal leukocyte response or even with leukopenia. Spurious increases in the white blood cell content may be due to drugs (e.g., epinephrine). The incidence of neonatal sepsis correlates inversely with gestational age and may be as great as 58% in VLBW infants.[85]

PLATELETS

Thrombocytopenia is a common hematologic finding in neonates, occurring in 1% to 2% of healthy term neonates.[86] Mechanical ventilation has been associated with a significant decrease in the platelet count in neonates.[87] There appears to be an inverse correlation between gestational age or birth weight and the severity of platelet reduction. A study of neonatal thrombocytopenia and its impact on hemostatic integrity showed that thrombocytopenic infants are at greater risk for bleeding than equally sick nonthrombocytopenic infants (see Chapters 10, 20, and 37).

COAGULATION

At birth, vitamin K–dependent factors (i.e., II, VII, IX, and X) are 20% to 60% of adult values; in preterm infants, the values are even less. The result is prolonged prothrombin times, normally encountered in full-term and preterm neonates. Synthesis of vitamin K–dependent factors occurs in the liver, which, being immature, produces relatively small concentrations of coagulation factors, even with the administration of vitamin K. It takes several weeks for the levels of coagulation factors to reach adult values; the deficit is even more pronounced in preterm neonates. Vitamin K prophylaxis has been evaluated,[88] and the evidence demonstrates that the majority of cases of neonatal vitamin K deficiency occur in normal neonates. Thus all neonates should receive prophylactic vitamin K soon after birth to prevent hemorrhagic disease of the neonate. Its omission could lead to serious and life-threatening consequences, especially if surgery is undertaken. However, in theory, the increasing risk of bleeding is balanced by the protective effects of physiologic deficiencies of coagulation inhibitors, as well as by the decreased fibrinolytic capacity. Developmental hemostasis should be considered, as well as laboratory variations of coagulation tests that may render any diagnosis of bleeding disorder in infants difficult to establish.[89,90]

Infants of mothers who have received anticonvulsant drugs during pregnancy may develop a serious coagulopathy similar to that encountered with vitamin K deficiency.[91] Administration of Vitamin K_1 to neonates usually reverses this bleeding tendency, but deaths have occurred despite therapy. Other risk factors include maternal use of drugs such as warfarin, rifampin, and isoniazid. Breastfeeding may also be associated with severe vitamin K deficiency; exclusively breastfed infants should receive vitamin supplementation.

POLYCYTHEMIA

Neonatal polycythemia (central hematocrit greater than 65%) occurs in 3% to 5% of full-term neonates.[92] Using M-mode echocardiography, a study of neonates demonstrated an increase in PVR with hyperviscosity.[93] Partial exchange transfusion to reduce the hematocrit and decrease the blood viscosity improves systemic and pulmonary blood flow and oxygen transport, although one review questioned the efficacy when the exchange transfusion was conducted after 6 hours of life in asymptomatic infants.[94] The increased organ blood flow should prevent the cardiovascular and neurologic symptoms associated with the hyperviscosity syndrome.

Neurologic Development and Cognitive Development Issues

NEUROLOGIC DEVELOPMENT

Reduction of perinatal mortality during the past decade has not resulted in the expected reduction in the prevalence of cerebral palsy (1/500 live births). The most common etiologies of cerebral palsy are perinatal ischemic stroke, white matter disorder, and intrauterine inflammation.[95] Less than 5% of cases of cerebral palsy result from perinatal asphyxia. The strongest predictors of cerebral palsy appear to be congenital anomaly (congenital heart disease in particular), low birth weight, low placental weight, multiple fetuses, preterm delivery, intrauterine infection, or abnormal fetal position before labor and delivery.[96]

The nervous system is anatomically complete at birth; functionally it remains immature with the continuation of myelination and synaptogenesis. Myelination is usually complete by 7 years of age. An infant's normal mental development depends on the maturation of the central nervous system. This development may be affected by physical illness, inadequate psychosocial support, or poor nutrition. In a randomized trial of diet in preterm babies, a suboptimal diet resulted in reduced intelligence quotients 7 to 8 years later.[97]

The potential adverse effects of many medications used to provide anesthesia on the developing brain of animal models show how delicate this organ is and how its development may be affected by environmental agents (see Chapter 25). Two studies in humans lend support to the notion that a brief exposure to general anesthesia does not harm young children.[98,99]

The rate of brain growth is different from the growth rate of other body systems. The brain has two growth spurts: neuronal

cell multiplication between 15 and 20 weeks of gestation and glial cell multiplication commencing at 25 weeks and extending into the second year of life. Myelination continues into the third year. Malnutrition during this phase of neural development may have profound handicapping effects.

Plasma membrane transport selectively promotes the passage of essential substrates such as glucose, organic acids, and amino acids across the blood-brain barrier. Hypoxemia and ischemia may lead to a breakdown in this barrier, with resulting edema and increased intracranial pressure. Injury to the blood-brain barrier may result from abnormal entry of calcium or formation of free radicals. Further studies of the mechanism of this breakdown will lead to rational approaches to therapy. In preterm neonates stressed by hypoxia, the blood-brain barrier may become particularly permeable to the water-soluble unbound bilirubin, with possible damage to the brain.[100]

Full-term neonates show various primitive reflexes including the Moro response and grasp reflex. Milestones of development are useful indicators of mental and physical development guiding expectations for both normal and abnormal development. These milestones represent the *average child,* but there is a range of maturation of different body functions that are within the normal range.[101] The Denver Developmental Screening Test is useful for assessing these milestones. The test focuses on four areas of development: (1) gross motor function, (2) fine motor and adaptive skills, (3) language, and (4) personal and social skills. Developing infants rapidly acquire motor skills beginning with control of posture in a cephalocaudal direction; this begins with head control and rapidly progresses to sitting, standing, walking, and finally running (Table 2.11).

Adaptive skills are performed through well-coordinated fine motor movements (Table 2.12). Abnormal development may be reflected in a delay in appearance of a particular milestone or in its pathologic persistence with maturation in a child. For example, at 5 months, a child reaches and retrieves objects, frequently placing them in his or her mouth. As an infant matures, however, this behavior pattern usually ceases at 12 to 13 months of age; in infants with developmental delay, this oral practice may continue for a longer period of time.

Language development correlates closely with cognitive skills (Table 2.13). Personal and social skills are modified by environmental factors and cultural patterns (Table 2.14). Development of walking, speech, and sphincter control is most important. For appropriate evaluation consider familial patterns, level of intelligence, and physical illness. Deafness may cause delayed speech.

INTERACTIONS WITH THE EXTERNAL WORLD DURING GROWTH AND DEVELOPMENT

The environment with all its potential toxins and pollutants may have a direct influence on growth and development, interfering with both physiologic and pathologic aspects. For the two past decades, we have known that programmed cell death (or apoptosis) is part of normal development[102] and that triggering factors result from both evolutionary pathways and external influences. This occurs at both anatomic and functional levels and opens the potential for many and varied investigations. Neurogenesis, particularly in specific parts of the brain such as the hippocampus, has long been thought to occur only during development, but recent evidence has shown that it continues throughout human life and both genetics and inflammation may hold the keys to neurodegenerative disorders.[103,104] Implications of an interaction between memory and its influence on degenerative neurologic diseases are now firmly established.[105] Anesthetic drugs have been shown to adversely affect the developing brain in rodents and primates, but with the discovery of neurogenesis in adults, we now know that similar changes occur in adults as well.[106–108] However, recent evidence suggests it is quite unlikely that anesthetics affect the neurobehavioral changes in human infants and toddlers (see also Chapter 25).

Evidence has confirmed that the functional aspect of brain development in the fetus is far more complex than previously thought and is not limited just to the last weeks before birth.[109] A waking-like brain state exists that is present earlier in gestation and inducible with maternal behavioural changes and external stimuli (e.g., music).[110] These factors may have long-term neurodevelopmental effects and the beginning of memorization likely occurs earlier than previously thought.[111] A mother's voice, heartbeat, speech, and language all impact the fetal neural plasticity.[112–115]

In addition, a large number of interactions between the neonate and the external world exist. The child has some direct influences on his or her external environment. The ethnologic concept of

TABLE 2.11 Relationship of Motor Milestones to Age

Motor Milestone	Age
Supports head	3 months
Sits alone	6 months
Stands alone	12 months
Balances on one foot	3 years

TABLE 2.12 Relationship of Fine Motor/Adaptive Milestones to Age

Fine Motor/Adaptive Milestones	Age
Grasps rattle	3 months
Passes cube hand to hand	6 months
Pincer grip	1 year
Imitates vertical line	2 years
Copies circle	3 years

TABLE 2.13 Relationship of Language Milestones to Age

Language Milestones	Age
Squeals	1.5–3 months
Turns to voice	6 months
Combines two words	1.5 years
Composes short sentences	2 years
Gives entire name	3 years

TABLE 2.14 Relationship of Personal-Social Milestones to Age

Personal-Social Milestones	Age
Smiles spontaneously	3 months
Feeds self crackers	6 months
Drinks from cup	1 year
Plays interactive games	2 years

"baby schema" was proposed by Lorenz,[116] who suggested that some type of positive features can result in a positive response in the human.[117,118] Infantile physical features, such as a round face and big eyes, are perceived as cute and motivate caretaking behavior in the human, with the evolutionary function of enhancing offspring survival. This has been observed across animal species.[119] A baby's smile, for example, can increase the speed of the caring response[120,121] and narrow the intentional focus of the mother independently of face recognition.[122,123] Comparisons between neurophysiologic and neuropsychological studies are difficult but may prove an important confounding factor in our search to understand the complexities of human growth and development.

ACKNOWLEDGMENT

Sottas C, Cumin D, Anderson BJ. Blood pressure and heart rates in neonates and preschool children; an analysis from ten years of electronic recording. *Pediatr Anesth*. 2016;26:1064-1070.

Blood pressure in children undergoing anesthesia is generally lower than that observed in healthy awake children. There is concern about what is an acceptable lower limit, particularly in the very young. The authors review observed blood pressure from a single institution involving 54,896 anaesthetics in children younger than 6 years. A mean blood pressure drop of 28.6% was noted in infants 0-10 weeks of age.

Summary

INTEREST IN CHILDREN'S PERIOPERATIVE behavior has increased dramatically over the past 20 years. Specifically, the recognition of the importance of developmental factors in perioperative research has created a dramatic growth of investigation in this area. In this chapter, we discuss developmental considerations that are relevant to the child's perioperative experience (cognitive development, attachment and separation, temperament). We then offer a review and synthesis of recent data on preoperative anxiety and maladaptive behavioral and cognitive outcomes associated with surgery and anesthesia.

Developmental Issues

COGNITIVE DEVELOPMENT AND UNDERSTANDING OF ILLNESS

The perioperative period is stressful for many individuals undergoing surgery, and this is especially true for children. Children's stress during the perioperative period results from multiple sources, one of which is a limited understanding of illness and the need for surgery. Early developmental theorists (e.g., Piaget,[1,2] Werner[3]) suggested that a child's understanding of illness changes qualitatively as cognitive maturation occurs. The most widely cited model for understanding a child's perspective on illness posits that the child's understanding of illness evolves from prelogical explanations, such as phenomenalism (e.g., magical thinking), to concrete-logical explanations, such as contamination (e.g., eating bad food), to formal-logical explanations (e.g., physiologic causes), and differences in understanding occur according to the child's differentiation between the self and others.[4]

Children's understanding of the treatments for illnesses is thought to follow a similar developmental pattern. In terms of surgery, a child's concepts are particularly underdeveloped. Young children have difficulty defining "an operation," suggesting that it is the same as being sick, going for a doctor's checkup, or taking a nap.[5] Given these developmental considerations, it is not surprising that young children are more likely to have misconceptions about hospitalization and surgery than are older children and adults[6] and therefore are at unique and disparate risk for perioperative stress.

ATTACHMENT

Attachment style is another developmental consideration unique to children in the perioperative setting. Although adults also undergo separation from family, the separation of children from their parents is particularly stressful and affected by the parent-child relationship.

Coping with separation is inevitable and necessary for a child's normal, healthy development.[7] Separation experiences, such as saying good-bye at school or sleeping overnight at a friend's house, facilitate normal childhood psychological growth and personality organization by mobilizing opportunities for learning and adaptation. Other separation experiences, especially those occurring in the context of loss, illness, or other stressors, can precipitate states of confusion, anger, and anxiety. Brief separations, such as those associated with surgery, are most stressful for infants, toddlers, and preschool-aged children. Indeed, for school-aged children, responses to separation may reflect, in part, response patterns established early in the preschool years.[7] For children with biologically based vulnerabilities, such as a sensitivity to novelty and changes in routines, even expected separations may impose a greater degree of stress than for less sensitive children.[7] Similarly, for children with developmental delay, separation may be experienced with a degree of anxiety and developmental stress more like that experienced by a younger child.

Attachment affects a child's response to separation and is shaped through early experiences with the primary caregiver. Through these interactions, an infant has the opportunity to develop a sense of trust and security in the reliability and predictability of his or her relationship and the world.[8] The style of attachment exhibited by infants is evident in their responses to brief separations from the primary caregiver and is conceptualized as *secure*, *insecure*, or *anxious*.

Children who are more "securely attached" to their parents deal more adaptively with the stress of brief separation and with the novelty of the hospital experience. Such children are more willing to explore their world and respond positively to their caregivers' return, using the caregivers as a secure, stable base from which to approach strangers and new situations.[9,10] In contrast, children classified as "anxiously attached" to their parents tend

to be distressed in unfamiliar situations, like the perioperative environment, even in the presence of their caregivers. When their parents return after brief separations, these children exhibit anger and distress and avoid physical contact. Another form of "insecure attachment" is avoidance. Avoidant children do not explore their surroundings as much as securely attached infants, rarely show distress at separation, and tend to ignore their parents on reuniting. Conversely, "insecurely attached" children are more easily distressed by even brief separations and spend more time trying to stay close to their parents.

TEMPERAMENT

Responses of young children to the stress of the perioperative period also reflect the child's temperament. Temperament refers to stable emotional and behavioral responses (e.g., emotionality, activity, attention, reactivity, sociability) that appear in infancy and are thought to be primarily genetic in nature.[11] Three main dimensions have been proposed to classify infant temperament: emotionality, activity, and sociability.[12] *Emotionality* refers to the ease with which an infant becomes aroused or anxious, especially in situations that might lead to fear, such as perioperative settings. *Activity* refers to the infant's customary level of energy and intensity of behavior. *Sociability* reflects the infant's tendency to approach or avoid others. These behavioral dimensions of temperament are also reflected in physiologic responses related to anxiety.[13,14] In long-term studies, infants who are inhibited in the face of novelty continue to be so through early school age.[15] Thus, temperament as a behavioral descriptor appears to characterize an enduring cluster of traits reflecting reactivity and anxiety regulation in the face of novelty.

In light of these issues, the child's developmental level is an important consideration relating to the child's perioperative behavior. The remainder of this chapter addresses specific behavioral issues related to surgery in children, including anxiety in the preoperative period and postoperative behavioral outcomes, such as emergence delirium, sleep, and other maladaptive behavioral changes.

Preoperative Anxiety

Anxiety in children undergoing anesthesia and surgery is characterized by feelings of tension, apprehension, and nervousness.[16] This response is attributed to separating from parents, loss of control, uncertainty about anesthesia, and uncertainty about the surgery and its outcome.[16] It is estimated that 40% to 60% of children develop significant fear and anxiety before their surgery.[17] Furthermore, separation from parents and induction of anesthesia have been found to be the most stressful times during the surgical and anesthesia experience. Some children verbalize their fears explicitly, whereas others express their anxiety only by behavioral changes. Children may appear scared or agitated, breathe deeply, tremble, stop talking or playing, and start to cry. Some may wet or soil themselves, display increased motor tone, and actively attempt to escape from medical personnel.[18] These behaviors may give children some sense of control in the situation and thereby diminish the damaging effects of a sense of helplessness.[16,18] In addition to the behavioral manifestations detailed here, several studies have documented that anxiety before surgery is associated with neuroendocrine changes, such as increased serum cortisol, epinephrine, growth hormone, and adrenocorticotropic hormone levels, as well as increased natural killer cell activity.[19,20] Significant correlations between heart rate, blood pressure, and behavioral ratings of anxiety have also been reported.[21,22]

RISK FACTORS

Preoperative anxiety is a clinically important phenomenon that should be treated as any other clinical phenomenon or disease. In epidemiologic terms, *all* diseases are characterized operationally by risk factors, interventions, and outcomes; preoperative anxiety is no exception. We review the phenomenon of preoperative anxiety using the classic epidemiologic model of a disease (Fig. 3.1).

Identifying the risk factors for preoperative anxiety is important because the routine use of pharmacologic and behavioral interventions is associated with both advantages and disadvantages. Routine administration of sedative premedication may increase indirect pharmacy costs, the need for nursing staff, and appropriately monitored bed space in the preoperative holding area. Children undergoing extremely brief outpatient procedures (<30 minutes) may also experience delayed discharge. Similarly, behavioral preparation programs administered preoperatively are associated with increased hospital operational costs. Likewise, anxious children can use hospital resources that would be reduced with appropriate pharmacologic preparation. Thus, identifying children who are at a particularly high risk for developing extreme anxiety and distress before surgery would help guide the most effective use of limited resources.

Variation in children's behavioral responses to the perioperative experience has its origin in at least four domains:

- Age and developmental maturity
- Previous experience with medical procedures and illness
- Individual capacity for affect regulation and trait (baseline) anxiety
- Parental state (situational) and trait anxiety

Previous studies that examined the behavioral responses to induction of anesthesia in children did so in terms of these four domains.[23–27] Children between the ages of 1 and 5 years are at greatest risk for developing extreme anxiety and distress. This is not surprising because separation anxiety often does not peak until 1 year of age and children older than 5 years can more easily cope with new situations. A history of previous stressful medical encounters, such as previous hospitalization, affects how a child reacts to new medical encounters; these are important risk factors for preoperative anxiety. Children who are shy and inhibited, as identified by temperament tests, and those who lack good social adaptive abilities are also at increased risk for developing anxiety and distress before surgery.[27]

Parental characteristics also have a strong influence on a child's behavior. Children of parents who are more anxious, children of parents who use avoidance coping mechanisms, and children of separated or divorced parents all appear to be at high risk for developing preoperative anxiety.[28] Because children of anxious parents are more likely to experience high levels of preoperative anxiety, it is important to identify the predictors of increased *parental* preoperative anxiety. Parent gender (mothers are more anxious than fathers[29]), the child's age (<1 year), children with repeated hospital admissions, and the child's temperament are all predictors of increased parental preoperative anxiety.[28,30–32] Identification of children and parents who are at the greatest risk for preoperative anxiety and distress allows for appropriate intervention for this "at-risk" population.

BEHAVIORAL INTERVENTIONS

Pharmacologic (e.g., premedication) and behavioral (e.g., psychological preparation programs) interventions are used to attenuate preoperative anxiety and distress in children and their parents.[17,33]

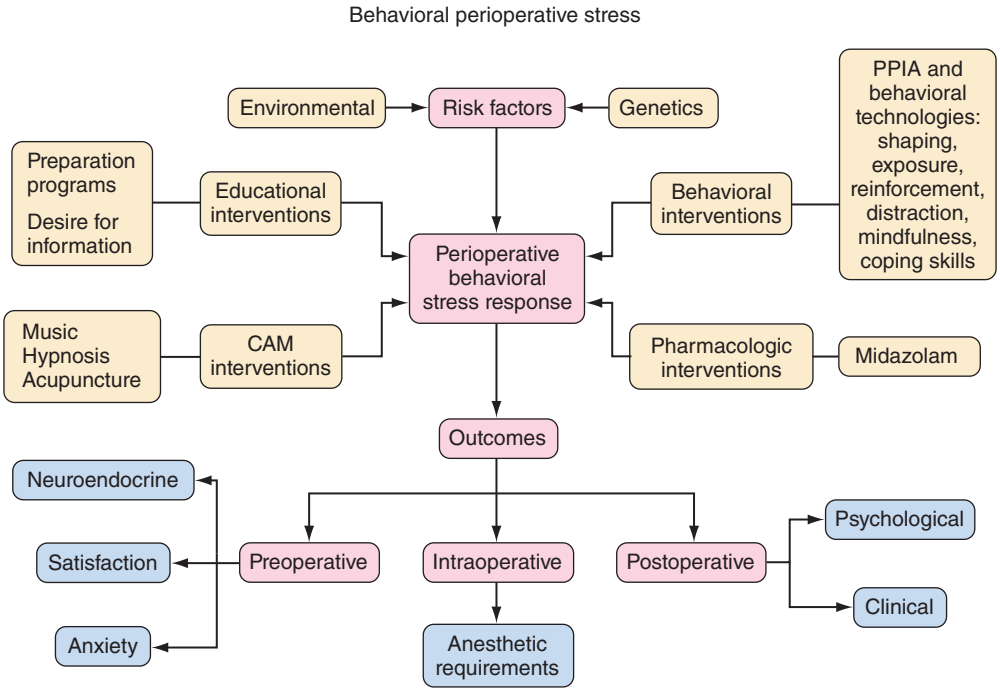

FIGURE 3.1 Operational Overview of Perioperative Anxiety. *CAM*, Complementary alternative medicine; *PPIA*, parental presence during induction of anesthesia.

Preoperative Preparation Programs

Psychological preparation for children undergoing anesthesia and surgery has been widely advocated. These preparation programs may provide narrative information, an orientation tour of the operative facility, role rehearsal using dolls, modeling using videotapes or a puppet show, child-life preparation, or coping education and relaxation skills.[34–36]

Although there is general agreement in the medical community regarding the benefit of preparation programs, recommendations regarding the content of behavioral preoperative preparation differ widely. Early programs were information oriented and often incorporated modeling techniques using videos or a puppet show.[37,38] These techniques were augmented in the late 1980s with child-life preparation and coping skills education.[35] Child-life specialists are trained individuals who facilitate development of coping skills and the adjustment of children and parents to the perioperative environment by providing play experiences, presenting information about events and procedures, and establishing supportive relationships with children and parents.[36] Currently, the development of coping skills is considered the most effective preoperative intervention, followed by modeling, play therapy, operating room (OR) tour, and printed material.[39] Interestingly, coping skills preparation with child life specialists was associated with less anxiety on the day of surgery when compared with lesser rated techniques; however, no differences were found immediately or up to 2 weeks after surgery.[40] Thus, from a cost-effectiveness point of view, one must decide whether the additive cost of child life specialists justifies the reduction in anxiety that occurs *only* during the preoperative period.

It is important that preparation programs are age-appropriate and tailored to the individual child's needs. Several variables influence the responses of children to preparation programs.[28] For example, children who are 6 years of age or older benefit the most if they participate in a preparation program more than 5 days before the scheduled surgery and benefit the least if they participate in one only 1 day before surgery. In fact, older children prepared a week in advance showed an *increase* in anxiety level during and immediately after the preparation program, but they demonstrated a gradual decrease in anxiety during the 5 days before the day of surgery.[41] To prevent excessive anticipatory anxiety, older children should have sufficient time to process the new information and to rehearse newly acquired coping skills. It is also important to realize that there may be a *negative* effect of a preparation program in children younger than 3 years of age. This may be a result of their inability to distinguish fantasy from reality.[1] A reality-based preparation program may do little to calm young children and may even exacerbate anxiety or sensitize the young child to the surgery. From age 3 to 6 years, children demonstrate an increasing ability to distinguish fantasy from reality and by the age of 6 this distinction is usually accomplished.[1] Therefore, to provide the most benefit, both the age of the child and timing must be factored into delivery of the program.

In addition to age and timing, previous experience in a hospital setting also influences the effectiveness of a preparation program. A child who was previously hospitalized is more likely to develop an exaggerated emotional response to a behavioral preoperative preparation program and the perioperative experience.[28,41–43] Information about what will occur, as demonstrated by sensory expectation and doll play, does *not* provide new information for these children. Furthermore, if the child has had a previous negative medical experience, the routine preparation may increase anxiety by triggering negative memories. In this case, alternative behavioral interventions, such as extensive individualized coping skills training

combined with desensitization and actual practice, may be better suited and indicated.[42]

Because increased parental preoperative anxiety has been shown to increase preoperative anxiety in their children, preparation programs for surgery should also be directed at parents.[23] Although a number of interventions are routinely used to reduce a child's anxiety, there is a paucity of information regarding interventions directed toward reducing parental anxiety.[44] One study demonstrated that parental preoperative anxiety decreased after viewing an educational videotape.[45] Most studies to date suggest that preoperative preparation programs for children reduce preoperative anxiety and enhance coping.[35,41,46]

Children whose parents have been taught to be active in distracting their child during stressful medical events may evidence reduced anxiety compared with parents who receive no intervention.[47] Indeed, this was the case in a randomized controlled trial evaluating a family-centered behavioral preparation program (ADVANCE) (Table 3.1). Parents and children who received ADVANCE were less anxious before and during induction of anesthesia than parents and children who did not receive this program. In fact, ADVANCE was as successful as midazolam in managing children's compliance with and anxiety at induction of anesthesia (Table 3.2).[48] It is important to note that ADVANCE also decreased the time spent in the postanesthesia care unit and decreased the analgesic requirements during the postoperative period. A major disadvantage of ADVANCE, however, is its high cost and personnel requirements. Accordingly, efforts to dismantle this multimodal intervention indicate that behavioral shaping through exposing children to the anesthesia mask before surgery and distraction on the day of surgery proved to be the most effective components of the program.[49]

TABLE 3.1 The ADVANCE Preoperative Preparation Program

Anxiety reduction
Distraction on the day of surgery
Video modeling and education before surgery
Adding parents to the child's surgical experience and promoting family-centered care
No excessive reassurance—a suggestion made to parents for communication with children about surgery
Coaching of parents by researchers to help them succeed
Exposure/shaping of the child via induction mask practice (the mask placed over the child's nose and mouth to deliver anesthetic drugs)

Parental Presence During Induction of Anesthesia

It is well established that most parents and children prefer to remain together during procedures such as immunization, bone marrow aspiration, and dental treatment.[50,51] Most parents prefer to be present during induction of anesthesia regardless of the child's age or previous surgical experience.[52,53] This is the case even for those parents who have had previous experience with pharmacologic interventions. Indeed, parents of children undergoing repeated surgery were likely to request parental presence regardless of their experience with prior parental presence or premedication with midazolam.[54] That is, even if children were calm after midazolam during their first surgery, parents still preferred to be present during induction of anesthesia during subsequent surgeries.

It is important to note, however, that parental presence during induction of anesthesia (PPIA) does not necessarily equate with appropriate choice of interventions. For example, mothers who were most highly motivated to be present at induction of anesthesia also reported high levels of anxiety and their children were more distressed at induction.[55] In fact, more than 90% of parents report some degree of anxiety during the anesthesia induction process.[56] The most upsetting factors include seeing their child become flaccid during induction and separation from their child.[56] This observation was confirmed in a study that examined heart rate, blood pressure, and skin conductance levels in mothers as they observed their child's induction of anesthesia.[57] Mothers who were present during induction of anesthesia showed a moderate increase in heart rate and blood pressure (Fig. 3.2). However, no cardiac arrhythmias or ischemic episodes were noted. Another

study examined whether parental auricular acupuncture would reduce parental preoperative anxiety and thus allow children to benefit from PPIA.[58] A multivariate model demonstrated that children whose mothers had received the acupuncture intervention were less anxious on entrance to the OR and during placement of the anesthesia mask on their child's face.

Potential benefits from PPIA include minimizing the need for premedication and avoiding the screaming and struggling of the child that may result on separation from the parents. Whether PPIA decreases child anxiety during induction and affects the long-term behavior effects of surgery and anesthesia remains controversial. Common objections to PPIA include concern about disruption of the OR routine, compromising operative sterility, crowded ORs, and possible adverse parental reactions. For some children, their behavioral response to stress may be more negative when a parent is present than when the parent is absent.[59] In several reports, PPIA resulted in disruptive behavior, parents refusing to leave the room when requested, and even removal of a child from the OR by a grandmother during the second stage of anesthesia.[60,61] However, one report has described a 4-year experience with 3086 children in a freestanding ambulatory surgery center in which no parent needed to be escorted from the OR because of undue anxiety and only two parents developed syncope, with prompt recovery.[62] Despite objections, the prevalence of PPIA is becoming more common in the United States. In fact, there was an increase in the overall prevalence in PPIA from 1995 to 2002, and geographic differences in PPIA use decreased during the 7-year period but more recent data are lacking (Fig. 3.3).[63,64]

Evidence to date has been ambivalent regarding the routine use of PPIA.[65–67] Although early studies suggested that PPIA reduced anxiety and increased cooperation,[68,69] more recent investigations indicate that routine PPIA may *not* always be beneficial.[65–67] Characteristics of the parent and child have an impact on the effectiveness of parental presence. For example, older children (>4 years), children with a "calm" and less active baseline temperament, parents with less situational anxiety, and parents with lower external locus of control, benefit most from PPIA.[30,65] The match between parent and child anxiety level also appears to be important. Calm children with anxious parents do more poorly during induction compared with calm children with calm parents or anxious children with either calm or anxious parents.[30] When interpreting the results of these studies, however, several factors should be considered. First, the design of a randomized controlled study, while considered a gold standard in research, may *not* reflect the practice of *all* anesthesiologists. That is, although a randomized controlled study is applicable to centers that offer PPIA for *all* parents, it may not be applicable to centers in which each request for PPIA is considered individually based on personality characteristics of each child and parent. Such centers may have different results with PPIA than were demonstrated in experimental studies. Second, allowing PPIA without adequate preparation of the parent may be counterproductive. Some parent behaviors, such as criticism, excessive reassurance, and commands, are associated with greater distress.[70]

Given these drawbacks, interest in this area has begun to shift toward an emphasis on what parents actually do during induction of anesthesia. The development of a new tool for assessing child and adult behavior in the perioperative setting (Perioperative Child-Adult Medical Procedure Interaction Scale [P-CAMPIS]) has been developed to facilitate such research (Fig. 3.4).[71] Preliminary validation of this measure indicates that parental behavior affects the child's anxiety during induction, much as it affects a child's distress during immunizations.

The Preoperative Interview

Although not obvious, the preoperative interview is a behavioral intervention that is routinely administered to *all* children undergoing anesthesia and surgery.[72] It is clear that anesthesiologists have an ethical and legal responsibility to disclose to children and

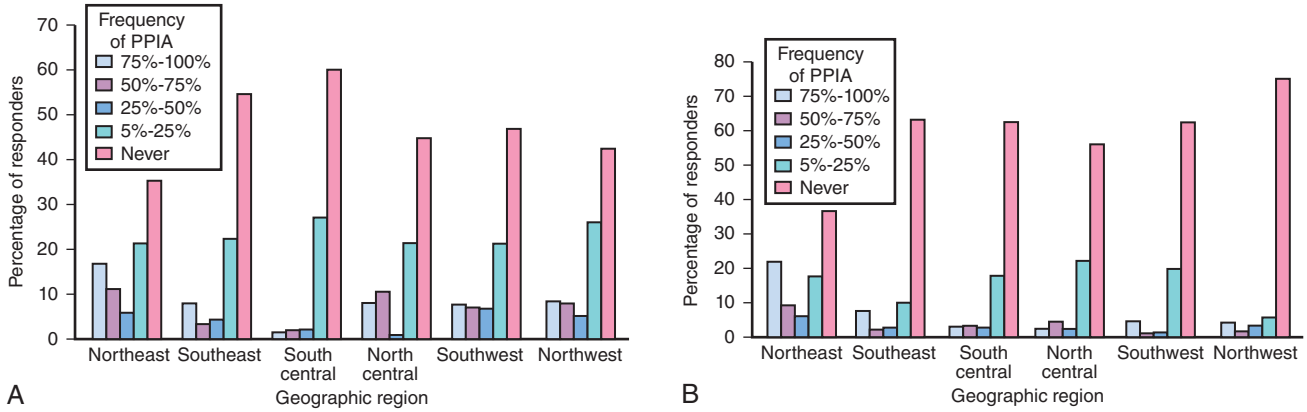

FIGURE 3.3 **A**, Frequency of parental presence during induction of anesthesia (*PPIA*) practice in the United States as of 2002. **B**, Frequency of PPIA practice in the United States as of 1995/1996. Data reported are medians (range, 0%–100%). (From Kain ZN, Caldwell-Andrews AA, Krivutza DM, et al. Trends in the practice of parental presence during induction of anesthesia and the use of preoperative sedative premedication in the United States, 1995-2002: results of a follow-up national survey. *Anesth Analg.* 2004;98:1252-1259.)

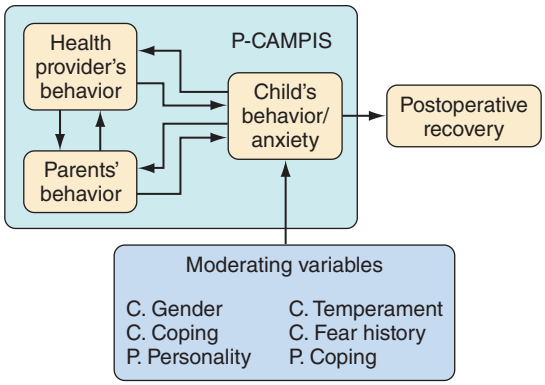

FIGURE 3.4 The conceptual framework that underlies the relation between a child's preoperative anxiety, parental behaviors, health care providers' behaviors, moderating variables, and postoperative recovery. *C*, Child; *P*, parent; *P-CAMPIS*, Perioperative Child-Adult Medical Procedure Interaction Scale. (From Caldwell-Andrews AA, Blount RL, Mayes LC, Kain ZN. Behavioral interactions in the perioperative environment: a new conceptual framework and the development of the perioperative child-adult medical procedure interaction scale. *Anesthesiology* 2005;103:1130-1135.)

parents detailed anesthetic risk information when obtaining informed consent, but how far this disclosure must extend remains controversial. A common reason given for not providing detailed anesthetic risk information is that it may increase the child's or parents' anxiety. Comparative studies investigating anxiety levels in adult patients given a limited amount of information, versus more detailed information concerning procedural and anesthetic risks, report conflicting results. Although early studies provided mixed data regarding whether detailed information delivered preoperatively increased anxiety,[73–75] several studies in the United States and Australia have demonstrated that patients and parents who received detailed information, including numerical estimates of anesthesia-related complications, were no more anxious than those given minimal information regarding risks.[76–78] Furthermore, parents have expressed their desire to have as much perioperative information about their child's surgery as possible,[77] and even children have expressed a desire for detailed perioperative information, including information about pain, anesthesia, and potential complications.[79] Thus, the presentation of very detailed anesthetic information of what might go wrong should not increase parental or patient anxiety and has the advantage of allowing for fully informed choices. It should be emphasized, however, that anesthesiologists should note the particular coping style of the parents. Parents use different strategies to cope with or handle difficult, unclear, or unpleasant life experiences, such as a child undergoing surgery. Whereas some parents try to avoid information about unpleasant or unclear situations ("avoidance behavior"), others may seek any available information ("monitoring behavior").[80] Although a "monitoring" parent will benefit from a large amount of perioperative information, an "avoiding" parent may react to the information with increased anxiety and distress. Thus, the amount of information provided should be tailored to the needs of the individual parent.

HEALTH CARE PROVIDER INTERVENTIONS

In addition to behavioral interventions targeting children and their parents, a promising new line of research supports the use of behavioral interventions targeting health care providers–both anesthesiologists and nurses. Specifically, an empirically derived intervention titled Provider-Tailored Intervention for Perioperative Stress (P-TIPS) was shown to be successful in changing anesthesiologist and nurse behaviors in the perioperative setting and represents a new clinical avenue for decreasing perioperative anxiety in children.[81] The development of P-TIPS was based on research documenting that adult behaviors (parents and health care providers) affect children's distress during invasive medical procedures, including surgery. Specifically, the use of distraction, nonprocedural talk, and humor are conceptualized as "coping promoting" behaviors and have been shown to decrease children's distress.[82–88] Conversely, adults' use of reassurance, apology, empathy, criticism, or allowing the child too much control over the medical procedure are conceptualized as "distress promoting" behaviors and lead to increased distress in children.[82,87–90] With P-TIPS, a new behavior that affected child distress also emerged: medical reinterpretation (i.e., reconceptualizing medical experiences and equipment as

nonthreatening) and was found to increase a child's coping when used with medical experiences that were in the child's immediate environment, but it increased distress when used in reference to objects outside the immediate environment.[87]

Preliminary investigation revealed that P-TIPS was successful at both increasing desired behaviors (coping promoting) and decreasing undesired (distress promoting) behaviors among health care providers.[81] Both resident and attending anesthesiologists were included in this study and evidenced behavior change, as did OR nurses, who were charged with changing their own as well as parent behaviors in the perioperative setting. In fact, nurses demonstrated appropriate behavior change and, in turn, parents demonstrated increases in desired and decreases in undesired behaviors. One important benefit to the type of approach offered by P-TIPS is that it is not necessary to conduct individual training with parents of children undergoing surgery; rather, health care providers who interact with multiple children and parents are targeted, which reduces both logistical and financial constraints of behavioral interventions.

PHARMACOLOGIC INTERVENTIONS

The primary goals of administering a premedication to children are to facilitate an anxiety-free separation from their parents and a smooth, stress-free induction of anesthesia. Other effects that may be achieved by pharmacologic preparation of the child include amnesia, anxiolysis, prevention of physiologic stress (e.g., avoiding tachycardia in patients with cyanotic congenital heart disease), and analgesia (see Chapter 4).

The pattern of use of sedative premedications in the United States has evolved between 1996 and 2002. In 1996, premedication was least often prescribed for children younger than 3 years of age and most often for adults younger than 65 years of age (25% vs. 75%).[63] Premedication prescriptions also varied substantively with the geographic location. In 2002, a follow-up study revealed that the use of premedications in children had increased from 30% to 50%, whereas geographic variability had diminished compared with the results of the 1996 survey (Fig. 3.5).[64] In both surveys, the most commonly used sedative premedicant was midazolam; when data from several surveys were reviewed, it was noted that anesthesiologists in the United States who allowed PPIA the *least* were those who prescribed sedative premedication the most.[63,91] Thus, most anesthesiologists in the United States use either parental presence or sedative premedication to attenuate preoperative anxiety in children.

PHARMACOLOGIC INTERVENTIONS VERSUS BEHAVIORAL INTERVENTIONS

When pharmacologic interventions are directly compared with behavioral interventions, children receiving a sedative are less anxious and more compliant than those who are accompanied to the OR by a parent.[67] Interestingly, parental anxiety also decreased when the child was premedicated. When sedative premedication and PPIA were compared, the combination of PPIA and sedative premedication was more effective than medication alone for reducing anxiety in the parents and improving parent satisfaction.[92] However, PPIA offered no additional anxiolysis for children who received a premedication preoperatively. Nonetheless, parents who accompanied their sedated children into the ORs were themselves less anxious and more satisfied both with the separation process and with the overall anesthetic, nursing, and surgical care provided. It is important to note that these parents had no preparation for their presence at anesthesia induction. Premedication combined with an advanced behavioral preparation resulted in similar outcomes on child and parent anxiety at induction and child compliance with induction.[48] Furthermore, children who received behavioral preparation evidenced significantly less emergence delirium and required less analgesia in the recovery room compared with those who received only premedication.

In conclusion, although sedative premedications are effective for treatment of preoperative anxiety, they should *not* be used routinely in all children undergoing surgery. Their use should be directed to children who are at a significant risk for developing preoperative anxiety. Variables, such as age, duration of surgery, and potential recovery delays, should also be considered. Nonetheless, it is important that premedication is not withheld if the premedication would likely benefit the child. For example, a child undergoing a very brief procedure who is very anxious would likely benefit from a premedication regardless of the negative effects on recovery and discharge.

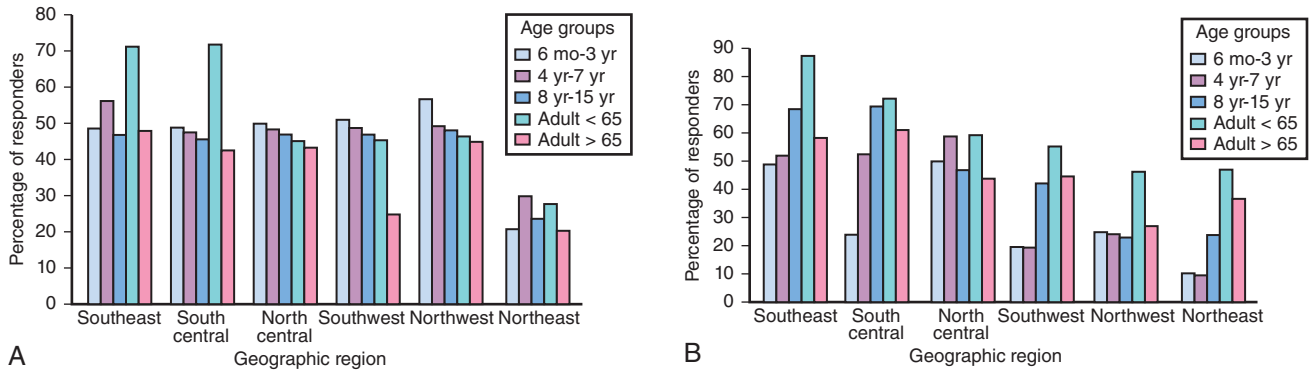

FIGURE 3.5 **A**, Frequency of sedative premedication practice in the United States as of 2002. **B**, Frequency of sedative premedication practice in the United States as of 1996. Data reported are medians (range, 0%-100%). (From Kain ZN, Caldwell-Andrews AA, Krivutza DM, et al. Trends in the practice of parental presence during induction of anesthesia and the use of preoperative sedative premedication in the United States, 1995-2002: results of a follow-up national survey. *Anesth Analg.* 2004;98:1252-1259.)

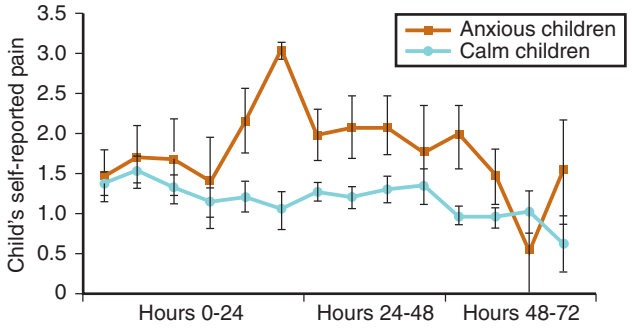

FIGURE 3.6 Children's self-reported postoperative pain as a function of preoperative anxiety. (From Kain ZN, Mayes LC, Caldwell-Andrews AA, et al. Preoperative anxiety, postoperative pain, and behavioral recovery in young children undergoing surgery. *Pediatrics* 2006;118:651-658.)

Postoperative Outcomes

Anxious children experience significantly more pain both during the hospital stay and during the first 3 days at home[93] (Fig. 3.6). During home recovery, anxious children also consume more codeine and acetaminophen compared with nonanxious children. Anxious children also had a greater incidence of emergence delirium (9.7% vs. 1.5%), postoperative anxiety, and sleep problems compared with nonanxious children. Preoperative anxiety in young children undergoing surgery is associated with a more painful postoperative recovery and a greater incidence of disrupted sleep and other problems.[93] Moreover, one study suggests that perioperative anxiety, rather than just preoperative anxiety, is associated with poorer surgical outcomes.[94] Children have traditionally been labeled as anxious or nonanxious after their anxiety was assessed before surgery, such as in the presurgical holding area or at the point of induction in the OR. By contrast, this study examined anxiety in children throughout the perioperative continuum (pre- and postoperatively) and replicated findings of associations between perioperative anxiety and both postoperative pain and new-onset behavioral changes.[94]

The assumption that minimal preoperative anxiety predicts good postoperative outcomes underlies many interventions that attenuate preoperative anxiety. To date, preoperative preparation studies in adult patients have used diverse postoperative outcome measures, including intensity of pain, analgesic requirements, postsurgical complications, length of hospital stay, patient satisfaction, blood cortisol levels, changes in blood pressure and heart rate, and behavioral indexes of recovery.[95–103] Reviews of this research, while critical of the methodology, concluded that psychologically prepared adult patients may have improved postoperative recovery.[96,104–106] As noted previously, children who received the ADVANCE preoperative program were less anxious preoperatively and experienced a reduced incidence of emergence delirium, had a briefer stay in the recovery area, reported less postoperative pain, and required fewer analgesics compared with a control group.[48]

EMERGENCE DELIRIUM

The first maladaptive behavioral change in children that may be evident after surgery is emergence delirium. This phenomenon is characterized by nonpurposeful restlessness and agitation, thrashing, crying or moaning, and disorientation in the recovery room. Published studies have reported that up to 80% of all children undergoing surgery and anesthesia develop emergence delirium.[107] However, in many of these studies, emergence delirium was not distinguished from pain as the scale to measure emergence delirium had not been validated, pain was present contemporaneously with the delirium, and analgesics were used to treat the delirium. In fact, the range of incidence of delirium using a validated scale in nonpainful surgery is 15% to 50%. Factors that are known to increase the incidence of emergence delirium include young age (2–6 years), preoperative anxiety (although controversial), and the type of anesthetic (sevoflurane, desflurane, and isoflurane ≫ total intravenous anesthesia [TIVA], halothane).[107–109] Other factors such as previous surgery and the type of procedure (painful ≫ nonpainful) may affect the incidence of delirium but more than likely were identified because of poorly designed studies. Rapid emergence and depth of anesthesia do not predict delirium. Furthermore, preoperative anxiety, emergence delirium, and postoperative maladaptive behavior changes have been shown to be closely related phenomena. One study found that the odds of children experiencing marked symptoms of emergence delirium increased in proportion to their preoperative anxiety scores, and that the odds of the onset of new maladaptive behavioral changes also increased with the presence of emergence delirium.[93] Thus the child's preoperative anxiety may help to identify those who are more likely to develop adverse postoperative phenomena, such as emergence delirium and postoperative behavioral changes.

SLEEP CHANGES

Changes in sleep patterns in the postoperative period have been well documented in adults and children. One study reported that 47% of children experienced sleep disturbances after anesthesia[110] and approximately 14% of children showed decreases in percentage of time spent asleep (in both rapid eye movement [REM] and non-REM sleep) after surgery. The most common predictor of sleep difficulties after surgery has been postoperative pain,[111] but psychological variables have also been shown to be important. Specifically, parental personality measures of anxiety and child measures of externalizing behavior have both been found to predict sleep efficiency in children after surgery.

OTHER BEHAVIORAL CHANGES

In addition to sleep, changes in daytime behavior in children after surgery and anesthesia have also been documented. As many as 60% of children undergoing outpatient surgery may develop negative *postoperative* behavioral changes within 2 weeks after surgery.[112–114] These negative behaviors include sleep and eating disturbances, separation anxiety, apathy, withdrawal, and new-onset enuresis.[23,94,114] In fact, some children may develop long-lasting psychological effects that could have an impact on their responses to subsequent medical care. Interference with normal development has also been described.[115] Some children demonstrate new negative behaviors postoperatively, such as new onset of general anxiety, nighttime crying, enuresis, separation anxiety, temper tantrums, and sleep or eating disturbances. These behaviors may occur in up to 44% of children 2 weeks after surgery; about 20% continue to demonstrate negative behaviors up to 6 months postoperatively.[23] The postoperative negative behavioral changes are likely the result of an interaction between the distress the child experiences during the perioperative period and the individual personality characteristics of the child. Previously, variables such as the age and temperament of the child and the state and trait anxiety of the parent have been identified as predictors for the occurrence of negative

postoperative behavioral changes.[23] There are a paucity of data, however, regarding a possible association between the distress the child experiences during induction of anesthesia and the occurrence of these negative postoperative behavioral changes. One investigation concluded that extreme anxiety, such as that which occurs with a "stormy induction" of anesthesia, was associated with an increased incidence of postoperative negative behavioral changes.[109] The investigators recommend that anesthesiologists advise parents of children who are anxious during induction of anesthesia of the increased likelihood that their children will develop postoperative negative behavioral changes, such as nightmares, separation anxiety, and aggression toward authority.[109]

Because the anxiety level of the child and parent in the preoperative holding area predicts negative postoperative behavioral problems,[23] it can be hypothesized that if sedative premedications reduce the anxiety of the child and the parents in the preoperative holding area, these agents may also reduce negative postoperative behavioral outcomes.[70] One study found that children who were premedicated exhibited a reduced incidence of negative behavioral changes during week 1 after surgery.[116] These data suggest that reducing preoperative anxiety may improve the child's behavior not only preoperatively, but also immediately postoperatively.[116]

Intraoperative Clinical Outcomes

It is commonly held that increased preoperative anxiety is associated with increased intraoperative anesthetic requirements.[117,118] However, this is based on early studies of questionable scientific validity[119,120]; many of these studies did not use validated scales to measure anxiety or control for potential confounding variables, such as sedative premedication and the surgical procedure.[22] One investigation indicated that an increased baseline (i.e., trait) anxiety is associated with increased intraoperative anesthetic requirements in adults. The investigators in that study controlled for the surgical procedure, used bispectral electroencephalographic analysis (bispectral index) monitoring to ensure the same anesthetic depth in all patients, and used a TIVA technique to ease the calculation of the anesthetics used.[121] As such, it does seem clear that an increased baseline, or trait, anxiety is associated with increased intraoperative anesthetic requirements.

Although several review articles suggest that increased anxiety before surgery and anesthesia is associated with postoperative nausea and vomiting,[122] experimental data suggest that a child's anxiety in the preoperative holding area is not predictive of postoperative nausea and vomiting either in the postanesthesia care unit or at home.[123]

Summary

Approximately 3 million children undergo anesthesia and surgery in the United States every year and 40% to 60% of them are believed to develop behavioral stress before their surgery. Multiple interventions have been proposed to attenuate the preoperative behavioral stress response, however; there is a trend toward a *reduction* in both behavioral and pharmacologic preoperative interventions aimed at children. One possible reason for this trend may be that some physicians believe that reducing parental anxiety during the preoperative period is a surrogate outcome. Rather than evaluating the effects of various preoperative interventions on the transient preoperative behavior, some believe that we should concentrate on research directed at demonstrating that a reduction in preoperative anxiety can dramatically change postoperative outcomes. It is well established that low levels of preoperative anxiety are associated with good postoperative behavioral recovery, whereas moderate and high levels of preoperative anxiety are associated with poor postoperative behavioral recovery. What is unknown is whether there is an association between preoperative anxiety and postoperative clinical recovery; quality research needs to examine these associations. Furthermore, shifting research focus toward development of economically and clinically feasible interventions that can be delivered to the large numbers of children undergoing surgery each year is vital. Accordingly, incorporating web-based technologies and changes in institutional practice (i.e., changing health care provider behaviors) represent two promising new avenues of intervention.

ANNOTATED REFERENCES

Fortier MA, Bunzli E, Walthall J, et al. Web-based tailored intervention for preparation of parents and children for outpatient surgery (WebTIPS): formative evaluation and randomized controlled trial. *Anesth Analg.* 2015;120:915-922.

WebTIPS is a newly developed, web-based intervention for preparation of parents and children for surgery that can be accessed in the home setting multiple times by families before and after surgery. This paper reported on both formative evaluation and preliminary efficacy using a randomized controlled trial (RCT) of the impact of WebTIPS of children's and parents' preoperative anxiety. A multimethod trial examining both qualitative and quantitative data from 13 families in which a family member had recently undergone surgery or had an upcoming surgery revealed that WebTIPS was well received by parents and children. The RCT demonstrated significant effects with moderate effect sizes (Cohen's d *= 0.59 and 0.63) on children's preoperative anxiety at entrance to the operating room and introduction of the anesthesia mask, respectively. Parents in the WebTIPS group were also significantly less anxious compared with parents in the control group in the preoperative holding area (Cohen's* d *= 0.65).*

Kain ZN, Caldwell-Andrews AA, Mayes LC. Parental intervention choices for children undergoing repeated surgeries. *Anesth Analg.* 2003;96:970-975.

Children were assigned to parental presence at induction (PPIA), premedication with midazolam, PPIA + premedication, or no intervention at initial surgery. Children were then followed up at subsequent surgery and parental preference for intervention was assessed. Of parents whose children were assigned to PPIA, 70% would choose PPIA as an intervention again. Of those assigned to premedication, only 23% would choose premedication again. Regardless of prior intervention, parents at subsequent surgery favored PPIA. Children's and parents' anxiety also affected parental preference for intervention.

Kain ZN, Fortier MA, Chorney JM, Mayes L. Web-based tailored intervention for preparation of parents and children for outpatient surgery (WebTIPS): development. *Anesth Analg.* 2015;120:905-914.

This study described the development of a Web-based Tailored Intervention for Preparation of parents and children undergoing surgery (WebTIPS). A multidisciplinary task force was comprised and determined that WebTIPS would consist of the most up-to-date, empirical evidence for preparing children and their parents for the surgical process and would be delivered via the web using an intake, matrix, and output modules covering the four temporal divisions of surgery (home before surgery, waiting area and anesthesia induction, postanesthesia care unit, home after surgery). The child component includes strategies such as information provision, modeling, play, and coping skills training and is fully animated. The parent component includes information provision, coping skills training, and cognitive and behavioral anxiety management skills (e.g., imagery, diaphragmatic breathing) and makes use of various multimedia modes (e.g., text, video, motion graphics).

Kain ZN, Mayes LC, Caldwell-Andrews AA, et al. Preoperative anxiety and postoperative pain and behavioral recovery in young children undergoing surgery. *Pediatrics.* 2006;118:651-658.

This study assessed preoperative anxiety and postoperative pain and behavioral outcomes after surgery in 241 children. Children who displayed more preoperative anxiety were rated as having higher pain after surgery by their parents. Anxious

children also consumed more analgesics at home after surgery and were more likely to experience emergence delirium and postoperative sleep disturbances.

Martin SR, Chorney JM, Tan ET, et al. Changing healthcare providers' behavior during pediatric inductions with an empirically based intervention. *Anesthesiology*. 2011;115:18-27.

This study described the development and evaluation of a new intervention (P-TIPS) focused on changing health care provider and parent behaviors in the perioperative setting to reduce children's preoperative anxiety. The intervention consisted of training providers and parents to increase use of behaviors empirically shown to promote children's coping (e.g., nonprocedural talk, humor, medical reinterpretation) and decrease use of behaviors shown to increase children's distress (e.g., reassurance, empathy, apology). The intervention was shown to successfully alter provider and parent behaviors, with meaning increases in rates of desired behaviors at anesthesia induction (average anesthesiologist Cohen's d *= 0.97, average nurse Cohen's* d *= 1.59) and show positive effects on children's preoperative anxiety.*

Preparation of Children for Anesthesia

FASTING

Infants and children are fasted before sedation and anesthesia to minimize the risk of pulmonary aspiration of gastric contents. In a fasted child, only the basal secretions of gastric juice should be present in the stomach. In 1948, Digby Leigh recommended a 1-hour preoperative fast after clear fluids.[1] Subsequently, Mendelson reported a number of maternal deaths that were attributed to aspiration at induction of anesthesia.[1a,1b] During the intervening 20 years, the fasting interval before elective surgery increased to 8 hours after all solids and fluids. In the late 1980s and early 1990s, an evidence-based approach to the effects of fasting intervals on gastric fluid pH and volume concluded that fasting more than 2 hours after clear fluids neither increased nor decreased the risk of pneumonitis should aspiration occur.[2–10] In the past, the risk for pneumonitis was reported to be based on two parameters: gastric fluid volume greater than 0.4 mL/kg and pH less than 2.5; however, these data were never published in a peer-reviewed journal.[1a,11] In a monkey, 0.4 mL/kg of acid instilled endobronchially, equivalent to 0.8 mL/kg aspirated tracheally, resulted in pneumonitis.[12] Using these corrected criteria for acute pneumonitis (gastric residual fluid volume >0.8 mL/kg and pH <2.5), studies in children demonstrated no additional risk for pneumonitis when children fast for only 2 hours after clear fluids.[2–9]

The incidence of pulmonary aspiration in modern routine elective pediatric or adult cases without known risk factors is small.[13–16] This small risk is the result of a number of factors including the preoperative fasting schedule. The half-life to empty clear fluids from the stomach is approximately 15 minutes (Fig. 4.1); as a result, 98% of clear fluids exit the stomach in children by 1 hour. Clear liquids include water, fruit juices without pulp, carbonated beverages, clear tea, and black coffee. Although fasting for 2 hours after clear fluids ensures nearly complete emptying of the residual volume, extending the fasting interval to 3 hours introduces flexibility in the operative schedule. The potential benefits of a 2-hour fasting interval after clear fluids include a reduced risk of hypoglycemia, which is a real possibility in children who are debilitated, have chronic disease, are poorly nourished, have metabolic dysfunction, or are preterm or formerly preterm infants.[17–20] Additional benefits include decreased thirst, decreased hunger (and thus reduced temptation that the fasting child will "steal" another child's food), decreased risk for hypotension during induction, and improved child cooperation.[2,11,21]

A scheduled operation on a preterm infant or neonate may occasionally be delayed, thus extending the period of fasting to a point that could be potentially dangerous (i.e., from hypoglycemia or hypovolemia). In this circumstance, the infants should be given glucose-containing intravenous (IV) maintenance fluids before induction of anesthesia. Alternatively, if the period may be protracted, the infant should be offered clear fluids orally until 2 hours before induction.

Breast milk, which can cause significant pulmonary injury if aspirated,[22] has a very high and variable fat content (determined by maternal diet), which will delay gastric emptying.[21] *Breast milk should not be considered a clear liquid.*[23] Two studies estimated the gastric emptying times after clear fluids, breast milk, or formula in full-term and preterm neonates.[24,25] The emptying times for

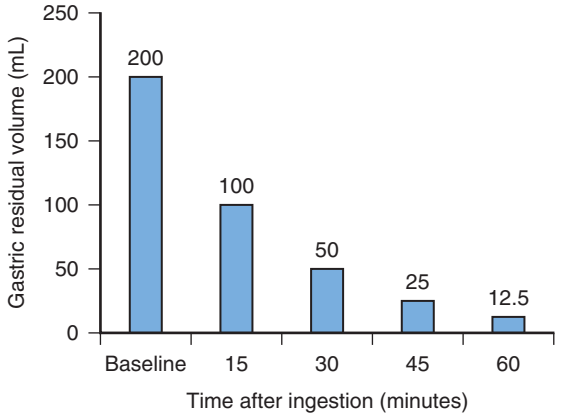

FIGURE 4.1 Clear liquids are rapidly absorbed from the stomach with a half-life of approximately 15 minutes. In this figure, for example, 200 mL of apple juice would be reduced to 12.5 mL after 60 minutes. (Data abstracted from Hunt JN, MacDonald M. The influence of volume on gastric emptying. *J Physiol* 1954;126:459-474.)

breast milk in both age groups were substantively greater than for clear fluids, and the gastric emptying times for formula were even greater than those for breast milk. With half-life emptying times for breast milk of 50 minutes and for formula of 75 minutes, fasting intervals of at least 3.3 hours for breast milk and 5 hours for formula are required. More importantly, perhaps, was the large (15%) variability in gastric emptying times for breast milk and formula in full-term infants (E-Fig. 4.1). Based in part on these data, the Task Force on Fasting of the American Society of Anesthesiologists (ASA) issued the following guidelines: for breast milk, 4 hours; and for formula, 6 hours (Table 4.1).[26]

Children who have been chewing gum must dispose of the gum by expectorating it, not swallowing it. Hansen and Rune[27] reported a 70% increase in gastric fluid volume in the first 15 minutes after initiating gum chewing, almost all from swallowing saliva. Chewing gum also increases gastric pH in children, leaving no clear evidence that it affects the risk of pneumonitis should aspiration occur.[28] A systemic review and meta-analysis of preoperative gum chewing in both children and adults concluded that chewing gum is unlikely to lead to a meaningful increase in the risk of major morbidity from pulmonary aspiration.[29] Consequently, we recommend that if the gum is discarded, then elective anesthesia can proceed without additional delay. If, however, the child swallows the gum, then surgery should be canceled, because aspirated gum at body temperature may be very difficult to extract from a bronchus or trachea.

Children can never be trusted to fast. Therefore, anesthesiologists must always be suspicious and question children just before induction as to whether they have eaten or drunk anything (although the veracity of the answer may always be questioned as well). It is not unusual to find bubble gum, candy, or other food in a child's mouth. This is another reason to ask children to open their mouth fully and stick out their tongue during the preoperative examination of the airway.

When the anesthesiologist suspects that the child has a full stomach, induction of anesthesia should be adjusted appropriately. The incidence of pulmonary aspiration of gastric contents during elective surgery in children ranges from 1:1163 to 1:10,000, depending on the study.[13–15,30,31] In contrast, the frequency of pulmonary aspiration in children undergoing emergency procedures

TABLE 4.1 Preoperative Fasting Recommendations in Infants and Children

Clear liquids[a]	2 hours
Breast milk	4 hours
Infant formula	6 hours[b]
Solids (fatty or fried foods)	8 hours

From Warner MA, Caplan RA, Epstein B. Practice guidelines for preoperative fasting and the use of pharmacologic agents to reduce the risk of pulmonary aspiration: application to healthy patients undergoing elective procedures. A report by the American Society of Anesthesiologists Task Force on Preoperative Fasting. *Anesthesiology* 1999;90:896–905.

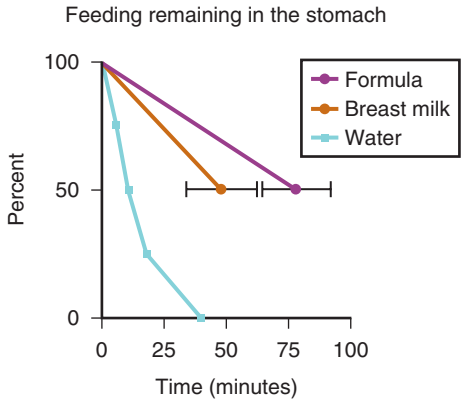
[a]Include only fluids without pulp, clear tea, or coffee without milk products.

[b]Some centers allow plain toast (no dairy products) up to 6 hours prior to induction.

is several times greater, 1:373 to 1:4544.[30,31] Risk factors for perianesthetic aspiration included neurologic or esophagogastric abnormality, emergency surgery (especially at night), ASA physical status 3 to 5, intestinal obstruction, increased intracranial pressure, increased abdominal pressure, light anesthesia, obesity, and the skill and experience of the anesthesiologist.[14,31]

The majority of aspirations in children occur during induction of anesthesia, with only 13% occurring during emergence and extubation. In contrast, 30% of the aspirations in adults occur during emergence. Bowel obstruction or ileus was present in the majority of infants and children who aspirated during the perioperative period in one study, with the risk increasing in children younger than 3 years of age.[30] A combination of factors predisposes the infant and young child to regurgitation and aspiration, including decreased competence of the lower esophageal sphincter, excessive air swallowing while crying during the preinduction period, strenuous diaphragmatic breathing, and a shorter esophagus. In one study, almost all cases of pulmonary aspiration occurred either when the child gagged or coughed during airway manipulation or during induction of anesthesia when neuromuscular blocking drugs were not provided or before the child was completely paralyzed.[30]

When children do aspirate, the morbidity and mortality are exceedingly small for elective surgical procedures and generally reflect their ASA physical status; most patients with clinical status of ASA 1 or 2 who aspirate clear gastric contents have minimal to no sequelae.[13,30] If clinical signs of sequelae from an aspiration in a child are going to occur, they will be apparent within 2 hours[30]; mortality is exceedingly low and estimated to be between 0 and 1:50,000.[13,14,30]



PIERCINGS

Body piercing is common practice in adolescents and young adults. Single or multiple piercings may appear anywhere on the body. To minimize the liability and risk of complications from metal piercings, they should be removed before surgery. Complications that may occur if they are left in situ during anesthesia are listed in E-Table 4.1.[32–34]

PRIMARY AND SECONDARY SMOKING

Primary Smoking

Unfortunately, cigarette smoking is not only limited to adults. Each day, 3800 American adolescents smoke their first cigarette and of these, more than 50% will become regular smokers. The annual burden of smoking-attributable mortality remains high

E-FIGURE 4.1 Percentage of gastric feeding remaining in the stomach after water, breast milk, or formula versus time after ingestion by infants. Data are expressed as mean ± standard deviation. The time to 50% gastric emptying of water was 15 minutes, of breast milk 50 minutes, and of formula 80 minutes. On the basis of these data, about 95% emptying (i.e., four half-lives) of gastric feedings should occur in about 1 hour after water, about 3.5 hours after breast milk, and about 5.5 hours after infant formula. However, note the wide standard deviations for the emptying times for breast milk and formula. (From Cavell B. Gastric emptying in preterm infants. *Acta Paediatr Scand*. 1979;68:725-730; Cavell B. Gastric emptying in infants fed human milk or infant formula. *Acta Paediatr Scand*. 1981;70:639-641.)

E-TABLE 4.1 Complications From Metal Piercings

Electrocautery Burns
All tissues adjacent to metal piercings are at risk; to avoid burns, use bipolar cautery or a harmonic knife; the cautery grounding pad should be remote from the piercing.

with 5.6 million youth currently 0 to 17 years of age projected to die prematurely from a smoking-related illness.[35] Even though the rate of new cigarette smokers in North America has declined over the past 2 decades, this has been offset with an increase in use of other nicotine products such as electronic cigarettes (e-cigarettes). Many factors, including lack of regulation at the federal level, "harmless water vapor" messaging, a strong social media presence with celebrity endorsements, and flavors targeting a young audience ("Cupcake," "Alien Blood," "Cherry Crush," "Chocolate Treat," etc.) play a significant role in influencing initiation of e-cigarette use in this age group.[36] A national survey indicated that e-cigarette use was at an all-time high among high school students at 13.4%, which was more prevalent than conventional cigarette use at 9.2%.[37] Youth e-cigarette users are more likely than nonusers to report initiation of conventional cigarettes within a year.[38]

Smoking is known to increase blood carboxyhemoglobin concentrations, decrease ciliary function, decrease functional vital capacity (FVC) and the forced expiratory flow in midphase ($FEF_{25\%-75\%}$), and increase sputum production. There is extensive evidence that smokers undergoing surgery are more likely to develop wound infections and postoperative respiratory complications.[39] Although stopping smoking for 2 days decreases carboxyhemoglobin levels and shifts the oxyhemoglobin dissociation curve to the right, stopping for at least 6 to 8 weeks is necessary to reduce the rate of postoperative pulmonary complications.[40,41]

Current harmful effects of e-cigarette use focus on nicotine exposure, the potential for these products to be a gateway to cigarette use, and the possibility of exposure to harmful flavoring chemicals such as diacetyl (2,3-butanedione).[42] This chemical is used to give foods a buttery or creamy flavor and has been shown to cause acute-onset bronchiolitis obliterans.[43,44] Data are lacking on long-term exposure and health effects of the use of e-cigarettes given the limited time span these products have been in the marketplace.

The perioperative period is the ideal time to abandon the smoking habit permanently, and anesthesiologists can perhaps play a more active role in facilitating this process. Physician communication with adolescents regarding smoking cessation has been shown to positively impact their attitudes, knowledge, intentions to smoke, and quitting behaviors.[45] In summary, during the preoperative visit with adolescents, anesthesiologists should inquire about cigarette smoking and emphasize the need to stop the habit by offering measures to ameliorate the withdrawal (e.g., nicotine patch).

Secondary Smoking

A national survey in the United States revealed the percentage of children 3 to 19 years of age without asthma exposed to environmental tobacco smoke (ETS) decreased from 57.3% to 44.2% from 1999 to 2010 while a higher percentage of children with asthma (54.0%) were exposed to ETS.[46]

Studies have shown that children exposed to ETS are more likely to have asthma, otitis media,[47] atopic eczema, hay fever,[48] and dental caries.[49] There is also an increased rate of lower respiratory tract illness in infants with ETS exposure.[50,51] A recent systemic review and meta-analysis revealed a nearly 2-fold increase in risk of hospitalization for an asthma exacerbation in children with asthma and ETS in westernized countries.[52] This is the first time this risk has been quantified and will enable health care providers to convey the harmful effects of ETS to parents about aggravation of asthma.

Several authors have demonstrated that ETS results in increased perioperative airway complications in children. In one study,[53] urinary cotinine, the major metabolite of nicotine, was used as a surrogate marker of ETS. A strong association was found between passive inhalation of tobacco smoke and airway complications on induction and emergence from anesthesia. A prospective investigation in Australia provided further insight on the effect of the smoking habits of different family members; the risk for perioperative adverse respiratory events was higher when children were exposed to maternal or both parents smoking than when only the father smoked.[54] Respiratory adverse events include laryngospasm, bronchospasm, airway obstruction, oxygen desaturation (<95%), severe or sustained cough, and stridor in the postanesthesia care unit (PACU).

The evidence for adverse perioperative events in children from ETS is clearly overwhelming. During the preoperative visit, the anesthesiologist should ascertain the child's exposure to ETS by asking parents or guardians about smoking within the household. This is an opportune time to educate parents and guardians about the dangers of ETS for their children.

PSYCHOLOGICAL PREPARATION OF CHILDREN FOR SURGERY

The perioperative period is stressful and anxiety-provoking for the child and family; many parents express more concern about the risks of anesthesia than those of the surgery. The factors that influence the ability of the child and family to cope with the stress of surgery include family dynamics, the child's developmental and behavioral status and cultural biases, and our ability to explain away misperceptions and misinformation. Because of logistics and today's practice constraints, there is limited time to evaluate family dynamics and establish rapport. It is therefore vital for the anesthesiologist to interact directly with the child in a manner consistent with the child's level of development. A specific child-oriented approach by the anesthesiologist, surgeon, nurses, and hospital staff is required.

Although the preoperative evaluation and preparation of children are similar to those of adults from a physiologic standpoint, the psychological preparation of infants and children is very different (see also Chapter 3). Many hospitals have an open house or a brochure to describe the preoperative programs available to parents before the day of admission.[55] However, printed material should not replace verbal communication with nursing and medical staff.[56] Anesthesiologists are encouraged to participate in the design of these programs so that they accurately reflect the anesthetic practice of the institution. The preoperative anesthetic experience begins when parents are first informed that the child is to have surgery or a procedure that requires general anesthesia. Parental satisfaction correlates with the comfort of the environment and the trust established between the anesthesiologist, the child, and the parents.[57] If parental presence during induction is deemed to be in the child's best interest, a parental educational program that describes what the parent can expect to happen if he or she accompanies the child to the operating room (OR) can significantly decrease parents' anxiety and increase their satisfaction.[58] The greater the understanding and amount of information the parents have, the less anxious they will be, and this attitude, in turn, will be reflected in the child.[59,60]

Informed consent should include a detailed description of what the family can anticipate and our role to protect the welfare of the child. Before surgery, the anesthetic risks should be discussed in clear terms but in a reassuring manner by describing the measures

that will be taken to carefully and closely monitor the safety of the child. Mentioning specific details and the purpose of the various monitoring devices may help diminish the parents' anxiety by demonstrating to them that the child will be anesthetized with the utmost safety and care. A blood pressure cuff will *"check the blood pressure,"* an electrocardiographic monitor will *"watch the heartbeat,"* a stethoscope will help us *"to continuously listen to the heart sounds,"* a pulse oximeter will *"measure the oxygen in the bloodstream,"* a carbon dioxide analyzer will *"monitor the breathing,"* an anesthetic agent monitor will *"accurately measure the level of anesthesia,"* and an IV catheter will be placed *"to administer fluid and medications as needed."* Children who are capable and their parents should be given ample opportunity to ask questions preoperatively. Finally, they should be assured that our "anesthetic prescription" will be designed specifically for their child's needs, taking into account the child's underlying medical conditions and the needs of surgery to ensure optimal conditions for surgery, the safety of the child, and analgesia.

It has been shown that parents desire comprehensive perioperative information, and that discussion of highly detailed anesthetic risk information does not increase parent's anxiety level.[61] Inadequate preparation of children and their families may lead to a traumatic anesthetic induction and difficulty for both the child and the anesthesiologist, with the possibility of postoperative psychological disturbances.[62] Numerous preoperative educational programs for children and adults have evolved to alleviate some of these fears and anxiety. They include preoperative tours of the ORs, educational videos, play therapy, magical distractions, puppet shows, anesthesia consultations, and child-life preparation.[63] The timing of the preoperative preparation has been found to be an important determinant of whether the intervention will be effective. For example, children older than 6 years of age who participated in a preparation program more than 5 to 7 days before surgery were least anxious during separation from their parents, those who participated in no preoperative preparation were moderately anxious, and those who received the information 1 day before surgery were the most anxious. The predictors of anxiety correlated also with the child's baseline temperament and history of previous hospitalizations.[64] Children of different ages vary in their response to the anesthetic experience (see also Chapter 3).[65] Even more important may be the child's trait anxiety when confronted with a stressful medical procedure.[66]

Child Development and Behavior

Understanding age-appropriate behavior in response to external situations is essential. Age-specific perioperative anxieties are outlined in E-Table 4.2 (see also Chapter 3 for further discussion of risk factors for preoperative anxiety). Special aspects of a child's perception of anesthesia should be anticipated; children often have the same fears as adults but are unable to articulate them. The reason and need for a surgical procedure should also be carefully explained to the child. It is important to reassure children that anesthesia is not the same as the usual nightly sleep, but rather a special sleep caused by the medicines we give during which they cannot be awakened and no matter what the surgeon does, they cannot feel pain. Many children fear the possibility that they will wake up in the middle of the anesthetic and during surgery. They should be reassured that they will awaken only after the surgery is completed.

The words the anesthesiologist uses to describe to the child what can be anticipated must be carefully chosen, because children think concretely and tend to interpret the facts literally. Examples of this are presented by the following anecdotes:

Example 1: A 4-year-old child was informed that in the morning she would receive a "shot" that would "put her to sleep." That night, a frantic call was received from the mother, describing a very upset child; the child thought she was going to be "put to sleep" like the veterinarian had permanently "put to sleep" her sick pet.

Example 2: A 5-year-old child admitted for elective inguinal herniorrhaphy received a heavy premedication and was deeply sedated on arrival in the OR. After discharge, the parents frequently discovered him wandering about the house at night. On questioning, the child stated that he was "protecting" his family. He stated: "I don't want anyone sneaking up on you and operating while you are sleeping."

In the first example, the child's concrete thought processes misunderstood the anesthesiologist's choice of words. The second case represents a problem of communication: the child was never told he would have an operation.

The importance of proper psychological preparation for surgery should not be underestimated. Often, little has been explained to both patient and parents before the day of surgery. Anesthesiologists have a key role in defusing fear of the unknown if they understand a child's age-related perception of anesthesia and surgery (see Chapter 3). They can convey their understanding by presenting a calm and friendly face (smiling, looking at the child, and making eye contact), offering a warm introduction, touching the patient in a reassuring manner (holding a child's or parent's hand), and being completely honest. Children respond positively to an honest description of exactly what they can anticipate. This includes informing them of the slight discomfort of starting an IV line or giving an intramuscular premedication, the possible bitter taste of an oral premedication, or breathing our magic laughing gas through the flavored mask.

The postoperative process, from the OR to the recovery room, and the onset of postoperative pain should be described. Encourage the child and family to ask questions. Strategies to maintain analgesia should be discussed, including the use of long-acting local anesthetics; nerve blocks; neuraxial blocks; patient-controlled, nurse-controlled, or parent-controlled analgesia or epidural analgesia; or intermittent opioids (see also Chapters 42, 43, and 44).

As children age, they become more aware of their bodies and may develop a fear of mutilation. Adolescents frequently appear quite independent and self-confident, but as a group, they have unique problems. In a moment their mood can change from an intelligent, mature adult to a very immature child who needs support and reassurance. Coping with a disability or illness is often very difficult for adolescents. Because they are often comparing their physical appearance with that of their peers, they may become especially anxious when they have a physical problem. In general, they want to know exactly what will transpire during the course of anesthesia. Adolescents are usually cooperative, preferring to be in control and unpremedicated preoperatively. The occasional overly anxious or rambunctious adolescent, however, may benefit from preanesthetic medication.

Monitoring the attitude and behavior of a child is very useful. A child who clings to the parents, avoids eye contact, and does not speak is very anxious. A self-assured, cocky child who "knows it all" may also be apprehensive or frightened. This know-it-all behavior may mask the child's true emotions, and he or she may decompensate just when cooperation is most needed. In some cases, nonpharmacologic supportive measures may be effective.

E-TABLE 4.2 Age-Specific Anxieties of Pediatric Patients

Age	Specific Type of Perioperative Anxiety
0–6 months	• Maximum stress for parent • Minimum stress for infants—not old enough to be frightened of strangers
6 months–4 years	• Maximum fear of separation • Not able to understand processes and explanations • Significant postoperative emotional upset and behavior regression • Begins to have magical thinking • Cognitive development and increased temper tantrums
4–8 years	• Begins to understand processes and explanations • Fear of separation remains • Concerned about body integrity
8 years–adolescence	• Tolerates separation well • Understands processes and explanations • May interpret everything literally • May fear waking up during surgery or not waking up at all
Adolescence	• Independent • Issues regarding self-esteem and body image • Developing sexual characteristics and fear loss of dignity • Fear of unknown

Modified with permission from Cruickshank BM, Cooper LJ. Common behavioral problems. In: Greydanus DE, Wolraich ML, eds: *Behavioral Pediatrics*. New York: Springer; 1992.

In the extremely anxious child, supportive measures alone may be insufficient to reduce anxiety, and premedication is indicated.

Identifying a difficult parent or child preoperatively is not always easy, especially if the anesthesiologist first meets the child or family on the day of surgery and has limited time to assess the situation. Occasionally, we receive a warning regarding a difficult parent or child from the surgeon or nursing staff, based on their encounters with the family. With experience, some anesthesiologists are able to identify difficult parents and children during the short preoperative assessment and make appropriate adjustments to the anesthetic management plan.

The "veterans" or "frequent flyers" of anesthesia can also be difficult in the perioperative period. They have played the anesthesia and surgical game before and are not interested in participating again, especially if their previous experiences were negative. These children may benefit the most from a relatively heavy premedication; reviewing previous responses to premedication will aid in the adjustment of the current planned premedication (e.g., adding ketamine and atropine to oral midazolam to achieve a greater depth of sedation).

It is important to observe the family dynamics to better understand the child and determine who is in control, the parent or the child. Families many times are in a state of stress, particularly if the child has a chronic illness; these parents are often angry, guilt ridden, or simply exhausted. Ultimately, the manner in which a family copes with an illness largely determines how the child will cope.[67] The well-organized, open, and communicative family tends to be supportive and resourceful, whereas the disorganized, noncommunicative, and dysfunctional family tends to be angry and frustrated. Dealing with a family and child from the latter category can be challenging. There is the occasional parent who is overbearing and demands total control of the situation. It is important to be empathetic and understanding but to set limits and clearly define the parent's role. He or she must be told that the anesthesiologist determines when the parent must leave the OR; this is particularly true if an unexpected development occurs during the induction.

Parental Presence During Induction

One controversial area in pediatric anesthesia is parental presence during induction. Some anesthesiologists encourage parents to be present at induction, whereas others are uncomfortable with the process and do not allow parents to be present. Inviting a parent to accompany the child to the OR has been interpreted by some courts as an implicit contract on the part of the caregiver who invited the parent to participate in the child's care; in one case, the institution was found to have assumed responsibility for a mother who suffered an injury when she fainted.[68] Each child and family must be evaluated individually; what is good for one child and family may not be good for the next.[69–72] (See Chapter 3 for a full discussion of this and other anxiolytic strategies in children.)

If the practice of having parents present at induction is to work well, then the anesthesiologist must be comfortable with such an arrangement. No parent should ever be forced to be present for the induction of anesthesia, nor should any anesthesiologist be forced into a situation that compromises the quality of care he or she affords a child in need.

Parents must be informed about what to anticipate in terms of the OR itself (e.g., equipment, surgical devices), in terms of what they may observe during induction (e.g., eyes rolling back, laryngeal noises, anesthetic monitor alarms, excitation), and when they will be asked to leave. They must also be instructed regarding their ability to assist during the induction process, such as by comforting the child, encouraging the child to trust the anesthesiologist, distracting the child, and consoling the child (Videos 4.1 and 4.2). Personnel should be immediately available to escort parents back to the waiting area at the appropriate time. Someone should also be available to care for a parent who wishes to leave the induction area or who becomes lightheaded or faints. An anesthesiologist's anxiety about parents' presence during induction decreases significantly with experience.[73]

Explaining what parents might see or hear is essential. We generally tell parents the following:

> *As you see your child fall asleep today, there are several things you might observe that you are not used to seeing. First, when anyone falls asleep, the eyes roll up, but since we are sleeping we do not generally see it. You may see your child do that today, and I do not want you to be frightened by that—it is expected and normal. The second thing is that as children go to sleep from the anesthesia medications, the tone of the structures in the neck decreases, so that some children will begin to snore or make vibrating noises. Again, I do not want you to be frightened or think that something is wrong. We expect this, and it is normal. The third thing you might see is what we call "excitement." As the brain begins to go to sleep, it can actually get excited first. About 30 to 60 seconds after breathing the anesthesia medications, your child might suddenly look around or suddenly move his or her arms and legs. To you it appears that he or she is awakening from anesthesia or that he or she is upset. In reality, this is a good sign, because it indicates to us that your child is falling asleep and that 15 to 30 seconds later he or she will be completely anesthetized. Also, you should know that even though your child appears to be awake to you, in reality he or she will not remember any of that. As soon as your child loses consciousness, we will ask you to give your child a kiss and step out of the operating room.*

This kind of careful preparation provides to the parents the confidence that the anesthesiologist really knows what he or she is talking about, and it avoids frightening the parents. In general, the more information provided, the lower the parental anxiety levels. A child-life specialist in surgical services may also prove valuable to the anesthesiologist by calming and preparing both children and parents for the OR experience (see "Inhalation Induction" later in this chapter for further details).

Occasionally, the best efforts to relieve a child's anxiety by parental presence or administration of a sedative premedication (or both) are not successful, and an anticipated smooth induction may not go as planned. There are three options that may be used depending on the age of the child: (1) renegotiating (which is seldom successful), (2) holding the mask farther away from the child's face, or (3) suggesting an IV or intramuscular induction. If an intramuscular shot or IV induction is proposed, the child will usually choose the mask. If the situation is totally out of control, either elective surgery can be rescheduled or intramuscular ketamine can be used if the parents choose to proceed. These situations are particularly difficult for the parents and the caregivers but must be handled on an individual basis.

HISTORY OF PRESENT ILLNESS

The medical history of a child obtained during the preanesthetic visit allows the anesthesiologist to determine whether the child is optimized for the planned surgery, to anticipate potential problems due to coexisting disease, to determine whether appropriate laboratory or other tests are available or needed, to select optimal premedication, to formulate the appropriate anesthetic plan including perioperative monitoring, and to anticipate postoperative concerns

TABLE 4.2 Review of Systems: Anesthetic Implications

System	Factors to Assess	Possible Anesthetic Implications
Respiratory	Cough, asthma, recent cold	Irritable airway, bronchospasm, medication history, atelectasis, infiltrate
	Croup	Subglottic narrowing
	Apnea/bradycardia	Postoperative apnea/bradycardia
Cardiovascular	Murmur	Septal defect, avoid air bubbles in IV line
	Cyanosis	Right-to-left shunt
	History of squatting	Tetralogy of Fallot
	Hypertension	Coarctation, renal disease
	Rheumatic fever	Valvular heart disease
	Exercise intolerance	Congestive heart failure, cyanosis
Neurologic	Seizures	Medications, metabolic derangement
	Head trauma	Intracranial hypertension
	Swallowing incoordination	Aspiration, esophageal reflux, hiatus hernia
	Neuromuscular disease	Neuromuscular relaxant drug sensitivity, malignant hyperpyrexia
Gastrointestinal/ hepatic	Vomiting, diarrhea	Electrolyte imbalance, dehydration, full stomach
	Malabsorption	Anemia
	Black stools	Anemia, hypovolemia
	Reflux	Possible need for full-stomach precautions
	Jaundice	Drug metabolism/hypoglycemia
Genitourinary	Frequency	Urinary tract infection, diabetes, hypercalcemia
	Time of last urination	State of hydration
	Frequent urinary tract infections	Evaluate renal function
Endocrine/metabolic	Abnormal development	Endocrinopathy, hypothyroid, diabetes
	Hypoglycemia, steroid therapy	Hypoglycemia, adrenal insufficiency
Hematologic	Anemia	Need for transfusion
	Bruising, excessive bleeding	Coagulopathy, thrombocytopenia, thrombocytopathy
	Sickle cell disease	Hydration, possible transfusion
Allergies	Medications	Possible drug interaction
Dental	Loose or carious teeth	Aspiration of loose teeth, bacterial endocarditis prophylaxis

including pain management and postoperative ventilatory needs. The history of the present illness is described to the physicians by the parents and verified by the referring or consultant surgeon's notes. If the child is old enough, it is helpful to obtain the child's input. The history should focus on the following aspects:

- A review of all organ systems (Table 4.2) with special emphasis on the organ system involved in the surgery
- A review of patient and parental smoking history
- Medications (over-the-counter and prescribed) related to and taken before the present illness, including herbals and vitamins, and when the last dose was taken
- Medication allergies with specific details of the nature of the allergy and whether immunologic testing was performed
- Previous surgical and hospital experiences, including those related to the current problem
- Timing of the last oral intake, last urination (wet diaper), and vomiting and diarrhea. It is essential to recognize that decreased gastrointestinal motility often occurs with an illness or injury.

In the case of a neonate, problems that may have been present during gestation and birth may still be relevant in the neonatal period and beyond (E-Table 4.3). The maternal medical and pharmacologic history (both therapeutic and drug abuse) may also provide valuable information for the management of a neonate requiring surgery.

PAST/OTHER MEDICAL HISTORY

The past medical history should include a history of all past medical illnesses with a review of organ systems, previous hospitalizations (medical or surgical), childhood syndromes with associated anomalies, medication list, herbal remedies, and any allergies, especially to antibiotics and latex. Whether the child was full-term or preterm at birth should be discerned; if preterm, any associated problems should be noted, including admission to a neonatal intensive care unit, duration of tracheal intubation, history of apnea or bradycardia (including oxygen treatment, home apnea monitor, intraventricular hemorrhage), and congenital defects.

Examination of previous surgical and anesthesia records greatly assists in planning the anesthesia. Particular attention should be paid to any difficulties encountered with airway management, venous access, or emergence. The response to or need for premedication and the route of administration used should be noted.

Herbal Remedies

The use of herbal medicinal products has become increasingly popular, likely driven by the notion that "natural" substances have fewer side effects. A survey in five geographically diverse centers in the United States found that 3.5% of pediatric surgical patients had been given herbal supplements or homeopathic remedies 2 weeks prior to surgery.[74] The findings of the National

E-TABLE 4.3 Maternal History With Commonly Associated Neonatal Problems

Maternal History	Commonly Expected Problems With Neonate
Rh-ABO incompatibility	Hemolytic anemia, hyperbilirubinemia, kernicterus
Toxemia	SGA and its associated problems,[a] muscle relaxant interaction with magnesium therapy
Hypertension	SGA and its associated problems[a]
Drug addiction	Withdrawal, SGA
Infection	Sepsis, thrombocytopenia, viral infection
Hemorrhage	Anemia, shock
Diabetes	Hypoglycemia, birth trauma, LGA, SGA, and associated problems[a]
Polyhydramnios	Tracheoesophageal fistula, anencephaly, multiple anomalies
Oligohydramnios	Renal hypoplasia, pulmonary hypoplasia
Cephalopelvic disproportion	Birth trauma, hyperbilirubinemia, fractures
Alcoholism	Hypoglycemia, congenital malformation, fetal alcohol syndrome, SGA, and associated problems[a]

SGA, small for gestational age; *LGA,* large for gestational age.
[a]See Table 2.2.

Health Interview Survey confirm a similar prevalence rate in which natural product usage among children age 0 to 17 years amounts to 3.9%.[75] Herbal medicine use is more common in adults; 32% of adult surgical patients take one or more herb-related compounds.[76] Nearly 70% of adults failed to disclose their use of herbal remedies when asked about medications during routine perioperative assessment. Herbal medicines are regulated as food supplements under the Dietary Supplement Health and Education Act of 1994 and as such manufacturers are not required to demonstrate safety or efficacy before placing a product on the market.[77] Without the Food and Drug Administration (FDA) regulation, there are no quality assurance requirements for manufacturing and labeling and much variation can occur in each preparation.[78] Anesthesiologists should include specific inquiries regarding the use of these medications because of the potential for adverse effects and drug interactions.

Herbal medicines are associated with cardiovascular instability, coagulation disturbances, potentiation of sedation, and immunosuppression.[79] The most commonly used herbal medications reported are garlic, ginseng, *Ginkgo biloba*, St. John's wort, and *Echinacea*,[80] with *Echinacea* and other herbal medicines for the treatment of coughs and colds taking the lead in the pediatric population.[74,81] The three "g" herbals, together with feverfew *(Tanacetum parthenium)*, potentially increase the risk of bleeding during surgery. The amount of active ingredient in each preparation and the dose taken may vary, thus making detection of a change in platelet function and other subtle coagulation disturbances difficult. St. John's wort is the herb that most commonly interacts with anesthetics and other medications, usually via a change in drug metabolism, because of potent inducing effects on the cytochrome P-450 enzymes (e.g., CYP3A4) and P-glycoprotein. A potentially fatal interaction between cyclosporine and St. John's wort has been well documented.[82–85] Heart, kidney, or liver transplant recipients who were stabilized on a dose of cyclosporine experienced decreased plasma concentrations of cyclosporine and, in some cases, acute rejection episodes after taking St. John's wort. A summary of the most commonly used herbal remedies and their potential perioperative complications is shown in E-Table 4.4.

To avoid potential perioperative complications, the ASA has encouraged the discontinuation of all herbal medicines 2 weeks before surgery,[86] although this recommendation is not evidence based. Recognizing that this is not always feasible, the ASA further recommends that anesthesiologists have knowledge of herbal medications and their potential interactions. Each herb should be carefully evaluated using standard resource texts, and a decision should be made regarding the timing of or need for discontinuation as determined on a case-by-case basis.[87]

Anesthesia and Vaccination

Children may present for surgery after having been recently immunized. The anesthesiologist and surgeon must then consider (1) whether the immunomodulatory effects of anesthesia and surgery might affect the efficacy and safety of the vaccine and (2) whether the inflammatory responses to the vaccine will alter the perioperative course.

What do anesthesiologists think about anesthesia and vaccination? An international survey[88] revealed that only one-third of responding anesthesiologists had the benefit of a hospital policy, ranging from a formal decision to delay surgery to an independent choice by the anesthesiologist. Sixty percent of respondents would anesthetize a child for elective surgery within 1 week of receiving a live attenuated vaccine (such as oral polio vaccine or measles, mumps, and rubella [MMR] vaccine), whereas 40% would not. The survey also revealed that 28% of anesthesiologists would delay immunization for 2 to 30 days after surgery.

A scientific review of the literature associating anesthesia and vaccination in children resulted in recommendations for the care of children under these circumstances.[89] The review demonstrated a brief and reversible influence of vaccination on lymphoproliferative responses that generally returned to preoperative values within 2 days. Vaccine-driven adverse events (e.g., fever, pain, irritability) might occur but should not be confused with perioperative complications. Adverse events to inactivated vaccines such as diphtheria-tetanus-pertussis (DPT) become apparent from 2 days and to live attenuated vaccines such as MMR from 7 to 21 days after immunization.[89] Therefore appropriate delays between immunization and anesthesia are recommended by type of vaccine to avoid misinterpretation of vaccine-associated adverse events as perioperative complications. Because children remain at risk of contracting vaccine-preventable diseases, the minimum delay seems prudent, especially in the first year of life. Likewise, it seems reasonable to delay vaccination *after* surgery until the child is fully recovered. These recommendations were adopted in a consensus guideline by the Association of Paediatric Anaesthetists of Great Britain and Ireland,* though to date, the US Centers for Disease Control and Prevention does not have a policy regarding the timing of vaccinations and surgery. Other immunocompromised patients, such as human immunodeficiency virus (HIV)-positive children, cancer patients, and transplant recipients, have distinct underlying immune impairments, and the influence of anesthesia on vaccine responses has not been comprehensively investigated.

Allergies to Medications and Latex

The details pertaining to all allergies to medications and materials should be described in the child's record. These include the age of onset, frequency, severity, investigations, and treatments. The vast majority of reported allergies on children's charts are either nonimmunologic reactions or known (or unknown) drug adverse effects. The most common medication- and hospital-related allergies in children are penicillin and latex allergy.

Most cases of reported penicillin allergy consist of a maculopapular rash after oral penicillin. This occurs in 1% to 4% of children receiving penicillin or in 3% to 7% of those taking ampicillin, usually during treatment.[90] Rarely are signs or symptoms that suggest an acute (immunoglobulin E–mediated) allergic reaction present (i.e., angioedema), and even less frequently is skin testing conducted to establish penicillin allergy. Given the frequency of penicillin allergy, most of these unverified allergies in fact are not allergies to penicillin but rather minor allergies to the dye in the liquid vehicle or a consequence of the (viral) infection. If the child has not received penicillin for at least 5 years since the initial exposure and has not been diagnosed with a penicillin allergy by an immunologist or allergist, then a reexposure is warranted. If the child has been tested immunologically for penicillin allergy, then it is best to avoid this class of antibiotics. Although there is a 5% to 10% cross-reactivity between first-generation cephalosporins and penicillin, there is no similar cross-reactivity with second- and third-generation cephalosporins. To date, there have been no fatal anaphylactic reactions in penicillin-allergic children from a cephalosporin.[90]

E-TABLE 4.4 Pharmacologic Effects and Potential Perioperative Complications of Eight Commonly Used Herbal Remedies

Name of Herb	Common Uses	Pharmacologic Effects	Potential Perioperative Complications
Echinacea, purple coneflower root	Prophylaxis and treatment of viral, bacterial, and fungal infection	Stimulation of the immune system. With long-term use may be immunosuppressive.	Reduced effectiveness of immunosuppressants. Potential for wound infection. May cause hepatotoxicity.
Ephedra, ma huang	Diet aid	Indirect- and direct-acting sympathomimetic	Dose-dependent increase in heart rate and blood pressure with potential for perioperative myocardial infarction and stroke. Arrhythmias with halothane. Tachyphylaxis with intraoperative ephedrine.
Garlic, ajo	Antihypertensive, lipid-lowering agent, anti-thrombus forming	Inhibits platelet aggregation (partially irreversibly) in a dose-dependent manner. Lowers serum lipid and cholesterol levels.	May potentiate other platelet inhibitors. Concerns for perioperative bleeding.
Ginkgo, maidenhair; fossil tree	Circulatory stimulant. Used to treat Alzheimer disease, peripheral vascular disease, and erectile dysfunction.	Inhibits platelet-activating factor. Antioxidant. Modulates neurotransmitter activity.	Concerns for perioperative bleeding. May potentiate other platelet inhibitors.
Ginseng	Used to protect the body against stress and restore homeostasis	Poorly understood. Inhibits platelet aggregation (partly irreversibly).	Potential to increase perioperative bleeding. Potential for hypoglycemia.
Kava, ava pepper	Anxiolytic	Possible potentiation of γ-aminobutyric acid (GABA) transmission	Potentiates sedative effects of anesthetic agents. Possible withdrawal syndrome after sudden abstinence. Kava-induced hepatotoxicity.
St. John's wort, goat weed, amber, hard hay	Treatment of depression and anxiety	Central inhibition of serotonin, norepinephrine, and dopamine. Induction of cytochrome P-450 3A4.	Decreased effectiveness of drugs metabolized by CYP3A4 such as cyclosporine, alfentanil, midazolam, lidocaine, calcium-channel blockers, and digoxin
Valerian, vandal root, all heal, Jacob's ladder	Anxiolytic and sleep aid	Potentiation of GABA neurotransmission	Potentiates sedative effects of anesthetic agents. Withdrawal-type syndrome with sudden abstinence.

Modified from Skinner CM, Rangasami J. Preoperative use of herbal medicines: a patient survey. *Br J Anaesth.* 2002;89:792-795.

Latex allergy is an acquired immunologic sensitivity resulting from repeated exposure to latex, usually on mucous membranes (e.g., children with spina bifida or congenital urologic abnormalities who have undergone repeated bladder catheterizations with latex catheters, those with more than four surgeries, those requiring home ventilation). It occurs more frequently in atopic individuals and in those with certain fruit and vegetable allergies (e.g., banana, chestnut, avocado, kiwi, pineapple).[91–97] For a diagnosis of latex anaphylaxis, the child should have personally experienced an anaphylactic reaction to latex, skin-tested positive for anaphylaxis to latex, or experienced swelling of the lips after touching a toy balloon to the lips or a swollen tongue after a dentist inserted a rubber dam into the mouth.[97] The avoidance of latex within the hospital will prevent acute anaphylactic reactions to latex in children who are at risk.[98] Latex gloves and other latex-containing products should be removed from the immediate vicinity of the child. Prophylactic therapy with histamine H_1- and H_2-receptor antagonists and steroids do not prevent latex anaphylaxis.[91,99] Latex anaphylaxis should be treated by removal of the source of latex, administration of 100% oxygen, acute volume loading with balanced salt solution (10 to 20 mL/kg repeated until the systolic blood pressure stabilizes), and administration of IV epinephrine (1 to 10 µg/kg according to the severity of the anaphylaxis). In some severe reactions, a continuous infusion of epinephrine alone (0.01 to 0.2 µg/kg per minute) or combined with other vasoactive medications may be required for several hours.

Family History

It is important to inquire about a family history, particularly focusing on a number of conditions, including malignant hyperthermia, muscular dystrophy, prolonged paralysis associated with anesthesia (pseudocholinesterase deficiency), sickle cell disease, bleeding (and bruising) tendencies, and drug addiction (drug withdrawal, HIV infection). The precise relationship to the proband must be documented.

LABORATORY DATA

The laboratory data obtained preoperatively should be appropriate to the history, illness, and surgical procedure. Routine hemoglobin testing or urinalysis is not indicated for most elective procedures; the value of these tests is questionable when the surgical procedure will not involve clinically important blood loss.[100] There are insufficient data in the literature to make strict hemoglobin testing recommendations in healthy children. A preoperative hemoglobin value is usually determined only for those who will undergo procedures with the potential for blood loss, those with specific risk factors for a hemoglobinopathy, former preterm infants, and those younger than 6 months of age. Coagulation studies (platelet count, international normalized ratio [INR], and partial thromboplastin time [PTT]) may be indicated if major reconstructive surgery is contemplated, especially if warranted by the medical history, and in some centers before tonsillectomy. In addition, collection of a preoperative type-and-screen or type-and-crossmatch sample is indicated in preparation for potential blood transfusions depending on the nature of the planned surgery and the anticipated blood loss.

In general, routine chest radiography is not necessary; studies have confirmed that routine chest radiographs are not cost-effective in children.[101,102] The oxygen saturation of children who are breathing room air is very helpful. Baseline saturations of 95% or less suggest clinically important pulmonary or cardiac compromise and warrant further investigation.

Selective preoperative laboratory tests, such as electrolyte and blood glucose determinations, renal function tests, blood gas analysis, blood concentrations of seizure medication and digoxin, electrocardiography, echocardiography, liver function tests, computed tomography (CT), magnetic resonance imaging (MRI), or pulmonary function tests, should be performed when appropriate. These tests may be ordered after consideration of specific information obtained from sources such as medical records, patient interview, physical examination, and the type and invasiveness of the planned procedure and anesthesia.

PREGNANCY TESTING

Although pregnancy rates among teenagers in the United States are declining,[103] a small percentage of adolescents may still present for elective surgery with an unsuspected pregnancy. Birth rates for teenagers in the United States declined to historic lows in 2014, to 24.2 births/1000 females aged 15–19 compared with 2003 when the birth rate in that age group was 41.6 births/1000.[103,104] The birth rate for girls aged 10 to 14 years also declined from 0.6/1000 in 2003[104] to 0.3/1000 in 2014.[103] However, routine preoperative pregnancy testing in adolescent girls may present ethical and legal dilemmas, including social and confidentiality concerns. This places the anesthesiologist in a predicament when faced with a question of whether to perform routine preoperative pregnancy screening. Each hospital should adopt a policy regarding pregnancy testing to provide a consistent and comprehensive policy for all females who have reached menarche.

A survey of members of the Society for Pediatric Anesthesia practicing in North America revealed that pregnancy testing was routinely required by approximately 45% of the respondents regardless of the practice setting (teaching versus nonteaching facilities).[100] A retrospective review of a 2-year study of mandatory pregnancy testing in 412 adolescent surgical patients[105] revealed that the overall incidence of positive tests was 1.2%. Five of 207 patients aged 15 years and older tested positive, for an incidence of 2.4% in that age group. None of the 205 patients younger than the age of 15 years had a positive pregnancy test. A prospective study of 261 menarcheal patients 10 to 34 years of age revealed 3 pregnancies but none of 107 children <15 years.[106]

The most recent ASA Task Force on Preanesthesia Evaluation recognized that a history and physical examination may not adequately identify early pregnancy and issued the following statement: *"The literature is insufficient to inform patients or physicians on whether anesthesia causes harmful effects on early pregnancy. Pregnancy testing may be offered to female patients of childbearing age and for whom the result would alter the patient's management."*[107] Because of the risk of exposing the fetus to potential teratogens and radiation from anesthesia and surgery, the risk of spontaneous abortion, and the risk of apoptosis reported in the rapidly developing fetal animal brain (see Chapter 25), elective surgery with general anesthesia is not advised during early pregnancy. Therefore, if the situation is unclear, and when indicated by medical history, it is best to perform a preoperative pregnancy test. If the surgery is required in a patient who might be pregnant, then using an opioid-based anesthetic such as remifentanil and the lowest concentration of inhalational agent or propofol that provides adequate anesthesia is preferred.

Premedication and Induction Principles

GENERAL PRINCIPLES

The major objectives of preanesthetic medication are to (1) allay anxiety, (2) block autonomic (vagal) reflexes, (3) reduce airway secretions, (4) produce amnesia, (5) provide prophylaxis against pulmonary aspiration of gastric contents, (6) facilitate the induction

of anesthesia, and (7) if necessary, provide analgesia. Premedication may also decrease the stress response to anesthesia and prevent cardiac arrhythmias.[108] The goal of premedication for each child must be individualized. Light sedation, even though it may not eliminate anxiety, may adequately calm a child so that the induction of anesthesia will be smooth and a pleasant experience. In contrast, heavy sedation may be needed for the very anxious child who is unwilling to separate from his or her parents.

Factors to consider when selecting a drug or a combination of drugs for premedication include the child's age, ideal body weight, drug history, and allergic status; underlying medical or surgical conditions and how they might affect the response to premedication or how the premedication might alter anesthetic induction; parent and child expectations; and the child's emotional maturity, personality, anxiety level, cooperation, and physiologic and psychological status. The anesthesiologist should also consider the proposed surgical procedure and the attitudes and wishes of the child and the parents.

The route of administration of premedicant drugs is very important. Premedications have been administered by many routes, including the oral, nasal, rectal, buccal, IV, and intramuscular routes. Although a drug may be more effective and have a more reliable onset when given intranasally or intramuscularly, most pediatric anesthesiologists refrain from administering parenteral medication to children without IV access. Many children who are able to verbalize report that receiving a needle puncture was their worst experience in the hospital.[109,110] In most cases, medication administered without a needle will be more pleasant for children, their parents, and the medical staff. Oral premedications do not increase the risk of aspiration pneumonia unless large volumes of fluids are ingested.[111] In general, the route of delivery of the premedication should depend on the drug, the desired drug effect, and the psychological impact of the route of administration. For example, a small dose of oral medication may be sufficient for a relatively calm child, whereas an intramuscular injection (e.g., ketamine) may be best for an uncooperative, combative, extremely anxious child. Intramuscular administration may be less traumatic for this type of child than forcing him or her to swallow a drug, giving a drug rectally, or forcefully holding an anesthesia mask on the face.[112]

Since Waters'[113] classic work in 1938 on premedication of children, numerous reports have addressed this subject. Despite the wealth of studies, no single drug or combination of drugs has been found to be ideal for all children. Many drugs used for premedication have similar effects, and a specific drug may have various effects in different children or in the same child under different conditions.

MEDICATIONS

Several categories of drugs are available for premedicating children before anesthesia (Table 4.3). Selection of drugs for premedication depends on the goal desired. Drug effects should be weighed against potential side effects, and drug interactions should be considered. Premedicant drugs include tranquilizers, benzodiazepines, barbiturates, nonbarbiturate sedatives, opioids, ketamine, α2 agonists, and drugs that increase gastric motility.

Tranquilizers

The major effect of tranquilizers is to allay anxiety, but they also have the potential to produce sedation. This group of drugs includes the benzodiazepines, phenothiazines, and butyrophenones. Benzodiazepines are widely used in children, whereas phenothiazines and butyrophenones are infrequently used.

TABLE 4.3 Doses of Drugs Commonly Administered for Premedication

Drug	Route	Dose (mg/kg)
Barbiturates		
Methohexital	Rectal	(10% solution) 20–40
	Intramuscular	(5% solution) 10
Thiopental	Rectal	(10% solution) 20–40
Benzodiazepines		
Diazepam	Oral	0.1–0.5
	Rectal	1
Midazolam	Oral	0.25–0.75
	Nasal	0.2
	Rectal	0.5–1
	Intramuscular	0.1–0.15
Lorazepam	Oral	0.025–0.05
Phencyclidine		
Ketamine[a]	Oral	3–6
	Nasal	3
	Rectal	6–10
	Intramuscular	2–10
α_2-Adrenergic Agonist		
Clonidine	Oral	0.004
Opioids		
Morphine	Intramuscular	0.1–0.2
Meperidine[b]	Intramuscular	1–2
Fentanyl	Oral	0.010–0.015 (10–15 µg/kg)
	Nasal	0.001–0.002 (1–2 µg/kg)
Sufentanil	Nasal	0.001–0.003 (1–3 µg/kg)

[a]With atropine 0.02 mg/kg.
[b]Only a single dose is recommended due to metabolites that may cause seizures.

Benzodiazepines

Benzodiazepines calm children, allay anxiety, and diminish recall of perianesthetic events. At low doses, minimal drowsiness and cardiovascular or respiratory depression are produced.

Midazolam, a short-acting, water-soluble benzodiazepine with an elimination half-life of approximately 2 hours, is the most widely used premedication for children.[114,115] The major advantage of midazolam over other drugs in its class is its rapid uptake and elimination.[116] It can be administered intravenously, intramuscularly, nasally, orally, and rectally with minimal irritation, although it leaves a bitter taste in the mouth or nasopharynx after oral or nasal administration.[117–123] Most children are adequately sedated after receiving a midazolam dose of 0.025 to 0.1 mg/kg intravenously, 0.1 to 0.2 mg/kg intramuscularly, 0.25 to 0.75 mg/kg orally, 0.2 mg/kg nasally, or 1 mg/kg rectally.

Orally administered midazolam is effective in calming most children and does not increase gastric pH or residual volume.[124,125] Evidence suggests that the required dose of midazolam increases as age decreases in children, similar to that for inhaled agents and IV agents.[126] An increased clearance in younger children contributes to their increased dose requirement.[127] A number of medications that affect the cytochrome oxidase system significantly affect the first-pass metabolism of midazolam, including grapefruit juice, erythromycin, protease inhibitors, and calcium-channel blockers

that decrease CYP3A4 activity, which in turn increases the blood concentration of midazolam and prolongs sedation.[128–134] Conversely, anticonvulsants (phenytoin and carbamazepine), rifampin, St. John's wort, glucocorticoids, and barbiturates induce the CYP3A4 isoenzyme, thereby reducing the blood concentration of midazolam and its duration of action. The dose of oral midazolam should be adjusted in children who are taking these medications.

Concerns have been raised about possible delayed discharge after premedication with oral midazolam. Oral midazolam, 0.5 mg/kg, administered to children 1 to 10 years of age, did not affect awakening times, time to extubation, postanesthesia care unit, or hospital discharge times, after sevoflurane anesthesia.[135] Similar results have been reported in children and adolescents after 20 mg of oral midazolam; however, detectable preoperative sedation in this group of children was predictive of delayed emergence.[136] In children aged 1 to 3 years undergoing adenoidectomy as outpatients, premedication with oral midazolam, 0.5 mg/kg, slightly delayed spontaneous eye opening by 4 minutes and discharge by 10 minutes compared with placebo; children who had been premedicated, however, exhibited a more peaceful sleep at home on the night after surgery.[137]

Likely the greatest effect of oral midazolam on recovery occurs with its use in children undergoing myringotomy and tube insertion, a procedure that normally takes 5 to 7 minutes. After oral midazolam premedication (0.5 mg/kg), induction of anesthesia with propofol, and maintenance with sevoflurane, emergence and early recovery were delayed by 6 and 14 minutes, respectively, in children 1 to 3 years of age compared with unpremedicated children, although discharge times did not differ.[138] Increased postoperative sedation may be attributed to synergism between propofol and midazolam on γ-aminobutyric acid (GABA) receptors.[139]

Although anxiolysis and a mild degree of sedation occur in most children after midazolam, a few develop undesirable adverse effects. Some children become agitated after oral midazolam.[140] If this occurs after IV midazolam (0.1 mg/kg), IV ketamine (0.5 mg/kg) may reverse the agitation.[141]

Anxiolysis and sedation usually occur within 10 minutes after intranasal midazolam[142]; nasal administration is not well accepted because it produces irritation, discomfort, and a burning aftertaste.[143–145] Another theoretical concern for the nasal route of administration of midazolam is its potential to cause neurotoxicity via the cribriform plate.[123] There are direct connections between the nasal mucosa and the central nervous system (CNS) (E-Fig. 4.2). Medications administered nasally reach high concentrations in the cerebrospinal fluid very quickly.[146–148] To date, no such sequelae have been reported. Because midazolam with preservative has been shown to cause neurotoxicity in animals, we recommend only preservative-free midazolam for nasal administration.[149,150]

Sublingual midazolam (0.2 mg/kg) has been reported to be as effective as, and better accepted than, intranasal midazolam.[151] Oral transmucosal midazolam given in three to five small allotments (0.2 mg/kg total dose) placed on a child's tongue (8 months to 6 years of age) was found to provide satisfactory acceptance and separation from parents in 95% of children.[152]

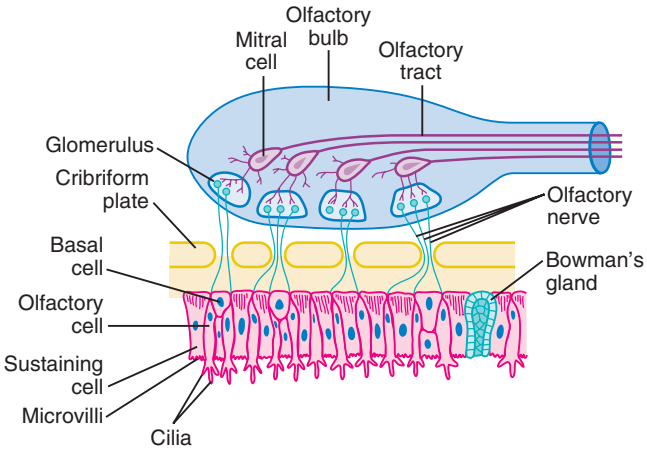
Diazepam is used only for premedication of older children. In infants and especially preterm neonates, the elimination half-life of diazepam is markedly prolonged because of immature hepatic function (see Chapter 7). In addition, the active metabolite (desmethyldiazepam) has pharmacologic activity equal to that of the parent compound and a half-life of up to 9 days in adults.[153] The most effective route of administration of diazepam is intravenous, followed by oral and rectal. The intramuscular route is not recommended because it is painful and absorption is erratic.[154–158] The average oral dose for premedicating healthy children with diazepam ranges from 0.1 to 0.3 mg/kg; however, doses as large as 0.5 mg/kg have been used.[159] The recommended dose of rectal diazepam is 1 mg/kg, and the peak serum concentration is reached after approximately 20 minutes.[160] Compared with rectal midazolam, rectal diazepam is less effective.[161]

Lorazepam (0.05 mg/kg) is reserved primarily for older children. Lorazepam causes less tissue irritation and more reliable amnesia than diazepam. It can be administered orally, intravenously, or intramuscularly and is metabolized in the liver to inactive metabolites. Compared with diazepam, the onset of action of lorazepam is slower and its duration of action is prolonged. The IV formulation of lorazepam is avoided in neonates because it may be neurotoxic.[162,163]

Barbiturates

Barbiturates are infrequently used for premedication as they have been replaced by oral midazolam. The advantages of barbiturates include minimal respiratory or cardiovascular depression, anticonvulsant effects, and a very low incidence of nausea and vomiting.

The relatively short-acting barbiturates *thiopental* and *methohexital* may be given rectally as a 10% solution in the presence of the parents who may hold the toddler until he or she is sedated.[164] The usual dose of rectal thiopental or methohexital is 30 mg/kg via a shortened suction catheter, which produces sleep in about two-thirds of the children within 15 minutes.[165–169] In some cases, the sedation may be profound, resulting in airway obstruction and laryngospasm. Hence, all children should be closely monitored with a source of oxygen, suction, and a means for providing ventilatory support; rectally administered methohexital has been reported to cause apnea in children with meningomyelocele.[170,171] Children chronically treated with phenobarbital or phenytoin are more resistant to the effects of rectally administered methohexital, probably because of enzyme induction.[166,172]



Additional disadvantages of rectal methohexital include unpredictable systemic absorption, defecation after administration, and hiccups. Contraindications to methohexital include hypersensitivity, temporal lobe epilepsy, and latent or overt porphyria.[173–175] Rectal methohexital is also contraindicated in children with rectal mucosal tears or hemorrhoids because large quantities of the drug can be absorbed, resulting in respiratory or cardiac arrest.

Nonbarbiturate Sedatives

Chloral hydrate and *triclofos* are orally administered nonbarbiturate drugs used to sedate children; both have slow onset times and are relatively long acting. Recommended dosing is outlined in Chapters 7 and 48. Chloral hydrate is rarely used by anesthesiologists because it is unreliable, has a prolonged duration of action, is unpleasant to taste, and is irritating to the skin, mucous membranes, and gastrointestinal tract. Use in neonates is not recommended because of impaired metabolism.[176,177] Commercially prepared chloral hydrate is no longer available in the United States but a powdered form can be reconstituted by the hospital pharmacy for oral administration.

Opioids

Opioids may be useful to provide analgesia and sedation in children who have pain preoperatively, but they also confer side effects, including nausea, vomiting, respiratory depression, sedation, and dysphoria. Therefore all children who receive an opioid

E-FIGURE 4.2 Anatomy of the nasal mucosa–cribriform plate interface. The nasal mucosa is the only location in the body that provides a direct connection between the central nervous system (CNS) and the atmosphere. Drugs administered to the nasal mucosa rapidly traverse through the cribriform plate into the CNS by three routes: (1) directly via the olfactory neurons, (2) through supporting cells and the surrounding capillary bed, and (3) directly into the cerebrospinal fluid. (From Hilger PA. *Fundamentals of Otolaryngology: A Textbook of Ear, Nose, and Throat Diseases*. 6th ed. Philadelphia: Saunders; 1989:184.)

premedication should be continuously observed and monitored with pulse oximetry.

Morphine sulfate, 0.05 to 0.1 mg/kg intravenously, may be given to children with preoperative pain. It is also effective when given orally; rectal administration is not recommended owing to erratic absorption. Neonates are more sensitive to the respiratory depressant effects of morphine, and it is rarely used to premedicate that age group.[178]

Fentanyl was introduced in a "lollipop" delivery system known as oral transmucosal fentanyl citrate (OTFC) for premedication in children in the United States but is no longer available for that indication, in part due to the high incidence of preoperative nausea and vomiting. Its current use is to treat breakthrough cancer pain. Fentanyl has also been administered nasally (1 to 2 µg/kg) but primarily after induction of anesthesia as a means of providing analgesia in children without IV access.[179]

Sufentanil is 10 times more potent than fentanyl and is administered nasally in a dose of 1.5 to 3 µg/kg. Children are usually calm and cooperative, and most separate from their parents with minimal distress.[142] In a study that compared the adverse effects of nasally administered midazolam and sufentanil, midazolam caused more nasal irritation, whereas sufentanil caused more postoperative nausea and vomiting and reduced chest wall compliance. In addition, children in the sufentanil group were discharged approximately 40 minutes later than those in the midazolam group.[144] The potential adverse effects and prolonged hospital stay after nasal sufentanil make it an unpopular choice for premedication.

Tramadol is a weak µ-opioid receptor agonist whose analgesic effect is mediated via inhibition of norepinephrine reuptake and stimulation of serotonin release. Tramadol is devoid of action on platelets and does not depress respirations in the clinical dose range.[180] Serum concentrations peak by 2 hours after oral dosing with clinical analgesia maintained for 6 to 9 hours. Tramadol is metabolized by CYP2D6 and is subject to variable responses based on polymorphisms of this enzyme.[181] IV tramadol (1.5 mg/kg) given before induction of general anesthesia has been compared with local infiltration of 0.5% bupivacaine (0.25 mL/kg) for ilioinguinal and iliohypogastric nerve blocks. Tramadol was as effective as the regional blocks in terms of pain control, although the incidence of nausea and vomiting was greater in the tramadol group. Time to discharge was similar in both groups.[182]

Butorphanol is a synthetic opioid agonist-antagonist with properties similar to those of morphine that can be administered nasally.[183] The most frequent adverse effect is sedation that resolves approximately 1 hour after administration. A dose of 0.025 mg/kg administered nasally immediately after the induction of anesthesia was shown to provide good analgesia after myringotomy and tube placement at the expense of an increased incidence of emesis at home compared with nonopioid analgesics such as acetaminophen.[184]

When fentanyl or other opioids are combined with midazolam, they produce more respiratory depression than opioids or midazolam alone.[185] If opioids are used in combination with other sedatives such as benzodiazepines, the dose of each drug should be appropriately reduced to avoid serious respiratory depression. For example, if fentanyl is indicated to control pain in a child who has already received midazolam, the fentanyl dose should be titrated in small increments (0.25 to 0.5 µg/kg) to prevent desaturation and hypopnea or apnea.

Codeine is a prodrug that must undergo *O*-demethylation in the liver to produce morphine to provide effective analgesia. The usual oral dose of oral codeine is 0.5 to 1.5 mg/kg with an onset of action within 20 minutes and a peak effect between 1 and 2 hours. The elimination half-life of codeine is 2.5 to 3 hours. The combination of codeine with acetaminophen is effective in relieving mild to moderate pain. Importantly, between 5% and 10% of children lack the cytochrome isoenzyme (CYP2D6) required for this conversion and therefore do not derive analgesic benefit. On the other hand, a very small percentage of children are ultrarapid metabolizers who rapidly convert this prodrug to morphine (see Chapters 6 and 7 for further discussion). As a result, they will have excessive blood levels of morphine and the potential for severe adverse effects such as respiratory depression and cardiac arrest, particularly if excessive or frequent doses of codeine are prescribed. Children with obstructive sleep apnea have been shown to have altered mu receptors and increased analgesia; thus a normal dose in such children can be a relative overdose.[186–191] As a result of deaths following tonsillectomy, the FDA issued a black box warning regarding the use of codeine in children undergoing tonsillectomy.[192] Most children's hospitals have now removed codeine from their formulary as a result of these concerns.[193]

Ketamine

Ketamine is a phencyclidine derivative that produces dissociation of the cortex from the limbic system, producing reliable sedation and analgesia while preserving upper airway muscular tone and respiratory drive.[194] Ketamine may be administered by IV, intramuscular, oral, nasal transmucosal, and rectal routes. The disadvantages of ketamine include sialorrhea, nystagmus, an increased incidence of postoperative emesis, and possible undesirable psychological reactions such as hallucinations, nightmares, and delirium, although to date no psychological reactions have been reported after oral ketamine. Concomitant administration of midazolam may eliminate or attenuate these emergence reactions.[195,196] The addition of atropine or glycopyrrolate is recommended to decrease the sialorrhea caused by ketamine.[197]

Intramuscular ketamine is an effective means of sedating combative, apprehensive, or developmentally delayed children who are otherwise uncooperative and refuse oral medication. A low dose of 2 mg/kg is sufficient to adequately calm most uncooperative children within 3 to 5 minutes so that they will accept a mask for inhalation induction of anesthesia and does not prolong hospital discharge times even after brief procedures.[112] However, the combination of intramuscular ketamine (2 mg/kg) and midazolam (0.1 to 0.2 mg/kg) significantly prolongs recovery and discharge times, making the ketamine-midazolam combination less suitable for brief ambulatory procedures.[198]

Larger doses of intramuscular ketamine are particularly useful for the induction of anesthesia in children in whom there is a desire to maintain a stable blood pressure and in whom there is no venous access, such as those with congenital heart disease. Larger doses (4 to 5 mg/kg) sedate children within 2 to 4 minutes, and very large doses (10 mg/kg) induce deep sedation that may last from 12 to 25 minutes. Larger doses and repeated doses may be associated with hallucinations, nightmares, vomiting, and unpleasant, as well as prolonged, recovery from anesthesia.[112,199] Concentrations of ketamine of 100 mg/mL are available in the United States and several other countries for intramuscular injection. It is imperative to label these syringes to avoid a syringe swap with syringes containing more dilute concentrations of ketamine.

Oral ketamine alone and in combination with oral midazolam is an effective premedication and has been used to alleviate the distress of invasive procedures (e.g., bone marrow aspiration) in pediatric oncology patients.[200,201] In a dose of 5 to 6 mg/kg, oral

ketamine alone sedates most children within 12 minutes and provides sufficient sedation in more than half of the children to permit establishing IV access.[198,202] A larger dose of 8 mg/kg prolongs recovery from anesthesia, although by 2 hours the recovery was no different from that after 4 mg/kg.[203] Oral doses of up to 10 mg/kg have been described as a premedicant for children having procedures for burns; the relative bioavailability was 45%, and absorption was slow with an absorption half-life of 1 hour.[204]

The combination of oral midazolam (0.5 mg/kg) and ketamine (3 mg/kg) provides more effective preoperative sedation than either drug alone. This oral lytic cocktail is a good alternative for children who were not adequately sedated with oral midazolam alone and did not prolong recovery after surgical procedures that lasted more than 30 minutes.[205]

Nasal ketamine in a dose of 6 mg/kg is also an effective premedication for children, with sedation developing by 20 to 40 minutes.[206] In theory, nasally administered ketamine could cause neural tissue damage if it reaches the cribriform plate (see E-Fig. 4.2). Because the preservative in ketamine is neurotoxic, preservative-free ketamine may be safer to administer by the nasal route, although this has not been established.[207] If ketamine is given by this route, we recommend the 100 mg/mL concentration to minimize the volume that must be instilled.

Rectal ketamine (5 mg/kg) produces good anxiolysis and sedation within 30 minutes of administration.[208] However, the rectal route does not provide reliable absorption.

α_2-Agonists

Clonidine, an α_2-agonist, causes dose-related sedation by its effect in the locus coeruleus.[209] It acts both centrally and peripherally to reduce blood pressure, thereby attenuating the hemodynamic response to intubation.[210] Clonidine appears to be devoid of respiratory depressant properties, even when administered in an overdose.[209] The sedative and CNS properties of clonidine reduce the minimum alveolar concentration (MAC) of sevoflurane for tracheal intubation[211] and the concentration of inhaled anesthetic required for the maintenance of anesthesia,[212–214] without prolonging emergence from anesthesia nor leading to airway-related complications.[215]

During the first 12 hours after surgery, oral clonidine (4 μg/kg) reduced the postoperative pain scores and the requirement for supplementary analgesics.[216,217] In children scheduled for tonsillectomy, those who received oral clonidine (4 μg/kg) exhibited more intense anxiety on separation and during induction than those who received oral midazolam (0.5 mg/kg). Even though discharge readiness, postoperative emesis, and 24-hour analgesic requirements were similar in both groups, midazolam was judged to be the better premedicant for children undergoing tonsillectomy.[218] Oral clonidine (4 μg/kg) reduces the incidence of vomiting after strabismus surgery compared with a placebo, clonidine (2 μg/kg), and oral diazepam (0.4 mg/kg).[219]

Although oral clonidine offers several desirable qualities as a premedication, particularly sedation and analgesia, the need to administer it 60 minutes before induction of anesthesia makes its use impractical in busy outpatient settings.[218]

Dexmedetomidine is a sedative with properties that are similar to those of clonidine except that it has an 8-fold greater affinity for the α_2-adenoreceptors than clonidine. Based on bioavailability studies in adults,[220] it is well absorbed through the oral mucosa. In a study of 13 children aged 4 to 14 years, of whom 9 had neurobehavioral disorders, an oral dose of 2 μg/kg of dexmedetomidine provided adequate sedation for a mask induction within 20 to 30 minutes of administration. It was postulated that a larger dose of 3 to 4 μg/kg might be more effective.[221]

Intranasal administration of 3 μg/kg dexmedetomidine produced greater success with auditory brainstem response testing than oral chloral hydrate with a more rapid onset of sedation and more rapid return to baseline activity.[222]

In children with burns, both 2 μg/kg intranasal dexmedetomidine and 0.5 mg/kg oral midazolam administered 30 to 45 minutes before induction of anesthesia provided adequate conditions for induction of anesthesia and emergence, although dexmedetomidine produced more sleep preoperatively.[223] Oral midazolam (0.5 μg/kg given 30 minutes before surgery), oral clonidine (4 μg/kg given 90 minutes before surgery), and transmucosal dexmedetomidine (1 μg/kg given 45 minutes before surgery) all produced similar preanesthetic sedation and response to separation from parents in a comparative trial, although children who received dexmedetomidine and clonidine experienced attenuated mean arterial pressure and heart rate preoperatively and reduced pain scores postoperatively compared with midazolam.[224]

Antihistamines

Antihistamines are rarely used for premedication in children, in part because their sedative effects are quite variable. They are very rarely given to infants but may occasionally be indicated for older children, especially those who are hyperkinetic.

Hydroxyzine is mainly administered for its tranquilizing properties[225,226]; it also has antiemetic, antihistaminic, and antispasmodic properties, with minimal respiratory and circulatory effects. It is commonly administered with other classes of drugs as an intramuscular "cocktail" in a dose of 0.5 to 1.0 mg/kg.

Diphenhydramine is an H_1-receptor blocker with mild sedative and antimuscarinic effects. The dose in children is 2.5 to 5 mg/kg per day (maximum 300 mg/d) in four divided doses orally, intravenously, or intramuscularly. Although the duration of action is 4 to 6 hours, it does not appear to interfere with recovery from anesthesia.[227] The combination of oral diphenhydramine (1.25 mg/kg) and oral midazolam (0.5 mg/kg) has been used to provide sedation for healthy children undergoing MRI.[228] The combination was more effective than midazolam alone without a delay in discharge and recovery times.

Anticholinergic Drugs

In the past, anticholinergic agents were used (1) to prevent the undesirable bradycardia associated with some anesthetic agents (halothane and succinylcholine), (2) to minimize the autonomic vagal reflexes manifested during surgical manipulations (e.g., laryngoscopy, strabismus repair), and (3) to reduce secretions. The most commonly used anticholinergic drugs are atropine, scopolamine, and glycopyrrolate. Anticholinergics also provide undesirable effects, including tachycardia, dry mouth, skin erythema, and hyperthermia, as a result of inhibited sweating. Atropine and scopolamine cross the blood-brain barrier and may cause CNS excitation manifested as agitation, confusion, restlessness, ataxia, hallucinations, slurred speech, and memory loss if given in excessive doses.

Because most modern inhalational anesthetics are not associated with bradycardia and succinylcholine is infrequently used in children, the routine use of an anticholinergic drug is not generally warranted. Most anesthesiologists administer these agents only when indicated, such as before IV succinylcholine, combined with ketamine, before laryngoscopy and intubation in neonates, and when surgery stimulates vagal reflexes, such as

during strabismus repair. In the majority of cases, anticholinergics need not be given preoperatively but rather should be given after IV access is established.

The recommended doses of anticholinergics are *atropine,* 0.01 to 0.02 mg/kg, and *scopolamine,* 0.005 to 0.010 mg/kg. Atropine is more commonly used and blocks the vagus nerve more effectively than scopolamine, whereas scopolamine is a better sedative, antisialagogue, and amnestic. Infants who are at risk for or show early evidence of a slowing of the heart rate should receive the atropine before the heart rate actually decreases to ensure a prompt onset of effect to maintain cardiac output.[229] *Glycopyrrolate* is a synthetic quaternary ammonium compound that does not cross the blood-brain barrier. It is twice as potent as atropine in decreasing the volume of oral secretions, and its duration of effect is three times greater. The recommended dose of glycopyrrolate (0.01 mg/kg) is half that of atropine. The routine use of an anticholinergic drug for the sole purpose of drying secretions is probably unwarranted, because a dry mouth can be a source of extreme discomfort for a child. Therefore, it is best to reserve the use of glycopyrrolate for specific indications such as to limit sialorrhea associated with ketamine.

Topical Anesthetics

The child's exaggerated fear of the needle makes topical anesthetic creams an attractive alternative to intradermal infiltration and intramuscular injections. There are several needleless methods to minimize procedural pain, each with its own limitations.

EMLA cream (eutectic mixture of local anesthetic; Astra Zeneca, Wilmington, DE) is a mixture of two local anesthetics (2.5% lidocaine and 2.5% prilocaine). One-hour application of EMLA cream to intact skin with an occlusive dressing provides adequate topical anesthesia[230] for a variety of superficial procedures, including IV catheter insertion, lumbar puncture, vaccination, laser treatment of port-wine stains, and neonatal circumcision.[231–236] However, EMLA causes venoconstriction and skin blanching, both of which obscure superficial veins, making IV cannulation more difficult.[237] The prilocaine in EMLA may cause methemoglobinemia,[238] although a 1-hour application at a maximum dose of 1 g did not induce methemoglobinemia when applied to intact skin in full-term neonates and infants younger than 3 months of age.[239] Lidocaine toxicity has been reported when EMLA was applied to mucosal membranes for extended periods.[240]

Ametop gel is a topical local anesthetic (4% tetracaine) available in the United Kingdom, Europe, and Canada (Smith & Nephew, Lachine, Quebec) but not in the United States. Its indications are identical to those of EMLA, but its properties are different. When applied to intact skin under an occlusive dressing, it anesthetizes the skin within 30 to 40 minutes, and it produces no venoconstriction or skin blanching and zero risk of methemoglobinemia.

ELA-Max (4% lidocaine; Ferndale Laboratories, Ferndale, MI) is another topical anesthetic cream that decreases the pain associated with dermatologic procedures[241] and IV catheter insertion after only a 30-minute application.[242] ELA-Max causes some blanching of the skin like EMLA, but to a lesser extent, and dilates the veins better than EMLA.[243]

The *S-Caine Patch* (ZARS, Inc., Salt Lake City, UT) is a eutectic mixture of lidocaine and tetracaine (70 mg of each per patch) that uses a controlled heating system to accelerate delivery and effectiveness of the local anesthetic. After 20 minutes of application, the pain associated with venipuncture is reduced. This patch causes mild and transient local erythema and edema and no blanching of the skin.[244]

Needle-free injection systems for lidocaine are also available for pain-free insertion of IV cannulae or other needle-based procedures such as lumbar puncture.[245,246] One such system is the needleless jet injection system (J tip) (NDC:8164-2001 National Medical Products, Inc., Irvine, CA) that provides local anesthetic at the site of administration in less than 1 minute. The device uses air, instead of a needle, to deliver 0.25 mL of local anesthetic subcutaneously prior to IV insertion. In one study, jet-delivered lidocaine was found to be no more effective than jet-delivered placebo in providing local anesthesia for needle insertion and both may provide superior analgesia compared with no device use; the majority of patients receiving the jet device reported that they would request this for future needle insertions.[247] In a retrospective study, the use of the J tip did not affect first-attempt success for IV line placement in children.[248]

Nonopioid Analgesics

Acetaminophen is the most common nonopioid analgesic used for treatment of postoperative pain in children. It can be administered orally preoperatively, rectally immediately after induction of anesthesia but before the start of surgery, or intravenously (where available) once IV access has been established.

The oral doses of acetaminophen for antipyresis, 10 to 15 mg/kg, are as effective as ketorolac, 1 mg/kg,[249] given 10 or more minutes postoperatively for myringotomies and tube placement.[250] Oral acetaminophen is very rapidly absorbed with a bioavailability of 0.9-1.[250] Neonates may have a lower incidence of hepatotoxicity because the immature hepatic enzyme systems in neonates produce less toxic metabolites than in older children.[251–253] When given preemptively, acetaminophen has opioid-sparing properties that enhance analgesia in children after tonsillectomy.[254,255] Preoperative oral acetaminophen and codeine provided superior analgesia to acetaminophen alone after myringotomy and tube placement.[256] However, in children undergoing tonsillectomy, there was no difference in the level of pain control provided by acetaminophen and acetaminophen with codeine. Postoperative oral intake was significantly higher in children treated with acetaminophen alone.[257] A relationship between concentration and analgesic effect for pain relief after tonsillectomy has been observed in children. An effect compartment concentration of 10 mg/L was associated with a reduction of pain by 2.6 units (using a visual analogue scale ranging from 0 to 10).[258]

The time to the peak blood concentration of acetaminophen after rectal administration of 10, 20, and 30 mg/kg ranges between 60 and 180 minutes after administration. In addition, the equilibration half-time between plasma and effect compartment is approximately 1 hour.[258] This slow absorption and delayed effect-site concentrations require acetaminophen administration immediately after induction of anesthesia to provide sufficient time to achieve therapeutic blood concentrations by the end of surgery (primarily for operations that will take 1 hour or longer).[259] Furthermore, doses of 10 to 30 mg/kg rectal acetaminophen may not achieve peak or sustained blood concentrations that ensure effect (Fig. 4.2). Thus, an initial dose of rectal acetaminophen of 40 mg/kg has been recommended, followed by 20 mg/kg rectally every 6 hours. This dosing regimen was subsequently confirmed.[260] After 45 mg/kg rectal acetaminophen, the mean maximum blood concentration was 13 µg/mL (range 7 to 19 µg/mL), and the mean time to that maximum concentration was approximately 200 minutes.[261] Several other studies of single-dose rectal administration reported similar results.[261,262]

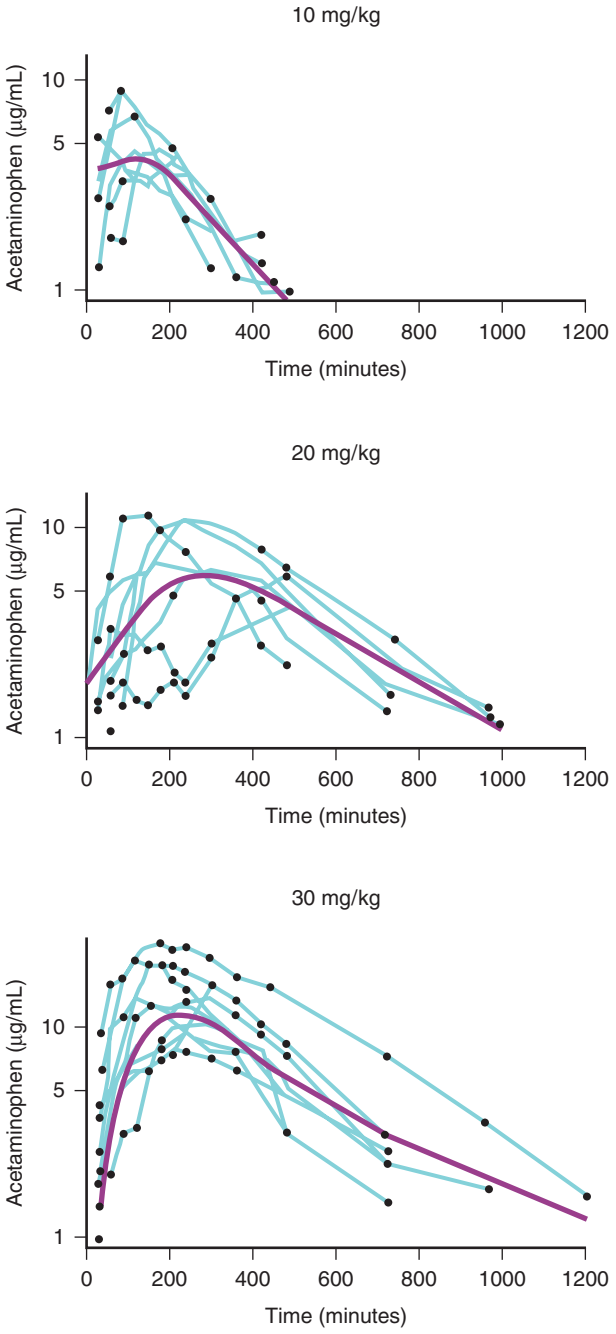


FIGURE 4.2 Acetaminophen concentrations after rectal administration of 10, 20, or 30 mg/kg were recorded. Values for serum concentration of acetaminophen (*solid circles, teal lines*) are plotted against time for each child. Thick (*magenta*) lines indicate "average" values. Note that only children who received 30 mg/kg achieved the antipyretic threshold of 10 to 20 µg/mL, but that even at this dose that range was not sustained. These data suggest the need to use a larger loading dose (approximately 40 mg/kg) followed by subsequent doses of 20 mg/kg every 6 hours; see text for details. (From Birmingham PK, Tobin MJ, Henthorn TK, et al. Twenty-four-hour pharmacokinetics of rectal acetaminophen: an old drug with new recommendations. *Anesthesiology* 1997;87:244-252.)

Until further safety data are developed, the initial dose of rectal acetaminophen should not exceed 40 to 45 mg/kg with a total 24-hour dose of not more than 75–100 mg/kg to avoid hepatic toxicity. Acetaminophen administered rectally in a loading dose of 40 mg/kg and then 20 mg/kg either orally or rectally every 6 hours after elective craniofacial surgery yielded greater plasma concentrations and lower pain scores than for those who received oral acetaminophen; this was in part related to some children vomiting the oral acetaminophen.[263] Note that these are excessive oral doses that cannot be recommended.

Excessive fasting, a very large loading dose of acetaminophen, and sevoflurane anesthesia may deplete glutathione stores and thus contribute to the development of hepatic failure.[264] The coadministration of antiepileptic drugs has also been implicated in hepatotoxicity from acetaminophen.[265] *Because hepatic toxicity is a real and potentially fatal complication of an acetaminophen overdose, a complete medication history of acetaminophen consumption and concomitant drugs should be completed preoperatively, and the recommended maximum daily dose should not be exceeded.*

Different IV formulations of acetaminophen are available in some countries.[266] One is a prodrug of acetaminophen *(propacetamol)* with a bioavailability of 50%. It may be administered in a dose of 30 mg/kg (15 mg/kg acetaminophen) every 6 hours to children 2 to 15 years of age. In a placebo-controlled trial in febrile children, this dose of propacetamol was superior to placebo.[267] Pharmacokinetic studies indicate that such a dose of propacetamol maintains mean steady-state blood concentrations of acetaminophen of 10 µg/mL.[268] Therapeutic blood concentrations are achieved in neonates 10 days of age or younger with 15 mg/kg of propacetamol 4 times daily, but neonates older than 10 days require twice the dose, or 30 mg/kg, at the same frequency.[269] Hemostatic effects of large (60 mg/kg) doses of propacetamol in adult volunteers showed transient but reversible inhibition of platelet aggregation as well as decreased thromboxane activity. Although these effects were less than those after ketorolac (0.4 mg/kg), the combination of acetaminophen and ketorolac may prolong these effects.[270]

IV acetaminophen, known as *paracetamol* in other countries, became commercially available in the United States in 2011. Paracetamol (15 mg/kg) was compared with propacetamol, 30 mg/kg, for postoperative pain relief after inguinal hernia repair. The outcomes were similar, but IV paracetamol was better tolerated at the injection site.[271]

Several investigations examined IV acetaminophen use in pediatric populations. In a study of 50 children, ages 2 to 5 years, undergoing elective adenoidectomy or adenotonsillectomy, IV acetaminophen 15 mg/kg or rectal acetaminophen 40 mg/kg resulted in equivalent pain scores. The time to the first rescue analgesic in the rectal acetaminophen group (median 10 hours, attributed to its slow absorption) was greater than in the IV acetaminophen group (median 7 hours), although few children in either group required any rescue analgesics during the first 6 hours.[272] IV acetaminophen (15 mg/kg) has been compared with intramuscular meperidine 1 mg/kg in children undergoing tonsillectomy. When compared with meperidine, IV acetaminophen resulted in comparable analgesia but less sedation and earlier readiness for discharge.[273] In children undergoing dental restoration with the same medications and doses, children in the acetaminophen group had greater pain scores but earlier readiness for recovery room discharge.[274] A study of 45 healthy children, ages 5 months to 5 years, presenting for primary cleft palate repair found that IV acetaminophen 12.5 mg/kg (age <2 years) or 15 mg/kg (age 2–5 years) every 6 hours for 24 hours resulted in improved analgesia and decreased postoperative opioid requirements.[275] Administration of IV nonnarcotic analgesics may also result in decreased nausea and vomiting compared with oral medications. Twenty-eight children undergoing craniosynostosis correction were random assigned to receive either oral ibuprofen (10 mg/kg) and

acetaminophen (15 mg/kg) versus IV ketorolac (0.5 mg/kg) and acetaminophen (15 mg/kg). There were significantly more vomiting episodes in the group receiving oral medication.[276]

The US FDA has approved IV acetaminophen for use in children 2 years and older. The recommended dose for children 2 to 12 years old weighing less than 50 kg is 15 mg/kg every 6 hours or 12.5 mg/kg every 4 hours with a maximum of 75 mg/kg per day. Use in children younger than 2 years is considered off-label. Practitioners in the United States who choose to use IV acetaminophen off-label should consider reduced dosage for patients younger than 2 years of age. In infants 1 month to 2 years of age, dosing from the pharmacokinetic data suggests a dose reduction of 33%, 10 mg/kg every 4 hours or 12.5 mg/kg every 6 hours, with a maximum dose of 50 to 60 mg/kg per day. In full-term neonates up to 28 days of age, the dose of IV acetaminophen should be reduced by 50% to 7.5 mg/kg every 6 to 8 hours with a maximum daily dose of 30 mg/kg. This dosing regimen produces a similar pharmacokinetic profile as in children older than 2 years of age.[277,278] The major concern in this age group is accidental overdose of acetaminophen and hepatic toxicity. Three near-fatal cases of infants who received 10- and 20-fold overdoses of IV acetaminophen have been reported.[279,280] In many instances, overdose errors resulted for dosages calculated in milligrams, but administered in milliliters.[281] Careful documentation of the dose of IV acetaminophen is warranted in infants.[282]

Antiemetics

Antiemetic administration should be considered in children undergoing high-risk procedures such as tonsillectomy and strabismus repair as well as those who have a history of motion sickness or prior history of postanesthesia nausea and vomiting. The uses of these medications are presented elsewhere in the text (see Chapters 7, 33, and 34).

Corticosteroids

Children who have been taking chronic corticosteroid therapy (e.g., for asthma, Crohn disease, lupus, acute lymphocytic leukemia) and those who have discontinued chronic corticosteroid therapy in the past 6 months may suffer from suppression of the hypothalamic-pituitary-adrenal axis.[283] There is a paucity of evidence to support the need for supplemental corticosteroids in children in the perioperative period who have been receiving long-term corticosteroid therapy. In the past, hypotension was reported in those who were receiving long-term corticosteroid therapy and underwent general anesthesia or another stress. This may be attributed to hypovolemia. Nonetheless, many endocrinologists continue to recommend a dose of supplemental corticosteroids before or shortly after induction of anesthesia for "stress" corticosteroid coverage. The usual recommended dose is 1 to 2 mg/kg of hydrocortisone intramuscularly or intravenously or an equivalent dose of dexamethasone (0.05 to 0.1 mg/kg) approximately 1 hour before the induction of anesthesia or as soon as IV access is established. For more complicated operations, the corticosteroid dose may be repeated every 6 hours for up to 72 hours (see Chapter 27).

Insulin

Optimal management of diabetic children undergoing surgery entails maintaining glucose homeostasis, avoiding hyperglycemia with resultant osmotic diuresis, impaired wound healing, increased infection rate, and avoiding hypoglycemia. Anesthesiologists should work together with the endocrinologist or primary care physician to design a plan for each child's specific diabetes treatment regimen, glycemic control, intended surgery, and anticipated postoperative care. Diabetes mellitus is the most common endocrine problem encountered in children. The preoperative fasting time should be the same as that recommended for nondiabetic children. Every attempt should be made to schedule these children as the first case of the day to minimize the fasting period. Preoperative laboratory tests generally include hematocrit, serum electrolytes, and glucose levels; blood glucose concentrations should be measured at frequent intervals during the perianesthetic period. Several protocols have been crafted to control the blood sugar in children who are diabetic[284]; these are described in more detail in Chapter 27 (see also Figs. 27.1 to 27.9, which describe a variety of management strategies).

Antibiotics

Antibiotics are frequently administered to prevent or reduce infection in surgical patients. Surgical site infection (SSI) accounts for 14% to 16% of nosocomial infections in the United States.[285] A recent retrospective review identified the overall rate of SSI in children undergoing a variety of surgical procedures as approximately 2.4%.[286] SSI increases morbidity and mortality and adds greatly to the cost of hospitalization.[287] The appropriate timing of antibiotics is now a source of performance benchmarking for some insurance carriers, making communication with surgeons essential for the success of this anesthesiology-directed quality assessment measure. Current guidelines define appropriate antibiotic prophylaxis for SSI as administration within 60 minutes prior to incision.[288] Intraoperative redosing is needed if the duration of the procedure exceeds two drug half-lives or there is excessive blood loss. Pediatric doses provided in these guidelines are based on pharmacokinetic data and the extrapolation of adult efficacy data to pediatric patients. *"With a few exceptions (e.g., aminoglycoside dosages), pediatric dosages should not exceed the maximum adult recommended dosages. If dosages are calculated on a milligram-per-kilogram basis for children weighing more than 40 kg, the calculated dosage may exceed the maximum recommended dosage for adults; adult dosages should therefore be used".*[288] Recommended doses and redosing intervals for commonly used antibiotics for surgical prophylaxis are listed in Table 4.4.

For prophylaxis against endocarditis in children with structural heart disease, antibiotics should ideally be administered either intravenously 30 to 60 minutes or orally 1 hour before the induction of anesthesia and surgery. In reality, in children these antibiotics are usually administered after induction of anesthesia and establishment of IV access (see also Tables 16.2 and 16.3).[289]

Antacids, H_2-Receptor Antagonists, and Gastrointestinal Motility Drugs

The risk of aspiration during induction of or emergence from anesthesia may be increased in children who are developmentally delayed, have gastroesophageal reflux, have experienced previous esophageal surgery, had a difficult airway, were obese, or had undergone a traumatic injury. Preanesthetic administration of drugs that reduce gastric fluid volume and acidity may decrease the risk of pulmonary acid aspiration syndrome (Table 4.5).[1,290] Gastric fluid pH may be increased by drinking a nonparticulate antacid such as sodium citrate; particulate antacids should be avoided because they can cause severe pneumonitis if aspirated.

Cimetidine and *ranitidine* are H_2-receptor antagonists that decrease gastric acid secretion, increase gastric fluid pH, and reduce gastric

TABLE 4.4 Current American Society of Hospital Pharmacists Recommendations for Surgical Antibiotic Prophylaxis (Weight-Normalized)

Antibiotic	Recommended Child Dose (mg/kg but not to exceed adult dose)	Recommended Adult Dose	Recommended Repeat Intraoperative Dosing Interval (Hours) or >15% EBV Loss
Ampicillin-sulbactam	50 (Ampicillin component)	3 g	2
Ampicillin	50	2 g	2

TABLE 4.5 Doses of Antacids, H_2-Receptor Antagonists, and Gastrointestinal Motility Drugs

Drug	Dose
Antacids	
Bicitra (oral)	30 mL (0.5–1 mL/kg up to 30 mL)
Prokinetic	
Metoclopramide (IV)	0.1–0.15 mg/kg
H_2-Receptor Antagonists	
Cimetidine (IV)	5–10 mg/kg
Ranitidine (PO/IV)	2–2.5 mg/kg
Famotidine (PO/IV)	0.5 mg/kg (not to exceed 40 mg/day)

residual volume.[291,292] These drugs can be given orally, intravenously, or intramuscularly.

Metoclopramide is often administered with an H_2-receptor antagonist to increase lower esophageal sphincter tone, relax the pyloric sphincter and the duodenal bulb, and promote gastric emptying by increasing peristalsis of the duodenum and jejunum. The drug effect is apparent 30 to 60 minutes after oral administration and 1 to 2 minutes after IV administration.[293] Adverse effects such as extrapyramidal signs relate to the effect of metoclopramide on the CNS through blockade of dopaminergic receptors.

Induction of Anesthesia

PREPARATION FOR INDUCTION

Adequate preparation includes warming the OR and ensuring that warming devices are functioning properly (e.g., heat lamps, warming blanket, forced air warmer) before the child's arrival, especially for young infants. The preinduction checklist should include a variety of sizes of masks, oral airways, laryngoscope blades, tracheal tubes (one-half size larger and one-half size smaller than the anticipated size), an appropriate size laryngeal mask airway (LMA), and functioning wall suction. The anesthesia machine and monitoring equipment should be prepared before the child's arrival in the OR to ensure that all appropriate equipment is on hand and to minimize any last-minute commotion. One of the most essential monitors used during the induction of anesthesia is the precordial stethoscope. The bell from the stethoscope should have a double-stick adhesive attached and ready for application before induction. A chair or stool for the child's parent to sit on helps avoid fainting episodes should the parent be present at induction of anesthesia. Ensuring a quiet, calm OR environment, free of clanging instruments and loud conversations among the staff, allows for a smoother and less upsetting induction.

There are a variety of techniques for inducing general anesthesia. The technique used depends on a number of factors, including the child's developmental age, understanding and ability to cooperate, and previous experiences; the presence of a parent; and the interaction of these factors with the child's underlying medical or surgical conditions.

INHALATION INDUCTION

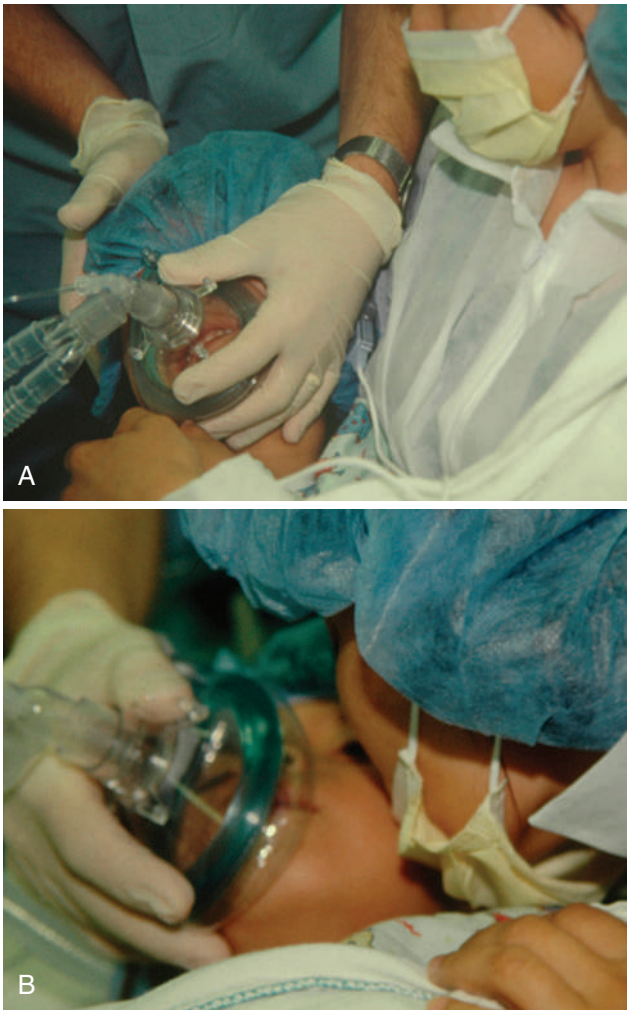
The most common method of inducing anesthesia in children is inhalation by mask of the nonpungent inhalational anesthetic agent sevoflurane or halothane. The anesthesiologist should be flexible and adapt an approach that suits the child, depending on age, degree of sedation, and cooperation.

If the child is already asleep on arrival in the OR, it is possible to use the "steal induction" technique. The child is not touched or disturbed. After priming of the breathing circuit with N_2O in O_2, the mask is gently placed near the child's face and gradually brought closer and closer until it is gently applied to the face. After the child has been breathing N_2O for 1 to 2 minutes, sevoflurane is administered in a single stepwise increase in concentration to 8% (halothane may be delivered in increasing concentrations as tolerated). Adequate monitoring must be instituted as soon as possible, and the child is then transferred to the operating table. This technique is atraumatic and avoids exposing the child to the strange OR surroundings while awake. However, it is possible that the child may suffer psychological harm when he or she awakens to pain without realizing what has transpired.

If a parent wishes to accompany a young child to the OR, we may allow the child to remain in the parent's lap for the induction. We request that the child be sitting facing forward in the parent's lap so that there is free access to the child's face. It is vital to instruct the parent that he or she must hold the child in a "bear hug"–that is, with the arms tightly wrapped around the child and holding the child's arms in such a way that the child cannot reach up to the face mask–and to warn the parents that as the child loses consciousness, the child will become limp. This approach can be difficult with either an inexperienced anesthesiologist or a very strong child who vigorously rotates his or her neck from left to right, preventing the tight application of a face mask. It is also important to have an experienced individual in front of the child and parent to hold onto the child as induction proceeds and help place the child on the OR table after successful induction. At this point, we invite the parent to kiss their child and then the parent is escorted to the waiting room (E-Fig. 4.3A and B).

The optimal induction sequence in toddlers is to avoid making them feel vulnerable by having the children pick a flavor of lip balm to flavor the mask and having them seated (not lying supine) on the OR bed with the back supported by the anesthesiologist's chest or on the anesthesiologist's or the parent's lap (E-Fig. 4.4A, Video 4.2). They may be distracted by asking them to try to "blow up the balloon" by taking deeper and deeper breaths, where the balloon refers to the reservoir bag. If the child is seated on the parent's or anesthesiologist's lap, it is strongly advised that this be undertaken only with children who are wearing diapers or are sitting on a thick blanket to limit the spread of urine should the bladder empty during induction. The anesthesia machine should be within easy reach during such an induction to allow control of the bag, pop-off valve, and vaporizer without interruption. An assistant should be at hand to help position and hold the child when needed. Other distraction techniques may be used, including allowing them to bring their favorite toy or security blanket into the OR (see E-Fig. 4.4B). Older children may be distracted by allowing them to play electronic handheld games or to watch a movie on a portable electronic device.

Child-life specialists are helpful allies in preparing patients and parents to cope with the stress and uncertainty surrounding anesthesia and surgery. Such specialists are trained to explain procedures and equipment to children in age-appropriate language, and to introduce coping strategies to reduce anxiety such as therapeutic medical play. For example, children may be less afraid of an anesthesia face mask if allowed to hold the mask in the preoperative holding area, apply a scented flavor of their choosing, and decorate the mask with stickers. One technique often used by child-life specialists is to distract children by allowing them to play electronic handheld games on a portable electronic device. In this scenario, the child-life specialist accompanies the child to the OR, with the child continuing to play his or her preferred game on the portable electronic device during transport. The child-life specialist holds the device for the patient so that the handheld game may be continued as the face mask is applied and the anesthetic induction begins (Video 4.3).



Some children refuse to have the face mask placed anywhere near their face. They may have an unknown fear of masks or may have been traumatized previously with high concentrations of sevoflurane or halothane administered at the outset through the face mask, without premedication or pretreatment with nitrous oxide. One solution to this problem is to remove the mask, place the elbow of the breathing circuit between one's fingers, and then cup your hands below the child's chin. Because nitrous oxide is heavier than air, cupped hands act like a reservoir. The hands are gradually brought closer and closer to the face, while the child is distracted, until they gently cover the mouth. Once the child is becoming sedated, 8% sevoflurane can be introduced and the mask placed on the face. Younger infants who refuse a mask may be soothed by placing one's small finger ("pinky") in the child's mouth to suck on as the face mask is gently advanced to the nose and mouth for an inhalation induction (Fig. 4.3A and B).

Inhalation With Sevoflurane

The traditional mask induction of anesthesia is accomplished by placing the mask lightly on the child's face and administering a mixture of N_2O in O_2 (2:1) for 1 or 2 minutes until the full effect of N_2O is achieved. Offering children the choice of a scented mask or "sleepy air," such as bubble gum or strawberry flavor, applied to the inside of the face mask may disguise the odor of the plastic. Sevoflurane is then introduced and can be rapidly increased to 8% in a single stepwise increase, without significant bradycardia or hypotension in otherwise healthy children. After anesthesia is induced, the sevoflurane concentration should be maintained at the maximum tolerable concentration until IV access is established, but this concentration should be reduced if controlled ventilation is initiated to avoid overdose. The reason for maintaining delivery of a high concentration of sevoflurane is to minimize the risk of awareness during the early period of the induction sequence. Data from unmedicated children (aged ≥3 years) indicate that sevoflurane is associated with small increases in heart rate, although the heart rate does decrease to 80 to 100 beats/minute in some children after breathing sevoflurane for a period of time.[294] In contrast to halothane,[295] sevoflurane does not increase the myocardial sensitivity to epinephrine.[296] In a study of three techniques for delivering sevoflurane for induction of anesthesia, minimal differences were detected among the three: incremental increases in sevoflurane (2%, 4%, 6%, and 7%) in oxygen, a high concentration of sevoflurane (7%) in oxygen, and a high concentration of sevoflurane in a 1:1 mixture of N_2O and O_2.[297] When N_2O was added, there was a decreased time to loss of the eyelash reflex and a decreased incidence of excitement during the induction. Agitation or excitement in early induction (shortly after loss of eyelash reflex) with sevoflurane has been observed; this is discussed in detail in Chapter 7.

E-FIGURE 4.3 A, Some children are more comfortable sitting in the lap of the anesthesiologist (or parent). In this situation, asking the child to "blow up the balloon" is often a successful distraction, resulting in a smooth inhalation induction. **B,** Other children can be distracted and comforted by having a favorite toy, stuffed animal, or security blanket during induction; in this case, we allowed the child to hold a face mask on her stuffed rabbit while we held the mask on her face.

E-FIGURE 4.4 If a parent requests or is asked to accompany the child to the operating room, it is vital to explain to the parent all the things that might be seen in the operating room, as well as the child's responses during induction (see text for details). Often a small child can be anesthetized in the parent's lap, first starting with "laughing gas" (nitrous oxide). Note that this child is laughing during induction **(A)**. After observing the desired effect of nitrous oxide, the potent inhalation agent (sevoflurane or halothane) is introduced as tolerated. As soon as the child is induced, we place the child on the operating room table, briefly remove the mask, ask the parent to kiss the child **(B),** and then request that he or she leave the operating room. It is important to have someone available to escort the parent back to the waiting area.

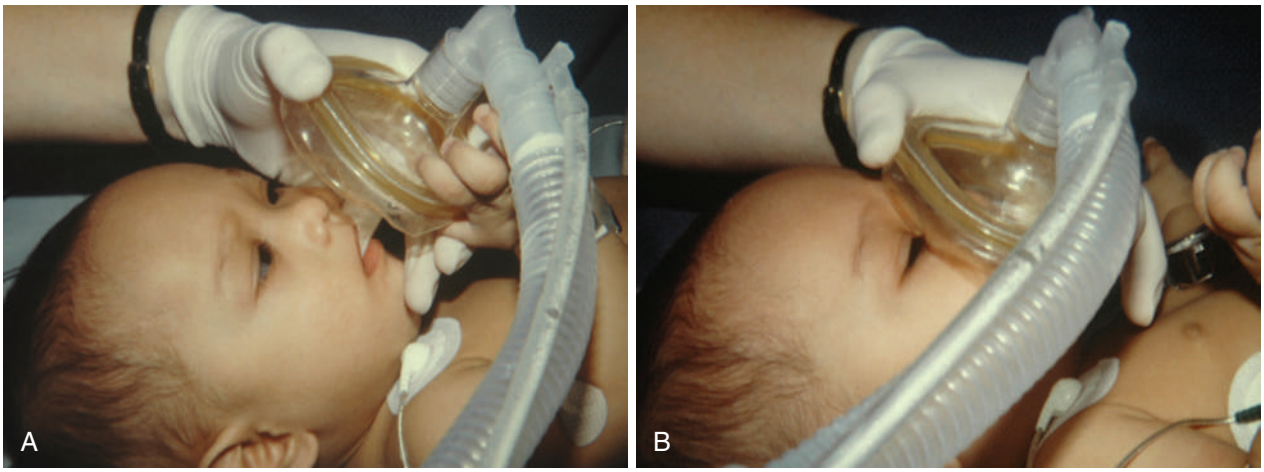


FIGURE 4.3 A, Infants 6 months of age or younger are often consoled during induction by placing the little finger ("pinky finger") of your hand in their mouth while you hold the face mask near their face with the rest of the hand. In general, they are so hungry that they will stop crying and eagerly suckle on your pinky finger. **B,** As the infant loses consciousness, the intensity of the suckling diminishes, the pinky finger is gently removed, and the face mask is fully applied.

Inhalation Induction With Halothane

Halothane has largely been replaced by sevoflurane for inhalation induction of anesthesia because of halothane's slower wash-in and emergence and greater incidence of bradycardia, hypotension, and arrhythmias. When anesthesia is induced with halothane, the inspired concentration is gradually increased by 0.5% every two to three breaths up to 5%. Alternatively, a single-breath induction of anesthesia with 5% halothane can yield a rapid induction of anesthesia without triggering airway reflex responses.[298]

The inspired concentration of halothane should be decreased as soon as anesthesia is established to avoid heart rate slowing and myocardial depression. The child will autoregulate the depth of anesthesia as long as he or she is allowed to breathe spontaneously; however, if respirations are controlled, then anesthetic overdose may easily occur (see Chapter 7).[299,300] Halothane sensitizes the heart to catecholamines, and ventricular arrhythmias may commonly be seen, especially during periods of hypercapnia or light anesthesia.[301]

If vital signs become abnormal during induction, the concentration of halothane should be reduced or discontinued and the circuit flushed with 100% oxygen. If bigeminy or short bursts of ventricular tachycardia occur, then the following strategies should be considered: (1) hyperventilation (to reduce the arterial carbon dioxide tension [$PaCO_2$]), (2) deepening of the halothane anesthesia, or (3) changing to an alternate potent inhalation agent.[301] There is no role for IV lidocaine to treat these arrhythmias.

During inhalation induction with either sevoflurane or halothane, if the oxygen saturation decreases (and there is no mechanical cause for the desaturation such as partial dislodgment of the oximeter probe, patient clenching of fingers or toes, or blood pressure cuff inflating), 100% oxygen should be administered until the oxygen saturation returns to normal while the cause of the desaturation is addressed. If the cause of the desaturation is not related to upper airway obstruction, the most common cause in a healthy child is a ventilation-perfusion mismatch due to segmental atelectasis. Recruitment of alveoli may be achieved by applying a sustained inflation of the lungs to 30 cm H_2O for 30 seconds or as tolerated.[302] This may be difficult to complete before tracheal intubation because the stomach may inflate. In such a case, recruitment should be abandoned. Alternatively, mild to moderate upper airway obstruction from collapse of the hypopharyngeal structures or the development of mild laryngospasm causes hypoventilation and desaturation. In general, this upper airway obstruction is readily relieved by gently applying a tight mask fit, closing the pop-off valve sufficiently to generate 5 to 10 cm of positive end-expiratory pressure, and allowing the distending pressure of the bag to stent open the airway until the child is adequately anesthetized to tolerate the placement of an oral airway (see Fig. 14.10 and Fig. 33.10). Cephalad pressure should be applied to the superior pole of the condyle of the mandible to sublux the temporomandibular joint because this maneuver opens the mouth and pulls the tongue off the posterior and nasopharyngeal walls, opening the laryngeal inlet.[303] This maneuver may supplant the need for an oral airway. It is very important to avoid applying digital pressure to the soft tissues of the submental triangle because this pushes the tongue and soft tissues into the hypopharynx, occluding the oropharynx and nasopharynx. If the child develops symptomatic bradycardia, then oxygenation and ventilation must first be established, followed by IV atropine (0.02 mg/kg) and, if necessary, chest compressions and IV epinephrine (see Chapter 40).

Inhalation Induction With Desflurane

Desflurane is very pungent, as evidenced by severe laryngospasm (49%), coughing, increased secretions, and hypoxemia during induction.[304] Therefore, *desflurane is not recommended for inhalation induction in children* but may be used safely for maintenance of general anesthesia after the trachea has been intubated.

Hypnotic Induction

Hypnosis can reduce anxiety and pain in children with chronic medical problems and those undergoing painful procedures[305,306] as well as reduce preoperative anxiety. Hypnosis is an altered state of consciousness with highly focused attention, based on the principle of dissociation.[307] Hypnosis results in a state of inner absorption that leads to a reduction in awareness of immediate

physical surroundings and experiences. Children are more likely to be absorbed in fantasy, and their natural power of play makes them more hypnotizable than adults.[308] Although an anesthesiologist may not have training in hypnosis, he or she can use hypnotic suggestions to help children even though an actual trance state is not induced. It may be helpful to engage children in age-appropriate scenarios, such as going to the zoo, a fancy tea party, a baseball game, or flying a jet. Words should be spoken slowly and rhythmically with descriptions of sights and sounds that are familiar to the child as well as repeated suggestions of "feeling good." The hypnotic suggestions distract the child so that the smell of the anesthetic agent becomes the scent of the zoo animals, the tea brewing, the aviation fuel, and so on. Any number of stories can be told with the same result as long as one remembers to repeatedly say things that can be identified by the child and that fit with what the child is experiencing at the time of induction.

When hypnosis was administered 30 minutes before surgery, it significantly reduced preoperative anxiety at the time of face mask application and the frequency of behavior disorders postoperatively when compared with oral midazolam (0.5 mg/kg).[309] Hypnosis provided a relaxed state of well-being and enabled children to actively participate in anesthesia, thus leaving them with a pleasant memory. Unlike the anterograde amnesia associated with midazolam, hypnosis offers the benefit of maintaining a pleasant memory to prevent fear during future anesthetics.

Modified Single-Breath Induction

The single-breath induction technique is especially appealing to children who desire to fall asleep "really fast" with a face mask, because loss of consciousness is achieved much more rapidly than with a traditional escalating-dose technique. It works best with older children, although some as young as 3 years of age can be anesthetized with this technique if they are cooperative. Before beginning, the child should be coached through a mock induction by instructing him or her to "breathe in the biggest breath possible" through the mouth (not the nose) and then "breathe all the way out until there is no more air in the lungs." If the child is used to swimming and holding the breath underwater, this makes the exercise much easier. Once this has been practiced a few times, then a practice run is repeated with only the mask (no circuit) on the face.

Before induction, the circuit and reservoir bag are primed with 70% N_2O in O_2 and the maximum concentration of halothane or sevoflurane the vaporizer can deliver. This is achieved by running modest fresh gas flows through the circuit and intermittently emptying the reservoir bag manually into the scavenger system (i.e., with the circuit Y-connector occluded). Once the circuit is primed with the maximum concentration of inhalation agent, the mask is placed on the Y-connector, then the distal end of the circuit is occluded (to avoid contaminating the OR), and the child is instructed to take a deep breath of room air and to exhale all the air and hold expiration. The face mask is then placed securely over the child's mouth and nose while he or she is instructed to take in the "deepest breath ever through the mouth" and "hold it, now just breathe normally." Loss of consciousness, as noted by loss of the eyelash reflex, occurs within 15 to 30 seconds after this vital capacity breath (Fig. 4.4A, B and C, and Video 4.4).[298,310]

INTRAVENOUS INDUCTION

IV induction is usually reserved for older children, those who request an IV induction, those with a previously established IV catheter, those with potential cardiovascular instability, and those who need a rapid-sequence induction (RSI) because of a full stomach. There are many different options as far as medications that can be used for an IV induction in a child (Table 4.6). Ideally, all children should breathe 100% oxygen before IV induction; if the face mask is met with objections, oxygen may be insufflated without a mask by simply holding the Y-connector of the circuit between your fingers over or near the child's face.

Thiopental

Thiopental (sodium pentothal) has been replaced by propofol as the most commonly used IV induction agent. The recommended induction dose of thiopental in healthy, unpremedicated children is 5 to 6 mg/kg[311]; neonates require a smaller dose (3 to 4 mg/kg).[312] Debilitated or severely ill patients, those who are hypovolemic, and those who have been premedicated may also require a smaller dose for induction of anesthesia. The beta-elimination half-life of thiopental in neonates is twice that in their mothers (15 vs. 7 hours), so a single dose may produce excessively prolonged effect in neonates.[313] This drug is no longer available in the United States.

Methohexital

Methohexital is an ultra-short-acting oxybarbiturate that is infrequently used for IV induction (1.0 to 2.5 mg/kg)[314]; premedicated children require a smaller dose. Recovery after IV administration is more rapid than after thiopental.[315] Larger doses cause skeletal muscle hyperactivity, myoclonic movements, and hiccups.[314] Pain at the injection site is common, necessitating pretreatment with IV lidocaine.

Propofol

Propofol is the most commonly used IV induction agent in children. The induction dose of propofol varies with age: the median effective dose (ED_{50}) for a satisfactory induction in healthy infants 1 to 6 months old is 3.0 ± 0.2 mg/kg, and in healthy children 10 to 16 years old it is 2.4 ± 0.1 mg/kg.[316] The 95% effective dose (ED_{95}) in healthy unpremedicated children 3 to 12 years of age is 2.5 to 3.0 mg/kg.[317] The early distribution half-life is about 2 minutes, and the terminal elimination half-life is about 30 minutes.[318] Clearance is very large (2.3 ± 0.6 L/minute) and exceeds liver blood flow.[318] Advantages to propofol for induction of anesthesia include a reduced incidence of airway-related problems (e.g., laryngospasm, bronchospasm), more rapid emergence,[319,320] and a reduced incidence of nausea and vomiting.[321,322] The major disadvantage of propofol is pain at the site of injection, especially when administered in small veins (e.g., the back of the hand).[316] The administration of lidocaine (0.5 to 1.0 mg/kg) while applying tourniquet pressure proximal to the injection site (mini-Bier block) for 30 to 60 seconds before injecting the propofol effectively eliminates the pain in more than 90% of patients. However, younger children may not tolerate even the discomfort from the Bier block, which is the reason to consider using nitrous oxide as an alternative and equally effective strategy (see Chapter 7). Other techniques reported to attenuate the pain include mixing lidocaine (0.5 to 1 mg/kg) with the propofol (but this should be done within 60 seconds of administration of the propofol), refrigerating the propofol, pretreating with an opioid or ketamine, and diluting propofol to a 0.5% solution.[323–331]

In addition to its use as an induction agent, propofol can be administered by infusion for total IV anesthesia (see

FIGURE 4.4 A single-breath induction is another useful method that is most appropriate for children 5 to 10 years of age. It is important to practice several times without the mask attached to the circuit before the actual induction (see text for details of preparing the circuit). This allows the child to become familiar with the feel of the mask as it is applied to the face and to properly time the sequence of events. **A** and **B,** Typically, we ask the child to take "the biggest breath possible and hold it." Then we ask the child to "breathe all the way out until you have no more air in your lungs and hold it" and place the face mask on the child's face. **C,** We then ask the child to take in "the biggest breath you have ever taken, hold it, then breathe normally." If a full vital capacity breath is taken with a good mask seal around the mouth and nose, most children will lose their lid reflex within 15 to 30 seconds, which is similar to IV induction agents.

TABLE 4.6 Doses of Commonly Used IV Induction Agents

Drug	Dose (mg/kg)
Thiopental or thiamylal[a]	5–8
Methohexital	1–2.5
Propofol	2.5–3.5
Etomidate	0.2–0.3
Ketamine	1–2

[a]No longer available in the United States.

Chapters 7 and 8) because of its relatively low context-sensitive half-life. It is especially useful for pediatric patients undergoing non-OR procedures such as CT, MRI, radiotherapy, bone marrow biopsy, upper and lower gastrointestinal endoscopy, and lumbar puncture.

Etomidate

Etomidate is a hypnotic induction agent that provides marked cardiovascular stability. Etomidate is available for use in the United States and several other countries, but it is not available in many others because of concern for adrenal suppression. It is indicated for the induction of anesthesia in children with sepsis, cardiac instability, cardiomyopathy, or hypovolemic shock. The recommended induction dose is 0.2 to 0.3 mg/kg depending on the cardiovascular status of the child. Etomidate causes pain and myoclonic movements when injected intravenously[332] and may suppress adrenal steroid synthesis (see also Chapter 7).[333]

Ketamine

Ketamine is a very useful induction agent for children with cardiovascular instability, especially in hypovolemic states, or for those who cannot tolerate a reduction in systemic vascular resistance, such as those with aortic stenosis or congenital heart disease in whom the balance between pulmonary and systemic blood flow is vital for maintaining cardiovascular homeostasis. In children whose circulation is already maximally compensated by endogenous catecholamines, ketamine is a myocardial depressant that can result in systemic hypotension.[334] The induction dose of ketamine in healthy children is 1 to 2 mg/kg. The dose should be reduced in the presence of severe hypovolemia. Smaller doses

of IV ketamine (0.25 to 0.5 mg/kg) have also been used successfully for procedural sedation.

Ketamine causes sialorrhea, psychomimetic side effects (hallucinations, nightmares), and postoperative nausea and vomiting. The administration of an antisialagogue and midazolam is recommended to attenuate these side effects.

INTRAMUSCULAR INDUCTION

Although it is preferable to avoid intramuscular injections in children, there are occasions when this route may be indicated, such as for the uncooperative child or adolescent who refuses all other routes of sedation (oral, intranasal, IV), those susceptible to malignant hyperthermia, those with congenital heart disease, and those who have poor venous access. In infants, but especially in older children, intramuscular ketamine is a very useful medication because it is available in a concentrated solution (100 mg/mL) (see earlier discussion).[112]

RECTAL INDUCTION

Rectal drug administration is ideally suited for an extremely frightened young child who rejects other forms of premedication and for those who are developmentally delayed. It is usually limited to children younger than 5 or 6 years of age or smaller than 20 kg, owing to volume limitations on the fluid injected and concern over emotional consequences. Methohexital, thiopental, ketamine, and midazolam have all been investigated as agents for rectal induction. For unpremedicated children, the induction doses are 30 mg/kg thiopental and methohexital,[335] 1.0 mg/kg midazolam,[336] and approximately 5 mg/kg ketamine.

Disadvantages of rectal drug administration include failure to induce anesthesia because of poor drug bioavailability or defecation and delayed recovery from anesthesia after brief procedures resulting from the variability of rectal drug absorption. Conversely, there can be a very rapid drug uptake, leading to respiratory compromise.

FULL STOMACH AND RAPID-SEQUENCE INDUCTION

A full stomach is one of the most common problems that pediatric anesthesiologists face. The preferred method to secure the airway in the presence of a full stomach is IV rapid sequence induction (RSI). Before this is undertaken, the anesthesiologist must ensure that the proper equipment is at hand (Table 4.7). After IV access is established, the child should breathe 100% oxygen (preoxygenated) if possible. Studies of adult patients demonstrated that oxygen saturation remains greater than 95% for 6 minutes after only four vital capacity breaths of 100% oxygen.[337] Similar studies have not been performed in either cooperative or uncooperative children; however, without preoxygenation, younger infants and children desaturate very rapidly after induction of anesthesia and much more rapidly than older children and adults.[338,339] One study demonstrated a more rapid increase in the inspired oxygen concentration in infants compared with older patients and that preoxygenation to a fractional concentration of O_2 in expired gas (FEO_2) of 0.9 can be achieved in 100 seconds.[340] Even with a crying child, it is possible to increase the arterial oxygen tension (PaO_2) by enriching the immediate environment with high gas flows of oxygen.

TABLE 4.7 Necessary Equipment for Rapid-Sequence Intubation

Functioning laryngoscope blades and handles (two)
Suction (two)
Anesthetic medications
Checked anesthesia workstation and breathing circuit
Tracheal tubes of appropriate sizes
Tracheal tube stylets
Functioning monitors (including pulse oximeter, blood pressure cuff, and precordial stethoscope)

Preoxygenation should not be carried out in a manner that upsets a child. Premedication (e.g., IV midazolam, 0.05 to 0.1 mg/kg) in divided doses may alleviate fear and anxiety before induction. It is important to preoxygenate children to avoid positive-pressure ventilation before tracheal intubation because positive-pressure ventilation might distend the already full stomach, leading to regurgitation and aspiration. After preoxygenation (and atropine 0.02 mg/kg), anesthesia is induced with IV thiopental (5 to 6 mg/kg),[311] propofol (3 to 4 mg/kg),[341,342] ketamine (1 to 2 mg/kg), or etomidate (0.2 to 0.3 mg/kg), followed immediately by 2 mg/kg of succinylcholine. Succinylcholine is still the paralytic agent of choice for rapid onset and short duration. However, high-dose rocuronium may be used as an alternative muscle relaxant for RSI if succinylcholine is contraindicated. Intubating conditions 30 seconds after 1.2 mg/kg rocuronium were similar to those after 1.5 mg/kg succinylcholine.[343] The mean time to return 25% of the twitch response was 46 ± 23 minutes (range, 30 to 72 minutes) for rocuronium compared with 5.8 ± 3.3 minutes (range, 1.5 to 8.2 minutes) for succinylcholine. However, if thiopental is used for induction of anesthesia and followed by rocuronium, the thiopental must be cleared from the tubing before the rocuronium is administered to prevent thiopental from precipitating.[344] The availability of the new reversal agent (sugammadex) for rocuronium (and potentially vecuronium) may reduce concern about the risks associated with a prolonged duration of action of rocuronium, particularly in the presence of a difficult airway, and eliminate the need for IV succinylcholine (see Chapter 7). Suggamadex was approved for use by the US FDA in November 2015. The ability to immediately reverse nondepolarizing neuromuscular blocking agents must be weighed against the short duration of action of succinylcholine when selecting a paralytic agent for RSI.

Cricoid pressure (Sellick maneuver) should be applied as anesthesia is induced, and the pressure should be maintained until the tracheal tube has been successfully placed between the vocal cords.[345,346] By obliterating the esophageal lumen, cricoid pressure is intended to prevent regurgitated material from passing from the stomach to the pharynx. Before induction of anesthesia, the cricoid ring is palpated between the thumb and the middle finger and as soon as the child loses consciousness, pressure is steadily increased using the index finger. To prevent passive gastroesophageal reflux, a force of 30 to 40 N (3 to 4 kg of force) must be applied to the upper esophagus (in adults), which creates an intraluminal pressure of approximately 50 cm H_2O in the upper esophagus.[347] However, active vomiting may create esophageal pressures in excess of 60 cm H_2O that could overcome cricoid pressure and result in regurgitation and pulmonary aspiration. Alternatively, if cricoid pressure is not relieved immediately, spontaneous rupture of the esophagus (Boerhaave syndrome) may occur. Hence, the contraindications to cricoid pressure should be carefully reviewed to avoid complications from this maneuver (Table 4.8). Gastric insufflation is prevented in children by cricoid pressure during mask ventilation with peak inspiratory pressures up to 40 cm H_2O.[348] The Sellick maneuver should seal the

TABLE 4.8 Contraindications to Cricoid Pressure

Contraindication	Potential Complication
Active vomiting	• Possible rupture of esophagus
Airway issues	• Fractured cricoid cartilage may be made worse. • Sharp foreign body in larynx may result in further laryngeal injury.
Esophageal issues	• Zenker diverticulum • Sharp foreign body in upper esophagus may result in further esophageal injury.
Vertebral/neurologic issues	• Unstable cervical spine may result in spinal cord injury. • Sharp foreign body in the neck may result in injury to other structures in the neck.

From Thiagarajah S, Lear E, Keh M. Anesthetic implications of Zenker's diverticulum. *Anesth Analg* 1990;70:109-111

esophagus in the presence of a nasogastric tube,[349] but removal of the nasogastric tube before intubation provides a better mask fit on the face and exposure for laryngoscopy and intubation. If the nasogastric tube is left in place, leaving it open to atmospheric pressure will vent liquid and gas present in the stomach.

The results of surveys from the United Kingdom showed that cricoid pressure was used in only 40% to 50% of children in whom it was indicated.[350,351] Reluctance to apply cricoid pressure may be attributed to a number of reasons, including the indications for its use and how often it is applied with the correct position and pressure.[352–354] In adults evaluated with MRI, the esophagus was situated lateral to the cricoid cartilage in more than 50% of patients without cricoid pressure and was laterally displaced more than 90% of the time when cricoid pressure was applied.[355] In addition, cricoid pressure may distort the anatomy of the upper airway, making laryngoscopy more difficult, and it must sometimes be released to facilitate a clear view of the larynx and tracheal intubation, particularly in infants.[356] Cricoid pressure also decreases the tone of the upper and lower esophageal sphincters.[347,357] However, properly applied cricoid pressure can facilitate intubation with RSI and mask ventilation.

Evidence suggests that the gastric residual volume in children undergoing emergency surgery is greater if a child is anesthetized within 4 hours after hospital admission (1.1 mL/kg).[358] If, on the other hand, surgery can be delayed for at least 4 hours, then the mean gastric residual volume is on average much less (0.51 mL/kg)[358]; this gastric residual volume is in fact similar to that observed in children who have fasted for routine surgical procedures (Fig. 4.5).[1] This does not imply that these children should not be regarded as having a full stomach; rather, the risk may be somewhat reduced if surgery can be delayed several hours. In addition, evidence suggests that in emergency cases, the gastric residual volume depends, in part, on the time interval between the last food ingestion and the time of the injury as well as the severity of the injury.[358] Children who last ate more than 4 hours before the injury have a gastric residual volume similar to those who fasted as if it were elective surgery (Fig. 4.6). *There is some comfort in these numbers, but one should never consider such children as not having a full stomach but rather as having a less full stomach.* Additionally, the possible value of H_2-receptor blocking agents, metoclopramide, and clear antacids may be considered, but their use in this regard is not evidence based.

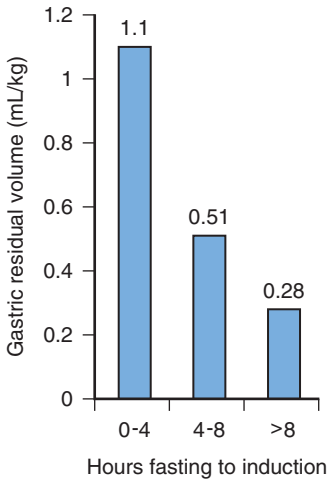

FIGURE 4.5 Mean gastric residual volume is plotted against hours of fasting before anesthetic induction in emergency pediatric cases. These data suggest that a 4-hour fast, if it does not compromise patient safety, may reduce gastric residual volume and therefore reduce (but not eliminate) risk for aspiration. (Data abstracted from Schurizek BA, Rybro L, Boggild-Madsen NB, Juhl B. Gastric volume and pH in children for emergency surgery. *Acta Anaesthesiol Scand*. 1986;30:404-408.)

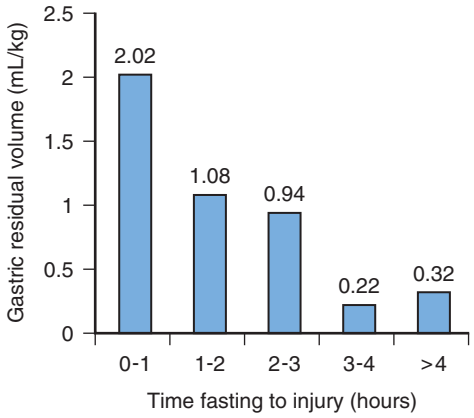

FIGURE 4.6 Mean gastric residual volume is plotted against time from last food ingestion to time of injury. These data suggest that the longer the time from ingestion to injury, the lower the risk for pulmonary aspiration of gastric contents. Also, if more than 4 hours has elapsed between the time of last food ingestion and time of injury, the risk is similar to that for patients with routine fasting. However, even with a 4-hour fasting time period, these patients must still be treated as though they have a full stomach. It should be noted that these volumes also relate to the severity of injury (increased volumes with increased injury severity). (Data abstracted from Bricker SRW, McLuckie A, Nightingale DA. Gastric aspirates after trauma in children. *Anesthesia* 1989;44:721-724.)

A modified RSI may be preferred in small infants who will likely desaturate during brief periods of apnea and will therefore require assisted ventilation before the trachea is secured. Despite face mask ventilation prior to intubation, there were no cases of pulmonary aspiration in a retrospective cohort analysis of 1001 pediatric patients who underwent modified RSI.[359] Neonates may be intubated while awake if indicated; this may provide a greater margin of safety because it preserves spontaneous ventilation as well as laryngeal reflexes. Skillfully performed awake intubation

in neonates is not associated with either significant adverse cardiovascular responses or neurologic sequelae[360] and may be preferred in infants with hemodynamic instability.[361]

Special Problems

THE FEARFUL CHILD

This is a difficult problem without a satisfactory solution. The child's fear is generally based on the child's developmental status, the hospital environment, and the impending surgery. This is why it is so vital that as much information as possible be presented and queries as to why the child is afraid are so important. Frequently, a few well-directed questions and honest answers will resolve most of the child's concerns. Often, allowing a parent to hold the child during induction of anesthesia or allowing the child to hold the anesthetic mask himself or herself will stop the flow of tears and settle the child's emotional upheaval. In other situations, one commonly practiced solution is to use intramuscular ketamine.

AUTISM

Autism spectrum disorder (ASD) is a neurodevelopmental disorder characterized by impairment in social and communication skills, restricted interests, repetitive behavior, and for some, touch, visual, taste, or sound hypersensitivity. Children present early in life but deficits may not become fully manifest until social communication demands exceed capabilities.[362] The diagnosis is based on observation and assessment of behavior and cognition and is aided by validated assessment tools. The fifth edition of *Diagnostic and Statistical Manual of Mental Disorders* (DSM-V) adopted the umbrella term ASD, which includes autism, Asperger syndrome, and pervasive developmental disorder.[363] How prevalence estimates will be affected by the new criteria remains to be assessed.

ASD was diagnosed in 1 in 68 (14.6 per 1000) children aged 8 years residing in US Autism and Developmental Disabilities Monitoring Network sites in 2012,[364] which is an increase over previous estimates of 1 in 88 (11.3 per 1000). The increased prevalence is likely due to broader diagnostic criteria, increased public awareness, and the development of more sensitive screening tools. Autism affects boys more commonly than girls with an overall prevalence ratio of 4.5.[364] Global prevalence of ASD is thought to be approximately 1%.[365] More than 70% of individuals with autism have concurrent medical (gastrointestinal, seizures, insomnia, mitochondrial disease), developmental (intellectual disability), or psychiatric problems (social anxiety disorder, attentive-deficit/hyperactivity disorder [ADHD], oppositional defiant disorder).[362]

Behavior and cognitive training is the most effective therapy for ASD, but it must be initiated at an early age to achieve the best possible neurologic improvement. The existing pharmacologic management for ASD has not been promising in treating core symptoms but has been effective in decreasing the burden of emotional and behavioral problems.[366] Antipsychotic drugs have been shown to effectively reduce repetitive behaviors in children with autism, but associated side effects limit their use to patients with severe impairment.[367] Serotonin reuptake inhibitors may reduce repetitive behaviors, although findings are inconsistent.[367–369] The effect of stimulants on symptoms of ADHD occurring in children with ASD requires more study but shows promise and has been recommended.[370] It is critical for the anesthesiologist to be familiar with these medications and their potential interactions with anesthetic agents (see Table 4.9).[371,372]

TABLE 4.9 Commonly Used Pharmacologic Agents for Children With Autism Spectrum Disorder

Medication	Target Symptoms	Potential Adverse Effects
Antipsychotics: Haloperidol Risperidone Aripiprazole	Aggression, irritability, self-injury	Weight gain, sedation, extrapyramidal symptoms, hypotension with general anesthesia and proarrhythmic properties (risperidone)
Atypical Antipsychotic: Clozapine	Repetitive behaviors	Agranulocytosis, hyperthermia, cardiac conduction problems, hypotension. Discontinuation can cause dystonia dyskinesia, delirium, and psychosis
Selective Serotonin Reuptake Inhibitors (SSRIs): Fluoxetine Citalopram	Repetitive behaviors	Agitation, gastrointestinal symptoms; reduced platelet aggregation and increased transfusion risk
Stimulants: Methylphenidate Amphetamines	Hyperactivity, inattention	Insomnia, decreased appetite, weight loss, headache, irritability, may increase anesthetic requirement, increase risk of hypertension and arrhythmias, lower seizure threshold and interact with vasopressors
Melatonin	Insomnia	No side effects recorded

The perioperative period can be a stressful time for children with ASD; they do not respond well to changes in routine and may challenge the ingenuity of the anesthesiologist. They are very sensitive to stimuli such as light, sound, touch, and pain and may be unable to articulate concerns they have. The hospital setting is anxiety-provoking and usually upsets most autistic children until they become totally disruptive and uncooperative.

The anesthesiologist's approach to the autistic child depends on the severity of the disorder. Information regarding the child's previous anesthetic experience, assessment of the child's behavior and idiosyncrasies, and bonding with parents or caregivers should be accomplished during the preanesthetic visit. The family should be encouraged to bring favorite toys, electronic devices, and other comforting items. Collecting pertinent information about baseline behavior, triggers of emotional outbursts, and signs of escalating anxiety is invaluable.[373] Sedative premedication can work very well in these children. The decision to administer premedication needs to be made on an individual basis (see "Premedication and Induction Principles"). Oral midazolam (0.5 to 1 mg/kg)[374] is the most commonly used preoperative anxiolytic for children, although other choices include oral ketamine (6 mg/kg)[202] and a combination of oral midazolam (0.5 mg/kg) and ketamine (3 to 6 mg/kg).[205] Oral dexmedetomidine (mean dose 2.6 µg/kg) has also provided adequate sedation prior to induction of anesthesia in children with ASD.[375] Some of these children may have problems with certain textures and tastes; administering oral premedication in a favorite drink should be considered in the context of NPO guidelines. The overly anxious child may be uncooperative with oral medication and may require intramuscular ketamine. Parents

can also offer insight into which strategies would make their child's life easier during this difficult time. It is important to take the time to address parental concerns and establish a trusting relationship with the family. In a recent retrospective review, no difference in the perioperative experience was found between children with ASD and healthy children undergoing dental rehabilitation, including no apparent difference in complications, postoperative pain, and time to discharge. The only significant difference was found in the type and the route of administration of the premedication where children with ASD had a higher rate of nonstandard premedication (ketamine intramuscularly with and without midazolam, intranasal ketamine, or an IV line placed preoperatively for IV premedication).[376]

There is great variation in the severity of autism and hospital needs of these children.[377] The focus for optimal management of these children in one institution was on early communication to provide a flexible and individualized admission process and anesthetic plan.[377] A quiet room, scheduling the case as early in the day as possible, minimizing the waiting period, and involving a child-life specialist may offer advantage preoperatively for more severe cases.[373]

Intraoperative goals should include adequate analgesia, prophylaxis of postoperative nausea and vomiting, and optimal intraoperative hydration to allow early removal of the IV cannula, which may prevent negative emotional outbursts in the recovery room. Finally, the appropriate use of parents in the postanesthesia care unit can facilitate the transition from surgery to recovery. Studies have shown that children who are reunited with their parents sooner require less pain medication and are discharged earlier in an ambulatory setting.[378]

ANEMIA

The minimum hematocrit necessary to ensure adequate oxygen transport in children has not been well established. Preoperative hemoglobin testing, however, is of limited value in healthy children undergoing elective surgery when minimal blood loss is expected.[379] Children with chronic anemia, such as those with renal failure, do not require preoperative transfusion because of compensatory mechanisms, such as increased 2,3-diphosphoglycerate, increased oxygen extraction, and increased cardiac output. Elective surgery for children who are anemic should take into consideration their medical history, underlying diseases (e.g., hemoglobinopathies, von Willebrand, sickle cell, other factor deficiency), the nature of the surgery, and its urgency. Most pediatric anesthesiologists would recommend a hematocrit greater than 25% before elective surgery in the absence of chronic disease. If significant blood loss is anticipated and the surgery is elective, then the cause of anemia should be investigated and treated and the surgery postponed until the hematocrit is restored to the normal range. *Healthy children scheduled for elective surgery that is not expected to cause substantive bleeding should not routinely receive a blood transfusion just to bring their hematocrit to an arbitrary limit such as 30%.*

Physiologic anemia of infancy occurs between 2 and 4 months of postnatal age. At this time, there is an increased production of hemoglobin A and an increase in red cell 2,3-diphosphoglycerate, which contribute to a right shift of the oxygen-hemoglobin dissociation curve (see Chapter 10). Therefore, in infants 2 to 4 months of age, a reduced hemoglobin value is acceptable. Anemia, with a hematocrit of less than 30%, in formerly preterm infants represents a special category of patients who may have an increased incidence of postoperative apnea (see later discussion), but transfusion is still not recommended.[380]

TABLE 4.10 Differential Diagnosis of a Child With a Runny Nose

Noninfectious Causes
Allergic rhinitis: seasonal, perennial, clear nasal discharge; no fever
Vasomotor rhinitis: emotional (crying); temperature changes
Infectious Causes
Viral infections
Nasopharyngitis (common cold)
Flu syndrome (upper and lower respiratory tract)
Laryngotracheal bronchitis (infectious croup)
Viral exanthems
Measles
Chickenpox
Acute bacterial infections
Acute epiglottitis
Meningitis
Streptococcal tonsillitis

UPPER RESPIRATORY TRACT INFECTION

The child with a nonpurulent active or recent upper respiratory tract infection (URI; within 4 weeks) often presents a conundrum, even for the most experienced anesthesiologist. Between 20% and 30% of all children have a runny nose during a significant part of the year. A differential diagnosis of a child with a runny nose is presented in Table 4.10. In the preanesthetic evaluation, we must rely on history, physical examination, and, rarely, laboratory data to decide whether to proceed with the anesthesia.

A number of perioperative anesthetic risks have been studied in children with URIs.[381] The risk of postintubation croup was similar in children who had an active URI and those who did not.[382] Bronchospasm occurs more frequently in children whose tracheas are intubated and who have active URIs.[383] The incidence of bronchospasm in children with a URI (41 : 1000) is 10-fold greater than it is in those without a URI.[384] The incidence of laryngospasm in children with a URI (96 : 1000) is 5-fold greater than it is in children without a URI (17 : 1000).[385] The incidence of minor but not major intraoperative hemoglobin desaturation events in children with a URI is greater than in those without a URI.[383] Lastly, the incidence of all respiratory-related adverse events combined in children with a URI was 9-fold greater than in those without a URI and 11-fold greater in children who had a URI and required tracheal intubation.[386]

When a tracheal tube and LMA were compared in children with a URI, the incidence of mild bronchospasm, major desaturation events, and overall respiratory events was reduced in the presence of a LMA, although the incidence of laryngospasm was similar with the two airway devices.[387,388]

Prognostic factors of adverse anesthetic events in children with URIs who were scheduled for elective surgery include the type of airway management (tracheal intubation > LMA); a parent's statement that the child has a "cold"; the presence of nasal congestion, snoring, passive smoking; the induction agent (thiopental > halothane > sevoflurane ~ propofol); sputum production; and whether the neuromuscular agent was antagonized.[389] Reactive airway disease and a history of prematurity have also been associated with adverse outcomes in children with URIs.[390] Age has not been

an independent predictor of adverse events in children with URIs in most studies, although one study suggested that the incidence of bronchospasm in infants younger than 6 months with active URIs was greater (20.8% vs. 4.7%, $P = .08$) than in older children.[391] In this study, the greatest incidence of adverse respiratory events occurred in children undergoing airway surgery (e.g., tonsillectomy and adenoidectomy, direct laryngoscopy, bronchoscopy).

Cancellation of cardiac surgery carries special import because of the risk that the child's heart will deteriorate or the disease process will progress (e.g., pulmonary hypertension), as well as the extensive time, materials, and personnel committed to a planned case. In a prospective study of children scheduled for cardiac surgery, the incidences of respiratory adverse events (29.2% vs. 17.3%, $P < .01$), multiple postoperative complications (25% vs. 10.3%, $P < .01$), and bacterial infection (5.2% vs. 1.0%, $P = .01$) were greater in those with a URI than in those without.[392]

A national survey suggested that more experienced anesthesiologists are less likely to cancel surgery because of the presence of a URI.[393] Cancellation may also impose emotional and economic burdens on the parents.[394,395] Factors that should be considered when deciding whether to proceed with elective surgery in a child with a URI are summarized in Table 4.11.

Insofar as which techniques will help to prevent complications from a URI, pretreating healthy children who either had a URI within the preceding 6 weeks or had an active URI with bronchodilators, either inhaled ipratropium or albuterol, before anesthesia provided no benefit.[396] However, in another study, children with a recent URI (≤2 weeks in duration) who received preoperative salbutamol experienced a significantly reduced incidence of laryngospasm, bronchospasm, oxygen desaturation (<95%) and severe coughing with an LMA or tracheal tube.[397] Humidification, IV hydration, and anticholinergics may also decrease perioperative complications,[393] although the results of at least one study suggested that glycopyrrolate did not reduce the incidence of perioperative adverse respiratory events when it was given after induction of anesthesia to children with URIs.[398] Use of LMAs coated with topical lidocaine in children with URIs was associated with decreased postoperative coughing[399,400] and lower overall perioperative complication rates.[400]

If the decision is made to postpone anesthesia, then how long should one wait before administering general anesthesia to a child? Bronchial hyperreactivity, which is associated with URIs in children, shows spirometric changes in the lungs for as long as 7 weeks after a URI.[401,402] Although studies suggest that surgery should be postponed for at least 7 weeks after resolution of a URI, this plan is impractical because most children will be infected with a new URI by that time. Postponing surgery until 2 weeks after resolution of the URI is a common but as yet unproven strategy. In fact, some data suggest that the incidence of adverse respiratory events is just as great in this population as it is in those who were anesthetized during the acute phase of the URI.[403,404] This 2-week waiting period may be acceptable in a child with uncomplicated nasopharyngitis.[405] Unfortunately, there is no consensus on the optimal time interval before surgery is rescheduled. In a survey of anesthesiologists, most wait 3 to 4 weeks before proceeding with surgery.[393] The rationale for this time period is that the risk of respiratory complications is unchanged for 4 to 6 weeks.[391]

In conclusion, good judgment, common sense, clinical experience, a measured discussion with the surgeon, and informed consent from the parents or guardians must be used when deciding whether to proceed or postpone the surgery. All of these deliberations and discussions including the risks and benefits should be documented in the chart (see Chapter 13 for additional discussion and perspectives).

TABLE 4.11 Factors Affecting Decision for Elective Surgery in a Child With Upper Respiratory Tract Infection

Proceed With Caution	Consider Cancellation
• Child has "just a runny nose," no other symptoms, "much better"	• Parents confirm symptoms: fever, malaise, cough, poor appetite, just developed symptoms last night
• Active and happy child	• Lethargic, ill-appearing
• Clear rhinorrhea	• Purulent nasal discharge
• Clear lungs and symptoms have leveled off or have improved	• Wheezing, rales that do not clear
• Older child	• Child <1 year, former premie
• Social issues: hardship for parents to be away from work, insurance will run out	• Other factors: history of reactive airway disease, major operation, endotracheal tube required
• No fever	• Fever >38.5°C
• Outpatient procedure that will not expose immunocompromised children to possible infectious agent	• Inpatient procedure that may result in exposure of immunocompromised children to viral/bacterial infection

From Tait AR, Malviya S. Anesthesia for the child with an upper respiratory tract infection: still a dilemma? *Anesth Analg.* 2005;100:59-65.

OBESITY

There are a variety of definitions for childhood obesity. In children and adolescents aged 2 to 19 years, the CDC defines obesity as a body mass index (BMI) at or above the 95th percentile for age, as defined by the 2000 CDC growth charts for normal children.[406] Overweight is defined as a BMI between the 85th and 95th percentiles. The World Health Organization uses standard deviations (BMI z scores) from the mean BMI for age to define childhood overweight and obesity.* A third standard developed by Cole[407] uses pooled international data to provide age-specific and gender-specific BMI cutoff points for childhood obesity.

The prevalence of childhood obesity is rapidly increasing worldwide. Globally, the World Health Organization estimates 42 million children under the age of 5 years were overweight or obese in 2013.† In the United States, approximately 8% of infants and toddlers had high weight for recumbent length, and 17% of children aged 2 to 19 years were obese per CDC standards in 2011-12.[406] The majority of childhood overweight and obesity cases are caused by excessive caloric intake and relative lack of physical activity, with the remaining cases resulting from conditions such as endocrine disorders, neurologic dysfunction, and genetic syndromes (e.g., Prader-Willi).[408]

Obesity is a complex endocrine state and is associated with numerous comorbidities (Table 4.12). The incidences of these

*See http://www.who.int/dietphysicalactivity/childhood_what/en (accessed April 23, 2016).

†See http://www.who.int/mediacentre/factsheets/fs311/en (accessed April 23, 2016).

TABLE 4.12 Comorbidities Associated With Childhood Obesity

Affected Organ System	Obesity-Related Comorbidity
Respiratory system	• Bronchial hyperreactivity • Asthma (present in 30%) • High incidence of upper airway infections • Obstructive sleep apnea (present in 13%–59%)
Cardiovascular	• Hypertension (present in 20%–30%) • Left ventricular hypertrophy (in adolescents)
Endocrine	• Metabolic syndrome (present in 40%–50% of obese adolescents) • Dyslipidemia (hyperlipidemia and hypercholesterolemia) • Polycystic ovarian syndrome
Gastrointestinal	• Gastroesophageal reflux (present in 20% of severely obese children) • Asymptomatic steatosis hepatis (present in 80%). Could progress to hepatic fibrosis, nonalcoholic acute steatohepatitis or rarely cirrhosis.
Neurologic/ psychological	• Pseudotumor cerebri • Low self-esteem • Poor school performance
Orthopedic	• Slipped femoral epiphysis

TBW, total body weight; *LBW,* lean body weight; *IBW,* ideal body weight.

comorbidities increase as BMI and the duration of obesity increase.[409] Weight loss may reduce perioperative risk factors.

Obese children have a higher incidence of perioperative adverse respiratory events compared with normal-weight children.[410,411] Functional residual capacity, expiratory reserve volume, forced expiratory volume in 1 second, and diffusion capacity are all reduced. High closing volumes may cause atelectasis and right-to-left intrapulmonary shunting.[412] Bronchial hyperreactivity and asthma are highly prevalent amongst obese children. A review of over 2200 referrals to a pediatric asthma specialist in the United States found that nearly 30% of patients with physician-diagnosed asthma were obese.[413] Asthma incidence and severity rose with increasing BMI. In addition, a cross-sectional study of 1129 preadolescent children found that overweight children with BMI greater than the 90th percentile for age had twice the risk of developing URIs, an independent risk of perioperative respiratory complications, compared with children with lower BMI (please refer to "Upper Respiratory Tract Infections" in this chapter for further discussion of risk).[414]

Obstructive sleep apnea syndrome (OSAS) affects 13% to 59% of obese children (see further).[415–417] Children with OSAS may display increased sensitivity to opioids. Opioids should be carefully titrated to respiratory responses. If apnea is seen after small doses of opioids, further doses of opioids should be reduced and respirations must be closely monitored. Similarly, caution must be used when administering benzodiazepines for premedication in obese children with OSAS given the risk of respiratory depression. If the child is regularly managed with continuous positive airway pressure (CPAP) or biphasic positive airway pressure (BiPAP), this therapy should be maintained postoperatively until the child is awake and can maintain a patent airway.

Obese children have increased blood volume, stroke volume, and cardiac output.[418] Hypertension is present in 20% to 30% of obese children; the incidence of hypertension increases with increasing BMI.[419,420] Blood pressure should be measured preoperatively and exercise tolerance determined to establish whether cardiopulmonary compromise exists.

Significant obesity leads to insulin resistance; nearly half of obese adolescents suffer from the metabolic syndrome and are at high risk of developing type 2 diabetes mellitus.[421] Fasting blood glucose levels should be obtained preoperatively, as type 2 diabetes mellitus may be present but undiagnosed.[422] Adolescents with type 2 diabetes mellitus display adverse measures of cardiac structure and function positively related to BMI and blood pressure.[423] Preoperative electrocardiography and echocardiography should be considered in obese diabetic children with suspected cardiac disease.

Childhood obesity is a risk factor for gastroesophageal reflux. Up to 20% of severely obese children have symptoms of gastroesophageal reflux, compared with 2% of normal-weight children.[424] Despite the increased prevalence of symptomatic reflux, gastric fluid volumes are identical across all BMI categories (when corrected for ideal body weight) and regardless of fasting interval. Overweight and obese children with gastroesophageal reflux may be allowed clear liquids 2 hours before surgery, similar to normal-weight children.[425]

Preoperative height, weight, blood pressure, heart rate, pulse oximetry, and fasting glucose level should be documented for all obese children. A thorough airway examination must be performed. The risk of difficult mask ventilation is higher in obese children than in normal-weight children.[411,426,427] Jaw thrust and CPAP are useful in reducing upper airway collapse during spontaneous ventilation. Equipment for difficult intubation should be readily available prior to the induction of anesthesia. Vascular access may be difficult to establish in obese children.

IV drug dosing is problematic as the pharmacokinetics of most anesthetics are affected by obesity. Unfortunately, there are few pharmacokinetic studies of obese children and data to guide drug dosing are limited. Drug doses for induction of anesthesia may be calculated based on the patient's total body weight, ideal body weight, or lean body weight (Table 4.13). In general, hydrophilic drugs should be dosed according to ideal body weight. One notable

exception is succinylcholine, which should be dosed according to total body weight owing to increased pseudocholinesterase activity in obese children (see also Chapters 6 and 7).[428]

OBSTRUCTIVE SLEEP APNEA SYNDROME

Sleep apnea is a sleep-related breathing disorder in children characterized by a periodic cessation of air exchange, with apnea episodes lasting longer than 10 seconds and an apnea-hypopnea index (AHI) indicating that the total number of obstructive episodes per hour of sleep is greater than 1 (AHI 1-5 = mild OSA, 6-10 = moderate OSA, >10 = severe OSA).[429] Sleep apnea may be defined as central (absent gas flow, lack of respiratory effort), obstructive (absent gas flow, upper airway obstruction, and paradoxical movement of rib cage and abdominal muscles), or mixed (due to both CNS defect and obstructive problems). Diagnosis is made by clinical assessment (see later discussion), nocturnal pulse oximetry, or polysomnography studies.

OSAS is manifested by episodes that disturb sleep and ventilation. These episodes occur more frequently during rapid eye movement (REM) sleep and increase in frequency as more time is spent in REM sleep periods as the night progresses. OSAS occurs in children of all ages (about 2% of all children) but is more common in children 3 to 7 years of age. It occurs equally in boys and girls, although the prevalence is greater in African American and Hispanic children compared with Caucasians.[430–433]

Signs of OSAS are sleep disturbances (including daytime sleepiness), irritability, night terrors, nocturnal enuresis, snoring loud enough to be heard through a closed door, pauses and/or gasps during the night, failure to thrive resulting from poor intake due to tonsillar hypertrophy, speech disorders, and decreased size (decreased growth hormone release during disturbed REM sleep). With the worldwide increase in childhood obesity, the presence of obesity in children with OSAS exacerbates the signs and symptoms of OSAS. Parents of obese children should be specifically asked about such signs and symptoms. This syndrome can cause significant cardiac, pulmonary, and CNS impairment caused by chronic oxygen desaturation. Indeed, both OSAS and obesity are systemic inflammatory responses.[434] When they occur together in a child, the severity of the signs and symptoms are greater than if only one had occurred, and resolution of the OSAS after tonsillectomy is less likely. In children with OSAS and morbid obesity, the incidences of hypertension and diabetes are greater than in the absence of these disorders. Therefore, it is important to evaluate the cardiovascular status; although right ventricular dysfunction with pulmonary hypertension is classic, biventricular hypertrophy can develop. It is more likely to occur in children with severe OSAS but has been reported in children with only mild OSAS.[435] Cardiac evaluation is recommended for any child with signs of right ventricular dysfunction, systemic or pulmonary hypertension, or multiple episodes of desaturation below 70% (see also Fig. 33.7). Electrocardiography and chest radiography are insensitive diagnostic tests; rather, echocardiography is recommended.[436] Relief of the tonsillar/adenoidal obstruction can reverse many of these disorders and prevent progression of others (pulmonary hypertension and cor pulmonale) within 6 months after tonsillectomy, although approximately 30% of children with severe OSAS will not have resolution of the OSAS after tonsillectomy.

Children with OSAS may be premedicated with caution with oral midazolam. Despite an incidence of self-limited preoperative desaturation of less than 1.5%, postpremedication monitoring of hemoglobin saturation in these children would seem reasonable.[437] Avoidance of premedication may, however, be more advantageous postoperatively.

Factors for children who are at increased risk for postoperative upper airway obstruction after tonsillectomy and/or adenoidectomy for OSAS include age younger than 2 years, craniofacial anomalies, failure to thrive, hypotonia, morbid obesity, previous upper airway trauma, cor pulmonale, a polysomnogram with a respiratory distress index greater than 40 or O_2 saturation nadir less than 85%, and a child undergoing an additional uvulopalatopharyngoplasty.[438] *Nocturnal desaturation to less than 85% upregulates the genes responsible for control of opioid receptors, resulting in an increased sensitivity to opioids; opioid requirement is reduced by approximately 50%, making standard doses of opioids a relative overdose in children with severe OSA*. This has been demonstrated in both animals and humans.[439,440] To attenuate the risk of perioperative respiratory complications, opioids should be carefully titrated to the respiratory responses during surgery, and if an increased sensitivity to opioids is detected, all perioperative opioids should be reduced accordingly (see Chapter 33 for further details).[441]

There is increasing evidence of marked ethnic variations in the cytochromes responsible for drug metabolism (see also Chapters 6 and 7). In 8% to 10% of children, a defect in CYP2D6 renders them unable to convert codeine to morphine. Codeine administration results in virtually no analgesia in such children. On the other hand, a small percentage of children (0.5% to 2%) have a duplication of the cytochrome portion responsible for codeine metabolism. Codeine is rapidly converted to morphine, yielding much higher blood levels in these "ultrarapid metabolizers" compared with children with normal cytochromes. This may lead to a relative morphine overdose, and has resulted in fatalities in children with OSA.[187–189] As a result, the FDA has added a boxed warning to codeine-containing products and recommends against the use of codeine, especially with "round-the-clock dosing," in children following tonsillectomy (see also previous discussion).*

If nocturnal upper airway obstruction continues after tonsillectomy, ancillary strategies that have been met with variable success have been used: nasal CPAP or BiPAP, nasal steroids, oxygen therapy, and weight loss, although nasal CPAP/BiPAP is rarely tolerated in children.[438]

The American Academy of Pediatrics (AAP) Clinical Practice Guidelines[442,443] provide recommendations for inpatient monitoring of children at high risk for postoperative complications who have OSAS and are undergoing adenotonsillectomy (Table 4.14). These guidelines advocate that high-risk patients undergo surgery in a facility capable of treating complex pediatric patients and be hospitalized overnight for close monitoring. In addition to the AAP guidelines, the ASA considers this such a growing problem for both adults and children that they also have formulated a Practice Guideline. Tables 4.15 and 4.16 (modified for children) help to clarify the identification and assessment of children potentially at risk for OSAS and offer a proposed (although as yet unvalidated) risk assessment scoring system.[443] This system attempts to characterize those patients who are at significantly increased risk for perioperative complications.

Despite these practice guidelines and risk identification scoring systems, a worrisome number of children with OSA have died or suffered neurologic injury as a result of apnea after tonsillectomy. A survey of Society for Pediatric Anesthesia members and review

*See http://www.fda.gov/Safety/MedWatch/SafetyInformation/SafetyAlertsforHumanMedicalProducts/ucm315627.htm (accessed March 29, 2016).

of the ASA Closed Claims Project yielded 111 reports of adverse events between 1990 and 2010 in children undergoing tonsillectomy.[444] Death or neurologic injury occurred in 77% of these cases. Nearly half of the events within 24 hours of the procedure occurred after hospital discharge. Children who fulfilled ASA criteria to be at risk for OSA were more likely to have the adverse event attributed to apnea, whereas all others were more likely to have the event attributed to hemorrhage. Patients at increased perioperative risk secondary to OSA must be closely monitored for apnea and should not be discharged from the recovery area to an unmonitored setting (i.e., home or unmonitored hospital bed) until no longer at risk of postoperative respiratory depression.[443]

Among children 1 to 18 years of age with OSAS, those without complicating medical conditions such as neuromuscular disease, obesity, or craniofacial abnormalities but with mild sleep apnea may have either no or some improvement in their airway obstruction on the night of surgery. Based on current literature, one may consider discharging children 3 to 12 years of age home on the day of surgery after an extended period of observation (4 to 6 hours) if they meet these criteria. However, those with moderate to severe OSA (particularly obese children) may actually experience worse OSA on the night of their surgery.[445,446] These children should receive reduced doses of opioids and be admitted for overnight monitoring with pulse oximetry and an apnea monitor.[447]

ASYMPTOMATIC CARDIAC MURMURS

The presence of a cardiac murmur is a common finding in children[448] and may have significant anesthetic implications. A history should be obtained to delineate the nature of the murmur. In most cases, the parents will report that the murmur was detected previously by the child's pediatrician and determined to be an "innocent flow murmur" without any anatomic or physiologic abnormalities. When a pediatric cardiologist confirms the classic

TABLE 4.15 Candidate Criteria for Identification and Assessment of OSA[a]

A: Clinical Signs and Symptoms Suggesting Obstructive Sleep Apnea (OSA)

1. Predisposing physical characteristics

a. ≥95th percentile for age and gender
b. Craniofacial abnormalities affecting the airway (e.g., Down syndrome)
c. Anatomic nasal obstruction
d. Tonsils nearly touching or touching in the midline (kissing tonsils)

2. History of apparent airway obstruction during sleep (two or more of the following are present; if patient sleep is not observed by another person, then only one of the following needs to be present)

a. Snoring (loud enough to be heard through a closed door)
b. Frequent snoring
c. Observed pauses in breathing during sleep
d. Awakened from sleep with choking sensation
e. Frequent arousal from sleep
f. Intermittent vocalizations during sleep
g. Parental report of restless sleep, difficulty breathing, or struggling respiratory efforts during sleep
h. Child with night terrors
i. Child sleeps in unusual positions
j. Child with new-onset enuresis

3. Somnolence (one of the following is present)

a. Frequent daytime somnolence or fatigue despite adequate "sleep"
b. Falls asleep easily in a nonstimulating environment (e.g., watching television, reading, riding in, or driving a car) despite adequate "sleep"
c. Parent or teacher comments that the child appears sleepy during the day, is easily distracted, is overly aggressive, or has difficulty concentrating
d. Child is often difficult to arouse at usual awakening time

B: Determination of Severity

a. If a child has signs or symptoms in two or more of the above categories, there is a significant probability that he or she has OSA. The severity of OSA may be determined by sleep study. If a sleep study is not available, such patients should be treated as though they have moderate sleep apnea unless one or more of the signs of symptoms above is severely abnormal (e.g., weight ≥95th percentile for age and gender, respiratory pauses that are frightening to the observer, child regularly falls asleep within minutes after being left unstimulated without another explanation), in which cases patients should be treated as though they have severe sleep apnea.
b. If a sleep study has been done, the result should be used to determine the perioperative anesthetic management of a child. (Review the polysomnogram for evidence of nocturnal desaturations <85%, which increases sensitivity to opioids). However, because sleep laboratories differ in their criteria for detecting episodes of apnea and hypoxemia, the Task Force recommends that the sleep laboratory's assessment (none, mild, moderate, or severe) take precedence over the actual apnea-hypopnea index (AHI, the number of episodes of sleep-disordered breathing per hour). If the overall severity is not indicated, it may be determined by using the following table:

Severity of OSA	Adult AHI	Pediatric AHI
None	0–5	0
Mild OSA	6–20	1–5
Moderate OSA	21–40	6–10
Severe OSA	>40	>10

Modified from Practice guidelines for the perioperative management of patients with obstructive sleep apnea: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea. *Anesthesiology.* 2014;120:268-286.
[a]Note: This table has been modified for children; the scoring system is intended only as a guide and has not been validated.

TABLE 4.16 OSA Risk Scoring System: Example[a]

A. Severity of Sleep Apnea Based on Sleep Study (or Clinical Indicators if Sleep Study Is Not Available: Point Score 0–3[b,c]) *Severity of OSA*	
None	0
Mild	1
Moderate	2
Severe	3
B. Invasiveness of Surgery and Anesthesia: Point Score 0–3 *Type of surgery and anesthesia*	
Superficial surgery under local or peripheral nerve block anesthesia without sedation	0
Superficial surgery with moderate sedation or general anesthesia	1
Peripheral surgery with spinal or epidural anesthesia (with no more than moderate sedation)	1
Peripheral surgery with general anesthesia	2
Airway surgery with moderate sedation	2
Major surgery with general anesthesia	3
Airway surgery with general anesthesia (e.g., tonsillectomy)	3
C. Requirement for Postoperative Opioids: Point Score 0–3 *Opioid requirement*	
None	0
Low-dose oral opioids (tonsillectomy)	1
High-dose oral opioids, parenteral or neuraxial opioids	3
D. Estimation of Perioperative Risk—Overall Score Equals the Score for "A" Plus the Greater of the Score for "B" or "C": Possible Score 0–6[d]	

Modified from Practice guidelines for the perioperative management of patients with obstructive sleep apnea: an updated report by the American Society of Anesthesiologists Task Force on Perioperative Management of Patients with Obstructive Sleep Apnea. *Anesthesiology* 2014;120:268-286.

[a]Note: This table has been modified for children. A scoring system similar to this table may be used to estimate whether a child is at increased perioperative risk of complications from OSA. This example has not been clinically validated, and such a scoring system is simply meant to provide guidance.

[b]One point may be subtracted if a patient has been on continuous positive airway pressure (CPAP) for noninvasive positive-pressure ventilation before surgery and will be using his or her appliance consistently during the postoperative period.

[c]One point should be added if a child with mild or moderate OSA also has a resting arterial carbon dioxide tension greater than 50 mm Hg.

[d]Children with a score of 4 may be at increased perioperative risk from OSA; children with a score of 5 or 6 may be at significantly increased perioperative risk from OSA.

TABLE 4.17 Grading of Heart Murmurs

Grade I	Heard only with intense concentration
Grade II	Faint, but heard immediately
Grade III	Easily heard, of intermediate intensity
Grade IV	Easily heard, palpable thrill/vibration on chest wall
Grade V	Very loud, thrill present, audible with only edge of stethoscope on chest wall
Grade VI	Audible with stethoscope off the chest wall

Modified from Emmanouilides GC, Allen HD, Riemenschneider TA, Gutgesell HP. *Moss and Adams Heart Disease in Infants, Children, and Adolescents Including the Fetus and Young Adult.* 5th ed. Baltimore: Williams & Wilkins; 1995.

TABLE 4.18 Symptoms and Signs of Heart Disease

Feeding difficulties: disinterest, fatigue, diaphoresis, tachypnea, dyspnea
Poor exercise tolerance
Tachypnea, dyspnea, grunting, nasal flaring, and intercostal, suprasternal, or subcostal retractions
Frequent respiratory tract infections (a result of compression of airways by plethoric vessels leading to stasis of secretions and atelectasis)
Central cyanosis (involving warm mucous membranes: tongue and buccal mucosa) or poor capillary refill
Absent or abnormal peripheral pulses

Modified from Pelech AN. Evaluation of the pediatric patient with a cardiac murmur. *Pediatr Clin North Am.* 1999;46:167-188.

clinical features of an innocent murmur, an echocardiogram seldom reveals heart disease, especially if the child is older at presentation.[449] *However, even an experienced cardiologist can occasionally make a misdiagnosis; the only certain means to exclude a structural defect within the heart is with an echocardiogram.*[450] "Appropriate use criteria" for initial transthoracic echocardiography in outpatient pediatric cardiology have been established in a joint project with the American College of Cardiology, the American Society of Echocardiography, and the Society of Pediatric Echocardiography to support the clinical decision as to the appropriateness of care delivered to the pediatric patient.[451] A presumptively innocent murmur with no symptoms, signs, or findings of cardiovascular disease and a benign family history is rated as a "rarely appropriate" indication. In general, nonpathologic murmurs occur during systole and are soft and nonradiating with normal feel to peripheral pulses; there are normal blood pressures in both upper and lower extremities. However, if the murmur is harsh and difficult to localize, if there are bounding pulses, if the murmur is louder than grade II/VI, or if it is accompanied by other findings (Tables 4.17 and 4.18), then further evaluation is warranted.[452] If the murmur has not been detected previously, referral to a pediatric cardiologist is indicated or an echocardiogram by an experienced pediatric echocardiographer should be obtained before induction of anesthesia.[453]

FEVER

The presence of a low-grade fever before elective surgery poses a dilemma whether to proceed with anesthesia or to delay. In general, if a child has only 0.5°C to 1.0°C of fever and no other symptoms, this degree of fever is not a contraindication to general anesthesia. However, if the fever is associated with a recent onset of rhinitis, pharyngitis, otitis media, dehydration, or any other sign of impending illness, it is prudent to postpone the procedure. If the planned surgery is of an urgent nature, every effort should be made to reduce the fever before induction of anesthesia, primarily to reduce oxygen demands. Reduction of the fever should not include administration of aspirin, because aspirin may interfere with platelet function and is associated with Reye syndrome. Ibuprofen may be associated with an increase in bleeding time[454] and should be avoided before surgery. On the other hand, acetaminophen has no effect on platelet function and is an excellent antipyretic. It is rapidly absorbed when administered orally, producing adequate blood concentrations within several minutes. In contrast, rectal administration requires at least 60 minutes to achieve a significant blood concentration.[259,455] There is no evidence

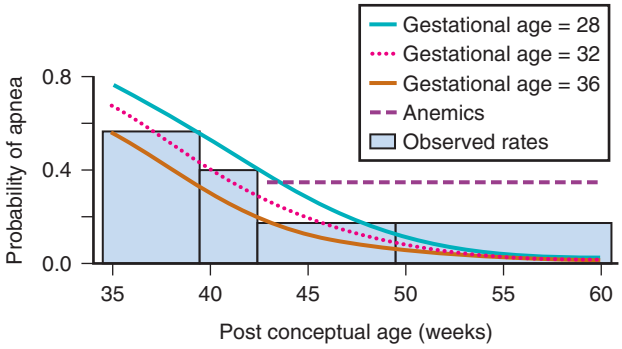

FIGURE 4.7 The predicted probability of apnea for all infants was inversely related to gestational age at the time of birth and postconception age at the time of surgery. The probability of apnea was the same regardless of postconception age or gestational age for infants with anemia *(dashed magenta line)*. (From Coté CJ, Zaslavsky A, Downes JJ, et al. Postoperative apnea in former preterm infants after inguinal herniorrhaphy: a combined analysis. *Anesthesiology.* 1995;82:807-808.)

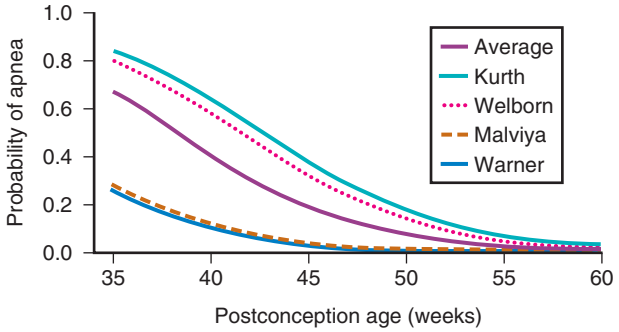
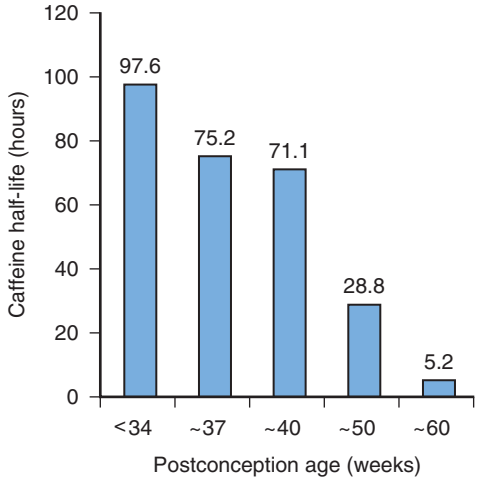
that an existing fever predisposes to a malignant hyperthermic reaction.[456]



POSTANESTHESIA APNEA IN FORMER PRETERM INFANTS

Former preterm infants have a multitude of residual problems owing to intensive care therapy, prolonged intubation, and still-maturing organogenesis. The incidence of subglottic stenosis is increased and they are prone to perioperative respiratory complications.[457] At the time of surgery they may or may not have apnea spells, although they often appear normal for their age; a number of prospective studies have defined the population at greatest risk for postoperative apnea.[380,457–466] Former preterm infants <44 weeks postconception age (PCA) are at a greater risk for apnea after general anesthesia than are those older than 44 weeks PCA.[467] In an analysis of eight published prospective papers from four institutions conducted over 6 years, the incidence of apnea varied inversely with both the gestational age and PCA (E-Fig. 4.5).[467] For example, consider two infants who are now 45 weeks PCA: one was born at 28 weeks and the other at 32 weeks of gestation. The risk of apnea in the 28-week gestational age infant is twice that in the 32-week gestational age infant (Fig. 4.7).[467] Similarly, consider two infants of the same gestational age: one anesthetized at 45 weeks PCA and the other at 50 weeks PCA; the younger-PCA infant would be at greater risk for postoperative apnea. The recognition of apnea events depends on the type of device used to monitor the infants (E-Fig. 4.5); simple observation and impedance pneumography are more likely to miss apneic events than continuous recording devices.[467–469] Preterm infants with anemia (hematocrit <30%) are more prone to apnea, and the incidence is unrelated to PCA or gestational age (see Fig. 4.7).[380,467] It appears that the risk for apnea exceeds 1% with statistical certainty until approximately 56 weeks PCA in infants with a gestational age of 32 weeks or 54 weeks PCA in those with a gestational age of 35 weeks, if one excludes anemic infants and those with obvious apnea in the recovery room. This analysis determined that (1) apnea was strongly and inversely related to both gestational age and PCA; (2) ongoing apnea at home is a risk factor; (3) small-for-gestational-age infants are protected from apnea compared with appropriate- and large-for-gestational-age infants; (4) anemia is a significant risk factor, particularly for infants of more than 44 weeks PCA; and (5) a history of necrotizing enterocolitis, neonatal apnea, respiratory distress syndrome, bronchopulmonary dysplasia, or operative use of opioids or muscle relaxants did not correlate with postoperative apnea.[467] Each clinician must decide how to balance the risk of an unrecognized apnea with the benefit of proceeding with the surgery in terms of cost savings and not hospitalizing the infant for overnight monitoring.[470] The most practical and appropriate plan is to admit and monitor all formerly preterm infants who are less than 60 weeks PCA until they are free of apnea for a minimum of 12 hours.



One study examined the effects of inhalation agents; four anesthetic techniques were compared: sevoflurane induction and maintenance, halothane induction and maintenance, halothane induction/desflurane maintenance, and thiopental induction/desflurane maintenance.[471] No major episodes of apnea occurred in any of the 40 former preterm infants who were <60 weeks PCA and undergoing hernia repair, although there was at least one episode of breath-holding or self-limited apnea in each group. In view of the small sample size in this study, the upper 95% confidence interval that no apnea episodes will occur in all formerly preterm infants is only 92%. *Although the majority of former preterm infants in our microanalysis were anesthetized with halothane,[467] apnea has been reported with all anesthetics, including sevoflurane, desflurane, and regional anesthesia (spinal or caudal epidural, discussed later).*[472–474]

The preoperative evaluation of these infants requires reserving a monitored bed postoperatively and a clear discussion with the family regarding the perioperative risks of anesthesia and apnea. If the child is receiving theophylline or caffeine preoperatively, this therapy should be continued postoperatively.[475] If the child is not receiving theophylline or caffeine, there is no evidence to support the administration of aminophylline postoperatively, but there is weak evidence that caffeine (10 mg/kg) may reduce postoperative apnea spells in high-risk infants.[465,466] The pharmacokinetics of caffeine in preterm and full-term neonates suggest that a single IV dose of caffeine will have a clinical effect that may last for several days. However, the pharmacokinetics of caffeine change dramaticaly with age: in older infants (e.g., those who are 60 weeks PCA), the half-life of caffeine is reduced to approximately 5 hours (E-Fig. 4.6).[476] A Cochrane review of prophylactic caffeine in formerly preterm infants concluded that although caffeine can be used to prevent postoperative apnea, bradycardia, and episodes of oxygen desaturation, there was insufficient evidence to adopt this as routine anesthetic practice.[477] *If caffeine is administered to a former preterm infant, postoperative admission and overnight respiratory monitoring are still required, because caffeine is not 100% effective in preventing postoperative apnea.*

Apnea may be related to many causes besides prematurity (Fig. 4.8); the most common causes after surgery, however, relate to metabolic derangements, pharmacologic effects, or CNS immaturity. Metabolic causes of apnea such as hypothermia, hypoglycemia, hypocalcemia, acidosis, and hypoxemia should be avoided (see Chapter 37). However, pharmacologic effects on respirations cannot be avoided because most drugs used in anesthesia depress the respiratory system either directly or indirectly.[478] Respiratory depression is probably even more likely to occur in neonates who have an immature respiratory center; residual anesthetic action may contribute to the development of postoperative apnea.[479] In addition, most drugs or inhalation agents decrease muscle tone of the upper airway, thus contributing to the development of upper airway obstruction, more labored breathing, fatigue, and subsequent apnea.[464] Potent inhalation anesthetic agents also decrease intercostal muscle tone, reducing functional residual

E-FIGURE 4.5 Predicted probability of apnea in the recovery room and after the recovery room by weeks postconceptional age for all patients for each investigator. The curves for the Kurth et al. and Welborn et al. studies are nearly identical in the upper range, and for the Malviya et al. and Warner et al. studies in the lower range. There was significant institution-to-institution variability. The reasons for this are unclear but may represent differences in monitoring technology as well as patient populations, because the studies with the highest rate of apnea were also those that used continuous recording devices. (From Coté CJ, Zaxlavsky A, Downes JJ, et al. Postoperative apnea in former preterm infants after inguinal herniorrhaphy: a combined analysis. *Anesthesiology* 1995;82:809-822.)

E-FIGURE 4.6 The approximate caffeine beta-elimination half-life (hours) is plotted against weeks of postconceptional age. Note that there is rapid maturation of the ability to excrete caffeine and that by 60 weeks of postconceptional age the half-life is only about 5 hours. One should not expect a single dose of caffeine to completely eliminate the potential for apnea in formerly preterm infants. (Data from DeCarolis MP, Romagnoli C, Muzil U, et al. Pharmacokinetic aspects of caffeine in premature infants. *Dev Pharmacol Ther.* 1991;16:117-122.)

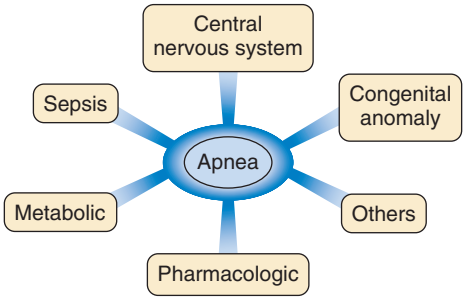


FIGURE 4.8 Apnea, defined as the absence of movement of air at the mouth or nose, may have many causes. Those that anesthesiologists are most often involved with are of metabolic, pharmacologic, or respiratory origins.

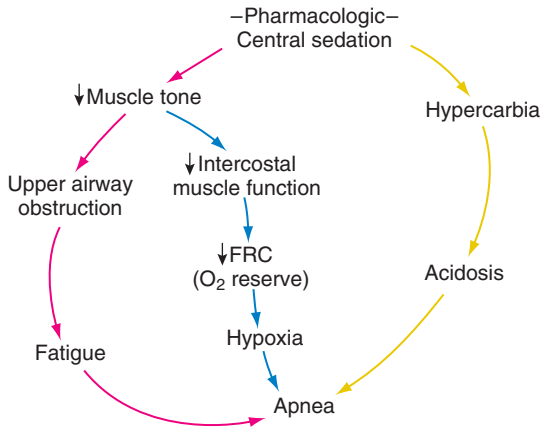

FIGURE 4.9 Pharmacologic interventions may result in several sequences of events leading to apnea. *FRC*, functional residual capacity.

capacity and thereby increasing the propensity to develop hypoxemia (Fig. 4.9).[480]

Regional anesthesia has been used to reduce the risk of postoperative apnea.[459,481–483] A multicenter, multinational study comparing **g**eneral **a**nesthesia with **s**pinal anesthesia (the GAS study) for former preterm and full-term infants found no difference in the incidence of apnea comparing spinal to general anesthesia (~6% in former preterm infants). However, the severity of the apnea was less and the incidence was lower in the first 30 minutes in the PACU following spinal anesthesia.[474,484] Thus spinal anesthesia may offer potential advantages; however, several infants who had spinal anesthesia experienced life-threatening events many hours after discharge from PACU (similar to our 1995 analysis).[467] Thus although spinal anesthesia offers advantage, it does not eliminate our need for vigilance. In addition, since all of the infants in the general anesthesia group were anesthetized with sevoflurane compared with the 1995 study, in which all were anesthetized with halothane, the use of a more modern anesthetic agent did not seem to have any salutary effects on apnea as some practitioners have suggested.

A Cochrane review found *"no difference in the effect of spinal compared to general anesthesia on the overall incidence of postoperative apnoea, bradycardia, oxygen saturation, need for postoperative analgesics or respiratory support."*[485] Additive drugs used to prolong the duration of a spinal or caudal block, such as clonidine, or sedatives, such as midazolam and dexmedetomidine, have been associated with postoperative or intraoperative apnea.[486–490] Spinal anesthesia is also associated with a significant failure rate (20% in some studies) and the need for multiple attempts to achieve accurate placement of the needle,[474,491,492] although in experienced hands, the success rate for placing a spinal block was 97.4% and an adequate level of spinal anesthesia was achieved in 95.4% of infants.

Since our microanalysis in 1995,[467] much has changed: new inhalation agents have replaced halothane, artificial surfactant has rescued many infants, and improved respiratory strategies have reduced barotrauma-induced chronic pulmonary disease. Although it would seem logical that these advances should have reduced the incidence of postanesthesia apnea in former preterm infants, little has changed. *Despite these medical advances, former preterm infants should not be anesthetized as outpatients even when a regional technique has been used; they require admission for postoperative monitoring overnight for apnea.*

With respect to full-term neonates, three reports have described infants who developed apnea after apparently uneventful general anesthesias.[493–495] Therefore, if a full-term infant who is younger than 44 weeks PCA demonstrates any abnormality of respiration after anesthesia, we recommend that they be admitted overnight for apnea monitoring. The algorithms in Fig. 4.10 can be used as a decision tree for outpatient surgery in term and former preterm infants.

HYPERALIMENTATION

The anesthesiologist frequently encounters chronically ill infants and children who are unable to tolerate enteral feedings and are therefore maintained on total parenteral nutrition (TPN). It is important to identify the composition and rate of administration of these fluids so that potential intraoperative complications can be avoided. Most of these solutions are hypertonic, have high glucose content, and must be administered through a centrally placed IV route.

The basic principles of care are as follows:

1. Avoid contaminating the line. It is best not to puncture the line for administering medications or changing fluid.
2. Do not discontinue the glucose-containing solution, because the relative hyperinsulinemic state could induce hypoglycemia, the signs of which might be masked by general anesthesia. In contrast, intralipid infusions should be discontinued before surgery, because it is a culture medium if contaminated.
3. An infusion device should be used at all times so that the rate of infusion is constant. Accidental rapid infusion of large amounts of TPN fluid can cause a hypertonic nonketotic coma.[496] There is no consensus on the intraoperative management of TPN solutions. Some clinicians reduce the infusion rate by 33% to 50% to avoid hyperglycemia resulting from a reduced metabolic rate due to the effects of anesthetic agents and a reduced body temperature, whereas others leave the infusion rate unchanged to avoid intraoperative hypoglycemia.
4. Perioperative and intraoperative monitoring of glucose, potassium, sodium, and calcium, as well as acid-base status, is important for long procedures.
5. Preoperative confirmation of correct intravascular line placement (radiography or aspiration of blood) is important to avoid intraoperative complications such as hydrothorax or hemothorax.

DIABETES

Diabetes mellitus is the most common endocrine problem encountered in children. Preoperative assessment should include a thorough knowledge of the child's insulin schedule. The preoperative fasting

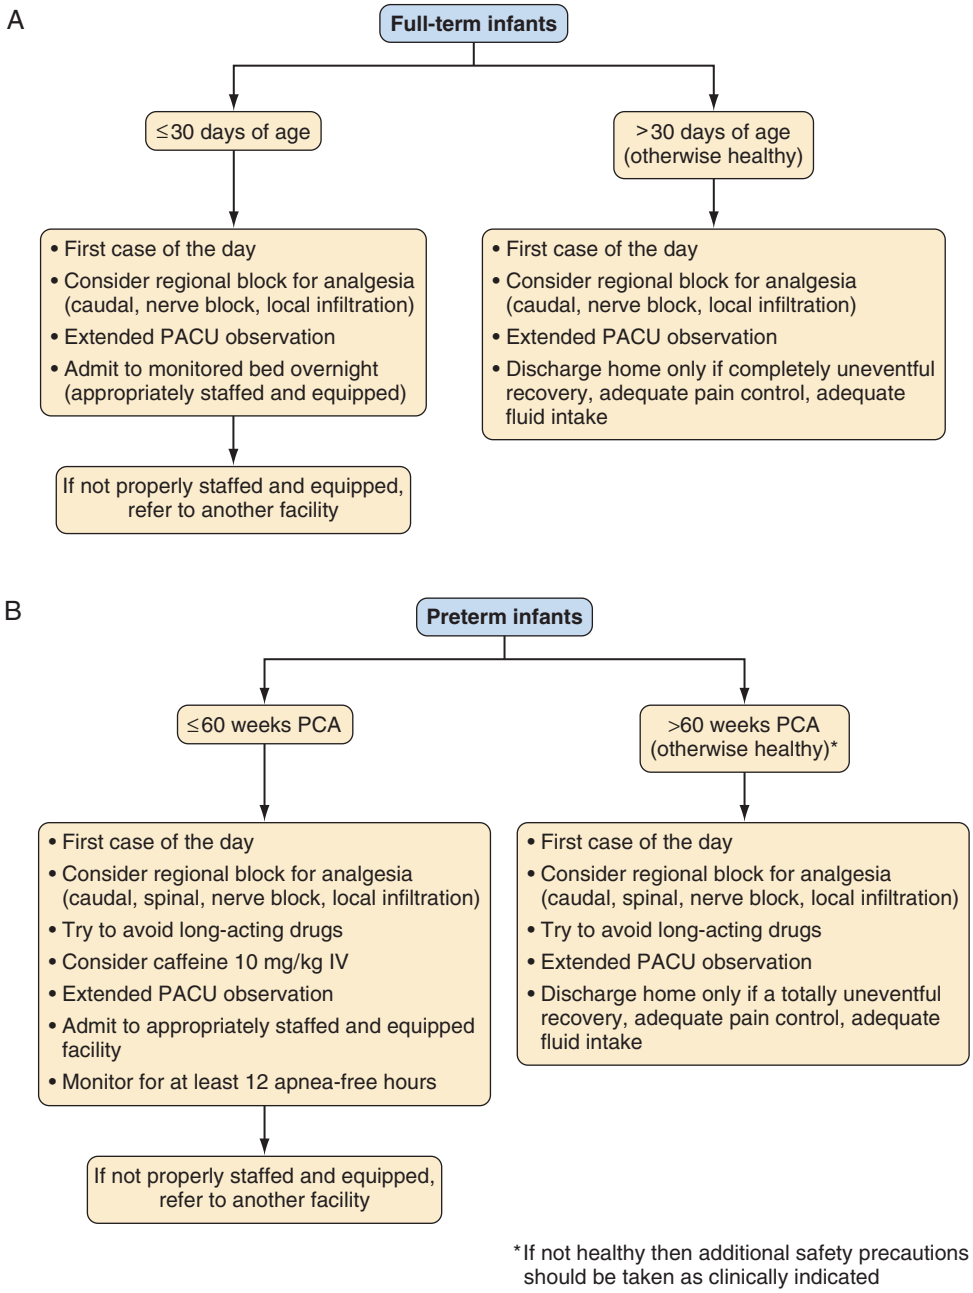

FIGURE 4.10 Algorithms used as a decision tree for outpatient surgery in term infants **(A)** and in former preterm infants **(B)**. *PACU,* postanesthesia care unit; *PCA,* postconceptional age.

time should be the same as that recommended for nondiabetics. Every attempt should be made to schedule a diabetic child as the first case of the day to minimize the fasting period. Several protocols have been advocated for glycemic control in diabetics. An IV infusion that contains 5% glucose and electrolytes at a maintenance infusion rate should be started to avoid hypoglycemia. Blood glucose concentrations should be monitored just prior to induction, intraoperatively, and postoperatively until the child is back on a routine schedule. A more detailed discussion of the perioperative management of the child with diabetes is presented in Chapter 27.

BRONCHOPULMONARY DYSPLASIA

Bronchopulmonary dysplasia (BPD) is a form of chronic lung disease associated with prolonged mechanical ventilation and oxygen toxicity in preterm neonates. Antenatal glucocorticoids, surfactant therapy, and gentle ventilation strategies to minimize lung injury have changed the clinical characteristics of BPD.[497] The current definition of BPD has been validated in early infancy and determines three levels of severity (mild, moderate, or severe) using gestational age, oxygen dependence at 36 weeks and post-conceptual age, total duration of oxygen supplementation, and positive pressure requirements.[498,499] The clinical manifestations

of BPD include tachypnea, dyspnea, and airway hyperactivity, as well as oxygen dependence. These infants suffer from hypoxemia, hypercarbia, abnormal functional airway growth, tracheomalacia, bronchomalacia, subglottic stenosis, increased pulmonary vascular resistance, and congestive heart failure. Pulmonary function abnormalities, including a reduced functional residual capacity, reduced diffusion capacity, airway obstruction, and reduced exercise tolerance, may persist into the school-age years.[500] Even in the postsurfactant era, retrospective studies estimate a 25% to 35% prevalence of pulmonary hypertension among extremely low–birth-weight infants with BPD requiring prolonged positive pressure ventilation and is an important determinant of mortality.[501] These children are often cared for at home on oxygen therapy with diuretics, digoxin, and β_2-agonists. Preoperative preparation should focus on optimizing oxygenation, reducing airway hyperactivity, and correcting electrolyte abnormalities caused by chronic diuretic therapy. Particular attention should be paid to fluid balance and avoiding excessive hydration. Adequate expiratory time to avoid excessive positive-pressure ventilation is important, and the potential for subglottic stenosis may necessitate using a smaller than expected tracheal tube. The possibility of pulmonary hypertension and right ventricular dysfunction should be considered and, when indicated, evaluated via electrocardiogram and echocardiography. Stress-dose steroid administration is indicated in children with a history of corticosteroid use in the past 6 months.

SEIZURE DISORDER

Management of children with seizure disorders requires a knowledge of the antiseizure medications, medication schedule, and possible interactions between these medications and anesthetic drugs. The stress of surgery and anesthesia may lower the seizure threshold and cause a seizure. Seizure medications should be continued until the time of elective surgery. Characterization of the clinical manifestations of the seizure is useful to be able to diagnose potential seizures postoperatively. If the child is expected to have a significant problem with oral intake postoperatively, then a game plan with the child's neurologist should be developed to build a transition to IV antiseizure medications. Preoperative and postoperative management of anticonvulsant blood concentrations may also ensure proper therapeutic effect (see also Chapter 24).

A ketogenic diet, which is high in fat and low in protein and carbohydrate, has been used to treat some patients with refractory seizures since the 1920s.[502] The classic ketogenic diet uses a 4 : 1 ratio of fat to carbohydrate and protein. The exact mechanism by which the diet works is unclear. A recent resurgence in interest has resulted in more patients presenting to the OR while consuming ketogenic diets.

A retrospective study examined the perioperative courses of nine children on ketogenic diets who received general anesthesia for surgical procedures lasting between 20 minutes and 11.5 hours.[503] The children continued their ketogenic diets until made NPO for the surgical procedure and resumed the diets postoperatively. All patients were in ketosis, as demonstrated by preoperative serum β-hydroxybutyrate levels. Medications used for general anesthesia varied but included fentanyl, halothane, isoflurane, sevoflurane, nitrous oxide, propofol, thiopental, and ketamine. Only carbohydrate-free solutions were administered intravenously. Glucose levels remained stable intraoperatively, even during the longer procedures. However, there was a tendency for children following ketogenic diets to develop metabolic acidosis during the longer procedures. No other perioperative complications were reported, and children appeared to recover from anesthesia at a usual rate. None of the patients were noted to have increased seizure activity postoperatively. Several additional case reports also describe successful administration of general anesthesia to children following ketogenic diets without adverse events.[504–506]

Unfortunately, there are no consensus guidelines providing clear recommendations for the management of patients undergoing general anesthesia while following a ketogenic diet. Some centers advocate tapering or discontinuing ketogenic diets prior to general anesthesia, while others allow patients to continue ketogenic diets during the perioperative period.[503] The plan for perioperative ketogenic diet management should be discussed with the patient's neurologist or nutritionist preoperatively. For longer procedures, serum pH or bicarbonate levels should be checked preoperatively and at routine intervals intraoperatively (e.g., every 2 to 3 hours) to monitor for acidosis. Serum pH and bicarbonate monitoring should be continued postoperatively until the patient restarts a full ketogenic diet. IV bicarbonate may be required for correction of acidosis. Long-term (>2 hours) propofol infusions, which impair fatty acid oxidation, are not recommended in patients following ketogenic diets as fatal propofol infusion syndrome has been described, but brief infusion should not be problematic (see also Chapter 24).[507,508]

SICKLE CELL DISEASE

Whenever a child presents with either sickle cell disease or sickle cell trait, the anesthetic and postanesthetic management must be modified (see also Chapters 10 and 13). It is important to obtain a detailed family history, and if the child has not been previously tested, a sickle preparation should be obtained. If a sickle test is positive and the surgery is elective, then surgery should be postponed pending hemoglobin electrophoresis to more carefully delineate the nature of the hemoglobinopathy. It must be emphasized that the status of hydration and oxygenation is critical for all children with sickle cell disease or trait. A secure IV route with hydration of at least 1.5 times maintenance is recommended well into the postoperative period, especially after procedures in which ileus may result. Meticulous attention to detail to ensure stable cardiovascular and ventilatory status establishes adequate oxygenation to prevent sickling. Pulse oximetry is of particular value in managing these children by providing an early warning of desaturation. Children with hemoglobin SC are especially at risk because they have a relatively normal hemoglobin level yet are extremely vulnerable to sickling. Further recommendations regarding management of these children, including indications for preoperative transfusion to bring the hemoglobin concentration to 10 g/dL, are discussed in Chapter 10.

ACKNOWLEDGMENT

We wish to thank John F. Ryan, MD; Letty M.P. Liu, MD; I.D. Todres, MD; Nishan G. Goudsouzian, MD; and Leila Mei Pang, MD, for their prior contributions to these topics.

Premedication of children with midazolam is not only beneficial in reducing preoperative anxiety but also results in fewer negative behavioural changes during the first postoperative week.

Practice advisory for preanesthesia evaluation: an updated report by the American Society of Anesthesiologists Task Force on Preanesthesia Evaluation. *Anesthesiology*. 2012;116(3):522-538.

An updated practice advisory for preanesthesia evaluation including preoperative testing based on "analysis of expert opinion, clinical feasibility data, open forum commentary and consensus surveys."

Schwengel DA, Sterni LM, Tunkel DE, Heitmiller ES. Perioperative management of children with obstructive sleep apnea. *Anesth Analg*. 2009;109:60-75.

An excellent review article on the diagnosis, treatment, and anesthetic management of children with obstructive sleep apnea syndrome.

Taghizadeh N, Davidson A, Williams K, et al. Autism spectrum disorder (ASD) and its perioperative management. *Paediatr Anaesth*. 2015;25:1076-1084.

An excellent review article surveying the current literature on autism spectrum disorder and its perioperative management.

Tait AR, Malviya S, Voepel-Lewis T, et al. Risk factors for perioperative adverse respiratory events in children with upper respiratory tract infections. *Anesthesiology*. 2001;95:299-306.

Several risk factors for perioperative adverse respiratory events in children were identified: use of an endotracheal tube (<5 years of age), history of prematurity, history of reactive airway disease, paternal smoking, surgery involving the airway, presence of copious secretions, and nasal congestion.

Wang Z, May SM, Charoenlap S, et al. Effects of secondhand smoke exposure on asthma morbidity and health care utilization in children: a systemic review and meta-analysis. *Ann Allergy Asthma Immunol*. 2015;115:396-401.

This review and meta-analysis found that children with asthma and secondhand smoke exposure are "nearly twice as likely to be hospitalized with asthma exacerbation and more likely to have lower pulmonary function test results."

A complete reference list can be found online at ExpertConsult.com.

The Ethics Consultation Service

CLINICIANS MUST TAKE SERIOUSLY "the experience, perspective, and power of children."[1] Clinicians should treat every child and family with the grace and consideration with which they would want their own child and family treated. Taking the experience of children seriously means involving interested children in developmentally appropriate decision making. Clinicians should not solicit a child's views without intending to consider them. *Pro forma* solicitations are harmful.

Treating every child like your own means taking time to allow premedication to work, even if it leads to criticism for a delayed anesthesia start time. It means rigorously following sterile practice protocols for central lines. It means patiently explaining anesthetic options to the parents as many times as needed.

Bioethics helps motivated physicians to identify and resolve ethical dilemmas. Solving ethical dilemmas is not solely a matter of being moral. Consider a child with an upper airway respiratory infection. Usually the surgery would be postponed, but suppose the child has missed two previous surgical dates because of an unstable home situation. While the clinician is explaining the risks of proceeding, the mother distractedly requests to proceed with surgery because "we're already here." The clinician has to determine what is in the child's best interest by balancing the risks of proceeding with those of not proceeding, the duty to ensure that the child receives necessary health care, the weight to be given to the mother's consent to proceed, and the duty to "do no harm." Mindful clinicians will seek to identify lurking conflicts of interest in considering whether to proceed.

Informed Consent

The American Academy of Pediatrics (AAP) bases pediatric informed consent on assent, informed permission, and the best interest standard.[1]

THE INFORMED CONSENT PROCESS

Assent: The Role of the Patient

Although most children cannot legally consent to medical care, children should share in decision making to the extent that their development permits (Table 5.1). As children grow older, participation in decision making should increase, depending on both their maturity and the consequences involved in the decision.

School-age children are developing decision-making capacity, so anesthesiologists should seek both informed permission from the parent and assent and participatory decision making from the child. School-age children are capable of using logic and reason and are able to define and relate multiple aspects of a situation. Such situations may include whether to sedate a 6-year-old before an inhalation induction, whether to use an inhalation or intravenous induction of anesthesia in an 8-year-old, and whether to insert an epidural in a 12-year-old.

Many adolescents older than 14 years of age have the ability to use abstract thought, apply complex reasoning, foresee outcomes, simultaneously evaluate multiple options, and understand concepts such as probability. Although some adolescents have cognitive abilities similar to those of adults, adolescents may be hindered by insufficient psychosocial and emotional development and they may not have developed a reasonably stable set of values.[2] Anesthesiologists should try to fulfill the ethical requirements of consent while obtaining assent. Situations involving these aspects include obtaining consent from a 16-year-old for a sedated thoracic epidural placement for a pectus repair.

Informed Permission, the Best Interest Standard and the Harm Threshold Standard

Parents have traditionally acted as the surrogate decision makers for their children, and legally they give consent. However, surrogate consent does not fulfill the spirit of consent, which is based on obtaining an individualized autonomous decision from the patient receiving the treatment. The AAP has suggested that the proper role for the surrogate decision maker is to provide *informed permission*.[1] Informed permission has the same requirements as informed consent, but it recognizes that the doctrine of informed consent cannot apply.

The *best interest standard* requires decision makers to select the objectively best care. It acknowledges that the cornerstone of informed consent, the right to self-determination, is inapplicable when it is impossible to know or surmise from previous interactions a child's likely preference. Using this standard requires determining

TABLE 5.1 Graduated Involvement of Minors in Medical Decision Making[a]

Age	Decision-Making Capacity	Techniques
<6 years	None	Best interests standard
6–12 years	Developing	Informed permission Informed assent
13–18 years	Mostly developed	Informed assent Informed permission
Mature minor	Developed, as legally determined by a judge, for a specific decision. Although particulars vary by state, the mature minor doctrine in general requires adolescents to be at least 14 years old and tends to permit decisions of lesser risk.	Informed consent
Emancipated minor	Developed as determined by statutes defining eligible situations (e.g., being married, in the military, economically independent).	Informed consent

[a]This broad outline should be viewed as a guide. Specific circumstances should be taken into consideration.

(1) who will make the decision and (2) what is the best care. The difficulties arise in assuming that there is always one best choice, because if there is, it should not matter who makes the decision. In our society, acceptable decision making is broadly defined. Parents capable of participating in the decision-making process are the appropriate primary decision makers because of society's respect for the concept of the family and the assumption that parents care greatly for their children. Although a child's preferences cannot be known, it is reasonable to assume that because children will incorporate some of the parents' values as they mature, parental values are a good first approximation for the child's future values. A few have questioned the presumption that parents are the best decision makers.[3] Objections center on the legitimacy of the parents' knowledge of the preferences of the child's future self. Although these concerns are theoretically interesting and help clinicians understand the complexities of the best interest standard, the standard is that parents have extensive leeway in determining what is in their child's best interest.

The best interest of a child can be defined by what choices fall outside the range of acceptable decision making. Criteria to make this determination include the extent of harm to the child from the intervention or its absence, the likelihood of success, and the overall risk-to-benefit ratio.

The best interest standard can guide treatment among acceptable options and determine the limits of parental decision-making authority, but the best interest standard can be indeterminate, particularly for the decision to attempt to limit parental authority. Given the broad reluctance to override parents, limiting parental authority is a high-stakes decision.

Some suggest using a harm threshold standard rather than a best interest standard to determine whether to limit parental authority. The standard for whether a decision exceeds the harm threshold is if a parental decision threatens the health and safety of the child, which is a "lower standard" than whether the decision is one of the "best" options. This harm threshold is a standard similar to the one in assessing for child maltreatment. Whether this concept of harm threshold is a new cognitive approach or is already used in determining best interest depends in large part about how the borders of acceptable decision making are established; some clinicians may use the harm threshold in determining acceptable decision making and others may not.[4–8]

The harm threshold standard needs further clarification. It may not help clarify the best interest standard and it may not be useful in court, given the inconsistency in how courts assess cases.[9,10] Nonetheless, at the very least, it provides another conceptual way of evaluating whether a treatment is outside acceptable boundaries.

Disclosure

The "reasonable person" standard–the legal standard for most of the United States, Canada, and other countries–requires that the information disclosed be sufficient to satisfy a hypothetical reasonable person. This standard does not define exactly what information should be given, and it does not take into account the patient's desires and needs. The "subjective person" standard suggests that informed consent should be matched to the wants and needs of the decision makers. Although this patient-centered consent better fulfills the spirit of informed consent, its greater ambiguity makes it difficult to use as a legal standard.

Rather than rely on a rote informed consent process, anesthesiologists should seek to satisfy the needs of the decision makers by meeting their information and decision-making needs. Patients and surrogates differ in the extent to which they prefer to receive information and to participate in decision making.[11,12] In general, 10% to 15% of patients may prefer less information than their peers. Overall, most patients want some form of shared decision making.[12]

Anesthesiologists should inform families about matters that the anesthesiologist feels must be communicated and about options that affect the perioperative experience (e.g., regional versus general anesthesia)[13] and then ask whether the decision makers wish to know more. By being attentive to the words and actions of the decision makers, anesthesiologists can tailor the process. It is rare to be found liable for informed consent malpractice issues. The standard for being liable is that there is a duty, a breach of that duty, and a harm directly related to the breach of the duty. Liability in informed consent requires that the information not shared would have affected the patient's choices. Forming a bond with the parents is more effective in reducing malpractice lawsuits.[14]

Performing patient-centered informed consent often requires communication of the anesthesiologist's opinion along with an explanation of the supporting reasons. With this information, the decision makers are better able to determine which anesthetic approach provides the most desired benefits.

Decision makers often overrate the extent of their knowledge about risks and benefits.[15] We can increase the likelihood of the decision makers having sufficient knowledge by modifying practices. For example, informed consent documents often use poorly formatted, dense, incomprehensible text written at too high a reading level for most decision makers.[16] Straightforward language written at an eighth-grade reading level with reader-friendly formatting permits better understanding and thus better decision making about risk, benefits, and options.[17]

Patients may have difficulty understanding quantitative aspects of risk. Risks should be presented as absolute data (e.g., occurs 10% of time) rather than relative data compared with other treatments (e.g., decreases the risk by 50%).[18,19] Some decision

TABLE 5.2 Recommendations for Risk Communication to Patients[19]

1.	Consider presenting only the information that is most critical to the patient's or parents' decision making, even at the expense of completeness.
2.	Use language at the eighth-grade level to improve understanding of written and oral communications.
3.	Present data using absolute risks and frequencies.
4.	Use pictorial recommendations to communicate statistics when appropriate.
5.	The order in which risks and benefits are presented may affect risk perceptions. The last topic presented has more weight in decision making.
6.	Recognize that comparative risk information (e.g., the average person's risk) is persuasive as well as informative.

makers may understand frequencies better, so it is wise to include both absolute and frequency data. For example, the statement *"If she has regional anesthesia, she has a 20% chance of postoperative vomiting, which means 2 of 10 people will have postoperative vomiting, and if she has general anesthesia, she has a 40% chance of postoperative vomiting, which is 4 of 10 people will have postoperative vomiting. That means that 20 more people of 100 will have postoperative vomiting if we use general anesthesia"* is better than *"She has a 100% more likely chance of postoperative vomiting with general anesthesia as compared with regional anesthesia."* Pictorial representations improve understanding. In the above example, a graphic may be a picture of 10 people, with regional anesthesia having 2 people in one color and general anesthesia having an additional 2 people in a different color, showing the increased risk.

Risk perceptions may be affected by whether risks or benefits are presented last.[19] For example, oncology patients gave more weight to the last topic discussed, even though risks and benefits were presented in the same conversation.[20] Table 5.2 lists recommendations on communications.

Informed Refusal

The requirements to achieve an informed refusal of a procedure are similar to the requirements for informed consent such that decision makers should be substantially well versed about the risks, benefits, and alternatives before declining. When parents refuse what clinicians believe is necessary care for a child who cannot participate in the decision making process, clinicians may invoke the best interest standard or incorporate the harm threshold standard. This situation is more complicated when the child expresses significant decision-making capacity and refuses nonemergent procedures. Anesthesiologists should respect the right of children (typically those over the age of 10 years) not to assent to a procedure, and they should not coerce the child to proceed. In children, particularly adolescents, the distinction between persuasion and coercion is critical. *Persuasion,* the act of using argument and reason to influence a patient's decision, is appropriate. *Coercion,* the outright use of a credible threat, manipulation, or misleading information, is not. Achieving the child's assent may necessitate further discussions with the child, parents, and other providers, and such discussions may best take place away from the operating room.

Consider a 15-year-old who is scheduled for an elective knee arthroscopy. The day before the procedure, she gave assent and her parents gave informed permission for anesthesia and surgery. She is now crying in the preoperative area and refusing to cooperate. Rather than forcibly or surreptitiously sedating her, the anesthesiologist should discuss her concerns. If she is unable to discuss the issues, the anesthesiologist should consider removing her from the area and giving her time to regain composure before readdressing the situation. Simple actions often allow the situation to be resolved. If the withdrawal of assent was in part related to anxiety, the child may assent to receiving ample premedication before returning to the holding area. Anesthesiologists must obtain her assent before administering the sedation, however, and not simply assume that forceful or surreptitious administration is justified.

"Doctor, If This Were Your Child, What Would You Do?"

Clinicians should respond to requests for advice by using medical facts to explain how different paths support specific values so that decision makers can choose the most concordant path.[21–23] However, the question, *"If this were your child, what would you do?"* can be asked for a number of different reasons, forcing clinicians to put the question into a broader context. Do not duck this question. Not responding to this question may frustrate and confuse decision makers.

For example, parents may be declaring that they are having difficulty comprehending the overwhelming information and need help making a reasonable decision. Perhaps they are actually asking what would give their child the best chance of getting better. In this situation, clinicians should explain the reasons and values underlying their personal choice. Parents may be looking for support that they are making the right choice in an untenable situation. Clinicians should answer with their best judgment if they agree with the family. If they disagree, clinicians should lend support through comments such as *"Other parents in the same situation have made the same choice,"* or by acknowledging that it is normal to feel uncertain.[22] If the family persists in asking what they should do, clinicians may wish to acknowledge that their choice might have been different. Clinicians should emphasize, however, that parental values are more valid than clinician values when choosing for their own child.

Parents may be asking for help in making a life-altering decision. One approach to this question is to offer a process for answering the question (e.g., *"I would talk with the chaplain"*). Clinicians should feel comfortable admitting that they are unable to determine what they would do if in the same situation. Honesty reinforces the difficulty of the decision for the parents.

Disclosure and Apology of Medical Errors

Hiding medical errors is indecent and breaches informed consent.[24] Fear of consequences, inadequate support, limited trust in the institution, and lack of education prevent physicians from disclosing and apologizing appropriately.[25–28] Forthrightly disclosing medical errors, although upsetting, often strengthens the patient–physician relationship.[29,30] Learning about a hidden medical error destroys trust and rapidly triggers legal action.

Physician apologies or sympathetic comments often are prohibited as legal evidence of wrongdoing, but disclosures of errors are permitted as legal evidence.[30–32] Apologizing may influence whether patients pursue legal action and whether such action is successful.[31,33] Sincere (not *pro forma*!) apologies and subsequent redress to prevent future occurrences improves the patient–physician relationship, minimizing the likelihood of legal action.

Physicians without expertise in disclosure and apology often botch the process. Disclosure is a process over time. Initial

disclosure should take place as soon as possible after an event and should center on the medical implications. Do not speculate about cause or fault. When disclosing, it is wise to bring along an appropriate colleague who can help with the disclosure by providing psychological support for the patient and family. Soon thereafter, a specific, permanent liaison to the family should be identified. The liaison should be available to arrange meetings, explain the results of the investigation into the cause of the event, and describe plans to prevent future events. The liaison should be trained and experienced in apology and disclosure (e.g., a colleague in risk management).

An apology expresses regret or sorrow. Sincere apologies followed by consistent actions are priceless; insincere apologies are costly. It is always appropriate to apologize for the adverse effects of an event and although the standard teaching is that physicians should not assume responsibility for an event before an investigation is performed, it seems bizarre to dissemble about clear errors. As an example, after reassuring the parents that their child is unharmed, I would readily admit that because I had inadvertently given a muscle relaxant instead of an anticholinesterase, their child will require a brief stay in the intensive care unit until ready for tracheal extubation. To evade responsibility (e.g., "Somehow one drug was given when another was intended") for a clear error mocks the apology.

Different strategies are being tested to improve disclosure and apology. An approach called "disclosure, apology, and offer" shows promise.[34] Open disclosure, prompt and fair compensation, and a vigorous defense of acceptable care leads to a transparency that reduces adversarial relationships, contributes to patient safety, and curtails legal action and costs.[34–36] Success in this program requires aligning of incentives of the clinician and hospital system. Differing incentives, such as in whether to settle or not, lead to distrust and doom the program.

SPECIAL SITUATIONS IN PEDIATRIC INFORMED CONSENT

Confidentially for Adolescents

The obligation to maintain confidentiality requires clinicians to protect patient information from unauthorized and unnecessary disclosure.[37] Confidentiality is necessary for an open flow of information.[38–40] Clinicians enhance trust by interviewing the adolescent in private, acknowledging the adolescent's concerns about confidentiality, and keeping promises. Emancipated and mature minors have a right to complete confidentiality. For other adolescents, if maintaining confidentiality entails minimal harm, clinicians should encourage adolescents to be forthright with parents but respect their decision not to be. If maintaining confidentiality may result in serious harm to the adolescent, clinicians may be ethically justified in notifying the parents. State laws vary in their extent of requirements.

The Pregnant Adolescent

Anesthesiologists face confidentially issues when an adolescent has a positive pregnancy test before anesthesia. Given the principles of confidentiality, it is ethically appropriate to inform only the adolescent.[41,42] Because locales may statutorily prohibit sharing pregnancy information with anyone other than the adolescent, anesthesiologists must share this information with the adolescent without letting the parents know.[43] Anesthesiologists should involve pediatricians, gynecologists, and social workers with expertise in adolescent issues in this discussion.

Matters become more complex if the clinicians and adolescent believe the case should be postponed, and the adolescent chooses not to inform her parents about the pregnancy test.[44] Anesthesiologists must be careful not to inadvertently inform the parents of the pregnancy test while postponing anesthesia and surgery. Nor should anesthesiologists betray the adolescent by saying, *"The case is postponed. If you want to know why, ask your daughter."* Although such a statement is factually true and within the letter of the law of confidentially, terse obliqueness scorns the spirit of confidentially.

The desire to tell the parents is understandable. But, I would suggest that clinicians who feel that way are too narrowly applying their own experiences and expectations. Not all parents are wise and gentle, and not all homes are safe and healthy. Confidentiality statutes specifically address concerns about child abuse in pregnant adolescents.

The extent to which anesthesiologists should protect the adolescent's confidentiality is debatable. Nonetheless, because the parents have no legal right to that information, I believe that more active deception, although less desirable, is appropriate if necessary. Successful deception avoids initiating diagnostic evaluations or treatment and does not unduly worry parents. For example, do not attribute the delay to *"hearing a new murmur."* Vague, unremarkable reasons such as *"an oncoming cold"* are best.

It is rare to condone deception.[45,46] Deception should not be undertaken without serious reservations. But, under certain circumstances, the obligation to the patient may supersede prohibitions on deception. At times, the harms of not deceiving outweigh the harms of deceiving.

The Adolescent and Abortion

Even though pediatric patients who are pregnant may be statutorily or by practice emancipated, many states require some form of parental involvement, such as parental consent or notification, before an elective abortion.[47] If a state requires parental involvement, the ability of the minor to circumvent this regulation by seeking relief from a judge, known as *judicial bypass,* must be available. Requirements and enforcement of statutes vary from state to state.[47,48] The need for parental involvement in a minor's planned abortion is not always legally straightforward, and it may be best to consult with hospital counsel in determining these issues. Although this is an area in which honorable people disagree, note that both the AAP and the American Medical Association (AMA) have affirmed these rights.[48,49]

Children of Jehovah's Witnesses

Jehovah's Witnesses interpret biblical scripture as prohibiting transfusion therapy because blood holds the *"life force"* and anyone who takes blood will be "*cut off from his people*" and not earn eternal salvation.[50–52] For adults, it is a *"matter of conscience"* whether they accept transfusion products. Adults may refuse potentially life-sustaining transfusion therapy because it is assumed they are making an informed decision about the risks and benefits of transfusion. However, based on the obligations of the state to protect the interests of incompetent patients, courts have uniformly intervened when parents desire to refuse transfusion therapy on behalf of their children. Based on the mature minor doctrine, older adolescents who are able to articulate significant decision-making capacity and maturity have been permitted to refuse potentially life-sustaining transfusion therapy.[53] Most clinicians start considering this option when the patient is 16, but younger children have been permitted to refuse potentially life-sustaining transfusion therapy.[54]

Obtaining informed permission and assent for the care of a ward of a Jehovah's Witness should address transfusion therapy. Anesthesiologists should clarify which therapy is acceptable.

Synthetic colloid solutions, dextran, erythropoietin, desmopressin, and preoperative iron are usually acceptable. Note that erythropoietin is available in two forms: lyophilized, and dissolved in saline with trace concentrations of albumin. Jehovah's Witnesses who accept albumin will accept either formulation, whereas those who refuse albumin should be offered the lyophilized formulation. Some Jehovah's Witnesses accept the removal and return of blood in a continuous loop (e.g., cell saver blood). The family should understand, however, that in a life-threatening situation, the anesthesiologist will seek a court order authorizing the administration of life-sustaining blood. When the likelihood of requiring blood is high or the local judiciary is not very familiar with case law for Jehovah's Witnesses, the anesthesiologist may choose to obtain a court order in advance of the operation.

A common concern is the sudden need for an emergent transfusion in a healthy child undergoing a low-risk procedure. In emergencies, based on the obligation to protect children, anesthesiologists should take the legally correct and ethically appropriate action to protect the child by transfusing blood without a court order. A court order may then be sought if desired.

Clinicians may wonder if they should change their transfusion triggers for a child of a Jehovah's Witness. It may be appropriate for clinicians to delay transfusion as compared with their usual practices in an effort to honor the parents' preferences and in recognition of our inadequate knowledge of when to transfuse. Other clinicians, while acknowledging the difficulty in knowing when to transfuse, believe it is appropriate to use their usual transfusion triggers, in the belief that the requirement is to treat this child of a Jehovah's Witness as you would treat any other child.

Decision makers may consider postponing a procedure that can be delayed until the child is of sufficient age and maturity to decide about transfusion therapy. The complexity is whether the delay may increase the risk or decrease the likelihood of a good outcome. This decision requires the same balancing act as for determining best interest for a child. Relevant factors include the quantitative and qualitative change in risk or benefit. Consider that it may be easier to wait on a procedure that is purely cosmetic than on a procedure for which waiting has a small chance of leading to permanent injury. If individual clinicians choose to honor the wishes of a mature minor, they must ensure the fidelity of the agreement by making certain that postoperative and on-call clinicians will honor the mature minor's wishes.

Emergency Care

Anesthesiologists should provide necessary emergent care for minors who do not have a parent available to give legal consent.[55,56] Emergencies include problems that could cause death, disability, and the increased risk of future complications.

The right of an adolescent to refuse emergency care treatment turns on the adolescent's decision-making capacity and the resulting harm from refusal of care. If the harm is significant and the adolescent's rationale is decidedly short-term or filled with misunderstanding, it becomes necessary to consider whether the adolescent has sufficient decision-making capacity for this decision. In this situation, it may be appropriate to consider what is in the best interest of the adolescent. For example, a 15-year-old football player with a cervical fracture might refuse emergency stabilization, stating that he does not want to live life without football. Most would hold that his conclusion overly values short-term implications, especially in light of the suddenness of the injury, and that he should receive emergency treatment.

THE IMPAIRED PARENT

Parents may be unable to fulfill surrogate responsibilities because of acutely impaired judgment, such as being intoxicated.[57] Clinicians have to weigh the benefits of waiting for appropriate legal consent against what is in the best interest of the child. It may be in the child's best interest to proceed with a routine procedure in the situation of an impaired parent who is unable to give legal consent. Clinicians may wish to consult legal and risk management colleagues for guidance.

End-of-Life Issues

FORGOING POTENTIALLY LIFE-SUSTAINING TREATMENT

Perioperative Limitations on Life-Sustaining Treatment

The concept of limiting potentially life-sustaining medical treatment (LSMT) is the same for children as it is for adults. Decision makers choose to limit LSMT because they do not consider the potential burdens worth the potential benefits.[58,59] The AAP, the American Society of Anesthesiologists (ASA), and the American College of Surgery mandate "required reconsideration" of any limitations on LSMT before proceeding to the operating room.

Although the term "Do Not Resuscitate" (DNR) is commonly used, the term "Life-Sustaining Medical Treatment" is becoming more common. One purpose of this shift is to emphasize that desired limitations on medical treatment are continuous rather than dichotomous. The term "potentially" is often used to modify LSMT to emphasize the uncertainty about whether a therapy will be life-sustaining.

Reevaluation of LSMT preferences for the perioperative period starts with clarifying the patient's goals for the proposed surgery and end-of-life care (Table 5.3). Anesthesiologists should involve the patient, family, and other clinicians such as surgeons, intensivists, and pediatricians in determining what is in the best interest of the child.

Benefits of potentially LSMT include an improved quality of life and prolongation of life under certain circumstances. Burdens

TABLE 5.3 Components of a Pediatric Perioperative Life-Sustaining Medical Treatment Discussion

- Planned procedure and anticipated benefit to child
- Advantages and opportunities of having specific, identified clinicians providing therapy for a defined period
- Likelihood of requiring resuscitation
- Reversibility of likely causes for resuscitation
- Description of potential interventions and their consequences
- Chances of successful resuscitation, including improved outcomes of witnessed arrests compared with unwitnessed arrests
- Ranges of outcomes with and without resuscitation
- Responses to iatrogenic events
- Intended and possible venues and types of postoperative care
- Postoperative timing and mechanisms for reevaluation of the limitations on life-sustaining medical treatment
- Establishment of an agreement (which may include a full resuscitation status) through a goal-directed approach
- Documentation

Adapted from Truog RD, Waisel DB, Burns JP. DNR in the OR: a goal-directed approach. *Anesthesiology* 1999;90:289-295; and Fallat ME, Deshpande JK. Do-not-resuscitate orders for pediatric patients who require anesthesia and surgery. *Pediatrics* 2004;114:1686-1692.

include intractable pain and suffering, disability, and events that cause a decrement in the quality of life, as viewed by the patient.[60,61] These guidelines help in considering short- and long-term goals and putting into appropriate context specific fears such as long-term ventilatory dependency, pain, and suffering.

Legitimate procedures for a child with limitations on LSMT include procedures that decrease pain, provide vascular access, enable the child to be at home, treat an urgent problem unrelated to the primary problem (e.g., appendicitis), or treat a problem that may be related but is not considered a terminal event (e.g., bowel obstruction). However, seeking these interventions does not obviate the desire to avoid potential postresuscitation burdens such as need for extensive ventilator support, cognitive deficits, or physical limitations.

The goal-directed approach for perioperative limitations on LSMT permits decision makers to guide therapy by prioritizing outcomes rather than procedures. After defining desirable outcomes, decision makers ask anesthesiologists to use their clinical judgment to determine how specific interventions will affect achieving the specific goals. Predictions about the success of interventions made at the time of the resuscitation are more accurate than predictions made preoperatively, when the quality and nature of the problems are unknown. Therapy may be guided by goals rather than specific procedures (as is done on the ward), because during the perioperative period children are cared for by dedicated anesthesiologists for brief, defined periods. It is helpful to define a goal-directed approach by discussing the acceptable burdens, the desirable benefits, and the likelihood of distinct outcomes. Most decision makers choose a goal-directed approach of desiring therapy if the interventions and burdens were temporary and reversible (i.e., if they could return to the present state without suffering too much).

Prior determination of acceptable postoperative LSMT is less critical in pediatrics, because usually parents are available in the postoperative period to make decisions regarding therapy. Nonetheless, when a sufficiently mature child participates in discussions about LSMT, anesthesiologists should ensure that the discussion incorporates the child's preferences for postoperative trials of therapy. The willingness to undergo a trial of therapy indicates a belief that the burdens of the trial (e.g., a few days of ventilator support) may be worth the benefits (e.g., extubation of the trachea) initially, but at some point, the increasing burdens may not be worth the decreasing likelihood of the benefits. Flexibly inherent in the goal-directed approach is that it promotes trials of therapy to evaluate whether said therapy achieves its desired goals. This is particularly important given our ever-changing knowledge about the outcomes of resuscitation.[62]

A time-limited trial of therapy is *"an agreement between clinicians and a patient/family to use certain medical therapies over a defined period to see if the patient's condition improves or deteriorates according to the agreed on clinical outcomes."*[63] The results of a time-limited trial can help decision makers determine whether to continue therapy or shift to comfort care measures. Knowing the results of a burdensome therapy makes withdrawing a therapy that does not achieve the identified goals more ethically stout than simply withholding the therapy and not knowing what the effects of the therapy would be.

Iatrogenic problems such as cardiac arrest do not obviate decisions to limit LSMT.[64] To decision makers, the cause of the arrest is irrelevant. Decision makers care about the factors they considered in requesting limited resuscitation, including the likelihood of successful resuscitation and physical and mental status after the arrest. The benefits of continued therapy after certain types of iatrogenic arrests should be addressed as part of the perioperative discussion.[64]

The "temporary and reversible" goal-directed perioperative DNR order can be documented as *"The patient desires resuscitative efforts during surgery and in the postanesthesia care unit (PACU) only if the adverse events are believed to be both temporary and reversible, in the clinical judgment of the attending anesthesiologists and surgeons."* With the patient's permission, anesthesiologists may want to include selected family members in the reevaluation discussion to enable the best communication of the patient's preferences.

Barriers to Honoring Preferences for Resuscitation

Barriers to honoring limitations center on clinician attitudes, time pressures, and inadequate knowledge about policy, law, and ethics.[64–71] Although required reconsideration has been accepted for more than 20 years, and there has been some improvement, anesthesiologists and surgeons still have inadequate knowledge and practices about perioperative LSMT.[72–74] Deficiencies include lack of knowledge about required reconsideration, infrequent preoperative determination of the presence of an advance directive, and inadequate willingness to care for patients with perioperative limitations on LSMT.[75] On the whole, however, it seems that the extent of knowledge and practices is institution-dependent.

Anesthesiologists may falsely believe that law or hospital policy requires full resuscitation during the perioperative period. Clinicians who act in accordance with statutory requirements are often explicitly protected from liability when they honor a child's or family's refusal of resuscitation. Given the well-established right of children and parents to refuse medical treatment and the paucity of cases finding clinicians liable for honoring limitations on LSMT, the risk of liability for honoring an appropriately documented perioperative limitation on LSMT is not high and is likely to be less than the risk of not honoring the limitations.

Physicians Orders for Life-Sustaining Treatment

Physician orders for life-sustaining treatment (POLST) were designed in part to improve honoring resuscitation preferences and are becoming more common in pediatric patients. POLST have two main advantages compared with other forms of advance directives. POLST have the advantages of being a medical order that is valid across different locations, including schools. These features will likely increase compliance with the documented preferences, particularly in terms of emergency medical treatment. The POLST document defines code status and preferences for medical interventions, typically documented as full treatment, trial of treatment, and selective treatment.[76] Although clinicians feel that POLST limited unwanted resuscitation and that the declared preferences were durable, some clinicians report difficulty in using the form or having it honored across locations.[77–81] Research is needed to help optimize POLST practices.[80,82]

Potentially Inappropriate Interventions

It is more helpful to think about potentially inappropriate interventions instead of futile treatments. An intervention is futile only if it cannot accomplish a physiologic goal. A more common and difficult dilemma is how to handle potentially inappropriate interventions. Interventions may be inappropriate when *"there is no reasonable expectation that the patient will improve sufficiently to survive outside the acute care setting, or when there is no reasonable expectation that the patient's neurologic function will improve sufficiently to allow the patient to perceive the benefits of treatment."*[83] This useful concept may be less useful to pediatric decision making given the relatively sparse specific outcome data for the very young.[84,85]

Treatments with small likelihoods of success may be considered inappropriate because of the burden to the child, cost, or uncertain benefit. Discussions about inappropriate treatment should bear in mind the goals of the treatment and the likelihood of achieving a defined result. When offering the likelihood of a result, clinicians should be clear whether the information used to form the estimation is based on intuition, clinical experience, or rigorous scientific studies. Scoring systems that are useful for population predictions in determining potentially inadvisable care should be considered as contributory but not determinative for decision making for individuals.

Parents and clinicians may disagree about therapy for a child near the end of life. Hospitals should have defined processes to help resolve conflict about applying potentially inappropriate interventions (Table 5.4).[86]

IMPROVING COMMUNICATION IN PEDIATRIC INTENSIVE CARE UNITS

Pediatric intensivists should emphasize interdisciplinary communication, tailor the communication style to the parents, and maximize meaningful parental participation in the child's care.[87,88] The goal is to be an empathic professional who establishes compassionate relationships with the child and family by managing emotional, informational, and care needs. In almost all conversations, clinicians should explain the meaning of the conversation in terms of overall care.

Patient-centered characteristics–such as asking questions, using empathic statements, increasing the amount of parental contributions to the conversation, and focusing on psychosocial and lifestyle issues as compared with medical issues–improved parent satisfaction during family conferences.[89] When wanting to convey sympathy to patients and families, wish statements, such as *"I wish things were different"* seem effective.[90] Table 5.5 lists characteristics of good communication in the intensive care unit.

TABLE 5.4 Steps for Conflict Resolution of Requests for Potentially Inappropriate Treatment in Intensive Care Units[86]

1. Before initiation of and throughout the formal conflict-resolution procedure, clinicians should enlist expert consultation to aid in achieving a negotiated agreement.
2. Surrogate(s) should be given clear notification in writing regarding the initiation of the formal conflict-resolution procedure and the steps and timeline to be expected in this process.
3. Clinicians should obtain a second medical opinion to verify the prognosis and the judgment that the requested treatment is inappropriate.
4. There should be case review by an interdisciplinary institutional committee.
5. If the committee agrees with the clinicians, then clinicians should offer the option to seek a willing provider at another institution and should facilitate this process.
6. If the committee agrees with the clinicians and no willing provider can be found, surrogate(s) should be informed of their right to seek case review by an independent appeals body.
7. a. If the committee or appellate body agrees with the patient or surrogate's request for life-prolonging treatment clinicians should provide these treatments or transfer the patient to a willing provider.
   b. If the committee agrees with the clinicians' judgment, no willing provider can be found, and the surrogate does not seek independent appeal or the appeal affirms the clinicians' position, clinicians may withhold or withdraw the contested treatments and should provide high-quality palliative care.

From: Bosslet GT, Pope TM, Rubenfeld GD, et al. An official ATS/AACN/ACCP/ESICM/SCCM policy statement: responding to requests for potentially inappropriate treatments in intensive care units. *Am J Respir Crit Care Med*. 2015;191(11):1318-1330. doi:10.1164/rccm.201505-0924ST.

TABLE 5.5 Parents' Desires for Communication in the Intensive Care Units

1. **Honest and complete information** should be tailored to the parents' needs and information-receiving preferences. Comprehension of the child's potential trajectories permits better participation in care and a greater chance of appropriate end-of-life care.
2. **Ready access to staff** should include periodic scheduled informal visits to the bedside and the availability of e-mail interactions. The goal is to provide the parents with easy and frequent opportunities to have their questions answered, with sufficient repetition and clarification of the "big picture."
3. To maximize successful **communication**, clinicians should actively assess the parents' preferences for communication and decision making. This includes considering how to relate information to parents when clinicians have different management opinions. Parents frequently recognize that there are differences between options, and some prefer to hear the range of options, whereas others prefer to hear only the recommended option.
4. **Emotional expression and support by staff** are critical to parents. To do this successfully, clinicians should adapt their style to parents' preferences. Most clinicians should adopt practices that give parents more room to control the conversation, including talking less, listening more, and tolerating silence as parents gather themselves to continue communicating.
5. Parents respond and benefit from the **relational aspects of compassion, mercy, authenticity, and integrity**. More colloquially, the relational aspect is referred to as "being there"—interacting with the parents as a caring person with feelings and emotions. For example, although some clinicians may believe it is inappropriate to show emotion, parents appreciate compassion and some level of distress at the sharing of bad news, rather than cold hard professionalism.[88]
6. **Preservation of the integrity of the parent-child relationship** means enabling parents to continue in their self-identified and prominent role as decision maker and protector. Loss of this role harms parents and may impair their ability to participate in decision making for the child.
7. **Faith and spiritual matters** are highly personal, and parents may feel uncomfortable expressing their faith in an institutional setting. Spiritual matters should be accepted and integrated into the intensive care unit practice to assist those who benefit from spiritual support.
8. **Parents' lifelong views of these events** are profoundly colored by vivid memories and strong feelings about seminal discussions. How difficult discussions are handled and the quality of the communication among clinicians and families often become the basis for the family's lifelong narrative of these events.

Modified from Meyer EC, Ritholz MD, Burns JP, Truog RD. Improving the quality of end-of-life care in the pediatric intensive care unit: parents' priorities and recommendations. *Pediatrics* 2006;117:649-657.

TABLE 5.6 Ethical Issues Surrounding Donation After Cardiac Death (DCD)

Ethical Issue	Discussion Points
Should interventions be permitted prior to withdrawal of care?	The burdens from the interventions are not in the best interests of the child. On the other hand, the burdens of the interventions are mostly theoretical and may improve the quality of the transplanted organs.
Should withdrawal of therapy occur in the intensive care unit (ICU) or in the operating room?	Withdrawing therapy in the operating room may increase the quality of the organs transplanted. Withdrawing therapy in the ICU is likely to be less jarring to the family and more consistent with the premise of withdrawing therapy for the child's benefit. In addition, it may remove some of the awkwardness that may occur if the child does not die within the defined interval.
Who should withdraw therapy?	To be consistent with the premises of withdrawal of therapy, it should be the same person who would normally withdraw therapy from the child. Even if the decision is made to withdraw therapy in the operating room, an anesthesiologist who has not been caring for the child should not be asked to withdraw therapy because of the physical location of the event.
How long should cessation of cardiac function exist for a child to be declared dead?	Proposed times may be based on the premises of how long it would take to autoresuscitate compared with how long it would take to be resuscitated through medical intervention.
What are the contents of a good DCD policy?	Acceptable interventions before withdrawing therapy Acceptable locations of withdrawing therapy Amount of time to wait until death before forgoing procurement Which individual should withdraw therapy What to do if the family will not leave after death is declared

ORGAN DONATION AFTER CARDIAC DEATH

In organ procurement after a declaration of death through neurologic criteria (i.e., brain death), the child is declared dead before being brought to the operating room. The organs are then retrieved while total body homeostasis is maintained through mechanical ventilation, pharmacologic therapy, and other standard resuscitative techniques.

Concern about the limited availability of organs for transplantation has resulted in the now widely accepted concept of donation after cardiac death (DCD).[71,91,92] In DCD the child is not declared dead before being brought to the operating room for organ retrieval. Instead, after it is determined that therapy should be withdrawn based on a standard benefits and burdens assessment, the child is brought to the operating room and therapy is withdrawn. If the child dies after life-sustaining therapy is withdrawn, he or she is declared dead by cardiac criteria and the organs are retrieved. Ethical issues regarding DCD protocols center on whether the protocols seriously alter the dying process by shifting decision making away from the best interest of the dying child and by interfering with the family's ability to be with their dying child (Table 5.6).

Clinical and Academic Practice Issues

PEDIATRIC RESEARCH

The anesthesiologist Henry K. Beecher was one of the first to propose that pediatric research had different requirements compared with adult research.[93] Pediatric research is closely examined because children are incapable of consenting to experiments and because the developing child is at greater risk for long-term harm.[94] Federal guidelines give four categories of pediatric research, with each ascending category requiring greater scrutiny of the risk-to-benefit ratio, especially in research without therapeutic benefit for the subject (Table 5.7). Whereas obtaining the assent of the child whenever possible is important for therapeutic medical procedures, it is absolutely essential in the context of research, along with the informed permission of the parents.

TABLE 5.7 Federal Classification of Pediatric Research

1. Research not involving greater than minimal risk
   a. IRB determines minimal risk
   b. IRB finds and documents that adequate provisions are made for soliciting assent from children and permission from their parents or guardians
2. Research involving greater than minimal risk but presenting the prospect of direct benefit to the individual subject
   a. IRB justifies the risk by the anticipated benefit to the subjects
   b. The relationship of the anticipated benefit to the risk is at least as favorable as that presented by available alternative approaches
   c. Adequate provisions are made for assent and permission
3. Research that involves greater than minimal risk and no prospect of direct benefit to the individual subject but is likely to yield generalizable knowledge about the subject's disorder or condition
   a. IRB determines that the risk represents a minor increase over minimal risk
   b. The intervention or procedure presents experiences to subjects that are reasonably commensurate with those inherent in their actual or expected medical, dental, psychological, social, or educational situations
   c. The intervention or procedure is likely to yield generalizable knowledge . . . which is of vital importance for the understanding or amelioration of the subject's disorder or condition
   d. Adequate provisions are made for assent and permission
4. Research not otherwise approvable, which presents an opportunity to understand, prevent, or alleviate a serious problem affecting the health or welfare of children

Where research is covered by numbers 3 and 4 above and permission is to be obtained from parents, both parents must give their permission unless one parent is deceased, unknown, incompetent, or not reasonably available, or when only one parent has legal responsibility for the care and custody of the child.
IRB, institutional review board.
From U.S. Department of Human Services: 45 CFR 46 Subpart D. Additional Protections for Children Involved as Subjects in Research.

Minimal Risk

Minimal risks are defined as those risks that are not greater in and of themselves than those ordinarily encountered in daily life or during the performance of routine physical or psychological examinations. Most interpret this to mean the risks encountered in daily life by healthy children, such as running in the backyard, playing sports, or riding in a car.[95–97] A less favored relative interpretation uses as a benchmark those risks encountered in the

daily lives of children who will be enrolled in the research. In other words, if a child were living in a manner that exposed the child to risk (e.g., undergoing repeated general anesthesia), then it would be acceptable to expose the child up to that level of risk in a study.

Individuals are poor at estimating the risk levels of activities and often correlate risk to familiarity, control of the activity, and reversibility of the potential harms. Institutional review boards may reject low-risk studies because they involve unfamiliar matters while approving studies that have excessive risks.

Minor Increase Over Minimal Risk

The pediatric research category that involves *"greater than minimal risk and no prospect of direct benefit to the individual subject but is likely to yield generalizable knowledge about the subject's disorder or condition … which is of vital importance"*[98] is based on the idea that it is acceptable to expose a child to a "minor increase over minimal risk" under certain conditions. Parsing the regulation may help clarify this somewhat unhelpful definition. One suggestion has been that "minor increase" means that the pain, discomfort, or stress must be transient, reversible, and not severe.[99] The condition of the subject should be used to mean a set of characteristics *"that an established body of scientific or clinical evidence has shown to negatively affect children's health and well-being or to increase the risk of developing a health problem in the future."* Interpreting "condition" to include "having the potential to have the condition" permits otherwise healthy children to participate in research for diseases that they may develop (e.g., cellulitis). Vital importance implies that the evidence supporting the relevance of the study should require a higher order of proof.

Socioeconomic Concerns and Distribution of Risk

Socioeconomically disadvantaged children living in urban areas may be overrepresented in research studies because urban academic centers in disadvantaged areas perform the majority of clinical research.[100] Children living in socioeconomically disadvantaged areas are often more affected by diseases associated with their environment, such as asthma or nutritional disorders complicated by limited access to stocked grocery stores. One could argue that this unequal burden of risk, primarily manifested by greater participation of socioeconomically disadvantaged children in research studies, is reasonable because these children are more likely to develop these diseases and therefore are more likely to benefit from the research. Most reject that view and believe that in some sense, socioeconomically advantaged patients gratuitously gain the benefits of the research without sharing the risks. The disproportionate risk borne by one segment of society compared with another likely breeches the most accepted interpretation of the core ethical value of justice.

Socioeconomically disadvantaged families may be more likely to be influenced by the small gifts offered to research participants. Aside from compensating for costs (e.g., parking vouchers), gifts should not of themselves encourage participation. The problem is that gifts that represent a small expression of gratitude for some families may provide an incentive for participation for socioeconomically disadvantaged families.[100]

Imperative for Pharmacologic Research

Through the mid-1990s, more than 70% of new molecular entities were without pediatric drug labeling. Inadequate information exposed children to age-specific adverse reactions, ineffective treatment owing to inappropriate dosing, and lack of access to new drugs because physicians tended to prescribe less effective, known medications. Inadequate research into pediatric drugs forced physicians to prescribe drugs in nonstandard ways, such as sprinkled or crushed tablets. Even when there is some pediatric labeling, there is scant labeling for children younger than 2 years of age. In 2009 a survey of a Canadian pediatric tertiary hospital found that even when comparing off-label (see below) use with contemporary pediatric references (an unofficial and very liberal interpretation), 16% of drug administrations during the perioperative period were considered off-label. Based on a more traditional standard of the *Canadian Compendium of Pharmaceutical Specialties*, 55% of drugs administered were used off-label.[101] Neonatology and pediatric intensive care units are particularly at risk for off-label use. In a study of more than 65,000 patients, drugs that were considered to have high-risk status or high priority for study by the Food and Drug Administration [FDA] were used off-label in 85% of patients.[102] Off-label drugs included dexmedetomidine, dopamine, hydromorphone, lorazepam, and milrinone.

The following selective history highlights the overall intent to ensure that (1) children get the same benefits of pharmacologic advances as adults and (2) research is performed in the youngest children. Readers should also learn from this history that persistent advocacy is often required before regulatory change can be successfully obtained. In 1962 the Kefauver-Harris Amendments (passed after the thalidomide disaster) required that drug companies demonstrate safety and efficacy before marketing a drug. Because the vast majority of drugs did not undergo pediatric-specific investigation, this requirement actually led to less pediatric labeling, with the package insert (drug label) often reading, *"Safety and efficacy have not been demonstrated for children <12 years,"* because of the expense of getting this information. In 1994 the U.S. FDA began requiring sponsors to explain why pediatric labeling cannot occur but did not require sponsors to perform pediatric studies (see Chapter 7).

The 1997 FDA Modernization Act and the 1998 Final Rule were legislative initiatives designed to gain more data from drug companies through pediatric studies in exchange for the benefit of an additional 6 months of patent exclusivity. This effort was further codified with the passage of the Best Pharmaceuticals for Children Act (BPCA) in 2002. With these requirements, the FDA now had the legal power to mandate pediatric studies if a new drug might be used in a substantial number of children, if it might provide a meaningful therapeutic benefit, or if inadequate labeling could pose significant risks. The pharmaceutical industry responded with an explosion of pediatric studies. However, the exclusivity provision did not encourage study of generic drugs or drugs with insufficient sales. Further, once exclusivity was credited for older pediatric age groups, there was no incentive to conduct studies in younger groups.

In December 2003 the Pediatric Research Equity Act (PREA) required pediatric studies for all drugs and biologic products with a new indication, new dosage form, new route, new dosing regimen, or new active ingredient. Studies need to evaluate safety, efficacy, dosing and administration for a drug intended use for a specific pediatric subpopulation. Studies could be waived if they were impracticable, if the therapy would be ineffective or unsafe in pediatric patients, or if there would be no meaningful therapeutic benefit over existing therapies and the moiety would not be used in a substantial number of children.

In 2012 the Food and Drug Administration Safety and Innovation Act (FDASIA) made the BPCA and PREA permanent. The FDASIA initiated new requirements such as a Pediatric Study

Plan, which included an outline of the studies including study objectives, design, statistical approach, age of patients, relevant outcomes, and a timeline. An increased focus on the youngest patients included requiring that neonates be included in studies unless the disease did not affect neonates or studies were not feasible or safe. The FDASIA offered priority review for therapies for rare pediatric diseases. Through August 2016 the FDA granted pediatric exclusivity for 217 drugs.[103] In 2014 the FDA put in similar requirements for medical devices intended for use in children. Other nations have adopted similar regulatory requirements and incentives to encourage drug research.[104,105]

MANAGING POTENTIAL CONFLICTS OF INTEREST

A *conflict of interest* is *"a set of conditions in which professional judgment concerning a primary interest (such as a patient's welfare or the validity of research) tends to be unduly influenced by a secondary interest."*[106] Because these conditions in an individual are internal, they are best characterized by describing situations that may create the potential for conflicts of interest. Focusing on potential conflicts of interest moves the concept away from attacking an individual's morals and toward more uniform definitions. Potential conflicts of interest may be induced by financial, personal, and professional benefits such as prestige, promotion, and personal gratification.[107] Anesthesiologists should be mindful of these potential conflicts and attempt to identify them to better understand the likelihood of compromised judgment.

Conducting Research

Perhaps the most powerful conflict in conducting research is the loss of equipoise that can come from originating and developing an idea. Other sources of conflict related to research center on academic promotion and reputation**.** Research disclosures do not help identify conflicts of interest. In one study, only 80% of physicians disclosed payments related to the research, and only 50% disclosed payments from the same company but unrelated to the product being discussed. Indirect payments were just as likely to influence behavior as direct payment.[108]

In 2009 an anesthesiologist was falsifying data that had encouraged multimodal pain therapy. Concerns of an internal reviewer brought about the internal investigation that found significant irregularities in the research. Major journals retracted articles. The editor of *Anesthesia and Analgesia* was quoted as saying, *"We are left with a large hole in our understanding of this [multimodal pain therapy]."*[109,110] The editor of the journal called the scandal "*a tragedy*" for the profession, for patients, and for the anesthesiologist involved personally. Given that the anesthesiologist's studies were *"robust*" and influential, "*the big chunk of what people have based their [multimodal] protocol on is gone."* It is important to emphasize that the anesthesiologist's coauthors were deceived by him and were not complicit. If fact, they assisted in assessing the legitimacy of articles that were not retracted.[110]

Conflicts of interest also come from industry support of research. To be clear, the academic-anesthesia-industry research complex is necessary to continue the rapid advancement of science. Rigorous oversight minimizes these abuses.[111] Researchers need to be involved in trial development, must have access to raw data, and must be able to publish without the company's authorization. Cozy relationships between powerful members of the local academic community and industry should be examined and brought to light to minimize influence and potential conflicts of interest.[112]

Financial relationships among physicians, researchers, hospitals and industry are publicly available through the Open Payments program in the Sunshine Act (section 6002) of the Patient Protection and Affordable Care Act.[113,114] This program *"collects information about the payments drug and device companies made to physicians and teaching hospitals for things like travel, research, gifts, speaking fees and meals."*[115,116] From August 2013 through 2015, the Open Payments program reported data from 812,000 physician payments valued at more than 5 billion dollars.[117] The actual benefits from the Open Payments program are unclear.[118–121]

TABLE 5.8 Strategies Used by Drug Companies to Influence Physicians

1.	Teach sales people subtle verbal and nonverbal techniques to influence physicians.
2.	Instruct sales people to misdirect and to dissemble when questioned about possible complications.
3.	Cherry-pick which data are distributed to physicians.
4.	Prohibit distribution of studies that may criticize the product. (One strategy is to classify concerning studies as background studies and then prohibit distribution of background studies.)
5.	Seek "opinion leaders" to speak in favor of the product.
6.	Continue the well-established gift-giving strategy to subconsciously curry favor with the physician and to develop a positive association about the product and the company.

Interaction With Industry

Interaction with industry affects clinicians' prescribing behavior, often through unconscious feelings of gratitude, obligation, or fellowship.[112,122–125] Because clinicians are mostly unaware of the social dynamic industry is creating, clinicians can legitimately assert they do not consciously adjust their clinical practice, but stealthily creating familiarity and good feelings for a product or an individual is a core competency in advertising.

Be cynical about advertisements. Clinicians should independently evaluate information supplied by industry because they commonly overstate benefits and understate risks (Table 5.8).

Risks associated with industry misrepresentation will increase as increasing clinician workload decreases time for study. For these reasons, it is instructive to look more closely at this problem. Evidence published in the 2000 Vioxx Gastrointestinal Outcomes Research (VIGOR) study indicated that rofecoxib (Vioxx) dramatically increased the rate of myocardial infarction in patients. In 2001 the FDA determined that clinicians should be made aware of the cardiovascular effects of rofecoxib, and in 2004 it was withdrawn from the market. Congressman Henry Waxman later wrote the following[126]:

> *Merck, the manufacturer of Vioxx, … has an excellent reputation within the drug industry and supports many products, such as vaccines, that are medically essential but not very profitable. … Yet as we learned, even a company like Merck can direct its sales force to provide clinicians with a distorted picture of the relevant scientific evidence.*

On February 7, 2001 the Arthritis Drugs Advisory Committee of the FDA voted unanimously that physicians should be made aware of VIGOR's cardiovascular results. The next day, Merck sent a bulletin to its rofecoxib sales force [which] ordered, *"DO NOT INITIATE DISCUSSIONS ON THE FDA ARTHRITIS ADVISORY COMMITTEE … OR THE RESULTS OF THE … VIGOR STUDY."* It advised that if a physician inquired about VIGOR, the sales representative should indicate that the study

showed a gastrointestinal benefit and then say, *"I cannot discuss the study with you."*

Merck further instructed representatives to show those doctors who asked whether rofecoxib caused myocardial infarction a pamphlet called "The Cardiovascular Card." This pamphlet, prepared by Merck's marketing department, indicated that rofecoxib was associated with ⅛ the mortality from cardiovascular causes of that found with other antiinflammatory drugs.

The Cardiovascular Card did not include any data from the VIGOR study. Instead, it presented a pooled analysis of preapproval studies, in most of which small doses of rofecoxib were used for a short period. None of these studies were designed to assess cardiovascular safety. In fact, FDA experts had publicly expressed *"serious concerns" about using preapproval studies as evidence of the drug's cardiovascular safety:*

> *[B]ut it would be a mistake to restrict the lessons learned to a single company. The testimony we heard indicated that Merck's marketing practices may be less aggressive and more ethical than many of its competitors.*

Production Pressure

Production pressure is *"the internal or external pressure on the anesthetist to keep the operating room schedule moving along speedily."*[127] Almost half of surveyed anesthesiologists reported seeing what they considered unsafe anesthetic practices in response to this production pressure.[128] As a consequence, anesthesiologists may not want to take the time to allow a child to ask questions about the anesthetic, to adequately premedicate an anxious child, or to engage the parents in a lengthy discussion about postponing the surgery in a child with a cold. Anesthesiologists should be cognizant of their level of skill. For example, the "routine" tonsillectomy may be beyond some anesthesiologists' ability in a child with multiple congenital deficits. Anesthesiologists have an obligation to the patient and themselves to only provide care that is within their skills and to recognize when economic and administrative pressures may induce them to do otherwise.

PHYSICIAN OBLIGATIONS, ADVOCACY, AND GOOD CITIZENSHIP

An implicit social contract obligates physicians to serve society beyond direct patient caring. Society enables medical students, physicians in training, and physicians to train, perform research, and, perhaps most importantly, learn from and with patients. In return, society expects pediatric anesthesiologists to "*manage all things pediatric anesthesia*" (Table 5.9).[129–134] Clinicians should participate in relevant community advocacy, such as reducing variations in pediatric care secondary to issues like race, insurance status, and language barriers.[135–137]

Individual anesthesiologists do not need to fulfill every obligation. "Units" of anesthesiologists, such as private practice groups, academic departments, and state societies, should fulfill these obligations collectively.

TABLE 5.9 Examples of Obligations of Anesthesiologists to Participate and Advocate

Obligations of Pediatric Anesthesiologists[129–131,133,135–137,152,153]
Treat every child with the grace and consideration you would want for your child and family
Tailor the perioperative experience to the individual
Respond to problems that may harm children (e.g., impaired colleagues)
Practice mindfulness and critical self-reflection
Actively engage in continuing medical education
Support advancement of the science
Participate in quality improvement initiatives such as Wake Up Safe
Participate in professional organizations such as the Society for Pediatric Anesthesia and the American Academy of Pediatrics Section on Anesthesiology and Pain Medicine
Prepare future generations through teaching, mentoring, creating opportunities, and developing systems to enable anesthesiologists to fulfill these obligations
Community Advocacy and Participation
Raise public awareness about a health or social issue
Participate in public advocacy and lobbying
Work toward eliminating racial disparities in care
Encourage a medical society to act on an issue that concerns the public health
Serve in a local organization, political interest group, or political organization
Topics of particular relevance to pediatric anesthesiologists: • Pediatric obesity • Pediatric sedation safety in hospitals and non-hospital facilities • Child abuse • Health care access • Role of subspecialty training in improving care for children

Participating in Patient Safety Efforts

Medical errors come from human mistakes and system flaws.[138,139] Parents in particular are interested in medical errors. In one study, 39% of parents felt obligated to be vigilant for medical errors in their child's care.[140] Clinicians have an obligation to work to reduce system flaws, including participating in quality improvement activities and data collection, following policies meant to improve care in high-risk situations (e.g., nosocomial infections), and actively engaging in policies designed to reduce medical errors, such as universal standards of patient identification.[141] Clinicians should also participate in the data collection of national and international databases.

Although clinicians may not see the big picture and therefore resent doing "extra" steps, it is vital for clinicians to accept on faith that participation is good patient care.[129] Surreptitiously circumventing policies may harm patients, does not permit remediation of the policy, and weakens the fidelity of the entire system, encouraging others to "*make their own rules*."

Clinicians also have an obligation to report potential medical errors. Although the "blame-free" approach is well touted, clinicians perceive significant barriers to honestly reporting near-misses, hindering improved patient safety. Institutional barriers center on inadequate procedures and lack of trust in the administration.[142] When clinicians believe that policies are harmful or unnecessary, they are obligated to raise these questions through appropriate channels, particularly to address institutional barriers to reporting patient safety events.

Treating Suffering

Cassel described suffering as an intensely personal feeling that can be defined as *"the state of severe distress associated with events that threaten the intactness of the person."*[143] Suffering should be considered when managing pain, and adequate steps should be taken to find and alleviate sources of suffering. Factors that contribute to a child's suffering include not knowing the origin or meaning of the pain, believing that pain is a punishment, and fearing that

the pain will never be relieved. Anesthesiologists minimize suffering by clearly communicating about these issues with parents and children and affording children as much control of their care as possible.

Suspicion of Child Maltreatment

Child maltreatment includes acts of physical abuse, sexual abuse, emotional abuse, and neglect.[144–146] Anesthesiologists should be particularly sensitive to bruises or burns in the shape of objects, injuries to soft tissue areas such as the upper arms, unexplained mouth and dental injuries, fractures in infants, height and weight less than the fifth percentile, and injuries that are not explained by the history (see Fig. 39.2). Children with physical or mental handicaps are particularly prone to abuse.[147] Anesthesiologists, like all physicians, are legally required to report the suspicion of child abuse or neglect to appropriate authorities. Indeed, in most jurisdictions, a physician can be criminally prosecuted if found liable for failing to report suspected child abuse.

THE ETHICS CONSULTATION SERVICE

The ethical dilemmas that occur in the practice of anesthesiology may be difficult for the practitioner to resolve alone. Ethics committees and their consulting services act in an advisory role to help clinicians, patients, and families amicably resolve ethical dilemmas. Anesthesiologists may find ethics consultation helpful with questions about informed consent, decision-making capacity, and resuscitation decisions and in resolving disagreements among patients, families, and clinicians.

Although most ethics consultation services use a small group (typically three people) to perform consultations, some use the entire committee and some use a single individual.[148] Physicians, nurses, social workers, chaplains, administrators, and laypeople serve on ethics committees and perform consultations. Common characteristics of ethics consultation services are that they permit anyone to request an ethics consultation; that they require notification (not permission) of the patient, parents, and attending physician prior to the consultation; and that choosing to follow the recommendations is wholly voluntary. Ethics committees are also available to consult on policy development and to organize continuing educational programs.

For pediatric ethics consultations, the attending physician requested the majority of consults, but consult requests were also commonly received from nurses, social workers, nurse practitioners, and families.[149] Typical ethical concerns were on end-of-life care, goals of care, prognosis, quality of life, parental decision making, pediatric assent, cultural differences, professional obligations, and disagreement among professionals.[149,150] Ethics consultations seems to work efficiently, reaching consensus promptly and consistently.

The opinions of ethicists may differ from the opinions of subsets of physicians. For example, when interpreting the best interest standard for a neonate, ethicists are more likely to consider the infant's interests and the effects on the family. Neonatologists were influenced by parents' wishes, but were more likely to consider only the infant's interests and were less likely to consider the effects on the family.[151] After consultations, clinicians feel greater satisfaction in managing cases with ethical conflicts, not only because of their heightened awareness of the expert consulting services available, but also because of their increased knowledge and comfort in dealing with these issues.

Clinical Translation: Bench to Bedside: Where Are We Now?
Conclusion

U.S. PRESIDENT WILLIAM CLINTON, when announcing the relative completion of the Human Genome Project in July 2000, stated *"With this profound new knowledge, humankind is on the verge of gaining immense new power to heal. Genome science will have a real impact on all of our lives—and even more, on the lives of our children. It will revolutionize the diagnosis, prevention, and treatment of most, if not all, human disease."*[1] This marked the beginning of enhanced interest and vigor in the development of personalized medicine, which simply stated, means "right treatment for the right patient at the right time." This is especially relevant in anesthesia and analgesia as the perioperative period is a state of stress, inflammation, pain, and hemodynamic and metabolic shifts superimposed on chronic disease; all factors have interindividual variability in response.[2] Moreover, use of multiple drugs in a short course of time, as occurs in the perioperative period, introduces variability in metabolism and drug-drug interactions that can be dangerous. This is because genetic factors contribute to an estimated 50% of the variability in drug responses,[3] and it is reported that 59% of

drugs are involved in adverse drug reactions and metabolized by at least one gene with variants that affect its metabolism.[4] Hence, knowledge of pharmacogenomics (PG) and its applications for individualizing anesthetic care is critical.[5,6] In this chapter, we discuss the basics and current understanding of PG relevant to the practice of pediatric anesthesia.

Historical Perspectives

The current understanding of personalized medicine is traceable to the writings of Hippocrates, the "father of Western medicine," who lived in the fifth century BCE.[7] Anecdotally, it is said that in 510 BCE, Pythagoras noted that ingestion of fava beans caused a potentially fatal reaction in some, but not all, individuals.[8] The "seeds" of modern genetics were sown by Gregor Mendel, who presented his research on experiments in plant hybridization in 1865. Multiple scientists received Nobel Prizes for ground-breaking discoveries of "nuclein" (Albrecht Kossel in 1910), the double-helical structure of the nucleic acid (Watson, Crick, and Wilkins in 1962), cracking the genetic code (Nirenberg, Khorana, Holley in 1968), and pioneering DNA sequencing methods (Sanger, Gilbert, Berg in 1980). These revolutionized the science of genetic sequencing and in 2003, the Human Genome Project successfully completed the unraveling of the approximately 3 billion DNA base pairs that make up the human genome. Anesthesia is in no way a silent bystander in the history of PG. Some of the initial discoveries of genetic effects on drugs were related to interactions involving barbiturates in patients with porphyria (1937),[9] cholinesterase deficiency leading to succinylcholine-induced prolonged apnea (1957)[10] and malignant hyperthermia (1962).[11]

Basic Concepts and Nomenclature

The term *"pharmacogenetics"* was coined by Friedrich Vogel of Heidelberg, Germany, in 1959.[12] It refers to the role of genetic variation affecting drug response or adverse reactions to drugs. A broader term, "*pharmacogenomics,*" was introduced in the 1990s with emergence of the Human Genome Project and the development of the genome sciences, encompassing all genes in the genome that may determine drug responses.[13] We now know that the human genome contains about 21,000 genes. The most common type of allelic variation is a *single-nucleotide polymorphisms* (SNP) when two alternative bases occur at an appreciable frequency in a population (>1%).[14] Other genetic variations are called *mutations* (incidence <1%), which may be duplications, deletions, insertions, translocation, or inversion of DNA segments. However, since more than one *codon* (triplet of nucleotides) code for the same amino acid, not all mutations cause structural changes in the protein (called *nonsense variant*), whereas others do change the protein (called *missense variant*).

Cells use a two-step process of *transcription* (DNA to messenger RNA [mRNA]) and *translation* (mRNA to amino acid) to read each genetic code and produce amino acid sequences that make up proteins. Since proteins function as receptors, enzymes, and transporters for drugs, it was conventionally thought that exonic variants with "functional" roles in genes would affect protein structure and hence be of clinical significance. However, we now understand that the process is not quite as simple as previously thought. Transcription could be affected by alternative splicing and differential gene expression (depending on regulatory variants, microRNA, epigenetic factors), translation by RNA degradation, or inefficient translation. Moreover, protein formation depends on translation initiation sequences and then posttranslational modifications. Furthermore, protein expression varies in different parts of the body, affected by age, environmental conditions, and disease.[15] This complexity has given rise to various genomic technologies with exciting clinical potential for applications. Consequently, genotype may not always equate with a distinct phenotype in any particular individual.

Transcriptomics is the study of all mRNA molecules in the cell. For example, repeated exposure to high doses of ketamine, an *N*-methyl-D-aspartate (NMDA) receptor antagonist, can alter expression of apoptotic relevant genes and increase NMDA receptor gene expression in developing neurons (postnatal day 7 rat pup brains).[16]

Proteomics is the large-scale study of proteins, particularly their structures and functions. Tools of proteomic research mainly involve separation and elimination of contaminants with enzymes (e.g., DNAase, RNAase, denaturing agents) followed by protein separation by size (one- or two-dimensional polyacrylamide gel electrophoresis), cleavage into peptides and analysis by mass spectrometry (MS) (commonly matrix-assisted laser desorption time of flight [MALDI-ToF], electrospray ionization, surface-enhanced laser desorption time of flight [SELDI-ToF], and tandem MS/MS).[17] This is based on the property that six or more amino acids define a peptide sequence that can be used to identify the gene that coded for them.[18] Chromatin immunoprecipitation (ChIP) is a type of immunoprecipitation experimental technique used to investigate the interaction between proteins and DNA in the cell. It aims to determine whether specific proteins are associated with specific genomic regions, such as transcription factors on promoters or other DNA binding sites, and is an important investigational tool.

Proteomics has applications in identifying differential expression in the spinal cord after peripheral nerve injury in rat models,[19] including specific dorsal horn proteins involved in transmission and modulation of noxious information, cellular metabolism, plasma membrane receptor trafficking, oxidative stress, apoptosis, and degeneration under neuropathic pain conditions.[20] Proteomics has enabled identification of protein-binding sites of inhalation anesthetics.[21] After desflurane anesthesia, protein expression levels in the rat brain remained altered for at least 72 hours, which lends strength to the notion that the physiologic effects of anesthesia outlast the immediate postoperative period.[22,23] Effects on proteomic expression (proteins broadly classified into groups involved in cytoskeletal/neuronal growth, cellular metabolism, signaling, and cell stress/death responses) on the brain of rats were studied after sevoflurane and propofol anesthesia. The authors showed that proteins concerned with cell death and stress responses were downregulated by both agents, but they had variable effects on proteins in the other groups. Proteins such as ULIP-2 and dihydropyrimidinase-like 2 (DPYSL2; associated with cytoskeletal/neuronal growth) were regulated in opposite directions by propofol and sevoflurane. They also found that sevoflurane had more pronounced effects on a wider range of proteins and over an apparently greater duration than propofol. These findings revealed that sevoflurane could be considered a more disruptive anesthetic agent and suggest that the agents have different underlying mechanisms of protein regulation.[24] It is expected that in the future, proteomics will revolutionize preoperative risk stratification as well as approaches to anesthetic and analgesic drug delivery as they relate to specific protein binding.[15]

Metabolomics is the systematic study of the unique chemical fingerprints that specific cellular processes leave behind. Metabolomics of the live rodent brain differ during isoflurane and propofol anesthesia, with greater concentrations of lactate and glutamate characteristic of isoflurane anesthesia.[25] The use of high-resonance magnetic spectroscopy to measure metabolomics raises exciting avenues for noninvasive recognition of anesthesia-induced brain effects in humans and may be a way of recognizing differential anesthesia-induced apoptosis or neurotoxicity observed in the young, immature brain after exposure to anesthesia (see Chapter 25). Similarly, metabolic profiling of hearts exposed to sevoflurane and propofol in the isolated working rat heart model revealed distinct regulation of fatty acid and glucose oxidation, which could have clinical implications for the responses of a diseased heart under anesthesia.[26]

Another exciting field is of *epigenetics,* which encompasses nonstructural DNA modifications that control gene expression by altering transcription via histone modification and changes of DNA methylation.[27] The concept was initially proposed as a bridge between an organism's heritable genome and environmental influences[28]; such environmental influences are evident from reports of a high frequency of epigenetic differences between aging monozygotic twins.[29]

DNA methylation involves the addition of a methyl group to the 5′ carbon of the cytosine pyrimidine ring in a DNA dinucleotide by DNA methyltransferase enzymes (DNMT1, DNMT3A, DNMT3B), converting it into 5-methylcytosine. Regions in the DNA (60% in gene promoter regions) have been identified where cytosine and guanine appear next to each other in repeating sequence, held together by phosphodiester bonds, and are called CpG islands. Methylation has been found to prevent binding of transcription factors[30] or attracting methylated DNA-binding proteins that repress transcription, leading generally to gene silencing.[31,32] DNA methylation analysis either involves pyrosequencing of bisulfite-treated DNA or use of commercial arrays. There has been immense interest in the role of epigenetics in the transition from acute to chronic pain,[33] the functional regulation of μ-opioid receptors, the main receptor for endogenous as well as exogenous opioids,[34] and neuropathic pain.[35]

Histone deacetylation is modification of nucleosomes (histone octamers and surrounding DNA) that involves acetylation of the exposed *N*-terminal tails of histone by histone acetyl transferases (HATs) [36]; this alters chromatin structure and makes it less compact, thus allowing transcription factors to bind more easily. This results in increased gene expression, especially when located in gene promoter regions. This is analyzed using ChIP, and more recently, combined with sequencing (ChIP-seq).[37] An example of epigenetics as therapeutic targets for pain is provided by the study of the rat brainstem nucleus raphe magnus. This is important for central mechanisms of chronic pain, persistent inflammatory, and neuropathic pain where epigenetic suppression of *GAD2* (the gene that encodes glutamic acid decarboxylase 65 [GAD65], a γ-aminobutyric acid [GABA] synthetic enzyme that regulates pain) transcription through histone deacetylase (HDAC)-mediated histone hypoacetylation, results in impaired GABA synaptic inhibition. Importantly, HDAC inhibitors strongly increased GAD65 activity, restored GABA synaptic function, and relieved sensitized pain behavior, proving to have therapeutic potential.[38]

Epigenetics has been lauded as a possible "epicenter" for future anesthesia research.[39] The 20,000 genes that code for proteins account for only 1.5% of DNA. The National Human Genome Research Institute Encyclopedia of DNA Elements (ENCODE) project was implemented to elucidate the regulatory elements affecting gene expression, with the intention of understanding the role of the unaccounted (98.5%) DNA.[40] Small nucleolar RNAs, long noncoding RNAs, small interfering RNA (siRNA), and microRNA are now included in the list along with known messenger, transport, and ribosomal RNA. *MicroRNAs* are small (19-22 nucleotides) noncoding RNA that bind to mRNA via base pairing with complementary sequences and cause gene silencing or degradation. A short (5-7 nucleotides) sequence in the mature microRNA determines the specificity of binding to mRNAs, so microRNAs can bind multiple mRNAs, and one mRNA can be bound to multiple microRNAs simultaneously. Isoflurane protects mouse hearts from ischemia-reperfusion injury by a microRNA-21–dependent mechanism.[41] Since endogenous microRNAs in tissue can be easily increased or decreased with chemical mimics and inhibitors, this finding may hold clinical relevance for future therapeutic strategies to modulate cardiac gene regulation.

Hepatic Metabolism and Developmental Pharmacogenetics

Metabolism of many drugs involves the *cytochrome P-450 (CYP) enzyme* system. Multiple isoforms of the cytochrome P-450 enzyme system exist with different substrate specificities for different drugs.[42–44] Induction and inhibition of these enzymes by different drugs and chemicals requires a thorough understanding of both the nomenclature of the cytochrome P-450 system as well as the specific isoforms responsible for metabolism of the drugs used in pediatric anesthesia. There are both genetic and ethnic polymorphisms leading to clinically important differences in the capacity to metabolize drugs; these differences can make individual drug responses unpredictable.[45–50] In the future it may be possible to tailor drug doses to the individual's requirements by determining the child's unique metabolic capacity.[50,51]

CYTOCHROMES P-450: PHASE I REACTIONS

Cytochromes P-450 are heme-containing proteins that provide most of the phase I drug metabolism for lipophilic compounds in the body. The generally accepted nomenclature of the cytochrome P-450 isozymes begins with CYP and groups enzymes with more than 36% DNA homology into families designated with an Arabic number followed by alphanumeric letters for the subfamily of closely related proteins (>77% homology) followed by a number for the specific gene–for example, CYP3A4.[52,53] Isozymes that are important in human drug metabolism are found in the *CYP1, CYP2,* and *CYP3* gene families. Table 6.1 outlines the P-450 isozymes and their common substrates, inducers, inhibitors, and polymorphisms.

DEVELOPMENTAL CHANGES OF SPECIFIC CYTOCHROMES

For many drugs, metabolism in neonates is reduced and correlates with fewer cytochrome P-450 enzymes in the hepatic microsomes.[54] Although the concentrations of CYP enzymes increase with gestational age, they may reach only 50% of adult values at term.[54] In neonates, reduced cytochrome P-450 decreases clearance for many drugs, including theophylline, caffeine, diazepam, phenytoin, and phenobarbital.[43,44,55–59] Although many isozymes are immature in the neonate, some P-450 isozymes exhibit near-adult activity, whereas others produce unique metabolic pathways in the neonatal

TABLE 6.1 Common Relevant CYP450 Enzymes, Substrates, Their Inducers and Inhibitors, and Common Polymorphisms With Effect on Enzyme Activity

P450 Enzymes	Selected Substrates	Inducers	Inhibitors	Number of Variants Identified	Examples of Variants	Effect on Enzyme Activity
CYP2B6	Ketamine Methadone Propofol Meperidine	Carbamazepine (S)[a] Phenobarbital Phenytoin Rifampin (S)[a] Efavirenz (W)[c]	Clopidogrel (W)[f] Ticlopidine (W)[f] Prasugrel (W)[f]	>28	*6(516G>T, 785A>G) *16 *5 (172H-262K-487C)	Decreased

TABLE 6.2 Developmental Genetics for Important Hepatic Enzymes in the Neonate and Clinical Consequences

Enzymes	Developmental Patterns	Clinical Consequences
Uridine diphosphoglucuronyltransferase (UDP-GT) Substrates Morphine Acetaminophen Lorazepam	Ontogeny is isoform specific. In general, adult activity is achieved by 6-18 months of age.	Infants <3 months of age need lower morphine doses due to reduced clearance.[60]
Sulfotransferase Substrates Acetaminophen Dopamine	Ontogeny seems to be more rapid than UDP-GT; however, it is substrate specific. Activity for some isoforms may exceed adult values during infancy and childhood (e.g., that responsible for acetaminophen metabolism).	Higher APAP-sulfate formation in neonates provides "relative protection" from glucuronide formation deficiency.[61]
CYP1A2 Acetaminophen Caffeine	Not present to an appreciable extent in human fetal liver. Adult levels reached by 4 months of age and may be exceeded in children 1-2 years of age.	
CYP2C9	Not apparent in fetal liver. Inferential data using phenytoin disposition as a nonspecific pharmacologic probe suggest low activity during the first week of life, with adult activity reached by 6 months of age and peak activity reached by 3-4 years of age.	Large interpatient variability for ibuprofen effects is due to low levels of *CYP2C9* in premature infants.[62]
CYP2C19	CYP2C19 activity can be detected by 8 weeks of gestation and remains unchanged throughout gestation and at birth. Over the first 5 months of postnatal age, CYP2C19 activity increases linearly. Adult activity is reached by 10 years of age.	Allelic variations of *CYP2C19* produce PM phenotypes, which increase systemic exposure to PPI in neonates.[63] Diazepam half-life is prolonged in PM phenotype (*CYP2C19* *2/*2, *3/*3, *2/*3), causing delayed emergence from anesthesia.[64]
CYP2D6	Low to absent in fetal liver but uniformly present at 1 week of postnatal age. Poor activity (~20% of adult values) at 1 months of postnatal age. Adult competence reached by 3-5 years of age. Metabolism inhibited by cimetidine.	All newborns (<2c weeks) are PM phenotypes, susceptible to drug toxicity, although genetic variability contributes more than ontogeny to variability at all ages.[65]
CYP3A4	CYP3A4 has low activity in the first month of life, with approach toward adult levels by 6-12 months postnatally	Clearance of midazolam affected: adults>full-term neonates>preterm neonates.[66] Cisapride accumulation in neonates due to inadequate metabolism might explain QTc prolongation on ECG due to cisapride.[67]
CYP3A7	CYP3A7 is functionally active in the fetus; ~30%-75% of adult levels of CYP3A4.	

APAP, acetaminophen; *ECG*, electrocardiogram; *PM*, poor metabolizer; *PPI*, proton pump inhibitor.

period that invalidate broad generalizations about neonatal drug metabolism. Developmental patterns and clinical consequences of relevant genes are summarized in Table 6.2.

Cytochrome P4501A2 (CYP1A2) accounts for much of the metabolism of caffeine (1,3,7-trimethylxanthine)[69,70] and theophylline (1,3-dimethylxanthine)[71,72]; these methylxanthines are frequently used to treat neonatal apnea and bradycardia. *CYP1A2* activity is nearly absent in the fetal liver and remains minimal in the neonate.[73] This limits *N*-3- and *N*-7-demethylation of caffeine in the neonate. Renal clearance, the other method of elimination, is also immature[74] and elimination in preterm and term neonates is consequently poor[75,76]; these developmental issues hold important clinical implications for drug dosing and the timing between serial doses for the treatment of apnea of prematurity.[77–79] Adult levels of activity are reached between 4 and 6 months postnatally.[80,81] A similar pharmacokinetic pattern of reduced metabolism at birth occurs with theophylline in which CYP1A2 catalyzes *N*-3-demethylation and 8-hydroxylation.[71] Theophylline clearance reaches adult rates by 4 to 5 months, which coincides with the changes in *CYP1A2* activity as reflected in urine metabolite patterns.[82]

Other P-450 enzymes that are reduced or absent in the fetus include *CYP2D6* and *CYP2C9*.[66,83,84] *CYP2D6* has minimal activity (<5% of adult activity) in the last trimester but matures quickly in the first month postnatally to 50% to 75% of adult values, with large interindividual variability. *CYP2C9*, which is responsible for the metabolism of nonsteroidal antiinflammatory drugs (NSAIDs), warfarin, and phenytoin, has minimal activity antenatally[83] but develops rapidly postnatally[59,85] from 21% of adult values immediately after birth to peak (adult) activity by 3 months, when expressed as milligrams per kilogram per hour.[86] *CYP2E1* activity is minimal in utero, increasing by the third trimester, but surges within the first 24 hours postnatally and then increases steadily reaching adult activity levels by 1 year of age.[87] Infants younger than 90 days postnatal age have decreased expression of *CYP2E1* activity in vitro and slower metabolism of substrates during this early infant period compared with older infants, children, and adults.[88]

CYP3A is the most important cytochrome involved in drug metabolism. It comprises the majority of adult human liver cytochrome P-450 (see Table 6.1) and metabolizes a broad range of drugs.[89] *CYP3A* is detectable during embryogenesis as early as

17 weeks, primarily in the form of *CYP3A7*,[73] and reaches 75% of adult activity by 30 weeks gestation.[66] It has been hypothesized that this is due to the potential protective role of *CYP3A7* in preventing retinoic acid–induced human embryotoxicity.[90] In vivo, *CYP3A* activity appears to be mature at birth[91]; however, there is a poorly understood postnatal transition from the fetal *CYP3A7* to the predominant adult isoform *CYP3A4*.[92,93]

CYP2D6 is involved in the metabolism of β-blockers, antiarrhythmics, antidepressants, antipsychotics, and codeine. It is either absent or less than 1% of adult values in the fetus[94] and is eventually expressed postnatally (see Table 6.1).[66,95] *O*-demethylation begins postnatally with rapid maturation of this enzyme system irrespective of the gestational age at birth, although activity may remain less than 25% of adult values at 5 years of age. Interestingly, CYP2D6 is a noninducible enzyme whose activity, however, may vary with certain disease states, including malignancy, cigarette smoking, and some chronic inflammatory diseases (rheumatoid arthritis).[96]

PHASE II REACTIONS

The other major route of drug metabolism, designated phase II reactions, involves synthetic or conjugation reactions that increase the hydrophilicity of molecules to facilitate renal elimination.[97,98] The phase II enzymes include glucuronosyltransferase, sulfotransferase, *N*-acetyltransferase, glutathione S-transferase, and methyl transferase. The phase II enzymes also show developmental changes during infancy that influence drug clearance (see Table 6.2).[44,99–101]

Most conjugation reactions have limited activity during fetal development.[102] One of the most familiar synthetic reactions in young infants involves conjugation by uridine diphosphoglucuronosyltransferases (UGTs). This enzyme system includes numerous isoforms and is also responsible for glucuronidation of endogenous compounds, such as bilirubin (*UGT1A1*).[102] As with the maturation of bilirubin conjugation, UGT activity is limited immediately postnatally and the different isoforms mature at different rates postnatally.[103] Dose adjustments are often needed to avoid toxicity in neonates from drugs that require conjugation by UGT for clearance. Experience with chloramphenicol in the 1960s illustrated this lesson when neonates received standard pediatric doses of chloramphenicol without understanding the immaturity of UGT and its role in the elimination of chloramphenicol. Infants accumulated high concentrations of chloramphenicol and developed fatal circulatory collapse, a condition known as the gray baby syndrome.[104,105] Although the clearance of chloramphenicol is low during the neonatal period, appropriate dosage adjustments and monitoring allow safe treatment of preterm and term infants with chloramphenicol.[106]

Morphine, acetaminophen (APAP), dexmedetomidine, and lorazepam are all cleared by glucuronide conjugation. The major steps in the metabolic disposition of morphine in children and adults are glucuronidation in the 3- and 6- positions.[107] The limited ability of neonates to glucuronidate morphine necessitates dosage adjustment.[108–110] Morphine clearance,[109,111] in particular 3- and 6-glucuronide formation, is limited at birth and increases with birth weight,[110] gestational age,[42] and postnatal age.[107,108] Morphine clearance, expressed per kilogram, approaches adult values by 1 month.[108,112] However, size models such as the per kilogram model confound interpretation and clearance does not reach adult values until at least 5 to 6 months when scaled using allometry (see Chapter 7).[109,113] Overall, the maturation of UGT enzymes varies among isoforms, but, in general, adult activity is reached within the first 2 years of life.[53] The time courses of maturation of drug metabolism for morphine,[114,115] APAP,[116] and glomerular filtration rate (GFR)[117] are strikingly similar (see Fig. 7.11) with 50% of size-adjusted adult values reached between 8 and 12 weeks after full-term delivery. Drugs cleared predominantly by UGT that convert the parent compound into a water-soluble metabolite excreted by the kidneys have clearance maturation profiles matching GFR maturation.

In contrast to glucuronosyltransferase, the sulfotransferase enzyme system is well developed in the neonate, and for some compounds it may compensate for limited glucuronidation. Thus, drugs like APAP, which undergoes primarily glucuronidation in the adult, also undergo sulfate conjugation in neonates. Hence, the half-life of APAP is only moderately prolonged in neonates compared with older infants and adults.[61,118,119] This occurs because of the increased volume of distribution of the drug in neonates, and as explained earlier, increased sulfation of the drug, leading to a greater percent of the dose excreted as the APAP-sulfate conjugate.[61,119–122] However, this does not confer safety from hepatotoxicity because the toxic metabolite is created through the oxidative pathway mediated by *CYP2E1*. This is detailed later in this chapter.

ALTERATIONS IN BIOTRANSFORMATION AT BIRTH

Transition from the intrauterine to the extrauterine environment is associated with major changes in blood flow. There may also be an environmental trigger for the expression of some metabolic enzyme activities, resulting in a slight increase in maturation rate above that predicted by postmenstrual age.[123,124] Many biotransformation reactions, especially those involving certain forms of cytochrome P-450, are inducible before birth through maternal drug exposure, cigarette smoke, or other inducing agents. Postnatal biotransformation reactions may also be induced through drug exposure or slowed by hypoxia/asphyxia, organ damage, and/or illness. The reduced thiopental clearance estimated from data when the drug was given to control neonatal seizures caused by hypoxic-ischemic insults may not be applicable to healthy neonates undergoing anesthesia.[125,126]

Genomics of Drug Metabolism, Exposure, and Effects

Genetic variations can have impact on both pharmacokinetics and pharmacodynamics. Single-nucleotide changes or polymorphisms (SNPs) in the DNA sequence in CYP enzymes usually decrease but may also increase metabolic activity for a specific drug or drug substrate.[13] Some of the explanations for variations in drug responses within large populations described as "biologic variation" likely relate to genetic differences in drug metabolism, receptor binding, and intracellular coupling to effector mechanisms. A genetic cause for individuals who were either fast or slow acetylators (*N*-acetyltransferase, NAT) of isoniazid was identified in the 1950s.[127] Pseudocholinesterase deficiency causing prolonged apnea after succinylcholine deficiency was identified around the same time, although a more obscure variant, the Cynthiana (C5) or Neitlich variant that possesses much more activity that the usual plasma cholinesterase, causes an extremely brief duration of action of succinylcholine.[10,128,129] After recognizing that certain individuals demonstrated exaggerated hypotensive responses to debrisoquine, the enzyme responsible for its metabolism, CYP2D6, was also one of the early drug-metabolizing enzyme deficiencies identified.[130–132]

TABLE 6.3 CYP2D6 Polymorphisms and Recommendations for Codeine Therapy

Likely Phenotype[a]	Activity Score[c]	Examples of Diplotypes	Implications for Codeine Metabolism	Recommendations for Codeine Therapy[b]	Classification of Recommendation for Codeine therapy	Considerations for Alternative Opioids
Ultrarapid metabolizer (~1%–2% of patients)	>2.0	*1/*1xN, *1/*2xN	Increased formation of morphine following codeine administration, leading to higher risk of toxicity	Avoid codeine use due to potential for toxicity.	Strong	Alternatives that are not affected by this CYP2D6 phenotype include morphine and nonopioid analgesics. Tramadol, and to a lesser extent hydrocodone and oxycodone, are not good alternatives because their metabolism is affected by CYP2D6 activity.
Extensive metabolizer (~77%–92% of patients)	1.0–2.0	*1/*1, *1/*2, *2/*2, *1/*41, *1/*4, *2/*5, *10/*10	Normal morphine formation	Use label-recommended age- or weight-specific dosing.	Strong	
Intermediate metabolizer (~2%–11% of patients)	0.5	*4/*10, *5/*41	Reduced morphine formation	Use label-recommended age- or weight-specific dosing. If no response, consider alternative analgesics such as morphine or a nonopioid.	Moderate	Monitor tramadol use for response.
Poor metabolizer (~5%–10% of patients)	0	*4/*4, *4/*5, *5/*5, *4/*6	Greatly reduced morphine formation following codeine administration, leading to insufficient pain relief	Avoid codeine use due to lack of efficacy.	Strong	Alternatives that are not affected by this CYP2D6 phenotype include morphine and nonopioid analgesics. Tramadol, and to a lesser extent hydrocodone and oxycodone, are not good alternatives because their metabolism is affected by CYP2D6 activity; these agents should be avoided

[c]Some investigators define patients with an activity score of 0.5 and 1.0 as intermediate metabolizers and define patients with an activity score of 1.5 and 2.0 as extensive metabolizers. Classifying patients with an activity score of 1.0 as extensive metabolizers in this guideline is based on data specific for formation of morphine from codeine in these patients. https://www.pharmgkb.org/guideline/PA166104996

Variability in the clinical response to codeine prompted investigations into genetic variants or polymorphisms of *CYP2D6*. This enzyme is mapped to chromosome 22 at 22q13.1. Fifty-five polymorphisms of *CYP2D6* have been described to date with a frequency that exceeds 1% of the population.[133] These include both functional and nonfunctional polymorphisms and gene duplication. The polymorphisms are numbered with *1 denoting the normal or wild allele (the * denotes an allele) (Table 6.3). The mutant alleles, *3, *4, *5, *6, and*9, for example, confer no CYP2D6 activity.[96,133,134] The latter polymorphisms account for more than 90% of the poor metabolizers (PM). Variants *2, *10, and *17 have modestly reduced activity and are referred as intermediate metabolizers (IM).[96] To further complicate the genetic pattern, multiple copies of the same genes[134] may be present in some individuals, resulting in bizarre phenotypes. The wide array of *CYP2D6* polymorphisms of codeine may be summarized into three broad categories: PM (negligible morphine produced [PM]), extensive metabolizers (normals [EM]), and ultra-extensive metabolizers (rapid and large amounts of morphine [UM]). Up to 10% of Caucasians and 30% of Hong Kong Chinese are PM, rendering codeine an ineffective analgesic in these children.[96] Alternately, 29% of the Ethiopian and 1% of Swedish, German, and Chinese populations are UM, rendering codeine a dangerous analgesic as excessive doses of morphine may be rapidly produced after codeine is administered.[96] The frequency of *CYP2D6* polymorphisms, particularly in children who are PM, may be more common and more varied than previously thought. Earlier studies had shown that individuals might also possess normal or reduced metabolic activity (PM) for debrisoquine and sparteine.[132,135] The frequency of PM varied among ethnic groups, occurring in approximately 7% of Americans in the United States[45] and less than 1% of Chinese and Japanese.[136] The clinical relevance of *CYP2D6* polymorphisms on codeine metabolism are described later in this chapter. Allele frequencies in different races of the various relevant variants related to pharmacokinetics of anesthetic and analgesic drugs are given in Table 6.4.

Pharmacogenomics of Pain and Analgesia

One of the fundamental goals of a pediatric anesthesiologist is to have a comfortable patient in the postoperative period and beyond. Opioids remain the most commonly used medications

to provide analgesia in the perioperative period. However, safe and effective analgesia is still not achievable in about 50% of children[137,138] because of interindividual differences in pain perception and drug responses partly explained by PG.[139]

PAIN PERCEPTION AND GENETICS

Pain is both a subjective experience and a biopsychosocial phenomenon. It is well known that there is tremendous interindividual variability in pain responses, particularly in adolescents experiencing postoperative pain. Animal studies have identified genetic markers in more than 400 genes that affect nociception; these are presented in the Pain Genes Database, an interactive web browser of pain-related transgenic knockout studies.[140]

Neurotransmitters such as catecholamines (epinephrine, norepinephrine, and dopamine) are vital components in the pain perception pathway. Catecholaminergic neurons in the solitary nucleus integrate visceral and somatic sensory information when inflammation is present peripherally.[141,142] One of the genes that affect this pathway is catechol-O-methyltransferase (*COMT*) that codes for the enzyme COMT involved in degradation of catecholamines. Decreased COMT activity increases catecholamines and leads to increased pain. Four common SNPs (rs6269, rs4633, rs4818, and rs4680) are involved. SNP rs4680 is coded by 472G>A, which causes the substitution of valine by methionine at amino acid position 158 (Val158Met). These four SNPs define low pain sensitivity (LPS: $GCCG_{val}$), average pain sensitivity (APS: $ATCA_{met}$), and high pain sensitivity (HPS: $ACCG_{val}$) haplotypes.[143,144] The presence of these haplotypes was shown to cause differences in mRNA structure, enzymatic activity, and protein levels in cells expressing COMT.[145] The LPS haplotype exhibited the highest enzymatic activity, whereas the HPS haplotype exhibited the lowest enzymatic activity and protein levels in cells expressing COMT. Variations within *COMT* are associated with experimental pain responses to heat, cold, pressure, and mechanical stimuli. In addition, the *COMT* genotype is predictive of chronic pain in fibromyalgia, temporomandibular joint disorder,[143] and postsurgical pain.[146] Although there have been conflicting reports of Val/Val genotypes requiring larger doses of morphine in cancer patients[147] compared with Met/Met's larger pain ratings in experimental studies,[148] it is possible that population differences, haplotype differences, and other gene interactions might contribute to these contradictory observations. In a pediatric study involving 149 children undergoing tonsillectomy, associations of *COMT* SNPs (rs6269, rs4633, rs4818, and rs4680) and haplotypes with maximum pain scores and morphine consumption were studied. In addition to haplotype differences in morphine requirement, the authors found that minor allele carriers of *COMT* SNPs were approximately three times more likely to require analgesic interventions than homozygotes of major alleles.[68]

The metabolism of phenylalanine and the synthesis of serotonin, dopamine, epinephrine, norepinephrine, and nitric oxide (NO) are reliant on adequate cellular levels of tetrahydrobiopterin (BH4), an essential cofactor of enzymes involved in their synthesis (hydroxylases and NO synthases). GTP cyclohydroxylase 1 (GCH1), the rate-limiting enzyme responsible for the synthesis of BH4, is regulated by gene *GCH1*. *GCH1* transcription is induced in the presence of inflammatory markers and nerve injury, leading to increased BH4 production and increased NO production; NO sensitizes transient receptor potential vanilloid subfamily type 1 (*TRPV1*) and subfamily ankyrin repeats type 1 (*TRPA1*), causing increased calcium influx into the neuron and increased pain responses.[149] Concomitantly, loss-of-function haplotype defined by 3 polymorphisms (rs8007267G<A, rs3783641A<T, and rs10483639C<G) was associated with decreased *GCH1* activity in vitro and with pain protection in experimental pain models in volunteers[150] and in patients undergoing diskectomy for persistent radicular low back pain.[151] There have been negative association studies since, but whether the association is spurious or dependent on the effect size is not clear because of multiple confounding variables.

Combinatorial genetics likely contribute to a greater extent than single genes in predicting variability. In 201 Caucasians undergoing abdominal surgery, the authors tested associations among morphine consumption, postoperative pain, and SNPs within opioid receptor μ-1 *(OPRM1)*, COMT, uridine-5′diphosphate glucose-glucuronosyltransferase-2B7 (*UGT2B7*, and estrogen receptor *(ESR1)* gene loci to elucidate genetic predictors of opioid consumption. Age and 9 SNPs in *ESR1, OPRM1,* and COMT explained the greatest proportion of variance of morphine consumption (10.7%; P = 0.001). Three SNPs in *ESR1, OPRM1,* and *COMT* explained 5% of the variance (P = 0.007). There was also an interaction between rs4680 in COMT and rs4986936 in *ESR1* (P = 0.007) on opioid consumption.[152]

There are also some congenital conditions that lead to insensitivity to pain, caused by pathogenic mutations in genes such as the neurotrophic tyrosine kinase receptor type 1 gene (*NTRK1*) and nerve growth factor-β (*NGFB*) with an anhidrosis phenotype.[153] Various mutations of the sodium channel voltage-gated type IX, alpha subunit *SCN9A* gene leading to nonfunctional alpha subunits of NaV1.7 channels inhibit the generation and transmission of nerve signals, leading to pain insensitivity along with anosmia.[75] For a comprehensive overview of PG and pain, please refer to review articles beyond the scope of this chapter.[139,154]

Genetic Variations Affecting Opioid Pharmacokinetics

Pharmacogenetics affecting enzyme activity have been shown to affect both drug exposure and effect, leading to either decreased effectiveness or increased toxic effects of the drug. The U.S. Food and Drug administration (FDA) has issued warnings and guidelines for pharmacogenetics pertaining to the effects of some drugs used in pediatric anesthesia practice.

CODEINE

Codeine is a weak opioid endorsed by the World Health Organization as the second step on the analgesic ladder for cancer pain and has been used routinely for postoperative and breakthrough pain in chronic sufferers. It is a prodrug with a 200-fold weaker affinity for μ-opioid receptors than morphine. Although 80% of the administered drug is inactivated by glucuronidation to codeine-6-glucuronide by *UGT2B7* and *N*-demethylation to norcodeine by *CYP3A4*, 5% to 10% of codeine undergoes *O*-demethylation to morphine, its active form via *CYP2D6*[155] (Fig. 6.1) Without *O*-demethylation, codeine confers a small fraction of the analgesic potency of morphine, and much of its analgesic effect is likely contributed by a metabolite, codeine 6-glucuronide.[156]

A small proportion of the population (ranging from 2%-10% in different ethnic groups) are *CYP2D6* PM and thus have limited analgesia with codeine.[76,157] Alternative analgesics should be sought in children who are PM.

Recently, the safety and efficacy of codeine in children who are UM have been called into question. The frequency of UM

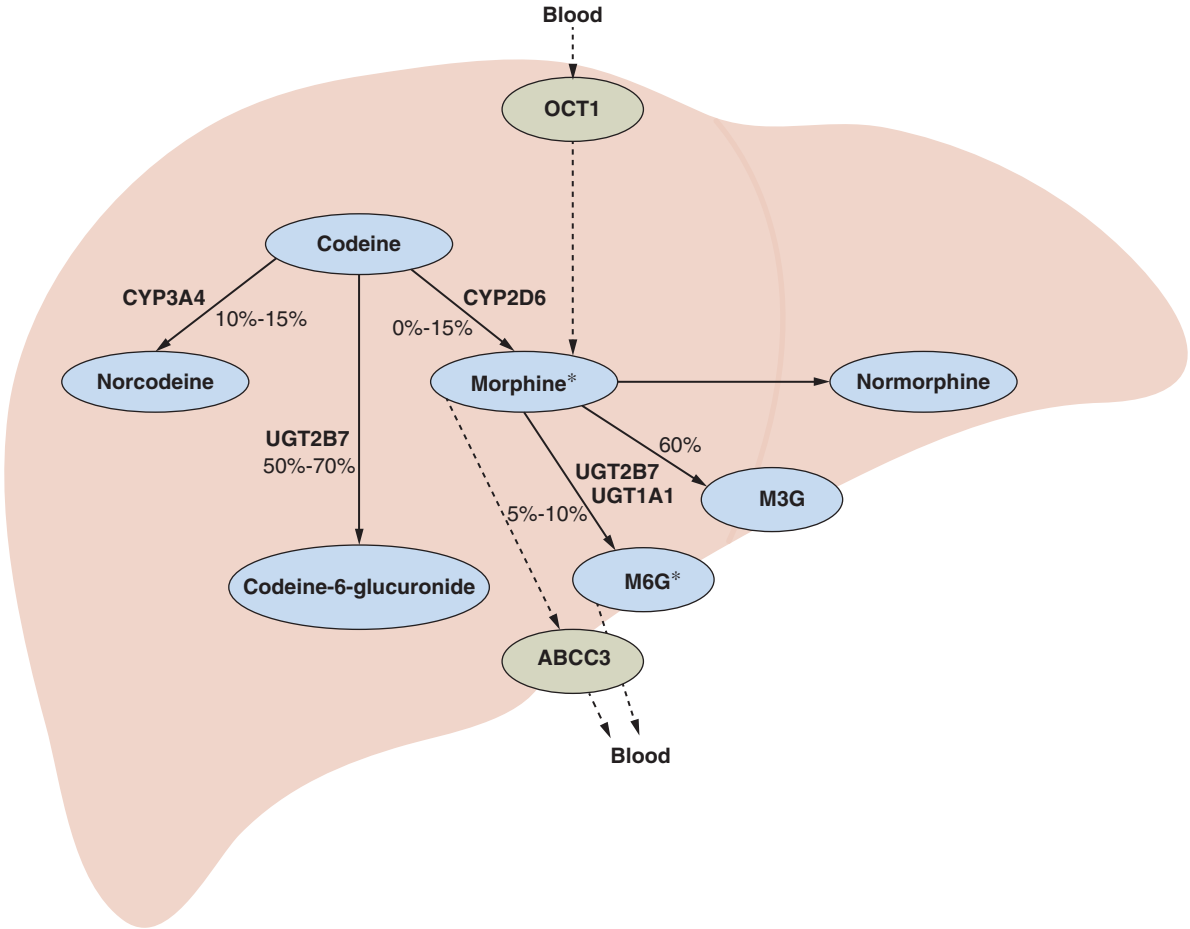

FIGURE 6.1 Diagrammatic presentation of the candidate genes involved in the pharmacokinetic pathway of codeine and morphine in the liver. Codeine, a prodrug is converted to active form* morphine primarily by cytochrome (*CYP2D6*). Approximately 50% to 70% of codeine is converted to codeine-6-glucuronide by uridine glucuronosyltransferase (*UGT2B7*); 10% to 15% of codeine is *N*-demethylated to norcodeine by cytochrome P450 enzyme *(CYP3A4)*. Both these metabolites have a similar affinity to codeine for the μ-opioid receptor. Between 0% and 15% of codeine is *O*-demethylated to morphine by *CYP2D6*, the most active metabolite*, which has 200-fold greater affinity for the μ-opioid receptor compared with codeine. Morphine is mainly (60%) glucuronidated to morphine-3-glucuronide (M3G), while 5% to 10% is glucuronidated to morphine-6-glucuronide (M6G) primarily by *UGT2B7*, and to a lesser extent, *UGT1A1*. M6G is the active metabolite with a higher affinity for the μ-opioid receptor. *OCT1* is a hepatic transporter responsible for transporting morphine from blood into liver cells. *ABCC3* is a hepatic efflux transporter and it transports morphine and morphine glucuronides from liver cells into blood.

genotypes is substantive from 1% in Denmark and Finland, 10% in Greece and Portugal, and 29% in Ethiopia.[158] Children with *CYP2D6* polymorphisms who also have upregulated opioid receptors as a result of chronic intermittent nocturnal hypoxia (obstructive sleep apnea) may be particularly vulnerable to a mishap after regular codeine use.[159] Consequently, the wide clinical response to a standard (or less than standard) dose of codeine necessitates careful monitoring in those with compromised cardiorespiratory status. Several deaths or near-deaths have been reported with "standard" doses of oral codeine in children later found to be UM.[160,161] A fatality after codeine administration was reported in a healthy 2-year-old boy given weight-appropriate codeine doses after adenotonsillectomy; he died on the second postoperative day. Increased blood concentrations of morphine (32 ng/mL) and reduced codeine concentrations (0.70 ng/mL) were found. Genotyping revealed functional duplication of the *CYP2D6* allele.[160] This was followed by further reports[162,163] that ultimately led to new regulations by the FDA, European Medicines Agency, and the U.K. Medicines and Healthcare Products Regulatory Agency. Restrictions were placed on pediatric use, and some centers have removed codeine from their formularies.[164] The 2012 Clinical Pharmacogenetics Implementation Consortium (CPIC) guidelines for *CYP2D6* genotype and codeine therapy were updated in 2014.[165] This guideline recommends using alternative analgesics to codeine in patients who are *CYP2D6* PM or UM (see Table 6.2). A new *boxed warning*, the FDA's strongest warning, was added to the drug label of codeine-containing products about the risk of codeine in postoperative pain management in children. The warning specifies that *"Health care professionals should prescribe an alternate analgesic for post-operative pain control in children who are undergoing tonsillectomy and/or adenoidectomy. Codeine should not be used for pain in children following these procedures"* (http://www.fda.gov/Drugs/DrugSafety/ucm339112.htm). It should be noted that these same concerns apply to children requiring analgesia for greater than one day

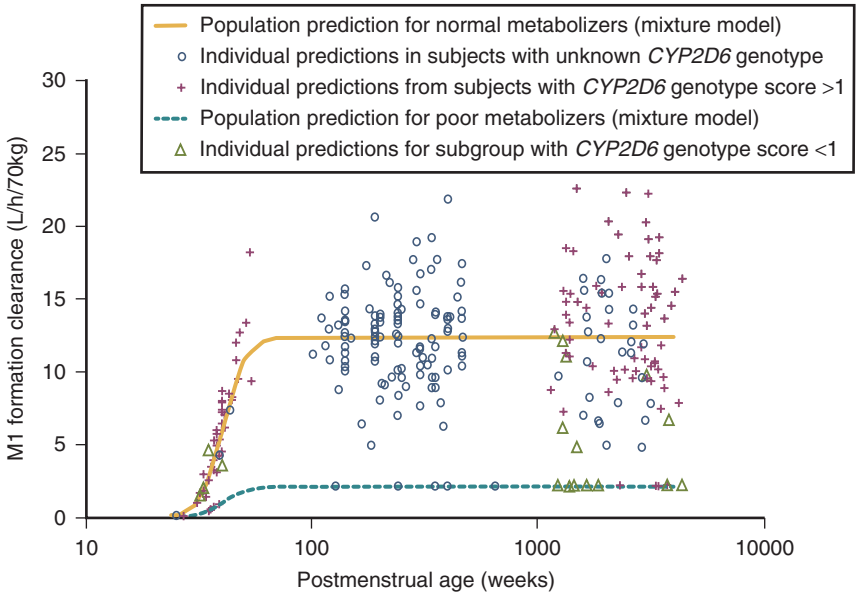

FIGURE 6.2 Maturation of tramadol formation clearance (CLPM) to *O*-desmethyl tramadol (M1 metabolite) labeled according to the availability of an individual *CYP2D6* genotype activity score. There is a distinct group of patients who are poor metabolizers identified by the phenotype *(dashed line)*. Not all subjects with a low genotype *CYP2D6* activity ($n = 20$) are included in this poor metabolizer group. (From Allegaert K, Holford NHG, Anderson BJ,et al. Tramadol and o-desmethyl tramadol clearance maturation and disposition in humans: a pooled pharmacokinetic study. *Clin Parmacokinet.* 2015;54(2):167–178. Used with permission from Springer.)

regardless of the surgical procedure, particularly obese children who may have obstructive sleep apnea (see also Chapter 33).

There are also safety concerns for breastfed babies whose mothers take codeine for pain relief. This was highlighted in 2006 with the report of death in a breastfed infant after codeine was administered to the mother; she was an UM of codeine and analysis of her breast milk revealed a very large blood concentration of morphine, 87 ng/mL.[166] Hence, the safest advice is to avoid codeine whenever possible as it is unlikely that the *CYP2D6* activity for any individual will be known; those with high levels of activity may suffer from toxicity, while those with low levels will suffer unnecessary pain. Others have taken a more active posture by identifying the 2D6 isoforms in their patients–in this case, children with sickle cell disease–and determined which patients would benefit from or suffer from codeine administration for chronic pain.[167] Although pharmacokinetic studies show increased conversion of codeine to morphine in *CYP2D6* UM versus EM,[168] it is important to remember that because of hitherto unknown factors, there is substantial variability within patients genotyped as EM, some of whom may have UM phenotypes.[162]

TRAMADOL

Tramadol is a weak opioid agonist metabolized by many pathways, including *CYP2D6*-mediated oxidation to *O*-desmethyltramadol, which has a 200-fold greater affinity for μ-opioid receptors than the parent drug.[169] Tramadol exerts its analgesic activity through complementary mechanisms: activating the μ-opioid receptor mainly by *O*-desmethyltramadol and weak inhibition of norepinephrine and serotonin reuptake (mainly tramadol). For children who are *CYP2D6* PM, both the plasma concentrations for the active metabolite and analgesia are less than with the EM, whereas for those who are 2D6 UM, both the plasma concentrations and analgesia and side effects are greater than in those who are EM.[170–172] However, as with codeine, genotype may not predict phenotype in all individuals. Not all subjects who are genotype *CYP2D6 PM* ($n = 20$) have slow clearance of its active metabolite (Fig. 6.2)[173]

HYDROCODONE

Hydrocodone is metabolized by *CYP2D6* to hydromorphone, which has 10- to 33-fold greater affinity for opioid receptors than hydrocodone. While pharmacokinetic studies have shown that the peak concentrations of hydromorphone in PM are less, there is no conclusive clinical evidence of *CYP2D6* genotype on its effects.[174,175]

OXYCODONE

Oxycodone is a semisynthetic opiate agonist; about 11% of the drug is *O*-demethylated by *CYP2D6* to the active metabolite oxymorphone, which has a 40-fold greater affinity and 8-fold greater opioid potency compared with oxycodone itself. The remaining 89% of the drug is *N*-demethylated by *CYP3A* to noroxycodone, a metabolite with weak antinociceptive properties. Both metabolites, oxymorphone and noroxycodone, are further degraded to noroxymorphone by *CYP2D6* and *CYP3A*.[176] The greatest oxymorphone/oxycodone concentration ratios occur in UM and the smallest occur in PM. The noroxycodone/oxycodone ratio and daily oxycodone escalation rate are greater in cancer patients with the *CYP3A5**3/*3 genotype.[177] Although postoperative analgesic requirement is less in UM,[178,179] other studies in postsurgical patients and cancer patients detect clinical differences among the genotypes.[180,181]

MORPHINE

Approximately 60% of morphine is glucuronidated to morphine-3-glucuronide (M3G). Only 5% to 10% is glucuronidated to morphine-6-glucuronide (M6G), principally by *UGT2B7* in the

liver, and in part, by *UGT1A1* and *UGT1A8*.[182] M6G is an active metabolite, with slower onset and more prolonged duration of action compared with morphine.[183] It is uncertain whether *UGT2B7* variants affect morphine PKPD. *UGT2B7*-840G allele and the -161 C>T SNP are associated with reduced glucuronidation of morphine,[184,185] although other studies refuted this finding. There was no correlation between 12 SNPs of *UGT2B7* and the morphine glucuronide/morphine serum ratios among 175 patients with normal hepatic and renal function who received long-term oral morphine therapy.[186]

In vitro studies have suggested that morphine has low transporter-independent permeability and 60% of total hepatic uptake is transporter dependent. Hence, there is an interest in the genetics of various hepatic transporters known to play a significant role in the disposition of morphine and its metabolites based on in vitro studies and mice.[182,187–192] *OCT1*, a member of the organic cation transporters (OCT), is predominantly expressed in the sinusoidal membrane of the human liver and mediates cellular uptake of morphine into hepatocytes (see Fig. 6.1). Approximately 10% of Caucasians are compound homozygous carriers of one of the four common coding polymorphisms for *OCT1* (Arg61Cys, Gly401Ser, Gly465Arg, and deletion of Met420) that result in reduced or lost *OCT1* transporter activity and greater plasma concentrations of morphine.[193] *OCT1* genotypes play a significant role in IV morphine clearance in children undergoing tonsillectomy.[194] Morphine clearance in homozygotes of loss-of-function *OCT1* variants (*OCT1*2–*5/*2–*5*) was reduced (20%) compared with the wild type (*OCT1*1/*1*) and heterozygotes (*OCT1*1/*2–*5*).[194] The relatively common allelic frequencies of defective *OCT1* variants among Caucasians may explain their reduced morphine clearance and possibly greater frequencies of adverse events compared with African American children.

Another transporter belonging to the ATP-binding cassette (ABC) subfamily, *ABCC3*, is expressed in the basolateral membranes of hepatocytes and is an efflux transporter of M3G and M6G from the hepatocyte into the bloodstream (see Fig. 6.1). *ABCC*3 SNP -211T (rs4793665) is located in the promoter region of the gene and has been reported to alter hepatic mRNA expression[195] and contribute to reduced efflux of morphine glucuronides.[196] In children undergoing tonsillectomy, in addition to the effects of polymorphisms of *OCT1* genotype on morphine pharmacokinetics, the C/C polymorphisms of *ABCC3* -211C>T significantly increased the transformation of morphine-6-glucuronide and morphine-3-glucuronide by ~40% compared with the C/T+T/T genotypes.[197] Similarly, in 316 children undergoing tonsillectomy, *ABCC3* variants rs4148412 (A allele) and rs729923 (allele G) caused a 2.36 (95% confidence interval [CI] = 1.28-4.37, P = 0.0061) and 3.7 (95% CI 1.47-9.09, P = 0.005) times increased odds ratio of morphine-induced respiratory depression, leading to prolonged postoperative care unit stay. These clinical associations were supported by increased formation clearance of morphine glucuronides in children with rs4148412 AA and rs4973665 CC genotypes in this cohort, as well as an independent spine surgical cohort of 67 adolescents.[198] Homozygotes with the 3435C>T variant of another ABC efflux transporter of morphine, *ABCB1*, expressed large cerebrospinal fluid concentrations of morphine. This efflux transporter is responsible for removing unwanted medications and toxins from the central nervous system and gastrointestinal tract. The *ABCB1* 3435 C>T allele is linked to greater analgesia with morphine in cancer-related pain and reduced morphine requirements in mixed chronic pain population.[199,200] Following tonsillectomy, children with GG and GA genotypes of *ABCB1* polymorphism rs9282564 have been shown to have fourfold higher risks of respiratory depression, resulting in prolonged hospital stays.[201]

METHADONE

Methadone is primarily cleared by hepatic *CYP2B6* to its inactive metabolite. Of the many variants of the very polymorphic gene *CYP2B6*, one of the most common and clinically significant variant allele is *CYP2B6*6* (516G>T, Q172H; 785A>G, K262R), which markedly reduces *CYP2B6* expression and activity.[202] Concomitantly, S-methadone concentrations were greater in *CYP2B6*6* homozygotes compared with heterozygotes and noncarriers, and these *CYP2B6*6* patients had reduced dose requirements.[203,204] In fact, genetic influence is found to be greater for oral than IV methadone and S- than R-methadone.[205]

Genetic Variations Affecting Opioid Pharmacodynamics

Genetic modulation of the density of opioid receptors, affinity, or coupling affects the variability in the intersubject responses to opioids. In a study of 121 adult twin pairs who were randomly assigned to receive alfentanil or placebo, there was significant heritability for respiratory depression (30%), nausea (59%), and drug disliking (36%), as well as significant familial effects for sedation (29%), pruritus (38%), dizziness (32%), and drug liking (26%) after alfentanil administration.[206,207]

OPIOID RECEPTOR (*OPRM1*)

This gene, located on chromosome 6q24-q25, is a member of the G protein–coupled receptor family and of major interest as it codes for the μ-opioid receptor, a molecular binding site of all clinically effective opioids and endogenous opioid peptides like β-endorphin.[208] It is widely distributed throughout the nervous system (periaqueductal grey area, in the substantia gelatinosa area in dorsal horn of the spinal cord, in the olfactory bulb, the cerebral cortex, the amygdala) as well as the gastrointestinal tract. This gene mediates opioid-induced analgesia and adverse effects including respiratory depression, and constipation. One of the most commonly studied SNPs of *OPRM1* is A118G (rs1799971), in which guanine (G) is substituted for an adenine (A) at base 118, which in turn causes the amino acid exchange at position 40 of the μ-opioid receptor protein from asparagine to aspartic acid (N40D), that leads to the loss of an *N*-glycosylation site in the extracellular region of the receptor.[209] The allele frequency shows a racial bias; it is greater in the Asian population (50%) than in Caucasians (10.5%–18.8%) and African Americans (5%–15%).[210]

In vitro studies have shown reduced cell-surface receptor binding site availability for morphine in cells expressing the G variant compared with the A variant, less efficient agonist-induced receptor signaling in postmortem human brain tissue in 118G carriers, and 1.5- to 2.5-fold increased mRNA expression in 118A human brain cells compared with the G variant.[211–213] An in vivo study investigating the effects of A118G genotype on μ-opioid receptor binding potential in human brains using carfentanil positron emission tomography, found that smokers homozygous with the wild-type AA genotype exhibited significantly greater levels of receptor binding potential than smokers carrying the G allele in the bilateral amygdala, left thalamus, and left anterior cingulate cortex.[214] In contrast, the variant receptor had a threefold greater binding affinity for endogenous β-endorphins with potentially

different connotations for pain sensitivity but not analgesic response to opioids.[215]

In accordance with the mechanistic findings mentioned previously, several studies in adults have shown that the opioid requirements (morphine, M6G, fentanyl, and alfentanil) were greater and the adverse effects such as nausea less in postoperative patients and volunteers with the GG/AG genotypes compared with those with the AA genotypes at the A118G SNP.[216–223] In postsurgical Asian adult patients undergoing knee arthroplasty, hysterectomy, and cesarean section,[216,217,221] carriers of the G allele had greater pain scores and greater morphine requirements than those with the AA genotypes. In a prospective genotype-blinded study of 88 healthy adolescents undergoing spine fusion for idiopathic scoliosis, the risk of morphine-induced respiratory depression in patients with the AA genotype was greater (odds ratio 5.6, 95% CI = 1.4–37.2, P = 0.03) compared with the AG/GG genotypes.[224] Similar results in human volunteers found a two to four times greater dose of alfentanil to produce the same level of analgesia as the wild type, and a 10- to 12-fold greater dose for the same level of respiratory depression in the homozygous 118GG volunteers.[225] However, no association was found for the A118G effects on morphine-6-glucuronide–induced respiratory depression (measured by the isocapnic acute hypoxic ventilatory response) and PONV after fentanyl.[222,226] A meta-analysis of the OPRM1 A118G effects concluded that the evidence that homozygous GG carriers of A118G exhibited slightly greater opioid requirements and slightly less nausea was weak.[227]

In addition to the rs1799971 (A118G) variant, a novel C-T variant (rs563649) has been identified in the 5′ untranslated region of the spliced isoform MOR1K that is preferentially expressed in the medulla oblongata.[228] This variant had the strongest single contribution to measured pain sensitivity responses in 196 pain-free European and American females. The C-T variant is located within a structurally conserved internal ribosome entry site upstream of exon 13 and affects both mRNA levels and translation efficiency of MOR1K isoforms. Strong linkage disequilibrium was identified between rs563649 and rs1799971, and the minor T allele of rs563649 tagged a 6-SNP (AGTCTG) haplotype associated with great pain sensitivity. Haplotype combinations rather than single variants may be a better predictor of OPRM1 effects.

BLOOD-BRAIN BARRIER TRANSPORTER (*ABCB1*)

P-glycoprotein (P-gp), a surface phosphoglycoprotein encoded by *ABCB1* and a member of the superfamily of ABC transporters, is an ATP-dependent drug efflux transporter. P-gp is expressed on the epithelial surface at the intestinal lumen, biliary canaliculi, renal proximal tubule, and in the choroid plexus as the blood-brain barrier (BBB). Morphine, fentanyl, methadone, sufentanil, alfentanil, morphine-6-glucuronide, and loperamide are all confirmed P-gp substrates.[188,229–232] Variations in the *ABCB1* efflux transporter at the BBB can significantly alter cerebral penetration and pharmacokinetics of opioids.[233] The most commonly studied variants in the coding region of *ABCB1* are c.1236C>T (rs1128503), c.2677G>T/A (rs2032582), and c.3435C>T (rs1045642) and these are in strong linkage disequilibrium.[234] *ABCB1* genotypes 1236 TT, 2677TT, and 3435TT, together with the 1236TT genotype alone, were associated with early and profound respiratory suppression in adults given intravenous (IV) fentanyl during spinal anesthesia.[235,236] The homozygous diplotype (GG-CC at c.2677G>T/A and c.3435C>T) were shown to have borderline association with morphine-associated postoperative nausea or vomiting (PONV)[234]; however, in another report of adults treated with morphine, a combined effect of 3435T of *ABCB1* and 80A of *OPRM1* was associated with increased pain relief but had no influence on the incidence of adverse effects.[199]

Another SNP that has been studied is *rs9282564*, a nonsynonymous polymorphism with a threefold greater maximum velocity for adenosine triphosphatase activity compared with the wild type.[237] Children with GG and GA genotypes of *ABCB1* rs9282564 have a greater risk for respiratory depression after tonsillectomy, resulting in prolonged PACU stays. Each additional copy of the minor allele (G) of the *ABCB1* SNP, rs9282564, increased the odds of respiratory depression that resulted in a 4.7-fold (95% CI: 2.1-10.8) greater duration of stay in PACU. This variant allele had also been reported to have a modest effect in reducing the trough levels of methadone.[238] Haplotypes of SNPs at positions 61, 1199, 1236, 2677, and 3435 influenced methadone requirements in opioid-dependent and nondependent patients, but they did not predict opioid dependence.[239] However, others have reported contradictory results that there was no association between *ABCB1* polymorphisms and the trough plasma concentrations, methadone dose, or methadone response.[240]

OPIOID-CANNABINOID SYSTEM INTERACTIONS

Fatty acid amide hydrolase (*FAAH*), opioid and cannabinoid systems reciprocally and synergistically, modulate functions at multiple levels. *FAAH* codes for an enzyme that hydrolyzes anandamide, the "bliss" molecule. Inhibition of *FAAH* increases the bioavailability of anandamide and thereby augments analgesia; this offers a potential therapeutic target for treating pain.[241,242] Five specific *FAAH* SNPs, including a missense variant (rs324420) that affects *FAAH* stability, were reported to be associated with more than twofold greater risk for refractory PONV in children undergoing tonsillectomy.[243]

Genes of Addiction

There is a genetic component to addiction, and variations of particular genes can predispose to addiction. This is especially relevant in adolescence and early adulthood, which is the prime time when these addictions happen. It is believed that 40% to 60% of the risk is genetic, regardless of the drug of addiction.[244] There were 34.2 million people in the United States (age ≥12 years) in 2011 who had used an opioid for nonmedical use sometime in their lives, and approximately 13% of high school seniors reported using prescription opioids such as oxycodone and hydrocodone.[245,246] A precursor to addiction is opioid exposure, including prescription opioids, and family history suggests genetic vulnerability for opioid use disorder.[247] A meta-analysis of 5-hydroxytryptamine (serotonin) 2A receptor gene *(HTR2A)* genotypes at SNPs rs6313 and rs6311 from available genetic association studies from different populations showed their contribution to genetic susceptibility to substance use disorders, especially alcohol dependence.[248] Certain variants of the glutamate receptor, the NMDA 2A *(GRIN2A)* gene that encodes the 2A subunit of the NMDA receptor, were shown to be involved in the development of heroin addiction.[249] Likewise, the dopamine D1 receptor *(DRD1),* which modulates opioid reinforcement, reward, and opioid-induced neuroadaptation, and the μ-1 opioid receptor gene (*OPRM1*), a target of opioids, also had variants that predicted opioid dependence or protection thereof, in association studies.[250] The A118G SNP of the *OPRM1* gene is the most studied and has been associated with phenotypes including opioid dependence and other substance dependencies.[251,252]

Nonsteroidal Antiinflammatory Drugs and Genetics

NSAIDs act by inhibiting cyclooxygenase enzymes (COX-1 and COX-2) coded for by the prostaglandin endoperoxide synthase genes, *PTGS I* and *II*. Commonly used NSAIDs such as ibuprofen and diclofenac undergo phase 1 detoxification (*CYP2C9* for S(+)-ibuprofen; *CYP2C8* for R(-)-ibuprofen; *CYP2C9* and *CYP3A4* for diclofenac)[253,254] followed by glucuronidation (mainly *UGT2B7*).[255] Multidrug resistance-associated proteins 2 (*MRP2/ABCC2*) and breast cancer resistance protein (*BCRP/ABCG2*) affect biliary excretion of diclofenac glucuronides, and *MRP3/ABCC3* was the main efflux transporter from liver to blood.[256] Dubin-Johnson syndrome is caused by acquired or hereditary deficiency of *ABCC2*, leading to increased concentration of bilirubin glucuronides.[257] As diclofenac shares the same *ABCC2* transporter pathway, it should be prescribed to those individuals with caution to avoid adverse reactions to diclofenac, particularly hepatotoxicity.[258]

There are two frequent allelic variants for *CYP2C9-CYP2C9**2 (430C>T Arg144Cys) and *CYP2C9**3 (1075A>C Ile359Leu) that decrease the activity in a number of in vitro and in vivo studies. *CYP2C9**2, *3, and *CYP2C8**3 allelic variants reduce ibuprofen metabolism and/or clearance.[259] However, *CYP2C8**3 is in strong linkage disequilibrium with the *CYP2C9**2 variant, making it difficult to distinguish whether the effects are due to *CYP2C8* or *CYP2C9*. Investigations into the association between *CYP2C9* and *CYP2C8* polymorphisms and response to ibuprofen therapy for patent ductus arteriosus closure in extremely preterm neonates showed that greater gestational age and non-Caucasian ethnicity were associated with ibuprofen response, but not the *CYP2C* polymorphism.[260] Gastroduodenal bleeding was strongly associated with *CYP2C9*3* carriers as opposed to noncarriers (adjusted odds ratio 7.3) in adults given NSAIDs, including diclofenac, ibuprofen, celecoxib, and naproxen.[261] These findings were reproduced by some[262] but not by others.[263]

Ketorolac, another nonselective COX inhibitor, is safe for use in neonates.[264] Nonetheless, in children (unlike adults), ketorolac does not significantly penetrate cerebrospinal fluid. The transporter gene, *MDR-1,* has been implicated in drug transport across the BBB.[265] Moreover, animal studies have shown developmental differences in COX-1 expression in the spinal cord, likely explaining the lack of analgesic efficacy of ketorolac in 3 day-old compared with 21-day-old pups[266] and 2-week-old compared with 4-week-old rats.[267] The authors extrapolated that "*should similar deficits occur in humans, COX-1 inhibitors may exhibit reduced efficacy in infants.*"[267] However, this lack of effectiveness was not observed in clinical studies of ketorolac in neonates, in whom analgesia was achieved in 94.4%.[264]

Selective COX-2 inhibitors produce less inhibition of COX-1 and are expected to have short-term gastrointestinal safety benefits, although, their long-term benefits are inconclusive.[268] COX-2 mRNA and protein expression are increased in the presence of gastric mucosal lesions, suggesting that they may be involved in the repair process of those lesions.[269] Thus selective COX-2 inhibition might disturb the COX-2 enzyme–mediated protective prostaglandin production.

Celecoxib, a COX-2 inhibitor metabolized by *CYP2C9,* has been investigated for *CYP2C9* variant effects on its pharmacokinetics. In a study in volunteers, those with the *CYP2C9**1/*3 and *CYP2C9**3/*3 variants experienced a greater concentration exposure (2-fold and 7.7-fold, respectively) and maximum concentration (1.5-fold and 1.8-fold, respectively) and a reduced clearance (2.3-fold and 10-fold, respectively) than those with the *CYP2C9**1/*1 variant.[270] A case report described severe drug-induced gastropathy in an IM of the *CYP2C9* gene, presumably resulting from prolonged drug exposure.[271] Children given celecoxib who had the genotype *CYP2C9**3 had less pain and improved functional recovery after tonsillectomy.[272] Celecoxib is currently on the FDA biomarker list, cautioning use in *CYP2C9* PM (dose reduction by 50% or alternate medication).

Acetaminophen and Genetics

APAP is primarily converted to two pharmacologically inactive conjugates: glucuronide (52%–57%) and sulfate (30%–44%), with a minor fraction undergoing oxidation to a reactive metabolite *N*-acetyl-p-benzoquinoneimine NAPQI (5%–10%).[273] *UGT1A1, UGT1A6, UGT1A9,* and *UGT2B15* are involved in APAP glucuronidation,[274] whereas a family of cytosolic enzymes, called *sulfotransferases* (*SULT*), are involved in the APAP sulfation (*SULT1A1, SULT1A3*).[275] APAP is bioactivated to the reactive intermediate (NAPQI)[276] by three CYP-450 isoforms: *CYP3A4, CYP2E1*, and *CYP1A2* of which *CYP2E1* is the most important. The contribution of *CYP3A4* to the production of NAPQI is controversial.[277,278] NAPQI is then conjugated with the sulfhydryl group of glutathione to form a nontoxic conjugate. APAP overdoses initially saturate sulfation, followed by glucuronidation; increased NAPQI production depletes glutathione stores, leading the NAPQI to bind to intracellular hepatic macromolecules to produce cell necrosis and damage.

Infants younger than 90 days postnatal age express less *CYP2E1* activity in vitro compared with older infants, children, and adults,[88] *CYP3A4* appears during the first week after birth, whereas *CYP1A2* appears later.[279] *CYP3A4* and *CYP1A2* activity in 12- to 48-month-old children exceeds that of all other stages of development and could potentially increase NAPQI production in 1- to 4-year-olds,[280] but this is favorably offset by an increased capacity to conjugate the drug with sulfate in this same age group. Nonetheless, two 10-fold overdoses of APAP and two reports of multiple doses from multiple caregivers who were unaware of the other doses[281] have been reported in infants and underscore the need for extreme care when administering and documenting IV acetaminophen.[282] Both infants with the massive APAP overdoses recovered fully.

UGT1A polymorphism c.2042C>G (rs8330) is associated with increased human liver APAP glucuronidation, an increased *UGT1A* exon 5a/5b splice variant/mRNA ratio, and decreased risk of unintentional APAP-induced acute liver failure.[283] Individuals carrying the *CYP3A5* rs776746 A allele were overrepresented among patients with acute liver failure who had intentionally overdosed with APAP with an odds ratio of 2.3 (95% CI = 1.1- 4.9, P = 0.034), although this was not significant after adjusting for multiple comparison testing.[284]

Chronic Pain, Persistent Postoperative Pain, and Genetics

Acute pain thresholds, in contrast to chronic pain levels, are less genetically determined (with estimated heritability scores of 22%–55%).[285] Chronic pain conditions of the neck and back pain in monozygotic versus dizygotic twins showed a heritable

component of up to 60%.[286] Imbalances in β_2-adrenergic receptor *(ADRβ2)* function increase the vulnerability to chronic pain conditions.[287] An association between a potassium channel modulatory subunit (KCNS1, also called Kv9.1) polymorphism and pain phenotype was identified in five of six independent chronic pain cohorts (including post–limb amputation and postmastectomy pain). The *KCNS1* allele missense rs734784 is one of the first described prognostic indicators of chronic neuropathic pain risk.[288]

Dramatically altered gene expression is also found in patients who subsequently develop persistent postoperative pain, with at least 10% of the transcriptome being dysregulated in traumatic injury models of neuropathic pain. These mechanisms involve sensitization of peripheral nociceptors (transient receptor potential, *TRPA1/TRPV1*),[289,290] central signaling systems affecting dorsal horn plasticity (for example, brainderived neurotrophic factor, *BDNF*),[291] and neuroimmune mechanisms including proinflammatory mediators (*interleukins, IL-6,* tumor necrosis factor *TNF*).[292] In chronic pain conditions such as inflammatory bowel disease, abdominal pain has been associated with increased capsaicin receptor *TRPV1* expressing sensory fibers in colonic biopsies.[293] The gene *BDNF*, a member of the neurotrophin family, also increased expression in colonic mucosa, along with structural alterations, suggesting contributions to the visceral hyperalgesia seen in these patients.[294] Systems that affect the distribution of δ- and μ-opioid receptors (*OPRM1*) also control heat pain, mechanical pain, opioid effects, and nerve injury–induced mechanical hypersensitivity.[295,296] Voltage-gated calcium channels control trafficking/pain conduction from the dorsal root ganglion to the presynaptic terminals at the dorsal horn[297] (*CACNA1A*), leading to hyperalgesia and allodynia, probably resulting from increased calcium-dependent release of pronociceptive neurotransmitters such as glutamate and substance P. Epigenetic effects on pain are illustrated by an epigenome study in identical twins, which showed the role of the *TRPA1* promoter in pain sensitivity,[298] association of *COMT* methylation with socioeconomic status,[299] and DNA demethylation at specific CpG sites in the *IL1B* promoter in response to inflammation.[300]

Pharmacogenomics Affecting Anesthesia

Genetics influence both the pharmacokinetics and pharmacodynamics of some agents commonly used in pediatric anesthesia, and hence could affect perioperative outcomes.

INTRAVENOUS ANESTHETICS

Propofol

The main enzyme that metabolizes propofol in hepatic as well as renal cortical microsomes is *UGT1A9* (53%), with secondary contribution from hydroxylation (38%), mainly through the *CYP2B6 and CYP2C9* in the liver.[301] Infants younger than 10 months have only 10% and at 1.3 years they have about 50% of adult CYP2B6 activity levels.[302] Very little is known about the developmental changes in *UGT1A9*. However, there is a 100-fold interindividual variability in activity of these enzymes throughout life. Propofol clearance varies more than 300% in the neonatal period with genetics thought to exert a greater influence on its clearance than age.[124,303] SNPs of *UGT1A9* affect glucuronidation: 2152C>T, -440C>T, -331T>C, -275T>A, and 98T>C.[304] In vitro studies of UGT1A9 expression from DNA isolated from Japanese volunteers showed that transversion of 766G>A in the *UGT1A9* gene that results in the substitution of amino acid D256N affected propofol glucuronidation kinetics.[305]

Propofol exerts its hypnotic actions by activation of the central inhibitory neurotransmitter GABA-A controlled by the *GABRE* gene.[306] Adverse effects of propofol have been described, including a rare but life-threatening complication called propofol infusion syndrome,[307] but it is not clear if genetic factors play a role. Although investigators report the time to loss of verbal contact and a bispectral index less than 70 varied 6.6- and 4.3-fold, respectively; after propofol induction in adults, there was 15.5- to 111-fold variability in the time to emergence, and the clearance of propofol varied greatly. However, there were no associations between variations in *CYP2B6* (R487C, K262R, and Q172) variants or *GABRE* variants (mRNA358G/T, 20118C/T, 20326C/T, and 20502A/T) and the observed interindividual variability in response.[308] To date, there is no conclusive evidence of PG variations affecting clinical outcomes with propofol anesthesia.

Dexmedetomidine is metabolized extensively in the liver by glucuronidation (*UGT1A4, UGT2B10*)[309,310] and hydroxylation, mediated by *CYP2A6*.[311] There is high interindividual variability in response to dexmedetomidine,[312] for which the role of CYP2A6 SNPs was evaluated for their effect on clearance. However, the studies concluded that CYP2A6 variants studied did not alter dexmedetomidine pharmacokinetics.[313,314] The sedative and anxiolytic effects of dexmedetomidine are mediated by subtypes of the α_2-adrenergic receptors, mainly by α-2A (*ADRA-2A*). Since receptor sensitivity would be expected to affect dexmetomidine pharmacodynamics, variants affecting *ADRA2A* have been studied. The effects of *ADRA2A* C1291G polymorphism on dexmedetomidine response were studied in 110 patients undergoing coronary artery bypass grafting. It was found that those with the G allele were less sedated than those with the C allele.[315] Similarly, certain SNPs were also found to be associated with statistically significant interindividual differences in blood pressure changes.[316]

INHALATIONAL ANESTHETICS

Inhalational anesthetics act through a different site on the *GABAA* receptor. Preschool-age children with the AA genotype in the *GABAγ2* nucleotide position 3145 in intron A/G exhibited a greater incidence of emergence agitation, compared with the non-AA genotype, after sevoflurane anesthesia.[317] The human melanocortin-1 receptor (*MC1R*) gene is expressed on the surface of melanocytes and affects melanin biosynthesis and pigmentation. Sex specificity in response to κ-opioid agonists has been demonstrated in both mice and humans. Women with two variant *MC1R* alleles displayed significantly greater analgesia from the κ-opioid, pentazocine, than all other groups.[318] Women with three particular mutations of the *MC1R* gene (R151C, R160W, and D294H) had increased desflurane anesthetic requirements.[319] Moreover, those with inactive variants had a particular phenotype of red hair and pale skin, lending credence to the perception of altered anesthetic and analgesic requirements in redheads. They are metabolized primarily by *CYP2E1* in the liver to varying degrees.[320] Although the tendency of halothane hepatitis to cluster in families points to a genetic contribution, the hereditary mechanisms involved have not been defined.[133]

Nitrous Oxide

The effects of genetic variants on nitrous oxide action are related to its inhibitory actions on methionine synthesis whose activated form, S-adenosylmethionine, is the principal substrate involved in the formation of the myelin sheath, neurotransmitters, and DNA synthesis in rapidly proliferating tissues. We know that nitrous oxide irreversibly oxidizes the cobalt atom of vitamin B_{12},

thereby inhibiting the activity of the cobalt-dependent enzyme methionine synthase, which is the catalyst for the formation of methionine. Hence, in a patient who has a deleterious mutation in the 5,10-methylenetetrahydrofolate reductase *(MTHFR)* gene, exposure to nitrous oxide can lead to neurologic deterioration. This occurred in a male infant whose neurologic status unexpectedly deteriorated; the infant died after two exposures to nitrous oxide for lumbar puncture.[321] Postmortem analysis showed 5,10-methylenetetrahydrofolate reductase deficiency in this infant's fibroblasts and a complex combination of mutations in his *MTHFR* gene, including C677T and A1298C SNPs associated with a reduction in the enzyme activity. Patients who were homozygote for these variants developed greater plasma concentrations of homocysteine after nitrous oxide anesthesia.[322] Although mitigated by B vitamin infusions, this was not found to be related to an increase in perioperative troponin.[323]

BENZODIAZEPINES

Midazolam exerts its primary effects by reversible interactions with the inhibitor GABA receptor in the central nervous system. It is primarily metabolized by the *CYP3A4/CYP3A5* enzymes in the liver to its hydroxyl derivatives. Hepatic CYP3A4 activity is reduced in neonatal versus adult livers, resulting in reduced midazolam clearance in the former.[324] Midazolam is metabolized mainly by hepatic hydroxylation (*CYP3A4*), followed by glucuronidation of the hydroxymetabolites.[325] *CYP3A7* is the dominant CYP3A enzyme in utero; it is expressed in the fetal liver and appears to have activity from as early as 50 to 60 days after conception. There appears to be a temporal switch in the immediate perinatal period and *CYP3A4* expression increases dramatically after the first postnatal week. Hepatic *CYP3A4* activity begins to dramatically increase at about 1 week of age, reaching 30% to 40% of adult expression by 1 month.[83] Drugs/foods that may interfere with the cytochrome isoforms that metabolize midazolam (*CYP3A4*) include grapefruit juice, erythromycin, calcium channel blockers, and protease inhibitors.[326–329] The net effect is to prolong the duration of action of midazolam.

Diazepam, which is mainly metabolized by the CYP2C19 enzyme[330] to desmethyldiazepam, acts by binding to a specific subunit on the GABAA receptor.[331] CYP2C19 polymorphisms found to affect diazepam clearance and emergence from general anesthesia in Japanese patients were classified as follows: no variants, *1/*1 (EM); one variant, *1/*2 or *1/*3 (intermediate metabolizers [IM]); and two variants, *2/*2, *2/*3 or *3/*3 (PM).[64] The presence of a SNP (G681A) of the CYP2C19 gene was found to be associated with impaired metabolism of diazepam in a gene-dosage effect manner (fourfold greater half-life in homozygotes and twofold greater half-life in heterozygotes carrying the SNP) in Chinese patients.[332] The human GABA-A receptor α-4 subunit is a unique diazepam-insensitive binding site, and it is hypothesized that variations at this site might explain differences in diazepam sensitivity among individuals.[333] A Pro385Ser (1236C>T) amino acid substitution in the human GABA-A α-6 subunit has also been found to play a role in benzodiazepine sensitivity.[334]

NEUROMUSCULAR BLOCKING DRUGS

Pseudocholinesterase deficiency and malignant hyperthermia are pharmacogenetic disorders recognized in the 1960s; the latter is discussed elsewhere (see Chapter 41). Butyrylcholinesterase (BChE) or pseudocholinesterase is the enzyme that hydrolyzes neuromuscular blocking agents such as succinylcholine and mivacurium, as well as ester local anesthetic agents. Deficient activity of the enzyme leads to prolonged apnea from succinylcholine and is caused by several factors, including genetic variants that affect the function of the enzyme.[335] More than 30 variants of the gene (*BChE*, 3q26.1-q26.3) have been described of which the two most common are the A (atypical) (209A>G, Asp70Gly) and the K (Kalow) variants (1615G>A, Ala539Thr).[336] The homozygosity incidence for the A variant is 3 : 1000 in Caucasians but may be as great as 1 : 175 individuals in some ethnicities in Iraq, Iran, and South India.[337,338] The BChE activity is decreased by 70% in A homozygotes and about 30% in the K homozygotes. Duration of apnea after 1.0 to 1.5 mg/kg of succinylcholine increases from 5 to 10 minutes in homozygous normal to 10 to 20, 20 to 35, and 35 to 60 minutes in heterozygous one abnormal gene, heterozygous two abnormal gene, and homozygous abnormal gene accordingly (see also Chapter 7).[339]

LOCAL ANESTHETICS

The effect of pseudocholinesterases on ester local anesthetics (LA) are less relevant in modern anesthesia. The more commonly used amide LAs, lidocaine and bupivacaine, are metabolized by *CYP3A4;* ropivacaine metabolized by *CYP1A2*. *CYP1A2* is not fully matured before age 3 years, and *CYP3A4* is not mature at birth, with the predominant fetal enzyme being *CYP3A7*. These developmental delays may explain increased risk for toxicity of amide LA in infants younger than 6 months of age.[340] Local anesthetics are sodium channel blockers; hence genetic mutations within the *sodium channel gene* are likely to cause variable binding and efficacy for these drugs. In vitro experiments have shown that the N395K mutation in the *SCN9A* gene attenuates the inhibitory effect of lidocaine on the Nav1.7 channels and produces greater resistance to lidocaine.[341] One case report indicated that bupivacaine induced electrocardiographic and arrhythmic manifestations of the Brugada syndrome in silent carriers of a cardiac sodium channel SCN5A missense mutation, leading to a reduction in sodium current by whole-cell patch-clamping analysis.[342] Lidocaine also acts on vanilloid receptors belonging to the *TRPA1* and *TRPV1* family on sensory neurons, whereby calcitonin gene-related peptide (CGRP), a vasodilatory and nociceptive transmitter, is released.[343,344] A point mutation induced at residue R701 of *TRPV1* led to diminished lidocaine sensitivity in mice.[344] Similar to inhalation anesthesia, *MC1R* variants (phenotypes with red hair) have been found to be more sensitive to thermal pain with reduced subcutaneous lidocaine effectiveness.[345]

Perioperative Outcomes

POSTOPERATIVE NAUSEA AND VOMITING

A genome-wide association study on motion sickness in 80,494 individuals concluded that 35 SNPs involved in balance, glucose homeostasis, and other nervous system roles played an important part in motion sickness and likely, PONV as well.[346] In addition, correlations have been reported between A2A2 alleles at the dopamine D2 receptor (*DRD2*) (Taq1A SNP)[347,348] as well as rs2165870 SNP in the promoter region of the M3 muscarinic acetylcholine receptor (*CHRM3*) gene with PONV.[349] *CYP2D6* is the enzyme that metabolizes commonly used agents for PONV, such as the 5-HT_3 receptor antagonists (ondansetron, palonosetron, and dolasetron), which are less effective in *CYP2D6* UM. The incidence of vomiting (and hence ondansetron failure) in women undergoing surgery with three *CYP2D6* copies was

significantly greater compared with those with two copies, but not from those with one copy. When analyzed by genotype, the incidence of vomiting in PM, IM, EM, and UM were 8%, 17%, 15%, and 45%, respectively ($P < 0.01$).[350] Only granisetron is primarily metabolized by *CYP3A4* and may have a better effect in *CYP2D6* UM patients.[351] Although palonosetron is metabolized by 2D6, its duration of action is independent of its clearance because it binds allosterically and exhibits positive cooperativity with the 5-HT_3 receptor, deforming the conformational structure of the receptor, which takes 36 to 48 hours to return to normal.

PERIOPERATIVE BLEEDING

Postoperative bleeding after cardiac surgery has been associated with SNPs of coagulation proteins and platelet glycoproteins (GPIaIIa-52C>T and 807C>T, GPIb alpha 524C>T, tissue factor -603A>G, prothrombin 20210G>A, tissue factor pathway inhibitor-399C>T, and angiotensin-converting enzyme [ACE] deletion/insertion).[352] Plasminogen activator inhibitor 1 (PAI-1) attenuates the conversion of plasminogen to plasmin, and the use of plasminolytic inhibitors may be subject to PAI-1 variants. In a study that evaluated the effectiveness of tranexamic acid (TXA) for reducing postoperative chest tube blood loss in adults undergoing cardiac bypass, patients with plasminogen activator inhibitor-1 5G/5G homozygotes who did not receive TXA showed more postoperative bleeding than those with other *PAI-1* genotypes. Those with 5G/5G homozygotes who received TXA showed the greatest blood-sparing benefit.[353]

HEMODYNAMIC RESPONSE

The β_2-adrenergic (β2-ADR) receptor is a member of the 7-transmembrane domain family of receptors which is encoded by a gene located on chromosome 5 (β2-ADR, 5q31-q32). The β2-adrenergic receptor controls vascular and bronchial smooth muscle tone, and hence controls both response to bronchodilators and may contribute to vasopressor responses after laryngoscopy[354,355] and regional anesthesia. While nine β2-ADR variants have been described,[356] the most extensively studied are the Arg16Gly and the Gln27Glu variants, which are in linkage disequilibrium. Mechanistically, it appears that 16Gly variants have enhanced agonist-induced β -ADR downregulation, while the Arg16 genotype shows complete absence of downregulation,[357] which implies that Arg16 and Gln27 homozygotes will be more sensitive to β_2-agonist effects. In accordance, blood pressure variability after neuraxial anesthesia was found to be predicted by variant Arg16Arg (less hypotension)[358] and Glu27 (more hypotension)[359] in two different studies. Similarly, phenylephrine dose was increased by 200 µg in women with the Arg16 homozygous genotype compared with those with the Gly16 homozygous genotype while undergoing cesarean delivery under spinal anesthesia.[360] A detailed review of the *β2-ADR* gene can be found elsewhere.[361]

EFFECT ON OTHER PERIOPERATIVE OUTCOMES

Genetic risk factors have been identified for perioperative cardiac ischemia and arrhythmias,[362] as well as neurologic outcomes such as cognitive dysfunction/stroke,[363] which are beyond the scope of this chapter. Readers are referred to a review on perioperative outcomes for further elaboration.[6] There is a potential mechanistic pathway for perioperative cardiac ischemia and stroke influenced by inflammatory superseded thrombosis-related genes. Associations between specific genetic variants and perioperative renal compromise,[364] protection against sepsis,[365] inflammatory response, and graft rejection after heart and lung transplants[366] have also been described.

Ancestry/Race and Genetics

The "Out of Africa" theory of human migration advocates for a common origin of human races.[367] The definitions of "race" defined by physical characteristics and "ethnicity" based on sociocultural factors are complicated by genetic admixture and interracial mating.[368] Consequently, genetic studies often use ancestry information markers (AIMs), which are a set of haploid makers (mitochondrial DNA or Y-chromosome haplotypes) or multiple unlinked autosomal markers that are diploid, that exhibit substantially different frequencies between populations from different geographic regions as a basis for race. An ideal AIM should have one allele that is fixed (i.e., allele frequency of 1.0) in one ancestral population and not present in the other,[369] but since the level of genetic variation between human populations is only 5% to 10%, there are challenges with genetic ancestry inference.[370]

The influence of race and ethnicity exists in frequency distribution of polymorphisms of genes encoding drug-metabolizing enzymes, transporters, and receptors.[371] As mentioned earlier, examples are the ethnic differences of pharmacokinetic enzymes such as CYP2D6; UM phenotypes, which are more prevalent among Sub-Saharan populations and low among Caucasians; and in *OPRM1,* where the frequency of the A118G allele is estimated to be much higher in the Asian (46%) compared with European and African American populations (5% to 25%).[210] African American children clear morphine more rapidly than their Caucasian counterparts, which is likely due to differences in allele frequencies for *OCT1* variants.[194,372]

Race has been associated with an unequal burden of perioperative pain and opioid adverse effects in children. Caucasian children had less postoperative pain and more opioid-related adverse effects postoperatively despite reduced opioid doses after tonsillectomy.[372] African American and Hispanic patients also have reduced tolerance for experimentally induced pain compared with Caucasians.[373,374] In another cohort of children who had tonsillectomies, ethnicity affected morphine-induced outcomes; children of Latin ethnicity had more adverse effects from morphine compared with those of non-Latin ethnicity. No genetic variants examined contributed to these differences.[375] While most studies have focused on Caucasian and African American group differences, some studies have reported reduced pain tolerance in Asian Americans compared with non-Hispanic whites.[376] These findings assume importance as race can affect differential treatment of groups, and while this will lead to individualization, it can also lead to overtreatment or undertreatment if it is unclear whether the differences are genetic versus based on race.

Racial disparities are reported in the prescription of opioid analgesics for management of postoperative pain.[377] African Americans and Hispanic Americans were prescribed fewer analgesics than their non-Hispanic white counterparts; these two groups also took their analgesics less frequently than prescribed and experienced limited pain relief from analgesic medications.[378] This has been contradicted by other studies showing decreased opioid requirements and higher sensitivity in African Americans.[379] The effects of race and ethnicity may be medication-specific and affected by numerous contextual factors and should be interpreted with care.[380]

Pharmacogenomics Methods

COMMON GENOTYPING METHODS

There are many options for genotyping. The most commonly used for anesthesia and pain-related pharmacogenetic research and clinical practice are the candidate gene approach and SNPs testing. Other more comprehensive and expensive genotyping include genome-wide association study (GWAS) platforms with 500,000 to 5 million SNPs, whole-exome sequencing (WES), and whole-genome sequencing (WGS) with different depth of coverages. In the past decade, the overall the cost of genotyping has decreased significantly. With the whole-exome and whole-genome sequencing approaches, large amounts of genetic data are typically generated per patient; analyzing and associating any clinical outcome or condition would require a large sample size and complex and robust analytical methods.

COMMON LIMITATIONS OF GENETIC RESEARCH STUDIES AND INTERPRETATION OF GENETIC STUDIES

Interpretation of genetic studies is often limited by study inadequacies (e.g., lack of adequate sample sizes needed to analyze multiple genes or polymorphisms), mostly owing to the expense of genetic testing and population stratification for different racial and ethnic backgrounds. Moreover, publication bias; the winner's curse; statistical and bioinformatics analytical challenges in adjusting for gene and environmental interactions; the lack of reproducibility of results in independent and external cohorts; and the inability to validate genetic associations with mechanistic studies also lead to inadequate proof for clinical implementation of genetic information in clinical care to personalize interventions and care. In addition to genetic risk factors, other factors may influence clinical outcome measures. Thus pharmacogenetic studies also need to be complemented by epigenetic, proteomic, transcriptomic, and metabolomic information to gain additional knowledge and insight to improving personalized care.

CURRENT COSTS OF GENOTYPING AND THIRD-PARTY COVERAGE FOR GENOTYPING

Currently, access to preoperative genotyping, robust evidence to change clinical practice based on underlying genetic risk factors, affordability, and payer coverage for genetic testing are limited. As compelling evidence for personalization of perioperative care based on genetic risk factors (e.g., *CYP2D6* and codeine-related deaths, *RYR1* and malignant hyperthermia) increases, there will be better adaptability of routine preoperative genotyping and coverage of such services by third-party payers. For example, many third party-payers are covering perioperative *CYP2D6* genotyping for prescription of oral opioids in our pediatric institution.

Genetic Counseling

Another ethical fallout of pharmacogenomic research, especially in pediatrics, is the need for genetic counseling. Findings need to be conveyed to children and parents. Assistance with interpretation of incidental findings from secondary analyses may be required. Genetic counselors help patients and their families understand and adapt to the medical, psychological, and familial implications of genetic contributions to clinical outcomes and/or disease, and need to be an integral part of such research efforts. Genetic counseling has been provided traditionally for single-gene conditions (e.g., malignant hyperthermia and *RYR1* gene). As we transition from single-gene testing and genetic counseling to a full genomic medicine approach, clinical implications will get more complex for most of health care professionals.[381] One potential solution would be development of clinical outcome or disease-related multigenic clinical decision support algorithms for more effectively helping patients and health care professionals.

Clinical Translation: Bench to Bedside: Where Are We Now?

As we routinely use the global positioning system to navigate maps and roads, in the future, it is anticipated that we will use a genomic prescribing system (GPS) to proactively identify underlying genetic risks and guide personalized care.[382] Proactive identification of patients at risk of adverse perioperative outcomes is an important first step in guiding personalized interventions, preferably with electronic health record (EHR)-implemented clinical decision support integrating genetic risk factors and their implications for clinical interventions.

To implement pharmacogenomics-based clinical decision support, there is a need for more robust study designs, independent validations, larger study populations, and robust statistical approaches.[383,384] To realize the promise of personalized medicine to perioperative care, we need better evidence in terms of validating clinical association studies engaging physicians, patients, the pharmaceutical industry, health care, payers, and policy makers.

In the field of perioperative pain management and opioid responses, polymorphisms of genes involved in pain pathways (*COMT*[68]), morphine's pharmacokinetics (*OCT1*[194]), ABC B1 and C3 genes (*ABCB1*[201] and *ABCC3*[194,197,198,385]), and pharmacodynamics[139,165,386–390] (*FAAH*[391]), and opioid μ-receptor 1 (*OPRM1*[224]) play a major role in determining postoperative clinical and economic outcomes. These genetic risk factors relevant to opioid pharmacogenetics and surgical pain management have translational promise to improve clinical practice and outcomes. Since genetic association studies do not explain causality, additional research to identify biologic and mechanistic pathways would be needed for better insight to risk stratification and targeted interventions influencing the mechanistic pathways.

Conclusion

Pharmacogenetics pertaining to anesthesia is still an evolving field with exciting prospects in the future, so that anesthesia and analgesia can be individualized using a reactive rather than "trial and approach" strategy. It is important to realize that genetics needs to be combined with other factors to make an individualized approach comprehensive. Completion of the Human Genome Project, as well as rapidly accumulating data in this field from knock-in and knock-out genetic animal models, laboratory-based cell line experiments, and human studies poses a huge challenge in the understanding, education, and interpretation of results and applicability. An average proteomic experiment, for example, might generate 10,000 to 1,000,000 individual data points, with countless potential interactions between data points. Hence, a few web-enabled resources may be worth mentioning, especially given the daily updates that happen with current publications (Table 6.5).

The ultimate goal of pharmacogenetics research is clinical translation. Examples of translational potential include the proposed genomic prescribing system to guide therapy,[382] the genotype-based dosing of opioids based on *OPRM1*, *COMT,* and *MC1R*,[392,393]

TABLE 6.5 Online Resources for Current Pharmacogenomics Information

Online Resource	Description and Uses
The Pharmacogenomics Knowledgebase www.pharmgkb.org	A comprehensive resource that curates knowledge about the impact of genetic variation on drug response for clinicians and researchers. This knowledge base can be searched by gene, drug or clinical phenotype, and provides in-depth information about pharmacogenomics, curated publications to clinical implementation guidelines.
Encyclopedia of DNA Elements (ENCODE) Consortium www.encodeproject.org	Provides a comprehensive parts list of functional elements in the human genome, including elements that act at the protein and RNA levels, and regulatory elements that control cells and circumstances in which a gene is active.
Genotype-Tissue Expression (GTEx) project www.gtexportal.org	This project provides the scientific community a resource with which to study human gene expression and regulation and its relationship to genetic variation. This project collects and analyzes multiple human tissues from donors for this purpose. By analyzing global RNA expression within individual tissues and treating the expression levels of genes as quantitative traits, variations in gene expression that are highly correlated with genetic variation can be identified as expression quantitative trait loci (eQTLs).

and genetic risk signatures for opioid-induced respiratory depression.[389] The Electronic Medical Records and Genomics (eMERGE) Network, announced in September 2007, is a National Institutes of Health –organized and –funded consortium of U.S. medical research made up of nine institutions with unique and valuable pioneer experience using a variety of commercial and homegrown EHRs. The challenges and solutions for integrating genomic data into the EHR, creation of integrated genomic decision support, and the human and electronic processes, including standards required for such successful integration, are still a work in progress.[394,395]

In conclusion, the future of precision medicine was aptly described and emphasized by President Barack Obama in his State of the Union address on January 20, 2015: "*I want the country that eliminated polio and mapped the human genome to lead a new era of medicine—one that delivers the right treatment at the right time.*"[396]

ANNOTATED REFERENCES

Andrzejowski P, Carroll W. Codeine in paediatrics: pharmacology, prescribing and controversies. *Arch Dis Child Educ Pract Ed.* 2016;101(3):148-151.

This article highlights the safety and efficacy aspects of codeine use in children, a very contemporary and important topic. The authors discuss the developmental pharmacology, pharmacokinetics, pharmacodynamics, and pharmacogenetics of codeine in children, how this relates to prescribing, as well as the practical issues and the recent regulatory framework surrounding its use.

Chidambaran V, Mavi J, Esslinger H, et al. Association of OPRM1 A118G variant with risk of morphine-induced respiratory depression following spine fusion in adolescents. *Pharmacogenomics J.* 2015;15(3):255-262.

This article is the first clinical study to show that the opioid receptor polymorphism A118G influences susceptibility to morphine-induced respiratory depression in children.

Chidambaran V, Venkatasubramanian R, Zhang X, et al. ABCC3 genetic variants are associated with postoperative morphine-induced respiratory depression and morphine pharmacokinetics in children. *Pharmacogenomics J.* 2017;17(2):162-169.

This article presents the first study to report association of ABCC3 variants with both morphine pharmacodynamics (opioid-related respiratory depression) and morphine pharmacokinetics (metabolite formation) in two independent surgical cohorts.

Crews KR, Gaedigk A, Dunnenberger HM, et al. Clinical Pharmacogenetics Implementation Consortium guidelines for cytochrome P450 2D6 genotype and codeine therapy: 2014 update. *Clin Pharmacol Ther.* 2014;95(4):376-382.

This article summarizes the evidence from the literature supporting the association of CYP2D6 activity and polymorphisms, provides therapeutic recommendations for codeine based on the CYP2D6 genotype, and includes essential guidelines for prescribing pediatric providers.

Sadhasivam S, Chidambaran V, Zhang X, et al. Opioid-induced respiratory depression: ABCB1 transporter pharmacogenetics. *Pharmacogenomics J.* 2015;15(2):119-126.

This article shows that ABCB1 polymorphisms may affect blood-brain barrier transport of morphine, and therefore individual response to its central analgesic and adverse effects in postsurgical children.

THE PHARMACOKINETICS AND PHARMACODYNAMICS of most medications in children, especially neonates, differ from those in adults.[1] Children exhibit different pharmacokinetics (PK) and pharmacodynamics (PD) from adults because of their immature renal and hepatic function, different body composition, altered protein binding, distinct disease spectrum, diverse behavior, and dissimilar receptor patterns.[2–8] PK differences necessitate modification of the dose and the interval between doses to achieve the desired concentration associated with a clinical response and to avoid toxicity.[9–12] In addition, some medications may displace bilirubin from its protein binding sites and possibly predispose to kernicterus in premature neonates.[13–18] Drug effect (PD) may be influenced by altered capacity of the end organ, such as the heart or bronchial smooth muscle, to respond to medications in children compared with adults. In this chapter we discuss basic pharmacologic principles as they relate to drugs commonly used by anesthesiologists.

Pharmacokinetic Principles and Calculations

Changes in drug concentrations within the body over time are referred to as *pharmacokinetics*. The principles and equations that describe these changes can be used to adjust drug doses rationally to achieve more effective drug concentrations at the site of action.[19,20] The equations in this section are intended for general and practical use, whereas the more rigorous mathematical intricacies of PK are covered elsewhere.[21,22]

Within the body, a drug may diffuse between several body fluids and tissues at different rates, yet the consistent change in its circulating concentration may be used to characterize its kinetics and to guide dosages. The rate of removal of drug from the circulation is usually described using either first-order or zero-order exponential equations. The difference between these two types of rates has important implications for drug treatment.

FIRST-ORDER KINETICS

Most drugs are cleared from the body with first-order exponential rates in which a constant fraction or constant proportion of drug is removed per unit of time. Because the proportion of drug cleared remains constant, the greater the concentration, the greater the amount of drug removed from the body. Such rates can be described by exponential equations that fit the following form:

$$C = C_0 e^{-kt} \qquad \text{Eq. 7.1,}$$

where C is the concentration at time t, C_0 is the starting concentration (a constant determined by the dose and distribution volume), e is the base of the natural logarithm (~2.71828), and k is the elimination rate constant with units of time^{-1}. First-order indicates that the exponent is raised to the first power ($-kt$ in Eq. 7.1). Second-order equations are those that are raised to the second power, such as $e^{(z)2}$. First-order exponential equations, such as Eq. 7.1, may be converted to the form of the equation of a straight line (y = mx + b, where x and y are variables [e.g., time and concentration], m is the slope parameter, and b is a constant) by taking the natural logarithm of both sides, after which they may be solved by linear regression.

$$\ln C = \ln C_0 + (-kt) \qquad \text{Eq. 7.2}$$

If ln C (i.e., natural logarithm of C) is graphed versus time, the slope is $-k$, and the intercept is ln C_0. If log C (i.e., common logarithm of C) is graphed versus time, the slope is $-k/2.303$, because ln x equals 2.303 log x. When graphed on linear-linear axes, exponential rates are curvilinear and on semilogarithmic axes, they produce a straight line.

HALF-LIFE

Half-life, the time for a drug concentration to decrease by one-half, is a familiar exponential term used to describe the kinetics of many drugs. *Half-life is a first-order kinetic process because the same proportion or fraction of the drug is removed during equal periods of time.* As described earlier, the greater the starting concentration, the greater the amount of drug removed during each half-life.

Half-life can be determined by several methods. If concentration is converted to the natural logarithm of concentration and graphed versus time, as described in Eq. 7.2, the slope of this graph is the elimination rate constant, k. For both accuracy and precision, at least three concentration-time points should be used to determine

the slope, and they should be obtained over an interval during which the concentration decreases at least by half. In clinical practice, for infants and small children, however, k is often estimated from just two concentrations obtained during the terminal elimination phase. With multiple data points, the slope of ln C versus time may be calculated easily by least squares linear regression analysis. Half-life ($T_{1/2}$) may be calculated from the elimination rate constant, k (time^{-1}), as follows:

$$T_{1/2} = \frac{Natural\ Logarithm(2)}{k} = \frac{0.693}{k} \qquad \text{Eq. 7.3}$$

Graphic techniques may be used to determine half-life from a series of timed measurements of drug concentration. The concentration-time points should be graphed on semilogarithmic axes and used to determine the best-fitting line either visually or by linear regression analysis. This approach is illustrated in Fig. 7.1, in which the least squares regression line has been fitted to the concentration-time points and crosses a concentration of 20 µg/mL at 100 minutes and a concentration of 10 µg/mL at 200 minutes. The concentration decreased by one-half in 100 minutes, so the half-life is 100 minutes. The elimination rate constant is 0.693/100 per minute or 0.00693 per minute.

Elimination half-life is of no value for characterizing the disposition of many intravenous (IV) anesthetic drugs during dosing periods relevant to anesthesia. A more useful concept is that of the context-sensitive half-time (CSHT) where "context" refers to the duration of the infusion. This is the time required for the plasma drug concentration to decrease by 50% after terminating the infusion.[23] The CSHT is the same as the elimination half-life for a one-compartment model and does not change with the duration of the infusion. However, most drugs in anesthesia conform to multiple compartment models and the CSHTs are markedly different from their respective elimination half-lives.

CSHT may be independent of the duration of the infusion (e.g., remifentanil, 2.5 minutes); be moderately affected (propofol, 12 minutes at 1 hour, 38 minutes at 8 hours); or display marked prolongation (e.g., fentanyl, 1 hour at 24 minutes, 8 hours at 280 minutes). This is a result of the return of drug from peripheral compartments to plasma after stopping the infusion. Peripheral compartment sizes and clearances in children differ from adults and at termination of the infusion, more or less drug remains in the body in children for any given plasma concentration compared with adults. The CSHT for propofol in children, for example, is greater than that in adults.[24] The CSHT gives insight into the PK of a drug, but the parameter may not be clinically relevant; the percentage decrease in concentration required for recovery from the drug effect is not necessarily 50%.

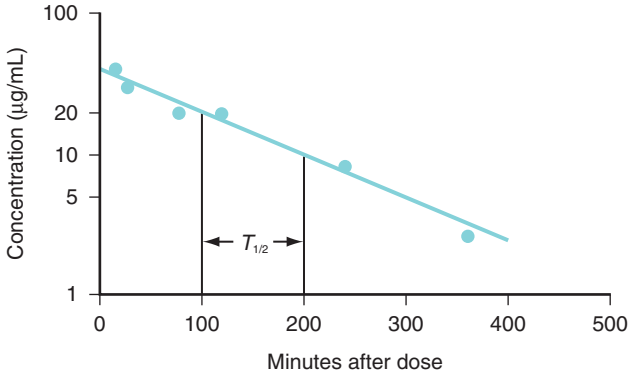

FIGURE 7.1 Graphic determination of half-life. Half-life can be determined from a series of concentration-time points on a semilogarithmic graph if the kinetics are first-order exponential. The concentrations are plotted on semilogarithmic axes; the best-fit line is drawn through the points; convenient concentrations are chosen that decrease in half, such as 20 µg/mL and 10 µg/mL, as illustrated; and the interval between those concentrations is the half-life, which is 100 minutes in the illustration.

FIRST-ORDER SINGLE-COMPARTMENT KINETICS

The number of exponential equations required to describe the change in concentration determines the number of compartments. Although a drug may diffuse among several tissues and body fluids, its clearance often fits first-order, single-compartment kinetics if it quickly distributes homogeneously within the circulation and is removed rapidly from the circulation through metabolism or excretion. This may be judged visually if a semilogarithmic graph of the change in drug concentration fits a single straight line. Kinetics may appear to be single-compartment, when they are really multiple compartments, if drug concentrations are not measured soon enough after IV administration to detect the initial distribution phase (α phase).

FIRST-ORDER MULTIPLE-COMPARTMENT KINETICS

If drug concentrations are measured several times within the first 15 to 30 minutes after IV administration as well as during a more prolonged period, more than one elimination phase is often present. This can be observed as a marked change in slope of a semilogarithmic graph of concentration versus time (Fig. 7.2). The number and nature of the compartments required to describe the clearance of a drug do not necessarily represent specific body fluids or tissues. When two first-order exponential equations are required to describe the clearance of drug from the circulation, the kinetics are described as first-order, two-compartment (e.g., central and peripheral compartments) that fit the following equation (see Fig. 7.2):

$$C = Ae^{-\alpha t} + Be^{-\beta t}, \qquad \text{Eq. 7.4}$$

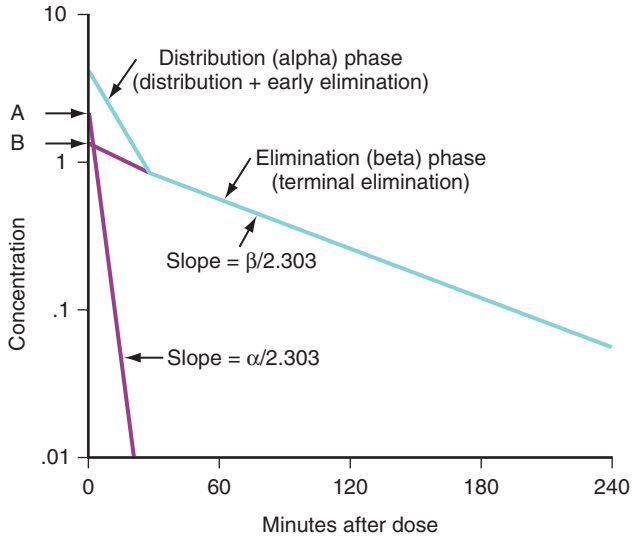

FIGURE 7.2 Two compartment kinetics in a semilogarithmic graph. The initial rapid decrease in serum concentration reflects distribution and elimination followed by a slower decrease because of elimination. *A* is the concentration at time 0 for the distribution rate. Subtraction of the initial decrease in concentration resulting from elimination, using the concentrations from the elimination line extrapolated back to time 0 at *B*, produces the lower line with a steep slope = α(distribution rate constant)/2.303. The terminal elimination phase has a slope = β(elimination rate constant)/2.303.

where concentration is C, t is time after the dose, A is the concentration at time 0 for the distribution rate represented by the purple line graph with the steepest slope, α is the rate constant for distribution, *e* is base of natural logarithm, B is the concentration at time 0 for the terminal elimination rate, and β is the rate constant for terminal elimination. Rate constants indicate the rates of change in concentration and each corresponds to the slope of the respective line divided by 2.303 for logarithm concentration versus time.

Such two-compartment or biphasic kinetics are frequently observed after IV administration of drugs that rapidly distribute out of the central compartment of the circulation to a peripheral compartment. In such situations, the initial rapid decrease in concentration is referred to as the α or distribution phase and represents distribution to the peripheral (tissue) compartments in addition to drug elimination. The terminal (β) phase begins after the inflection point in the line when elimination starts to account for most of the change in drug concentration. To determine the initial change in concentration as a result of distribution (see Fig. 7.2), the change in concentration that results from elimination must be subtracted from the total change in concentration. The slope of the line representing the difference between these two rates is the rate constant for distribution.

These parameters (A, B, α, β) have little connection with underlying physiology, and an alternative parameterization is to use a central volume and three rate constants (k_{10}, k_{12}, k_{21}) that describe drug distribution between compartments. Another common method is to use two volumes (central, V1; peripheral, V2) and two clearances (CL, Q). Q is the intercompartment clearance, and the volume of distribution at steady state (Vdss) is the sum of V1 and V2. A more detailed mathematical discussion may be found elsewhere.[19,22]

Although many drugs demonstrate multiple-compartment kinetics, traditional studies of kinetics in neonates did not include enough samples immediately after dosing to identify more than one compartment. For clinical estimates of dose and dosing intervals, it is often not necessary to use multiple-compartment kinetics. To minimize cost, limit blood loss, and simplify PK calculations, dose adjustments are often based on only two plasma concentrations (peak and trough), and linear, single-compartment kinetics (such as that of gentamicin and vancomycin) is assumed. Because the elimination rate constant should be determined from the terminal elimination phase, it is important that peak concentrations of multiple-compartment drugs not be drawn prematurely–that is, during the initial distribution phase. If drawn too early, the concentrations will be greater than those during the terminal elimination phase (see Fig. 7.2), which will overestimate the slope and the terminal elimination rate constant. Population modeling has improved analysis and interpretation of such data.[25,26]

ZERO-ORDER KINETICS

The elimination of some drugs occurs with loss of a *constant amount per time, rather than a constant fraction per time.* Such rates are termed zero-order, and because $e^0 = 1$, the change in the amount of drug in the body fits the following equation[27]:

$$-dA/dt = k_0, \qquad \text{Eq. 7.5}$$

where dA is the change in the amount of drug in the body (in milligrams), dt is the change in time, and k_0 is the elimination rate constant with units of amount per unit time. After solving this equation, it has the following form:

$$A = A_0 - k_0 t, \qquad \text{Eq. 7.6}$$

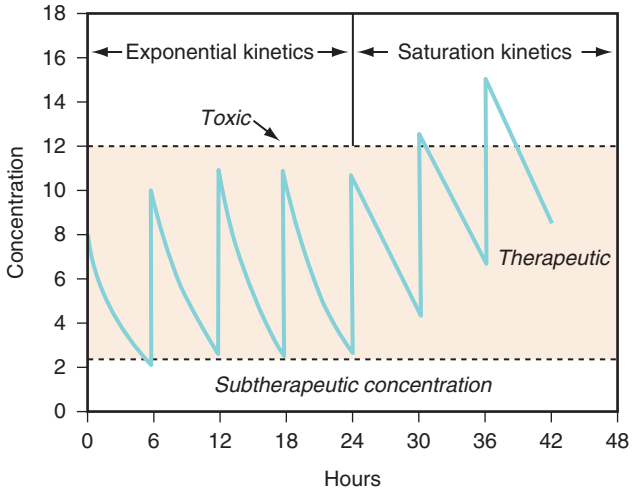

FIGURE 7.3 Transition from exponential to saturation kinetics. During every-6-hour dosing, concentrations during the first 24 hours reflect exponential kinetics with a half-life of 3 hours ($k = 0.231$/hour) followed by a change to saturation kinetics at 24 hours with elimination of 1 mg/hour, leading to drug accumulation to toxic concentrations.

where A_0 is the initial amount of drug in the body and A is the amount of drug in the body (in milligrams) at time t.

Zero-order (also known as Michaelis-Menten) kinetics may be designated saturation kinetics, because such processes occur when excess amounts of drug saturate the capacity of metabolic enzymes or transport systems. In this situation, only a constant amount of drug is metabolized or transported per unit of time. If kinetics are zero order, a graph of serum concentration versus time is linear on linear-linear axes and is curved when graphed on linear-logarithmic (i.e., semilogarithmic) axes. Clinically, first-order elimination may become zero order after administration of excessive doses or prolonged infusions or during dysfunction of the organ of elimination. Certain drugs administered to neonates exhibit zero-order kinetics at therapeutic doses and may accumulate to excessive concentrations, including thiopental, theophylline, caffeine, diazepam, furosemide, and phenytoin. Some drugs (e.g., phenytoin, ethyl alcohol) may exhibit mixed-order kinetics (i.e., first order at low concentrations and zero order after enzymes are saturated at greater concentrations). For these drugs, a small increment in dose may cause disproportionately large increments in serum concentrations (Fig. 7.3).

APPARENT VOLUME OF DISTRIBUTION

The apparent volume of distribution (Vd) is a mathematical term that relates the dose to the circulating concentration observed immediately after administration. It might be viewed as the volume of dilution that can be used to predict the change in concentration after a dose is diluted within the body (i.e., a scaling factor). Vd does not necessarily correspond to a physiologic body fluid or tissue volume, hence the designation "apparent." For drugs that distribute out of the circulation or bind to tissues, such as digoxin, Vd may reach 10 L/kg, a physical impossibility for a fluid compartment in the body. This illustrates the mathematical nature of Vd. The units used to express concentration are amount per unit volume, and dose is expressed as the amount per kilogram and the Vd as volume per kilogram that dilutes the dose to produce the concentration as the ratio:

$$\text{Concentration (mg/L)} = \frac{\text{Dose (mg/kg)}}{\text{Vd (L/kg)}} \qquad \text{Eq. 7.7}$$

If concentration is expressed with the unconventional units of milligrams per liter rather than micrograms per milliliter (which are equivalent), it is easier to balance the equation. This equation serves as the basis for most of the PK calculations because it is easily rearranged to solve for Vd and dose. It is also important to note that this equation represents the change in concentration after a rapidly administered IV dose of a drug. After a mini-infusion (e.g., of vancomycin or gentamicin), a more complex exponential equation may be required to account for drug elimination during the time of infusion. For neonates in whom drug elimination is relatively slow, only a small fraction of drug is eliminated during the time of infusion, and such adjustments can be omitted, whereas more complex equations may be needed in older children.

Knowledge of the apparent Vd is essential for dose adjustments. Vd may be calculated by rearranging Eq. 7.7:

$$\text{Vd (L/kg)} = \frac{\text{Dose (mg/kg)}}{\text{C (postdose)} - \text{C (predose) (mg/L)}} \qquad \text{Eq. 7.8}$$

The concentration after a drug infusion, C (postdose), must be measured after the distribution phase to avoid overestimating the peak concentration that would, in turn, lead to an erroneously low Vd. For the first dose, the predose concentration is 0.

Pharmacokinetic Example

The following example illustrates the application of these PK principles using a four-step approach: (1) calculate Vd; (2) calculate half-life; (3) calculate a new dose and dosing interval based on a desired peak and trough; and (4) check the peak and trough of the new dosage regimen.

For example, vancomycin was administered in a dose of 15 mg/kg IV over 60 minutes every 12 hours. The plasma concentrations were measured on the third day of treatment (presumed steady state). The predose or trough concentration was 12 mg/L; the peak concentration, measured 60 minutes after the *end* of the infusion, was 32 mg/L:

$$\text{Vd (L/kg)} = \frac{15 \text{ mg/kg}}{32 \text{ mg/L} - 12 \text{ mg/L}} = 0.75 \text{ L/kg}$$

Step 1: Substituting the data into Eq. 7.8, we calculate Vd.

Step 2: At steady state, peak and trough concentrations reach the same levels after each dose. The time between the peak and trough concentrations is 10 hours–that is, 12 hours minus 1 hour infusion minus 1 hour to peak concentration. Half-life may be solved by rearranging Eq. 7.2 to solve for k (elimination rate constant) and substituting the calculated k into Eq. 7.3. In this case, the calculated elimination rate constant is 0.098/hour and the corresponding half-life is 7.1 hours. However, a practical and clinically applicable "bedside" approach may be used without need for logarithmic calculations. For example, the plasma concentration decreased from 32 to 16 mg/L in one half-life and then from 16 to 12 mg/L in a fraction of the second half-life. At the end of the second half-life, the concentration would have decreased to 8 mg/L. Because 12 mg/L is the midpoint between the first and second half-lives, 1.5 half-lives have elapsed during the 10 hours between the peak and trough. Thus if one assumes a linear decline, the half-life may be estimated as 6.67 hours (10 hours ÷ 1.5 half-lives). Note that the error between the actual half-life of 7.1 hours and the estimated half-life (6.67 hours) is a result of the linear assumptions of this calculation between half-lives. In fact, first-order elimination is a nonlinear process and concentration will actually decline from 32 mg/L to 22.6 mg/L during the first 50% of the first half-life rather than from 32 mg/L to 24 mg/L using this linear approach. The same occurs during subsequent half-lives. However, the small error associated with this method is often acceptable for rapid bedside estimates of PK parameters.

Step 3: A new dosage regimen must be calculated if the concentrations are unsatisfactory. Accordingly, one must decide on a desired peak and trough concentration. If, for example, the desired vancomycin peak and trough concentrations were 32 mg/L (20–40 mg/L) and 8 mg/L (5–10 mg/L), respectively, then Eq. 7.8 may be rearranged to solve for the new dose:

$$\begin{aligned}\text{Dose (mg/kg)} &= \text{Vd (L/kg)} \times [\text{C (peak desired)} - \text{C (trough desired) (mg/L)}] \\ \text{Dose (mg/kg)} &= 0.75 \text{ L/kg} \times (32 \text{ mg/L} - 8 \text{ mg/L}) \\ \text{Dose (mg/kg)} &= 18 \text{ mg/kg}\end{aligned} \qquad \text{Eq. 7.9}$$

The current dose produces a peak of 32 mg/L that is in the recommended therapeutic range, and extending the dosing interval to 2 half-lives (hours) after the peak is reached (2 hours after beginning the dose infusion) will produce a trough concentration of 8 mg/L. The dose interval should be increased to 16 hours and the dose increased to 18 mg/kg.

Step 4: Estimating peak and trough concentrations with the new regimen provides a good double-check against a mathematical error. Sixteen hours after the 15 mg/kg dose is administered (or approximately 2 half-lives after the measured peak), the trough should be approximately 8 mg/L. At this time, administration of 18 mg/kg will increase the concentration by 24 mg/L (assuming a Vd of 0.75 L/kg) to a peak concentration of 32 mg/L.

REPETITIVE DOSING AND DRUG ACCUMULATION

When multiple doses are administered, the dose is usually repeated before complete elimination of the previous one. In this situation, peak and trough concentrations increase until a steady-state concentration (C_{ss}) is reached (see Fig. 7.3). The average C_{ss} ($AvgC_{ss}$) can be calculated as follows[20]:

$$\text{AvgC}_{ss} = \frac{1}{\text{Clearance}} \times \frac{f \times D}{\tau} \qquad \text{Eq. 7.10}$$

$$= \frac{1}{k \times \text{Vd}} \times \frac{f \times D}{\tau}$$

$$= \frac{1.44 \times T_{1/2}}{\text{Vd}} \times \frac{f \times D}{\tau} \qquad \text{Eq. 7.11}$$

In Eqs. 7.10 and 7.11, f is the fraction of the dose that is absorbed, D is the dose, τ is the dosing interval in the same units of time as the elimination half-life, k is the elimination rate constant, and 1.44 equals the reciprocal of 0.693 (see Eq. 7.3). The magnitude of the average C_{ss} is directly proportional to the ratio of $T_{1/2}/\tau$ and D.[20]

STEADY STATE

Steady state occurs when the amount of drug removed from the body between doses equals the amount of the dose.[28,29] Five half-lives are usually required for drug elimination and distribution among tissue and fluid compartments to reach equilibrium. When

all tissues are at equilibrium (i.e., steady state), the peak and trough concentrations are identical after each dose. However, before this time, constant peak and trough concentrations after intermittent doses, or constant concentrations during drug infusions, do not prove that a steady state has been achieved because the drug may still be entering and leaving deep tissue compartments. During continuous infusion, the fraction of steady-state concentration that has been reached can be calculated in terms of multiples of the drug's half-life.[20] After 3 half-lives, the concentration is 88% of that at steady state. When changing doses during chronic drug therapy, the concentration should usually not be rechecked until several half-lives have elapsed, unless elimination is impaired or signs of toxicity occur. Drug concentrations may not need to be checked if symptoms improve.

LOADING DOSE

If the time to reach a constant concentration by continuous or intermittent dosing is excessive (e.g., 3–5 half-lives), a loading dose may be used to reach the target concentration or plateau in the concentration more rapidly. Propofol is usually given as a loading dose before establishing an infusion for anesthesia.[24] The same principle is applied to the initial treatment with digoxin, which has a 35- to 69-hour half-life in term neonates and an even greater half-life in preterm infants.[30] Use of a loading dose increases the circulating concentration of drug earlier in the therapeutic course. Loading doses must be used cautiously, because they increase the likelihood of drug toxicity, as has been observed with loading doses of digoxin.[3,5,6,30]

Dose calculations using a one-compartment model (see Eq. 7.9) may not be applicable to many anesthetic drugs that are characterized using multi-compartment models. The use of V1 (central Vd) results in a loading dose that is too large, whereas the use of Vdss (Vd at steady-state) results in a loading dose that is too small. Too large a dose may cause transient toxicity, although slowing the rate of administration may prevent excessive concentrations during the distributive phase.

The time to peak effect (Tpeak) depends on the clearance and effect-site equilibration half-time ($T_{1/2}keo$). At a submaximal dose, Tpeak is independent of dose. At supramaximal doses, maximal effect will occur earlier than Tpeak and persist for a greater duration because of the shape of the response curve (see later discussion). The Tpeak concept has been used to calculate optimal dose for initial boluses,[31] because V1 and Vdss poorly reflect the required scaling factor. A new parameter, the Vd at the time of peak effect-site concentration (*Vpe*) is used and calculated as follows:

$$Vpe = \frac{V1}{\left(Cpeak \big/ C_0\right)}, \qquad \text{Eq. 7.12}$$

where C_0 is the theoretical plasma concentration at $t = 0$ after the bolus dose, and *Cpeak* is the predicted effect-site concentration at the time of peak effect-site concentration. Loading dose (*LD*) can then be calculated as

$$LD = Cpeak \times Vpe \qquad \text{Eq. 7.13}$$

Population Modeling

Pediatric anesthesiologists have embraced the population approach for investigating PK and PD. This approach, achieved through nonlinear mixed-effects models, provides a means to study variability in drug responses among individuals representative of those in whom the drug will be used clinically. Traditional approaches to interpretation of time-concentration profiles relied on "rich" data from a small group of subjects. In contrast, mixed effects models can be used to analyze "sparse" data (two to three samples) from each one of a large number of subjects. Sampling times are not crucial for population methods and can be fit around clinical procedures or outpatient appointments. Sampling time bands rather than exact times is equally effective and allows flexibility in children.[31,32] Interpretation of truncated individual sets of data or missing data is also possible with this type of analysis, rendering it particularly useful for pediatric studies. Population modeling also allows pooling of data across studies to provide a single robust PK analysis rather than comparing separate smaller studies that are complicated by different methods and analyses.

Mixed-effects models are "mixed" because they describe the data using a mixture of fixed and random effects. Fixed effects predict the average influence of a covariate, such as weight, as an explanation of some of the variability between subjects in a parameter like clearance. Random effects describe the remaining variability among subjects that are not predictable from the fixed effect average. Explanatory covariates (e.g., age, size, renal function, sex, temperature) can be introduced that explain the predictable part of the between-individual variability. Nonlinear regression is performed by an iterative process to find the curve of best fit.[33,34]

Pediatric Pharmacokinetic Considerations

Growth and development are two major aspects of children not readily apparent in adults. How these factors interact is not necessarily easy to determine from observations because they are quite highly correlated. Drug clearance, for example, may increase with weight, height, age, body surface area (BSA), and creatinine clearance. One approach is to standardize for size before incorporating a factor for maturation.[35]

SIZE

Clearance in children 1 to 2 years of age, expressed as liters per hour per kilogram, is commonly greater than that observed in older children and adolescents. This is a size effect and is not because of bigger livers or increased hepatic blood flow in that subpopulation. This "artifact of size" disappears when allometric scaling is used. *Allometry* is a term used to describe the nonlinear relationship between size and function. This nonlinear relationship is expressed as

$$y = a \cdot Body\ Mass^{PWR}, \qquad \text{Eq. 7.14}$$

where *y* is the variable of interest (e.g., basal metabolic rate [BMR]), *a* is a scaling parameter, and *PWR* is the allometric exponent. The value of *PWR* has been the subject of much debate. BMR is the most common variable investigated, and camps advocating for a *PWR* value of ⅔ (i.e., BSA) are at odds with those advocating a value of ¾. Support for a value of ¾ comes from investigations that show the log of BMR plotted against the log of body weight produces a straight line with a slope of ¾ across all species studied, including humans. Clearance is a metabolic process and the log of clearance plotted against the log of body weight also produces a straight line with a slope of ¾ when different species are studied. Fig. 7.4 exemplifies this for tramadol.[36] Fractal geometry

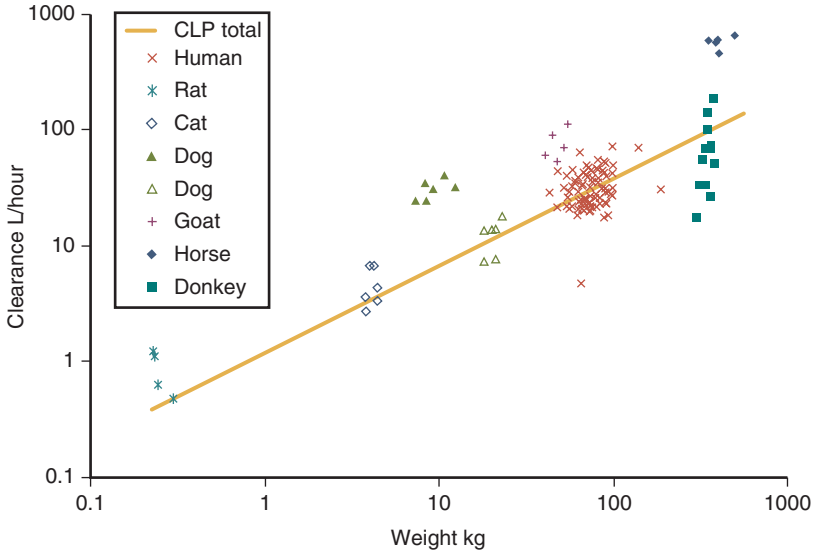

FIGURE 7.4 Weight-predicted tramadol total clearance *(CLP total)* compared with human allometric prediction *(solid line)* using a ¾-power exponent *(solid line)*. (From Holford SD, Allegaert K, Anderson BJ, et al. Parent-metabolite pharmacokinetic models for tramadol—tests of assumptions and predictions. *J Pharmacol Clin Toxicol.* 2014;2[1]:1023–1034, with permission.)

mathematically explains this phenomenon. The ¾-power law for metabolic rates was derived from a general model that describes how essential materials are transported through space-filled fractal networks of branching tubes.[37] A great many physiologic, structural, and time-related variables scale predictably within and between species with weight (*W*) exponents (*PWR*) of ¾, 1, and ¼, respectively.[38]

These exponents have applicability to PK parameters; for example, the exponent for clearance (CL) is ¾, volume (V) is 1, and half-time ($T_{1/2}$) is ¼.[38] The factor for size (*Fsize*) for total drug clearance may be expressed as

$$Fsize = \left(W/70\right)^{3/4} \qquad \text{Eq. 7.15}$$

Remifentanil clearance in children aged 1 month to 9 years is similar to adult rates when scaled using an allometric exponent of ¾.[39] Nonspecific blood esterases that metabolize remifentanil are mature at birth.[40]

MATURATION

Allometry alone is insufficient to predict clearance in neonates and infants from adult estimates for most drugs.[41,42] The addition of a model describing maturation is required. The sigmoid hyperbolic or Hill model[43] has been found useful for describing this maturation process (*MF*):

$$MF = \frac{PMA^{Hill}}{TM_{50}^{Hill} + PMA^{Hill}} \qquad \text{Eq. 7.16}$$

The TM_{50} describes the maturation half-time, while the Hill coefficient relates to the slope of this maturation profile. Maturation of clearance begins before birth, suggesting that postmenstrual age (*PMA*) would be a better predictor of drug elimination than postnatal age (PNA).[38] Fig. 7.5 shows the maturation profile for dexmedetomidine, expressed as both the standard per-kilogram model and by using allometry. Clearance is immature in infancy.

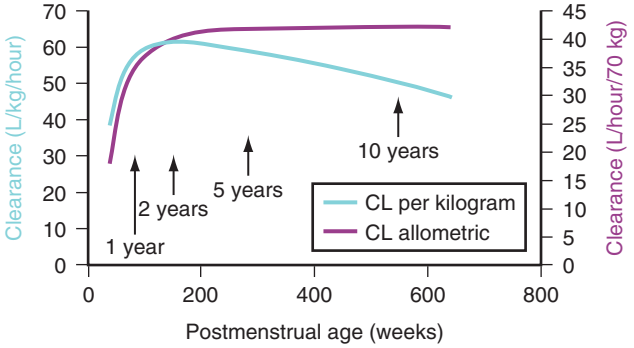

FIGURE 7.5 The clearance (*CL*) maturation profile of dexmedetomidine, expressed using the per-kilogram model and the allometric ¾-power model. This maturation pattern is typical of many drugs cleared by the liver or kidneys. (Data extracted from Potts AL, Anderson BJ, Warman GR, et al. Dexmedetomidine pharmacokinetics in pediatric intensive care—a pooled analysis. *Paediatr Anaesth.* 2009;19(11):1119–1129.)

Clearance, expressed as per kilogram, is greatest at 2 years of age, decreasing subsequently with age. This "artifact of size" disappears with use of the allometric model. Appropriate size scaling shows that the PK in children (>2 years old) is similar to adults. Maturation changes are generally completed within the first 2 years of postnatal life; consequently, infants may be considered as immature children, whereas children are just small adults.[44]

ORGAN FUNCTION

Changes associated with normal growth and development can be distinguished from pathologic changes describing organ function.[35] Morphine clearance is reduced in neonates because of immature glucuronide conjugation, but clearance was lower in critically ill neonates than healthier cohorts,[45–47] possibly attributable to reduced hepatic function. The impact of organ function alteration may be concealed by another covariate. For example, positive-pressure

ventilation may be associated with reduced morphine clearance.[48] This effect may be attributable to a consequent reduced hepatic blood flow with a drug that has perfusion limited clearance (e.g., propofol, morphine).

Creatinine clearance is commonly used as a measure of renal function and dictates dose of those drugs cleared by that organ. Renal function in children can be estimated using formulae that allow estimation of glomerular filtration rate (GFR) from clinical characteristics.[49] These formulae use simple markers such as height, plasma creatinine concentration and BSA. Estimation of GFR is acceptable in adults, but prediction is poor in children with a GFR value less than 40 mL/minute.[50] We might expect the maturation of creatinine clearance, a marker for GFR, to reflect the influences of size, maturation, and organ function. Estimation methods such as those of Schwartz incorporate a size factor (body length or height) and a scaling factor (k) that is age dependent (e.g., k = 0.33 for premature neonates; k = 0.45 for term infants 0–1 year; k = 0.55 for 1–12 years; k = 0.7 for 13- to 21-year old adolescent males[51–53]):

$$GFR = \frac{k \cdot height}{Serum\ Creatinine} \qquad \text{Eq. 7.17}$$

Creatinine clearance estimation overpredicts GFR in children, possibly because of tubular secretion. Tubular reabsorption may also create inaccuracies in premature neonates. Dosing of renally cleared drugs in premature neonates should be based on size- and maturation-based predictions of GFR alone, and serum creatinine should not be used as a base until creatinine production rate predictions in this age group are better established. Pharmacokinetic parameters (*P*) can be described in an individual as the product of size (*Fsize*), maturation (*MF*), and organ function (*OF*) influences, where *Pstd* is the parameter value in a standard size adult without pathologic changes in organ function[35]:

$$P = Pstd \cdot Fsize \cdot MF \cdot OF \qquad \text{Eq. 7.18}$$

Pharmacodynamic Models

Pharmacokinetics is what the body does to the drug, while *pharmacodynamics* is what the drug does to the body. The precise boundary between these two processes is ill defined and often requires a link describing movement of drug from the plasma to the effect site and its target. Drugs may exert effects at nonspecific membrane sites, by interference with transport mechanisms, by enzyme inhibition or induction, or by activation or inhibition of receptors.

MINIMAL EFFECTIVE CONCENTRATION

The minimal effective analgesic concentration can be established by titration of an analgesic to achieve satisfactory pain at rest or with a painful stimulus. Blood assay for analgesic drug concentration at these times can be used to determine the effective concentration. Further blood assays when pain recurs or when further analgesics are required improve the accuracy of assessment. This technique has been used to determine the minimal effective analgesic concentration of oxycodone.[54]

SIGMOID EMAX MODEL

The relation between drug concentration and effect may be described by the Hill equation or Emax model (see maturation model above)[43]:

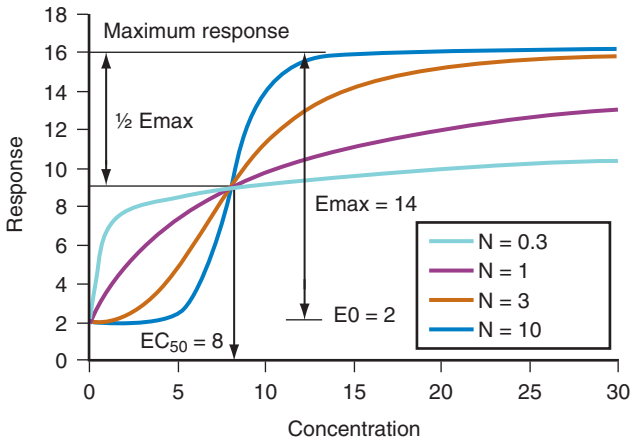

FIGURE 7.6 The sigmoid Emax model is commonly used to describe the relationship between drug response and concentration. Changing the Hill coefficient (*N*) dramatically alters the shape of the curve.

$$Effect = E_0 + \frac{(Emax \cdot Ce^N)}{(EC_{50}^N + Ce^N)}, \qquad \text{Eq. 7.19}$$

where E_0 is the baseline response, *Emax* is the maximum effect change, *Ce* is the concentration in the effect compartment, EC_{50} is the concentration producing 50% Emax, and *N* is the Hill coefficient defining the steepness of the concentration-response curve (Fig. 7.6). Efficacy is the maximum response on a dose or concentration-response curve. EC_{50} can be considered a measure of potency relative to another drug, provided N and Emax for the two drugs are the same.

This model has been used to describe propofol PD in children 1 to 16 years of age using bispectral index as an effect measure. The E_0 was estimated as 93.2, Emax –83.4, EC_{50} 5.2 mg/L, and *N* 1.4.[55] Similar relationships have been described in other groups of children.[56,57] Remifentanil hypotensive effects[58] and acetaminophen analgesic effects[59] in children have also been described using this model.

QUANTAL EFFECT MODEL

The potency of anesthetic vapors may be expressed by minimum alveolar concentration (MAC), and this is the concentration at which 50% of subjects move in response to a standard surgical stimulus. MAC appears, at first sight, to be similar to EC_{50}, but is an expression of quantal response rather than magnitude of effect. There are two methods of estimating MAC. Responses can be recorded over the clinical dose range in a large number of subjects and logistic regression applied to estimate the relationship between dose and quantal effect; the MAC can then be interpolated. Large numbers of subjects may not be available, so an alternative method is often used. The "up-and-down" method described by Dixon[60,61] estimates only the MAC rather than the entire sigmoid curve.[62] It usually involves a study of only one concentration in each subject and, in a sequence of subjects, each receives a concentration depending on the response of the previous subject; the concentration is either decreased if the previous subject did not respond or increased if they did. The MAC is calculated either as the mean concentration of equal numbers of responses and no responses or is the mean concentration of pairs of "response–no response." This technique has also been used to determine the EC_{50} of local anesthetic dugs used in central blockade.[63–65]

LOGISTIC REGRESSION MODEL

When the pharmacologic effect is difficult to grade, then it may be useful to estimate the probability of achieving the effect as a function of plasma concentration. Effect measures, such as movement/no movement or rousable/nonrousable, are dichotomous. Logistic regression is commonly used to analyze such data and the interpolated EC_{50} value refers to the probability of response. For example, an EC_{50} of 0.52 mg/L for arousal after ketamine sedation in children has been estimated using this technique.[66]

Linking Pharmacokinetics With Pharmacodynamics

A simple situation in which drug effect is directly related to concentration does not mean that drug effects parallel the time course of concentration. This occurs only when the concentration is low in relation to EC_{50}. In this situation the half-life of the drug may correlate closely with the half-life of drug effect. Observed effects may not be directly related to serum concentration. Many drugs have a short half-life but a long duration of effect. This may be attributable to induced physiologic changes (e.g., aspirin and platelet function) or may be a result of the shape of the Emax model. If the initial concentration is very high in relation to the EC_{50}, then drug concentrations 5 half-lives later, when we might expect a minimal concentration, may still exert considerable effect.

There may also be a delay as a result of transfer of the drug to the effect site (e.g., neuromuscular blockers [NMBDs]), a lag time (e.g., diuretics), physiologic response (e.g., antipyresis), active metabolite (e.g., valdecoxib), or synthesis of physiologic substances (e.g., warfarin). A plasma concentration-effect plot can form a hysteresis loop because of this delay in effect. Hull and Sheiner introduced the effect compartment concept for NMBDs.[67,68] A single first-order parameter ($T_{1/2}$keo) describes the equilibration half-time. This mathematical trick assumes that the concentration in the central compartment is the same as that in the effect compartment at equilibration, but that a time delay exists before drug reaches the effect compartment. The concentration in the effect compartment is used to describe the concentration-effect relationship.[69]

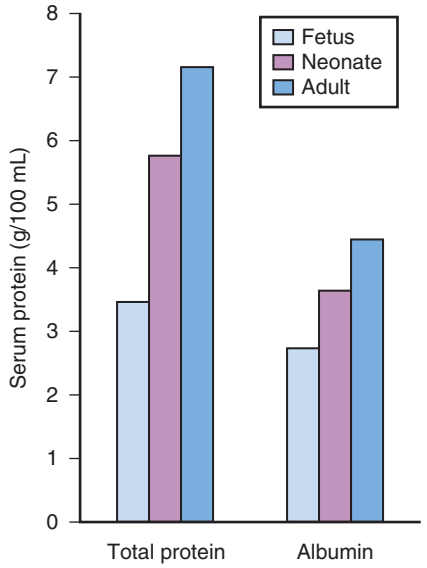
Adult $T_{1/2}$keo values are well described (e.g., morphine, 16 minutes; fentanyl, 5 minutes; alfentanil, 1 minute; propofol, 3 minutes). This $T_{1/2}$keo parameter is commonly incorporated into target-controlled infusion pumps to achieve a rapid effect-site concentration. The adult midazolam $T_{1/2}$keo of 5 minutes may be prolonged in the elderly, resulting in overdose if this is not recognized during dose titration.[67]

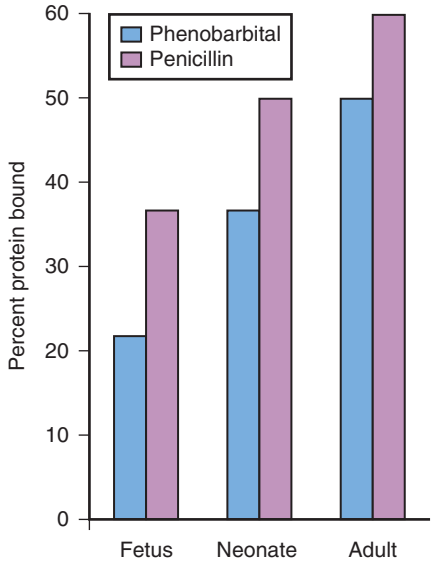
The $T_{1/2}$keo for propofol in children has been described. As expected, a shorter $T_{1/2}$keo with decreasing age based on size models has been observed.[55,68] Similar results have been demonstrated for sevoflurane and changes in the electroencephalogram (EEG).[70] If the effect site is targeted and Tpeak is anticipated to be later than it actually is because it was determined in a teenager or adult, this will result in excessive dose in a young child.

Drug Distribution

PROTEIN BINDING

Acidic drugs (e.g., diazepam, barbiturates) tend to bind mainly to albumin, whereas basic drugs (e.g., amide local anesthetic agents) bind to globulins, lipoproteins, and glycoproteins. In general, plasma protein binding of many drugs is decreased in the neonate relative to the adult in part because of reduced total protein and albumin concentrations (Fig. 7.7).[71] Many drugs that are highly protein bound in adults have less of an affinity for protein in neonates (E-Fig. 7.1).[71–75] Reduced protein binding increases the free fraction of medications, thus providing more free medication and greater pharmacologic effect.[2–4,6,76] This effect is particularly important for medications that are highly protein bound, because the reduced protein binding increases the free fraction of the medication to a greater extent than for low protein-bound drugs. For example, phenytoin is 85% protein bound in healthy infants but only 80% in those who are jaundiced. This equates to a 33% increase in the free fraction of phenytoin when jaundice occurs (E-Fig. 7.2). Differences in protein binding may have considerable influence on the response to medications that are acidic and are therefore highly protein bound (e.g., phenytoin, salicylate, bupivacaine, barbiturates, antibiotics, theophylline, and diazepam). In addition, some medications, such as phenytoin, salicylate, sulfisoxazole, caffeine, ceftriaxone, diatrizoate (Hypaque), and sodium benzoate, compete with bilirubin for binding to albumin (see E-Fig. 7.2). If large amounts of bilirubin are displaced, particularly in the presence of hypoxemia and acidosis, which open the blood-brain barrier (BBB), kernicterus may result.[a] Because these metabolic derangements often occur in sick neonates coming to surgery, special care must be taken when selecting medications for the anesthetic.[78] Medications that are basic (e.g., lidocaine or alfentanil) are generally bound to plasma α_1-acid glycoprotein (AAG); AAG concentrations in preterm and term infants are reduced but are





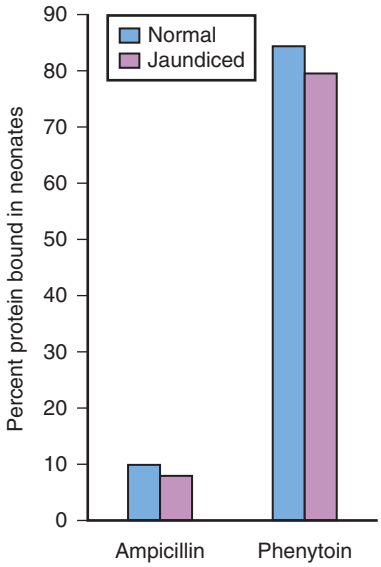


FIGURE 7.7 Changes in total serum protein and albumin values that occur with maturation. Note that total protein and albumin are less in fetuses than in neonates and less in neonates than in adults. The result may be altered pharmacokinetics and pharmacodynamics for drugs with a high degree of protein binding, because less drug is protein bound and more is available for clinical effect in the neonate and fetus. (Data from Ehrnebo M, Agurell S, Jalling B, et al. Age differences in drug binding by plasma proteins: studies on human foetuses, neonates and adults. *Eur J Clin Pharmacol*. 1971;3(4):189–193.)

[a]References 14, 15, 72, 75, 77, and 78.

E-FIGURE 7.1 Altered protein binding may affect the clinical response to any medication; note the much lower protein binding of phenobarbital and penicillin in the neonate and fetus compared with the adult. This reduced protein binding may partially account for the prolonged pharmacologic effects of barbiturates in neonates, because more unbound drug is able to be pharmacologically active. (Data from Ehrnebo M, Agurell S, Jalling B, Boréus LO. Age differences in drug binding by plasma proteins: studies on human foetuses, neonates and adults. *Eur J Clin Pharmacol*. 1971;3(4):189–193.)

E-FIGURE 7.2 Note that in the presence of hyperbilirubinemia, many drugs that are protein bound compete with bilirubin for binding sites, resulting in both elevated unbound bilirubin and unbound drug. This interaction may lead to an increased propensity for the development of kernicterus as well as more drug available for clinical effect. This effect is particularly important for drugs that normally are highly protein bound (e.g., phenytoin) but would be of minimal importance for drugs that have low protein binding (e.g., ampicillin). (Data from Ehrnebo M, Agurell S, Jalling B, Boréus LO. Age differences in drug binding by plasma proteins: studies on human foetuses, neonates and adults. *Eur J Clin Pharmacol*. 1971;3(4):189–193.)

similar to those in adults by 6 months, although between patient variability is high (e.g., AAG 0.32–0.92 g/L).[79] Therefore for a given dose, the free fraction of a drug is greater in preterm and term infants.[79–81] In contrast to drugs bound to plasma proteins, unbound lipophilic drugs passively diffuse across the BBB, equilibrating very quickly. This may contribute to bupivacaine's propensity for producing seizures in neonates. Decreased protein binding, as in the neonate, results in a greater proportion of unbound drug that is available for passive diffusion.

These binding changes in neonates differ from adults in whom protein binding changes are important for the relatively unusual case of a drug that is more than 95% protein bound, with a high extraction ratio and a narrow therapeutic index, that is given parenterally (e.g., IV lidocaine), or a drug with a narrow therapeutic index that is given orally and has a very rapid $T_{1/2}$keo (e.g., antiarrhythmic drugs; propafenone, verapamil).[82]

Maturational changes in tissue binding also affect drug distribution. Myocardial digoxin concentrations in infants are 6-fold greater than those in adults, despite similar serum concentrations. Erythrocyte/plasma concentration ratios of digoxin in infants are one-third smaller during loading digitalization than during maintenance digoxin therapy. These findings are consistent with a greater Vd of digoxin in infants and may explain, in part, the unusually large therapeutic doses needed in infants.[83]

BODY COMPOSITION

Preterm and term infants have a much greater proportion of body weight in the form of water than do older children and adults (Fig. 7.8).[8] The net effect on water-soluble medications is a greater Vd in infants, which in turn increases the initial (loading) dose, based on weight, to achieve the desired target serum concentration and clinical response.[2–4,84,85] Term neonates often require a greater loading dose (milligrams per kilogram) for some medications (e.g., digoxin, succinylcholine, and aminoglycoside antibiotics) than older children.[84–88] However, neonates also tend to be sensitive to the respiratory, neurologic, and circulatory effects of many medications and therefore tend to be more responsive to these effects at reduced blood concentrations than are children and adults. Preterm infants are usually more sensitive than term neonates and in general require even smaller blood concentrations.[2] On the other hand, dopamine may increase blood pressure (BP) and urine output in term neonates only at doses as large as 50 µg/kg per minute. This dose, which would induce intense vasoconstriction in adults, suggests that neonates are less sensitive in their cardiovascular responsiveness.[3,86,89–92] *It is important to carefully titrate the doses of all medications that are administered to preterm and term infants to the desired response.*

Compared with children and adolescents, preterm and term neonates have a smaller proportion of body weight in the form of fat and muscle mass; with growth, the proportion of body weight composed of these tissues increases (Fig. 7.9).[2,3,8,90,93–95] Therefore medications that depend on their redistribution into muscle and fat for termination of their clinical effects likely have a larger initial peak blood concentration. These medications may also have a more sustained blood concentration because neonates have less tissue for redistribution of these medications. An incorrect dose may result in prolonged undesirable clinical effects (e.g., barbiturates and opioids may cause prolonged sedation and respiratory depression). The possible influence of small muscle mass on the response to NMBDs is exemplified by achieving neuromuscular blockade at smaller serum concentrations in infants.[86]

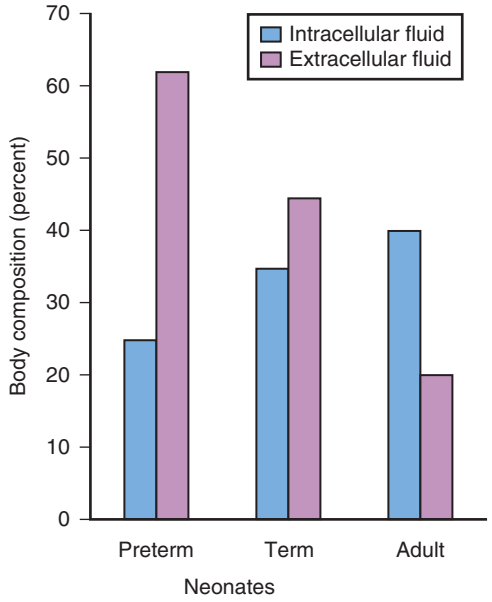

FIGURE 7.8 Changes in the intracellular and extracellular compartments that occur with maturation. Note the large proportion of extracellular water in preterm and term infants. This large water compartment creates an increased volume of distribution for highly water-soluble medications (e.g., succinylcholine, gentamicin) and may account for the large (by weight) loading dose required for some medications to achieve a satisfactory clinical response. (Data from Friis-Hansen B. Body composition during growth. In vivo measurements and biochemical data correlated to differential anatomical growth. *Pediatrics* 1971;47(1 Suppl 2):264+.)

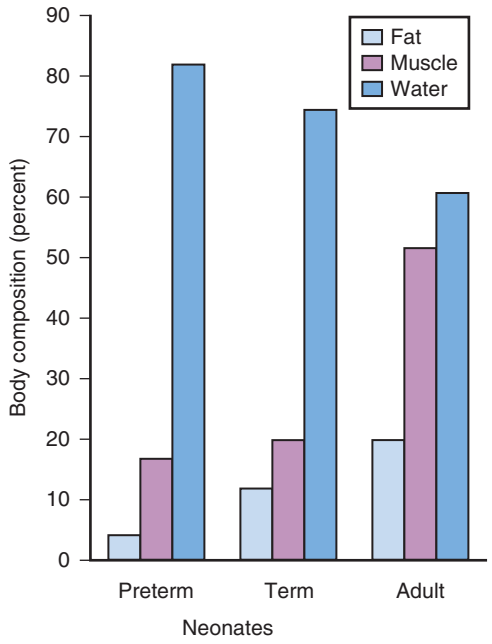

FIGURE 7.9 Changes in body content for fat, muscle, and water that occur with maturation. Note the small percentage of fat and muscle mass in preterm and term infants. These factors may greatly influence the pharmacokinetics and pharmacodynamics of medications that redistribute into fat (e.g., barbiturates) and muscle (e.g., fentanyl) because there is less tissue mass into which the drug may redistribute. (Data from Friis-Hansen B. Body composition during growth. In vivo measurements and biochemical data correlated to differential anatomical growth. *Pediatrics* 1971;47(1 Suppl 2):264+.)

REGIONAL BLOOD FLOWS

There are differences in relative organ mass and regional blood flow that change with growth and development during the first few months of life in addition to physiologic changes at birth. Kidney and brain receive an increasing proportion of the cardiac output, while the proportion to the liver decreases. The proportional mass of the head and liver are much greater in the infant than in the adult.[96] Mean CBF peaks in early childhood (70 mL/minute per 100 g) at about 3–8 years of age[97]; flows in both neonates and adults are less (50 mL/minute per 100 g).[98] The highly lipophilic drugs used for anesthetic induction rapidly achieve concentration equilibrium with brain tissue, but the reduced cerebral perfusion means that onset time after IV induction is slower in neonates that in early childhood. Offset time is also delayed because redistribution to the well-perfused and deep, underperfused tissues is less.

BLOOD-BRAIN BARRIER

The BBB is a network of complex tight junctions between specialized endothelial cells that restricts the paracellular diffusion of hydrophilic molecules from the blood to the brain substance. There are specific transport systems selectively expressed in the barrier endothelial cell membranes that mediate the transport of nutrients into the central nervous system (CNS) and of toxic metabolites out of the CNS. Small molecules can cross into fetal and neonatal brains more readily than they do into adult brains.[99] BBB function improves throughout fetal brain development, reaching maturity at term.[99] This maturation explains why kernicterus is more common in the preterm than the term neonate. BBB breakdown or alterations in transport systems may occur in some diseases. Proinflammatory substances and specific disease-associated proteins often mediate BBB dysfunction.[100] Fentanyl is actively transported across the BBB by a saturable adenosine triphosphate (ATP)-dependent process, while ATP-binding cassette proteins such as P-glycoprotein actively pump out opioids such as fentanyl and morphine.[101] P-glycoprotein modulation significantly influences brain opioid distribution and onset time and magnitude and duration of analgesic response.[102] Modulation may occur during disease processes, increased temperature, or other substances (e.g., verapamil, magnesium).[101] Genetic polymorphisms affecting P-glycoprotein–related genes may explain some individual differences in CNS-active drug sensitivity (see also Chapter 6).[103]

Absorption

Anesthetic drugs are mainly administered through the IV and inhalational routes, although premedication and postoperative pain relief is commonly administered enterally. Drug absorption after oral administration is slower in neonates than in children because of delayed gastric emptying (Fig. 7.10).

ENTERAL

Adult enteral absorption rates may not be reached until 6 to 8 months after birth.[104,105] Congenital malformations (e.g., duodenal atresia), co-administration of drugs (e.g., opioids), or disease characteristics (e.g., necrotizing enterocolitis) may further affect the variability in absorption. Delayed gastric emptying and reduced clearance may dictate reduced doses and frequency of repeated drug administration. For example, a mean steady-state target acetaminophen concentration greater than 10 mg/L at trough can be achieved by an oral dose of 25 mg/kg per day in preterm neonates at 30 weeks, 45 mg/kg per day at 34 weeks, and 60 mg/kg per day at 40 weeks PMA.[106] Because gastric emptying is slow in preterm neonates, dosing may only be required twice a day.[106] In contrast, the rectal administration of some drugs (e.g., thiopental, methohexital) is more rapid in neonates than adults. However, the interindividual absorption and relative bioavailability (F) variability after rectal administration may be more extensive compared with oral administration, making rectal administration less suitable for repeated administration.[107] The frequent passage of stools in the neonate may render suppository use ineffective. Variable absorption and bioavailability has resulted in respiratory arrest when repeat opioids are administered by the rectal route to children.[108]

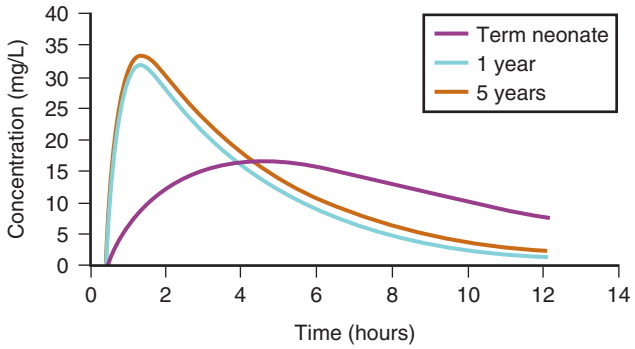

FIGURE 7.10 Simulated mean predicted time-concentration profiles for a term neonate, a 1-year-old infant, and a 5-year-old child given paracetamol elixir. The time to peak concentration is delayed in neonates because of slow gastric emptying and reduced clearance. (Reproduced with permission from Anderson BJ, van Lingen RA, Hansen TG, Lin YC, Holford NH. Acetaminophen developmental pharmacokinetics in premature neonates and infants: a pooled population analysis. *Anesthesiology* 2002;96(6):1336–1345.)

CUTANEOUS

The larger relative skin surface area, increased cutaneous perfusion, and thinner stratum corneum in neonates increase systemic exposure of topical drugs (e.g., corticosteroids, local anesthetic creams, antiseptics). Neonates have a greater tendency to form methemoglobin because of reduced methemoglobin reductase activity compared with older children. Furthermore, fetal hemoglobin is more readily oxidized by drugs such as prilocaine compared with adult hemoglobin. Combined with an increased transcutaneous absorption, these have resulted in reluctance to apply repeat or large surface area application of topical local anesthetics, such as EMLA (eutectic mixture of local anesthetics [lidocaine-prilocaine]) cream, in this age group.[109] Similarly, cutaneous application of iodine antiseptics in neonates may result in transient hypothyroidism.

INTRAMUSCULAR

The intramuscular (IM) route is frowned upon in children. Although bioavailability is high and approaches unity for most drugs, absorption is delayed compared to the IV route. Ketamine, however, remains popular, and peak concentrations are reached within 10 minutes after 4 mg/kg.[110]

NASAL

Exploration of alternative delivery routes in young children has centered on the nasal passages.[111] Nasal diamorphine 0.1 mg/kg, used in the United Kingdom for forearm fracture pain in the emergency room, is rapidly absorbed as a nasal spray in 0.2 mL of sterile water, with peak morphine plasma concentrations (Tpeak)

occurring at 10 minutes.[112] Nasal S-ketamine (2 mg/kg) results in peak plasma concentrations of 355 ng/mL within 18 minutes.[113] Nasal fentanyl (150 µg/mL) 1.5 µg/kg given to children (3–17 years) for fracture pain resulted in good analgesia; peak concentrations occurred at 13 minutes.[114,115] There remain concerns that intranasal drugs may pass through the posterior nasopharynx or irritate the vocal cords.[116]

Advances in aerosol delivery devices have improved dosing accuracy. Administration of ketorolac (15 mg [weight 30–50 kg] or 30 mg [weight >50 kg]) to adolescents by the intranasal route resulted in a rapid increase in plasma concentration (time to peak concentration was 52 ± 6 minutes) and may be a useful therapeutic alternative to IV injection. A target concentration of 0.37 mg/L in the effect compartment was achieved within 30 minutes and remained above that target for 10 hours.[117] The nasal passages change with age and so it would not be surprising if absorption by that route did not also change with age. Drug combinations may show benefits over single-drug therapy. Formulations containing two drugs may improve analgesia by additivity while decreasing adverse effects.[118]

Buccal and sublingual administration, like the nasal route, offer ease of administration, rapid systemic absorption, and avoidance of hepatic first-pass metabolism.[119] Midazolam administered by the buccal surface is now more popular than rectal administration for the acute management of seizures.[120]

Bioavailability

The oral biovailability of a drug may be affected by (1) interactions with food when feeding is frequent in the neonate (e.g., phenytoin[121]), (2) use of adult formulations that are divided or altered for pediatric use (nizatidine[122]), and (3) lower cytochrome P450 enzyme activity in the intestine. The last factor may cause an increased bioavailability of midazolam because CYP3A activity is reduced.[123] The use of drug vials designed for adult use may result in dose inaccuracy when proportioned for pediatric use, causing a relative increase or decrease in assumed bioavailability.[124]

Dose accuracy is lost when buccal and sublingual administration is attempted because those routes require prolonged exposure to the mucosal surface. Infants find it difficult to hold the drug in their mouth for the requisite retention time (particularly if taste is unfavorable) and this results in more swallowed drug or drug spat out than in adults.[125] If the drug has a high first-pass effect, then the lower relative bioavailability results in lower plasma concentrations. Although many analgesics are available in an oral liquid formulation, taste is a strong determinant of compliance and unpalatable preparations may be refused.[126] Taste preferences change with age.

First-pass effect impacts bioavailability and contribution of active metabolites to effect. The oral bioavailability of clonidine is low (F = 0.55) in children 3 to 10 years of age. Consequently, larger oral doses of clonidine (per kilogram) are required when this formulation is used to achieve concentrations similar to those reported in adults.[127] Oral absorption is slow (absorption half-time 0.45 hours), and peak concentrations are not reached until 1 hour. Similarly, oral ketamine needs to be given in doses of up to 10 mg/kg to achieve therapeutic effect in children 1 to 8 years of age who have suffered burns.[128] Not only was bioavailability reduced (F = 0.45) but absorption was also slow; absorption half-time was 59 minutes, and between-subject variability in this cohort was substantive.[128] Analgesic effect, however, may be supplemented by the increased concentration of the active metabolite norketamine.

Metabolism and Excretion

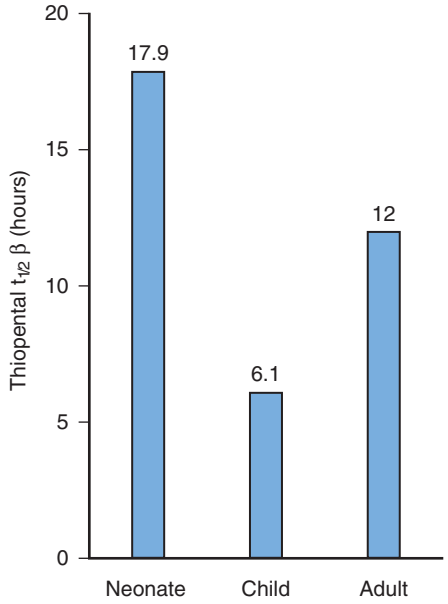
The main routes by which drugs and their metabolites leave the body are the hepatobiliary system, the kidney, and the lung. Microsomal enzyme activity can be classified into three groups[129]:

1. Mature at birth but decreasing with age (e.g., CYP3A7 responsible for methadone clearance in neonates)
2. Mature at birth and sustained through to adulthood (e.g., plasma esterases that clear remifentanil)
3. Immature at birth

The last group accounts for the majority of enzymatic activity; the concentrations, and activities of many microsomal enzymes are reduced or absent in the neonate.

HEPATIC METABOLISM

The liver is the most important organ in drug metabolism. Hepatic enzymatic drug metabolism usually converts the medication from a less polar state (lipid-soluble) to a more polar, water-soluble compound (see later discussion). The enzyme activities responsible for drug clearance are reduced in the neonate. However, clearance depends on enzyme activity, organ blood flow, and organ size; these change independently with age. Half-life is often used to describe maturation. The elimination half-lives of diazepam, thiopental, and phenobarbital are markedly increased in neonates compared with adults (i.e., the elimination half-life for thiopental in the neonate [17.9 hours] is almost three times that in children [6.1 hours] and 50% greater than that in adults [12 hours]) (E-Fig. 7.3).[74,76,130,131] In general, the half-lives of medications that are eliminated by the liver are prolonged in neonates, decreased in children 4 to 10 years of age, and reach adult values in adolescents, mirroring clearance changes with age (see Fig. 7.5). Half-life is confounded by clearance (CL) and volume (Vd); both change independently with age.



$$T_{1/2} = Ln(2) \cdot Vd / CL \qquad \text{Eq. 7.20}$$

Consequently, clearance is a better parameter to gauge maturation.

Some medications are extensively metabolized by the liver or other organs (e.g., the intestines or lungs) and are referred to as having high extraction ratios. This extensive metabolism produces a "first-pass" effect in which a large proportion of an enteral dose is inactivated as it passes through the organ before reaching the systemic circulation (e.g., propranolol, morphine, and midazolam). Clearance of these drugs is commonly termed "perfusion limited." In contrast, drugs with low intrinsic clearance (diazepam, phenytoin, aspirin) are termed "capacity limited."

Metabolism via cytochrome P-450 in the intestinal wall may also occur during drug absorption.[132–134] Competition between drugs for these intestinal wall enzymes may increase the bioavailability of one drug over another. The relative bioavailability of phenylephrine was increased when coadministered with acetaminophen owing to competition for gut wall sulfate conjugation.[135,136] Certain foods (e.g., grapefruit juice) may also induce or inhibit intestinal cytochromes, resulting in food–drug interactions.[137] The concentrations of these enzymes in neonates are less than in older children. These enzymes may also be affected by diseases such as cystic fibrosis or celiac disease.[138,139]

The opening or closing of a patent ductus may have profound effects on drug delivery to metabolizing organs in preterm infants.[140,141] The ability to metabolize and conjugate medications improves considerably with age as a result of both increased enzyme

E-FIGURE 7.3 Effects of hepatic maturity on thiopental metabolism. Note the markedly prolonged β-elimination half-life for thiopental in neonates compared with children or adults. Also note that children have a shorter β-elimination half-life compared with adults. This effect may in part be related to immature hepatic metabolic pathways in the neonate; a similar effect is observed with most medications metabolized by the liver. This phenomenon may also reflect a smaller proportion of the cardiac output delivered to the liver of a neonate. In the child, this likely reflects a relatively large liver in proportion to body size and a greater proportion of the cardiac output delivered to the liver, compounded by Vd changes with age. (Data from Christensen JH, Andreasen F, Jansen JA. Pharmacokinetics of thiopental in caesarian section. *Acta Anaesthesiol Scand*. 1981;25(2):174–179; Ghoneim MM, Van Hamme MJ. Pharmacokinetics of thiopentone: effects of enflurane and nitrous oxide anaesthesia and surgery. *Br J Anaesth*. 1978;50(12):1237–1242; and Sorbo S, Hudson RJ, Loomis JC. The pharmacokinetics of thiopental in pediatric surgical patients. *Anesthesiology* 1984;61(6):666–670.)

activity and increased delivery of drug to the liver. Other factors influence the rate of hepatic maturation and metabolism (e.g., sepsis and malnutrition may slow maturation, whereas previous exposure to anticonvulsants, such as phenytoin or phenobarbital, may hasten maturation).[142–144]

Metabolism through biotransformation to more polar forms is required for many drugs before they can be eliminated. Two types of drug biotransformation can occur: phase I and phase II reactions. Phase I reactions transform the drug via oxidation, reduction, or hydrolysis. Phase II reactions transform the drug via conjugation reactions, such as glucuronidation, sulfation, and acetylation, into more polar forms.[145,146] Hepatic drug metabolism activity appears as early as 9 to 22 weeks gestation, when fetal liver enzyme activity may vary from 2% to 36% of adult activity.[147] It is inaccurate to generalize that the preterm neonate cannot metabolize drugs; rather, the specific pathway(s) of drug metabolism must be considered.

PHASE I REACTIONS: CYTOCHROME P-450

Metabolism of many drugs involves the cytochrome P-450 (CYP) enzyme system. Multiple isoforms of the CYP enzyme system exist with different substrate specificities for different drugs. Induction and inhibition of these enzymes by different drugs and chemicals requires a thorough understanding of both the nomenclature of the CYP system, as well as the specific isoforms responsible for metabolism of the drugs used in pediatric anesthesia. There are both genetic and ethnic polymorphisms that may lead to clinically important differences in the capacity to metabolize drugs; these differences can make individual drug responses in some cases unpredictable. Epigenetics is a young and new area of research that examines variable but heritable differences in gene expression without modifications to the DNA sequence. This subject is discussed further in Chapter 6.

CYPs are heme-containing proteins that provide most of the phase I drug metabolism for lipophilic compounds in the body.[148] The generally accepted nomenclature of the cytochrome P-450 isozymes begins with CYP, and group enzymes with more than 36% DNA homology subgrouped into families designated with an Arabic number, followed by letters for the subfamily of closely related proteins (>77% homology), followed by a number for the specific enzyme gene, such as CYP3A4.[149,150] Isozymes that are important in human drug metabolism are found in the *CYP1*, *CYP2*, and *CYP3* gene families. Table 7.1 outlines the CYP isozymes and their common substrates.

TABLE 7.1 Developmental Patterns and Activities for Important Cytochrome P-450 Enzymes (Phase I Reactions) in the Neonate

Enzymes	Selected Substrates	Inducers	Inhibitors	Developmental Changes
CYP1A2	Acetaminophen, caffeine, theophylline, warfarin	Cigarette smoke, charcoal-broiled meat, omeprazole, cruciferous vegetables	α-Naphthoflavone	Not present to an appreciable extent in human fetal liver. Adult levels reached by 4 months of age and may be exceeded in children 1–2 years of age. Inhibited by phenobarbital and phenytoin.
CYP2A6	Warfarin, nicotine	Barbiturates	Tranylcypromine	
CYP2C9	Diclofenac, phenytoin, torsemide, *S*-warfarin tolbutamide	Rifampin	Sulfaphenazole, sulfinpyrazone	Not apparent in fetal liver. Inferential data using phenytoin disposition as a nonspecific pharmacologic probe suggests low activity during the first week of life, with adult activity reached by 6 months of age and peak activity reached by 3–4 years of age. Metabolism induced by rifampin and phenobarbital and inhibited by cimetidine.
CYP2C19	Phenytoin, diazepam, omeprazole, propranolol	Rifampin	Tranylcypromine	
CYP2D6	Amitriptyline, captopril, codeine, dextromethorphan, fluoxetine, hydrocodone, ondansetron, propafenone, propranolol, timolol	None known	Fluoxetine, quinidine	Low to absent in fetal liver but uniformly present at 1 week of postnatal age. Poor activity (approximately 20% of adult values) at 1 month of postnatal age. Adult competence reached by 3–5 years of age. Metabolism inhibited by cimetidine.
CYP3A4	Acetaminophen, alfentanil, amiodarone, budesonide, carbamazepine, diazepam, erythromycin, lidocaine, midazolam, nifedipine, omeprazole, cisapride, theophylline, verapamil, *R*-warfarin	Carbamazepine, dexamethasone, phenobarbital, phenytoin, rifampin	Azole antifungals, ethinyl estradiol, naringenin, troleandomycin, erythromycin	CYP3A4 has low activity in the first month of life, which approaches adult levels by 6–12 months postnatally.
CYP3A7	Dehydroepiandrosterone, ethinyl estradiol, various dihydropyrimidines	Carbamazepine, rifampin, phenytoin, dexamethasone, phenobarbital	Azole antifungals, erythromycin, cimetidine	CYP3A7 is functionally active in the fetus; approximately 30% to 75% of adult levels of CYP3A4.

Adapted from Leeder JS, Kearns GL. Pharmacogenetics in pediatrics: implications for practice. *Pediatr Clin North Am.* 1997;44(1):55–77.

For many drugs, the reduced metabolism in neonates relates to reduced total quantities of CYP enzymes in the hepatic microsomes.[151] Although the concentrations of CYP enzymes increase with gestational age, they may reach only 50% of adult values at term. Most isozymes are immature in the neonate, but some CYP isozymes exhibit near-adult activity, whereas others produce unique metabolic pathways in the neonatal period that invalidate broad generalizations about neonatal drug metabolism (see Table 7.1). Developmental changes of specific cytochromes are discussed in Chapter 6.

PHASE II REACTIONS

The other major route of drug metabolism, designated phase II reactions, involves synthetic or conjugation reactions that increase the hydrophilicity of molecules to facilitate renal elimination.[145,146] The phase II enzymes include glucuronosyltransferase, sulfotransferase, *N*-acetyltransferase, glutathione *S*-transferase, and methyltransferase. The phase II enzymes also show developmental changes during infancy that influence drug clearance (Table 7.2).[152–155]

Most conjugation reactions have limited activity during fetal development.[156] One of the most familiar synthetic reactions in young infants involves conjugation by uridine diphosphoglucuronosyltransferases (UGTs). This enzyme system includes numerous isoforms and is also responsible for glucuronidation of endogenous compounds, such as bilirubin (by UGT1A1).[156] As with the maturation of bilirubin conjugation, UGT activity is limited immediately postnatally and the different isoforms mature at different rates postnatally.[157] Dosage adjustments are often needed to avoid toxicity in neonates from drugs that require conjugation by UGT for clearance. Experience with chloramphenicol in the 1960s illustrated this lesson when neonates received standard pediatric doses of chloramphenicol without understanding the immaturity of UGT and its role in the elimination of chloramphenicol. Infants accumulated large concentrations of chloramphenicol and developed fatal circulatory collapse, a condition known as the gray baby syndrome.[158–160] Although the clearance of chloramphenicol is poor during the neonatal period, appropriate dosage adjustments and monitoring allow safe treatment of preterm and term infants with chloramphenicol.[161]

Morphine, acetaminophen, dexmedetomidine, and lorazepam also undergo glucuronidation. The major steps in the metabolic disposition of morphine in children and adults is glucuronidation in the 3- and 6-position.[162,163] The limited ability of neonates to metabolize morphine by glucuronidation necessitates dosage adjustment.[46,164,165] Detailed studies have shown that morphine clearance,[164,166] in particular 3- and 6-glucuronide formation, is limited at birth and increases with birth weight,[165] gestational age,[148] and postnatal age.[46,163] In some studies, morphine clearance, expressed as per kilogram, approaches adult values by 1 month,[46,167] although others reported that clearance does not reach adult values until at 5 to 6 months.[164,168] Overall, the maturation of glucuronosyltransferase enzymes varies among isoforms but, in general, adult activity is reached by 6 to 18 months of age.[150] Some of the confusion relating to maturation rates is attributable to the use of the per-kilogram size model. The use of allometry with a maturation model has assisted understanding. The time courses of maturation of drug metabolism for morphine,[45] acetaminophen,[169] dexmedetomidine,[170] and GFR[171] are strikingly similar (Fig. 7.11) with 50% of size-adjusted adult values reached between 8 and 12 weeks (TM_{50}) after full-term delivery. All three drugs are cleared predominantly by UGT that converts the parent compound into a water-soluble metabolite that is excreted by the kidneys; the clearance maturation profiles of these drugs matches that of GFR maturation. Glucuronidation is also the major metabolic pathway of propofol metabolism, although multiple CYP isoenzymes, including CYP2B6, CYP2C9, or CYP2A6, contribute to its metabolism and cause a faster maturation profile than expected from glucuronide conjugation alone.[172] A phase I reaction (CYP3A4) is the major enzyme system for oxidation of levobupivacaine, and clearance through this pathway is faster than those associated with UGT maturation.[45,169,171,173–176]

In contrast to glucuronosyltransferase, the sulfotransferase enzyme system is well developed in the neonate, and for some compounds it may compensate for limited glucuronidation. In adults, the primary pathway for acetaminophen metabolism is glucuronidation, yet its half-life is only moderately prolonged in neonates compared with older infants and adults.[177–179] This occurs partly because of the increased Vd in neonates (Eq. 7.20) and partly because the neonate forms more sulfate than glucuronide conjugate, leading to a greater percent of the dose excreted as the acetaminophen-sulfate conjugate.[106,178–181] Unfortunately, this does not confer safety from hepatotoxicity. The toxic metabolite is created through the oxidative pathway mediated by CYP2E1.

ALTERATIONS IN BIOTRANSFORMATION

Transition from the intrauterine to the extrauterine environment is associated with major changes in blood flow. There may also be an environmental trigger for the expression of some metabolic enzyme activities, resulting in a slight increase in maturation rate above that predicted by PMA.[172,175] Many biotransformation

TABLE 7.2 Developmental Patterns for Important Conjugation (Phase II) Reactions in the Neonate

Enzymes	Selected Substrates	Developmental Patterns
Uridine diphosphoglucuronyltransferase (UDP-GT)	Chloramphenicol, morphine, acetaminophen, valproic acid, lorazepam	Ontogeny is isoform specific. In general, adult activity is achieved by 6–18 months of age. May be induced by cigarette smoke and phenobarbital.
Sulfotransferase	Bile acids, acetaminophen, cholesterol, polyethylene, glycols, dopamine, chloramphenicol	Ontogeny seems to be more rapid than UDP-GT; however, it is substrate specific. Activity for some isoforms may exceed adult values during infancy and childhood (e.g., that responsible for acetaminophen metabolism).
N-Acetyltransferase 2	Hydralazine, procainamide, clonazepam, caffeine, sulfamethoxazole	Some fetal activity present by 16 weeks. Virtually 100% of infants between birth and 2 months of age exhibit the slow metabolizer phenotype. Adult activity present by 1–3 years of age.

Adapted from Leeder JS, Kearns GL. Pharmacogenetics in pediatrics: implications for practice. *Pediatr Clin North Am.* 1997;44(1):55–77.

reactions, especially those involving certain forms of CYP, are inducible before birth through maternal exposure to drugs, cigarette smoke, or other inducing agents. Postnatally, biotransformation reactions may be induced through drug exposure (see Tables 7.1 and 7.2) and may be slowed by hypoxia, asphyxia, organ damage, and/or illness. The reduced thiopental clearance estimated from data when the drug was given to control neonatal seizures that resulted from hypoxic-ischemic insults may not be applicable to healthy neonates undergoing anesthesia.[182,183]

EXTRAHEPATIC ROUTES OF METABOLIC CLEARANCE

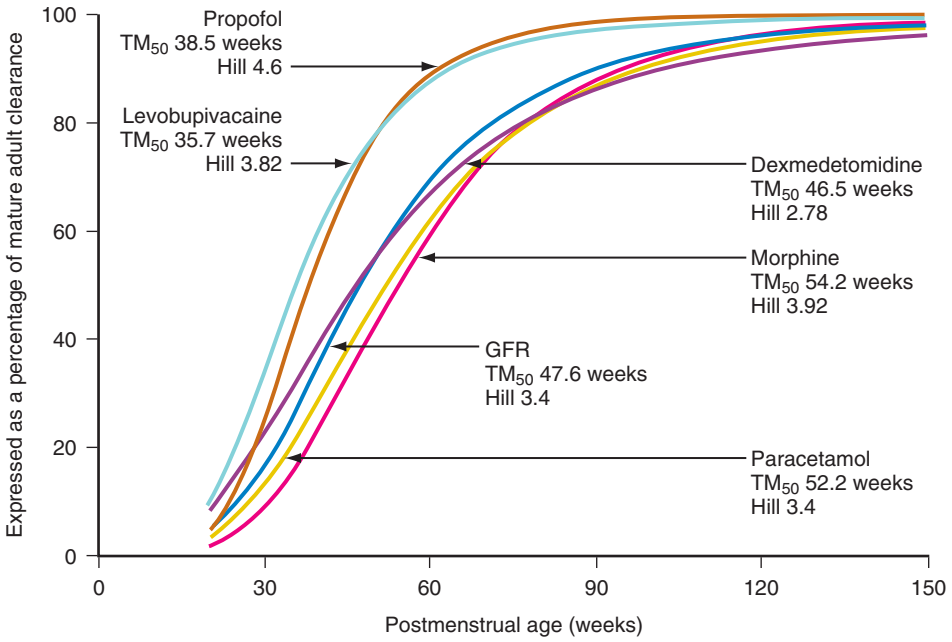
Many drugs undergo metabolic clearance at extrahepatic sites. Remifentanil and atracurium are degraded by nonspecific esterases in tissues and erythrocytes. Clearance, expressed per kilogram, is increased in younger children,[39,184–187] likely attributable to size, because clearance is similar when scaled to a 70-kg person using allometry.[39] Nonspecific blood esterases that metabolize remifentanil are mature at birth.[40]

Ester local anesthetics are metabolized by plasma butyrylcholinesterase, which is thought to be reduced in neonates. The in vitro plasma half-life of 2-chloroprocaine in umbilical cord blood is twice that in maternal blood,[188] but there are no in vivo studies of the effects of age on its metabolism. Succinylcholine clearance is increased in neonates when expressed as per kilogram, suggesting butyrylcholinesterase activity is mature at birth.[189,190]

RENAL EXCRETION

Renal function in preterm and term infants is less efficient than in adults, even after adjusting for the differences in body weight. This reduced efficiency is related to the combination of incomplete glomerular development, low perfusion pressure, and inadequate osmotic load to produce full countercurrent effects.[191–196] However, glomerular filtration and tubular function both develop rapidly during the first few months of life,[171] and are nearly mature by 20 weeks of age, and fully mature by 2 years of age (Figs. 7.11 and 7.12).[192–196] For these reasons, *drugs that are excreted primarily through glomerular filtration or tubular secretion, such as aminoglycoside and cephalosporin antibiotics, have a prolonged elimination half-life in neonates* (E-Fig. 7.4).[197–199]

In the presence of renal failure, one or two doses of drugs that are excreted via the kidneys often achieve and maintain prolonged therapeutic drug concentrations if there is no alternate pathway of excretion. Whenever administering a medication to a preterm or term infant, one must consider the contribution of renal function in the clearance of both the drug and any active metabolite.



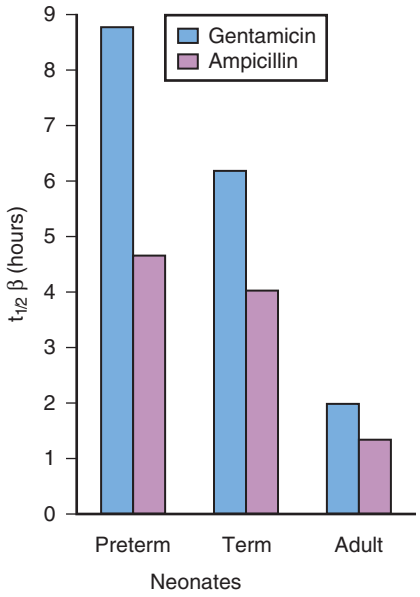


FIGURE 7.11 Clearance maturation, expressed as a percentage of mature clearance, of drugs where glucuronide conjugation (paracetamol, morphine, dexmedetomidine) plays a major role. These profiles are closely aligned with glomerular filtration rate (*GFR*). In contrast, cytochrome P-450 isoenzymes also contribute to propofol and levobupivacaine metabolism and cause a faster maturation profile than expected from glucuronide conjugation alone. *Hill*, Hill coefficient; TM_{50}, maturation half-time. Influence of hyperbaric oxygen on the pharmacokinetics of single-dose gentamicin in healthy volunteers. *Pharmacotherapy* 1993;13(4):382–385.)

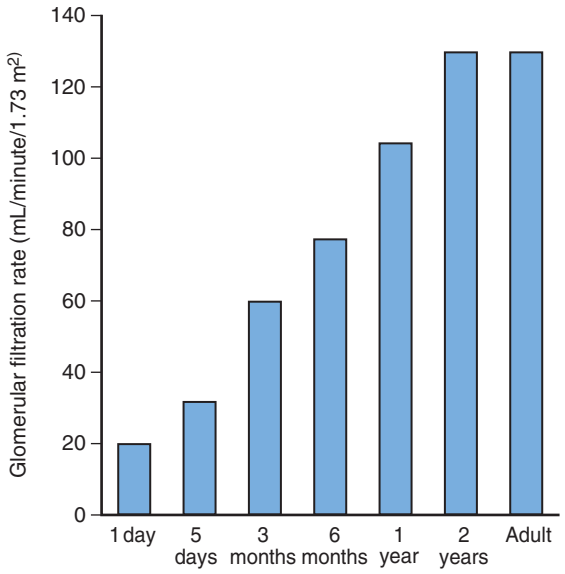

FIGURE 7.12 Changes in glomerular filtration rate versus age. Note the rapid development of glomerular function during the first year of life. Abnormal or immature renal function may delay drug excretion. (Data from Chantler C. *Clinical Pediatric Nephrology.* Philadelphia: JB Lippincott; 1976.)

The PK and PD of the old muscle relaxant, curare, exemplify the complex interaction of increased Vd, smaller muscle mass, and decreased rate of excretion as a result of immaturity of glomerular filtration. The initial dose (per kilogram) of curare needed to achieve neuromuscular blockade is similar in infants and adults.[86] In infants, however, this blockade is achieved at reduced serum concentrations compared with older children or adults, corresponding to differences in muscle mass and receptor immaturity. A larger Vd (total body water) accounts for the equivalent dose for each kilogram of body weight, and the reduced glomerular function in infants compared with older children or adults accounts in part for the longer duration of action.[86] As in the case of drugs excreted by the liver, there is a triphasic developmental response to drugs excreted by the kidneys when expressed as per kilogram (see Fig. 7.5): a prolonged half-life in neonates (immature renal function), a shortened half-life in young children, and a greater elimination half-life in adolescents and adults (size-related).

Reduced protein binding in neonates and preterm infants increases the free fraction of drugs delivered to the kidneys and liver for metabolism; however, reduced clearance results in a greater potential for toxicity.[2,3,5,6] An important example is the immature clearance of bupivacaine, which resulted in large plasma concentrations that increased sufficiently to cause seizures in neonates treated with epidural infusions at rates greater than that at which it was metabolized.[200]

Central Nervous System Effects

Laboratory data have demonstrated that the lethal dose in 50% of neonatal animals (LD_{50}) for many drugs depends on age: the LD_{50} is significantly less in neonatal than in adult animals.[201,202] The sensitivity of human neonates to most of the sedatives, hypnotics, and opioids is clinically well known and may in part be related to increased brain permeability (immature BBB or damage to the BBB) for some medications.[203–209] Laboratory studies have demonstrated greater brain concentrations of morphine and amobarbital in infant than in adult animals.[210]

However, respiratory depression, measured by CO_2 response curves or arterial oxygen tension, is similar from 2 to 570 days after birth at the same morphine blood concentration.[211] Altered PK may contribute to the increased sensitivity to morphine in neonates. A reduced clearance and a reduced Vd in neonates will result in greater plasma concentrations in this age group compared with older children given similar weight-scaled doses,[212,213] and this greater concentration contributes more to respiratory depression than the increased brain permeability in those who were not premature.

Drugs that are not particularly lipid soluble may enter the brain more easily in neonates with incomplete myelination than in infants where the BBB is intact.[203,204,210,214] When considering the use of any centrally acting medication in children younger than 1 year of age, and particularly those less than 48 weeks PMA, one must balance the potential risks and benefits. The dose must be carefully calculated and titrated to the minimum dose that achieves the desired response. Careful monitoring of vital signs is critical because prolonged effects or adverse clinical responses may occur in children at any age, but particularly in infants in whom CNS maturation may be incomplete.

Pharmacodynamics in Children

Children's responses to drugs have much in common with the responses in adults.[215] The perception that drug effects differ in children may be attributed to the patchy study of drugs in pediatric populations who have size- and maturation-related effects, as well as different diseases. Neonates and infants, however, often have altered PD. For example, the increased sensitivity of the neonate to morphine compared with children may be attributable, in part, to altered PK (reduced clearance, smaller Vd), but it may also be a reflection of the developmental regulation of opioid receptors.[216]

The MAC for most inhalational anesthetics is less in neonates than in infants, which in turn is greater than that observed in children and adults.[217] The MAC of isoflurane in preterm neonates less than 32 weeks gestation is 1.28%, and that in neonates 32 to 37 weeks gestation is 1.41%.[218] This value increases to 1.87% by 6 months of age before decreasing again throughout childhood.[218] The cause of these age-related differences is uncertain and may relate to maturational changes in cerebral blood flow (CBF), γ-aminobutyric acid (GABA) class A receptor numbers, or developmental shifts in the regulation of chloride transporters.[219–221]

Neonates have an increased sensitivity to the effects of NMBDs.[86] The reason for this is unknown, but it is consistent with the observation that there is a 3-fold reduction in the release of acetylcholine from the infant rat phrenic nerve as well as a relatively reduced muscle mass.[222–225] The increased Vd, however, means that a single NMBD dose (calculated as milligrams per kilogram) in the neonate results in blockade at a reduced plasma concentration while the decreased clearance prolongs the duration of effect.

Both the coagulation[226,227] and the fibrinolytic systems[228–231] are immature at birth. Consequently, the target plasma concentration of antifibrinolytic drugs required to achieve similar effects in neonates is less than that in adults. Although the concentration of ε-aminocaproic acid (EACA) required to inhibit fibrinolysis in adult plasma in vitro is 130 mg/L, the concentration required

in neonatal plasma is much smaller, 50 mg/L.[232,233] The dose of EACA must be adjusted in neonates because of both the immaturity of their antifibrinolytic clearance pathways and the coagulation cascade.

Cardiac calcium stores in the endoplasmic reticulum are reduced in the neonatal heart because of immaturity. Exogenous calcium has greater impact on contractility in this age group than in older children and adults. Conversely, neonates may suffer cardiac arrest if given the calcium antagonist, verapamil.[234] Immaturity of myocardial potassium channels prolongs the QT interval in neonates; neonates exhibit a greater sensitivity toward QTc (corrected QT) interval prolongation compared with older children. This made them more sensitive to sotalol given for supraventricular tachycardia (SVT).[235]

Amide local anesthetic agents induce blocks of briefer duration and require a larger weight-scaled dose to achieve similar dermatomal levels when given by subarachnoid block to infants. This may be due, in part, to myelination, spacing of the nodes of Ranvier, the length of nerve exposed, increased relative volume of CSF, as well as other size factors. There is an age-dependent expression of intestinal motilin receptors and the modulation of gastric antral contractions in neonates. Prokinetic agents may not be useful in very preterm infants, partially useful in older preterm infants, and useful in full-term infants. Similarly, bronchodilators in infants are less effective because of the paucity of bronchial smooth muscle that can cause bronchospasm.

Drug effects in neonates may not be evident until later in life. Neonates and young children may suffer permanent effects resulting from a stimulus applied at a sensitive point in development. For example, congenital hypothyroidism, if untreated, causes lifelong phenotypic changes. The incidence of vaginal carcinoma in children of mothers treated with stilboestrol during pregnancy is great.[236]

Corticosteroids are associated with growth retardation in children with asthma.[237] There are concerns that neonatal exposure to some anesthetic agents (e.g., ketamine, midazolam) may cause widespread neuronal apoptosis and long-term memory deficits (see Chapter 25).

MEASUREMENT OF PHARMACODYNAMIC ENDPOINTS

Outcome measures are more difficult to assess in neonates and infants than in children or adults. Measurement techniques, disease and pathology differences, inhomogeneous groups, recruitment issues, ethical considerations, and endpoint definitions for establishing efficacy and safety often confuse interpretation of the measures.[238]

Common effects measured in infancy include anesthesia depth, pain responses, depth of sedation, and intensity of neuromuscular blockade. A common effect measure used to assess depth of anesthesia is the EEG or a modification of detected EEG signals (spectral edge frequency, bispectral index [BIS], entropy). Physiologic studies in adults and children indicate that EEG-derived anesthesia depth monitors can provide an imprecise and drug-dependent measure of arousal. Although the outputs from these monitors do not closely represent any true physiologic entity, they can be used as guides for anesthesia, and in so doing, may improve outcomes in adults. In older children the physiology, anatomy, and clinical observations indicate the performance of the monitors may be similar to that in adults. In infants, however, their use cannot be supported in theory or in practice at this time.[239,240] During anesthesia, the EEG in infants is fundamentally different from the EEG in older children; there remains a need for specific neonate-derived algorithms if EEG-derived anesthesia depth monitors are to be used in neonates.[241,242] Examples of problems with BIS monitoring in infants and young children include the observations that BIS numbers paradoxically increase when sevoflurane concentrations exceed 3% (1.2 × MAC), there is often a difference between the right and left sides of the brain, equivalent MAC values yield different BIS values with each agent, and values in children tend to be greater than those in adults at equivalent MAC values (see also Chapter 52).[243–247]

The Children's Hospital of Wisconsin Sedation Scale has been used to investigate ketamine in the emergency department.[66,248] However, despite the use of such scales in procedural pain or sedation studies, few behavioral scales have been adequately validated in this setting and interobserver variability can be substantial.[249–251] Most scores are validated for the acute, procedural setting and are less robust for subacute or chronic pain or stress.

THE TARGET CONCENTRATION APPROACH

The goal of treatment is the target effect. A PD model is used to predict the target concentration given a target effect. Population estimates for the PD model parameters and covariate information are used to predict typical PD values in a specific patient. Population estimates of PK model parameter estimates and covariate information are then used to predict typical PK values in a typical patient. For example, a dexmedetomidine steady-state target concentration of 0.6 μg/L may be achieved with an infusion of 0.33 μg/kg per hour in a neonate, 0.51 μg/kg per hour in a 1-year-old, and 0.47 μg/kg per hour in an 8-year-old.[176] This target concentration strategy is a powerful tool for determining the clinical dose.[252] Monitoring the drug concentrations in serum and Bayesian forecasting may be used to improve the dose in individual patients.

This target effect approach is intrinsic to pediatric anesthesiologists using target-controlled infusion systems (see also Chapter 8). These devices target a specific plasma or effect-site concentration in a typical individual and this concentration is assumed to have a typical target effect. The target concentration is one that achieves a target therapeutic effect (e.g., anesthesia) without excessive adverse effects (e.g., hypotension). Unfortunately, these devices have still not been approved by the Food and Drug Administration (FDA) for use in the United States.

DEFINING TARGET CONCENTRATION

An effect-site target concentration has been estimated for many drugs used in anesthesia, analgesia, and sedation. For example, a propofol target concentration of 3 mg/L or 3 μg/mL in a typical patient can be achieved using preprogrammed target-controlled infusion devices. In teenagers, a BIS monitor can provide feedback to guide the infusion rate to achieve a desired target effect in the particular individual. The luxury of such a feedback system is not available for most drugs and unfortunately may be of little value in neonates and infants.

A target concentration of 10 μg/L may be used for morphine analgesia. Observations in children after cardiac surgery found that steady-state serum concentrations greater than 20 μg/L resulted in hypercarbia ($PaCO_2$ [partial pressure of carbon dioxide in arterial blood] >55 mm Hg) and flattened CO_2 response curves. During wash-out, morphine concentrations in excess of 15 μg/L caused hypercarbia in 46% of children, whereas concentrations less than 15 μg/L were associated with hypercarbia in only 13%. No age-related differences in the respiratory effect occurred at the same serum concentration of morphine.[211] Observation or self-reporting

pain scales are used as part of the feedback loop for dose incremental changes.

The target concentration may vary depending on the desired target effect. The target concentration for ketamine analgesia (0.25 mg/L) differs substantially from that of anesthesia (2 mg/L), and BIS monitoring would be totally useless because ketamine causes central excitation, thereby increasing bispectral monitoring numbers.[253–256]

Drug Interactions

There are many common examples of drug interactions that increase or decrease responses mediated through either PK or PD routes. Phenobarbital induction of CYP3A4 metabolism and consequent increased ketamine requirements for radiologic sedation[143] is an example of a PK interaction. PK interactions are often dealt with in mixed-effects modeling by including the effect of a second drug as a covariate on affected PK parameters such as those describing clearance (CL), volume of distribution (Vd), or bioavailability (F). The midazolam-propofol PK interaction has been investigated by adjusting midazolam CL and V using propofol plasma concentrations included in an exponential covariate model—that is,

$$CL_{IND} = CL_{POP} * \exp^{(cov(C_{PROP} - Median\ C_{PROP}))}, \qquad \text{Eq. 7.21}$$

where CL is clearance from the central compartment, for the population (CL_{POP}) and the individual (CL_{IND}). Here, the effect of plasma propofol concentration (C_{PROP}) on the CL parameter is estimated (the parameter "cov") and scaled to the population median C_{PROP}.

Interactions may also occur at entry into the effect site. An increase in the $T_{1/2}$keo of *d*-tubocurarine with increasing inspired concentrations of halothane has been reported.[257] Halothane is a negative inotrope[258] and reduces skeletal muscle blood flow,[259] so it is reasonable to interpret changes in $T_{1/2}$keo as a result of changes in organ blood flow.

Competitive antagonists reduce receptor availability by competing for occupancy at the same receptor site. Drugs that elicit an effect are called agonists, while those that do not are called antagonists, so the occupancy of some receptors by the antagonists results in less effect. In general, competitive antagonists shift the effect-concentration curve to the right by altering the C_{50}. The Emax equation (Eq. 7.19) can then be expressed as

$$Effect = E0 + \frac{Emax \cdot Ce^N}{\left(\left(EC_{50}{}^N \bullet \left[1 + \frac{A}{EA_{50}}\right]\right) + Ce^N\right)} \qquad \text{Eq. 7.22}$$

where Ce is the concentration in the effect site, and A and EA_{50} represent ligand A concentration and potency. Noncompetitive antagonists shift the observed maximum effect (Emax) rather than the C_{50}:

$$Effect = E0 + \frac{Emax \bullet \left(1 - \frac{A}{A + EA_{50}}\right) \bullet Ce^{\gamma}}{Ce^{\gamma} + C_{50}^{\gamma}} \qquad \text{Eq. 7.23}$$

PD interactions are not restricted to same-site binding interactions; some proteins have multiple binding sites, and ligands binding at these sites can also alter the above relationship (i.e., through changes in protein conformation that lead to downstream changes or modulate agonist-receptor affinity). These are referred to as "allosteric" interactions. Action at a receptor level may be studied in vivo. Several techniques exist for evaluating pharmacodynamic interactions in vivo.

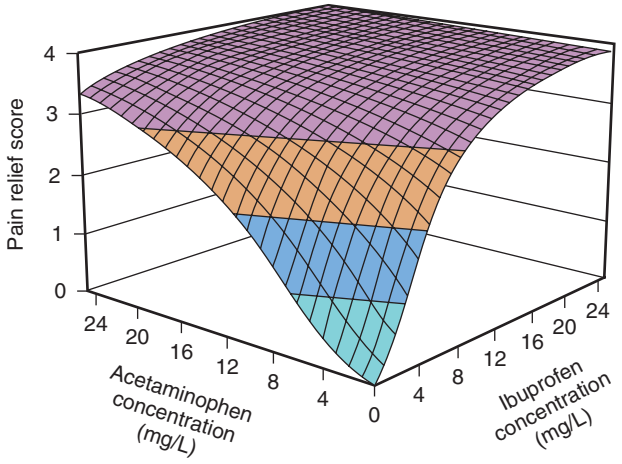

FIGURE 7.13 The response surface of analgesic effect for acetaminophen and ibuprofen. Concentrations are those in the effect compartment. The concentration response for acetaminophen is plotted on the *x-y* axis, while that for ibuprofen is on the *z-y* axis. The "surface" is that plotted between these axes. Each point on the surface is a measure of the pain relief provided by acetaminophen and ibuprofen combination. (From Hannam J, Anderson BJ. Explaining the acetaminophen-ibuprofen analgesic interaction using a response surface model. *Paediatr Anaesth*. 2011;21(12):1234–1240, with permission.)

Anesthetic drug interactions traditionally have been characterized using isobolographic analysis or multiple logistic regression. Minto[260] and Greco[261] proposed models based on response-surface methodology (see Chapter 8). Computer simulations based on interactions at the effect site predicted that the maximally synergistic three-drug combination (midazolam, propofol, and alfentanil) tripled the duration of effect compared with propofol alone. The response surface for ibuprofen and acetaminophen is shown in Fig. 7.13. The addition of acetaminophen to ibuprofen improved analgesia when the dose of ibuprofen was less than 100 mg (5 mg/kg) in a 5-year-old child.[262] Response surfaces can describe anesthetic interactions, even those between agonists, partial agonists, competitive antagonists, and inverse agonists.[260,263]

Inhalation anesthetic agents can prolong the duration of block, and this effect is agent specific. When compared with halothane, sevoflurane potentiates the effects of vecuronium to a greater extent. When compared with balanced anesthesia, sevoflurane and halothane decrease the dose requirements of vecuronium by 60% and 40%, respectively.[264]

Surface modeling techniques have been used to demonstrate strikingly synergistic effects from sevoflurane with alfentanil[265] and remifentanil with propofol[266,267] on respiration in adults.[265,266,268,269] It is little wonder that the use of three or more sedating medications is associated with significantly more adverse outcomes than the use of one or two medications.[266]

The Drug Approval Process, the Package Insert, and Drug Labeling

A great concern has been the general lack of regulatory approval of many of the medications for populations of pediatric patients.

This is particularly ironic because most of the changes in legislation pertaining to pharmaceuticals have been the result of adverse events in infants and children. The 1938 Federal Food, Drug, and Cosmetic Act[270] replaced the original Federal Food and Drugs Act of 1906 (Wiley Act)[271] because nearly 100 individuals, mostly children, were poisoned by diethylene glycol (an antifreeze analog for vehicles) that had been added to an elixir of sulfanilamide. This new legislation prohibited the addition of poisonous substances (unless they were demonstrated to be safe in small concentrations) and instituted other measures to protect the consumer. The next major piece of legislation was the Kefauver-Harris Amendments, which were passed in 1962 after the thalidomide catastrophe.[272] This legislation strengthened the safety standards by requiring the drug company to demonstrate effectiveness before marketing. The U.S. FDA then allowed drugs to be marketed to adults as *"safe and effective,"* but now the drug label was required to indicate that *"safety and effectiveness had not been established in children"* because no trials in children had been carried out. This had an enormous negative impact on drug development for children and led Shirkey to coin the now common expression *"therapeutic orphans"* when referring to drug development for children.[273]

Until the late 1990s, nearly 80% of approved medications contained language within the drug label (package insert) that excluded children of varying ages; it should be noted that the legislation described later in the text has now resulted in some pediatric labeling in ~60% of marketed medications, which is an unequivocal victory for drug safety in children.[274] The majority of the drugs used in the operating room (OR) and the intensive care unit (ICU) today have similar language.[275] Common examples of disclaimers for drugs used in our daily practice include those for bupivacaine (*"Until further experience is gained in children younger than 12 years, administration of Sensorcaine [bupivacaine HCl] injection is not recommended"*)[269] and for fentanyl (*"The safety of SUBLIMAZE in children younger than two years of age has not been established"*).[276] Such disclaimers are placed in the package insert because the contents of the package insert must, by law, be based on *"adequate, well controlled studies involving children."*[272,277–279] Any use of a drug that is not specifically described in the package insert is considered *"unapproved"* or *"off label."* The reason for the lack of labeling for children is that the appropriate controlled clinical trials were never supported by industry and the FDA did not have the legislative power to force the pharmaceutical companies to perform pediatric studies.[280] In 1994, the FDA passed a new interpretation of the original Food, Drug, and Cosmetic Act[270,278,281] that allowed manufacturers to review the published medical literature and submit these data to the FDA to support revised pediatric labeling.[279] This led to additional changes in the drug label for 48 medications. Unfortunately, for drugs that were no longer under patent protection, there was no financial incentive to force the issue, so many drugs remained unlabeled for children despite many publications that outlined their safe use in children of all ages.

During the early stages of the AIDS epidemic, there was great pressure placed on the FDA to reduce the time for the drug approval process. New legislation was passed to raise funds to pay for additional consultants and experts to help the FDA with this process (The Prescription Drug User Fee Act [PDUFA]).[282] This legislation was renewed in 1997, 2002, 2007, and 2012 and was redrafted for the sixth time (PDUFA VI) and signed into law in August 2017, thus providing "stable and consistent funding during fiscal years 2018–2022."[282a,282b] The PDUFA regulations have three components: (1) an application fee when a new drug or biologic is submitted to the FDA, (2) an annual product fee for nongeneric marketed drugs, and (3) an annual fee for each manufacturing site for nongeneric drugs.[282c] The goals of the new legislation are to further enhance scientific expertise and processes for regulatory decisions, improve patient perspectives in drug development, and provide longer stability of the PDUFA initiative. The monies from these fees greatly reduce the time from a New Drug Application (NDA) or Biologic License Application (BLA) to be marketed. The most recent iterations have expanded funding to support marketing safety and pharmacoepidemiology activities, as well as increased inspection of non–USA-based pharmaceutical manufacturing facilities. Approximately 72% of NDAs or BLAs were approved on the first application under PDUFA V compared with ~55% under PDUFA IV.[283,284]

Additional changes at the FDA occurred in the late 1990s when the Food and Drug Administration Modernization Act[268] and the Final Rule were passed.[285] Tacked onto this legislation was the Better Pharmaceutical Act for Children, which granted 6 months of patent extension in exchange for pediatric studies of drugs that were still patent protected. This was later replaced with the Best Pharmaceutical Act for Children (BPCA) in 2002, which earmarked money for the National Institutes of Health (NIH) to support study of drugs no longer patent protected.[286] This was subsequently challenged as giving excessive legal power to the FDA, but further legislation reinstituted the legal power to the FDA to now require drug companies to conduct research in children if the drug would have use in children (the Pediatric Research Equity Act).[287] PDUFA IV was a much larger bill entitled the Food and Drug Administration Amendments Act of 2007. This bill renewed PDUFA IV, the Medical Device User Fee and Modernization Act, and BPCA.[288] Of importance to researchers was the new requirement for registration of all clinical trials with an archive of thousands of trials that is easily searchable for clinicians as well as the public.[289] Many journals now will not publish clinical pharmaceutical trials that have not been registered. Since the first legislation for children passed in 1998, there has been an explosion of pediatric drug trials (>1000 requested or carried out since 1997) and new drug labels have been created for 703 drugs; between 2005 and 2017 patent extension has been granted to at least 79 medications (https://www.accessdata.fda.gov/scripts/sda/sdNavigation.cfm?sd=labelingdatabase).[290] Unfortunately, the money that was supposed to be earmarked to the NIH for generic drug trials has not been fully provided, so deficiencies in labeling for older drugs persist.[291]

It is important for clinicians to appreciate that despite language on the label regarding use in children, they are perfectly within their medical and legal rights to use these drugs based on their judgment. *"Unapproved use does not imply an improper use and certainly does not imply an illegal use."*[292,293] The use of a drug in a child is the decision of the individual physician and may be based on the available literature, despite the fact that formal FDA approval and labeling have not been achieved.[277,278] The Committee on Drugs of the American Academy of Pediatrics is very clear on this issue: *"Lack of approval for a specific use should not prevent physicians from prescribing an available drug in the best interest of their patients."*[292,293]

Inhalation Anesthetic Agents

PHYSICOCHEMICAL PROPERTIES

The potent inhaled anesthetics are ether-based anesthetics with either a methyl ethyl (enflurane, isoflurane, and desflurane) or a

methyl isopropyl (sevoflurane) polyhalogenated ether skeleton (E-Table 7.1). The single exception in chemical structure is halothane, which is a polyhalogenated alkane. Of the methyl ethyl ether anesthetics, isoflurane and enflurane, are constitutional isomers. Desflurane differs from isoflurane in the single atomic substitution of a fluoride for a chlorine atom on the α-carbon of isoflurane. Sevoflurane differs from isoflurane in the substitution of a trifluoromethyl group for the chlorine atom, resulting in a methyl isopropyl structure. Although the general chemical structures of the four ether agents are similar, the single atomic substitutions confer substantially different physicochemical and pharmacologic properties described in later text and contrasted to the properties of halothane (see E-Table 7.1).

In comparison to the potent inhaled anesthetics, nitrous oxide and xenon exist in gaseous form under atmospheric conditions. Nitrous oxide is a by-product of chemical processes, whereas xenon is a naturally occurring element (0.05 ppm in the atmosphere), produced by fractional distillation of atmospheric gas. Environmentally, nitrous oxide depletes the ozone layer, whereas xenon is environmentally inert. There is a wealth of data on the pharmacology of nitrous oxide in humans but far less on xenon in adults and none, to date, in children.

PHARMACOKINETICS OF INHALED ANESTHETICS

The rate of increase or equilibration of the partial pressures of alveolar to inspired anesthetic (also known as the wash-in) is a function of the rate of delivery of anesthetic to and uptake from the lungs. Six factors determine the wash-in of inhaled anesthetics (Table 7.3)[294]: the first three determine the delivery of anesthetics to the lungs, and the second three determine their rate of removal (uptake) from the lungs. The wash-in, defined as the ratio of the alveolar to inspired anesthetic partial pressures (FA/FI, or fractional alveolar to fractional inspired partial pressures), increases from zero to a value of unity (1), when the inspired and alveolar partial pressures have equilibrated (Fig. 7.14). Although not shown in the figure, the wash-in of xenon should be the most rapid of all inhaled anesthetics based on its physicochemical properties (see E-Table 7.1).[295] For the FA/FI to increase toward equilibration, the rate of delivery of anesthetic to the lungs must substantially exceed its uptake from the lungs.

The rates of increase of FA/FI of halothane (as well as isoflurane, enflurane, and nitrous oxide) in infants and children are more rapid than those in adults (Fig. 7.15).[296–298] The more rapid rate of increase of FA/FI in neonates compared with adults has been attributed to four factors (Table 7.4); the order in the table reflects their relative contributions to the rapid wash-in. Based on these factors and their physical chemical properties, we speculate that the wash-in of sevoflurane and desflurane in neonates and infants will be comparable to those in adults. This amounts to a safety factor for the latter anesthetics that was not previously afforded with halothane.

Reduced blood/gas solubility	

Factors Affecting Delivery of Inhaled Anesthetics to the Lungs

Inspired Concentration

The effect of the inspired concentration on the FA/FI of anesthetics relates only to those that are administered in large concentrations (i.e., nitrous oxide). The greater the FI of nitrous oxide, the more rapid the increase of FA/FI.[299] This effect, known as the concentration effect (second gas effect), depends on both a concentrating effect and an increase in alveolar ventilation that results from an increased uptake of nitrous oxide.[294] Hence, agents that depend on alveolar ventilation for their wash-in (i.e., the more soluble anesthetics) will have a more rapid wash-in when administered with nitrous oxide. This effect diminishes as the solubility of the anesthetic decreases and as time passes.[300–302]

Alveolar Ventilation and Functional Residual Capacity

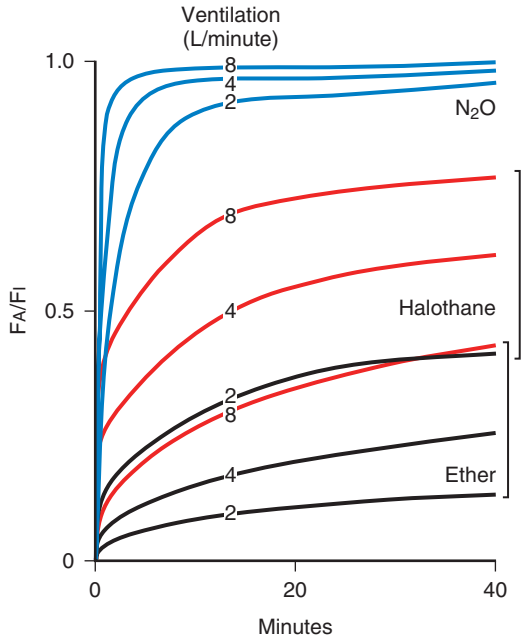
The ratio of alveolar ventilation (Va) to functional residual capacity (FRC), Va/FRC, is the primary determinant of the rate of the delivery of inhaled anesthetics to the lungs. The greater the Va/FRC ratio, the more rapid the FA/FI (E-Fig. 7.5). However, the ratio does not affect all anesthetics similarly: Va/FRC affects more soluble anesthetics (e.g., halothane) to a greater extent than less soluble anesthetics (i.e., sevoflurane and desflurane). In the case of soluble anesthetics (e.g., halothane), their increase in FA/FI depends substantively on a large Va/FRC ratio since their uptake from the lungs is great (because of their solubilities), and this limits the rate of increase in FA/FI. Changes in the Va/FRC directly affect the FA/FI of anesthetics in proportion to their blood solubilities.

In terms of age-related effects of FA/FI, the Va/FRC ratio accounts for most of the differences between the FA/FI of anesthetics in neonates and adults (see Table 7.4). The Va/FRC ratio is approximately 5 : 1 in neonates compared with only 1.5 : 1 in adults. The greater Va/FRC ratio in neonates may be attributed to the 3-fold greater metabolic rate and, therefore, 3-fold greater Va/FRC in neonates compared with adults. This is true for both spontaneous and controlled ventilation, depending on the settings used during controlled ventilation.

Factors Affecting the Uptake (Removal) of Inhaled Anesthetics From the Lungs

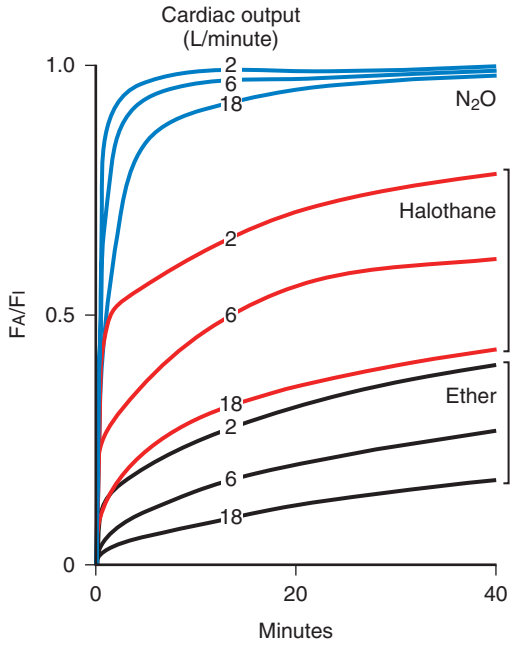
Cardiac Output

The rate of increase in FA/FI is inversely related to changes in cardiac output; that is, the smaller the cardiac output, the more rapid the increase in FA/FI and vice versa (E-Fig. 7.6). As cardiac output diminishes, less anesthetic is removed from the lungs, thus increasing the rate of equilibration of FA/FI. A patient in heart failure who receives an inhalational induction may achieve greater anesthetic concentrations in the lungs more rapidly than expected compared with a patient with a normal cardiac output. This very serious problem may be exacerbated if the "overpressure" technique has been used, because it may cause acute anesthetic-induced myocardial depression and decompensation in cardiac output. Conversely, in a high cardiac output state (as in the case of anxiety), the greater blood flow through the lungs removes more anesthetic from the alveoli, thus reducing the alveolar partial pressure of anesthetic, which slows the rate of equilibration of FA/FI. The impact of changes in cardiac output on FA/FI depends, in part, on the solubility of the anesthetic: the less soluble the anesthetic (sevoflurane and desflurane), the less this effect and vice versa.[294] This represents yet another safety feature of the less soluble anesthetics currently in use.



Paradoxically, the greater cardiac index in neonates actually speeds the increase in FA/FI. This has been attributed to the preferential distribution of the cardiac output to the vessel-rich group (VRG) of tissues (brain, heart, kidney, splanchnic organs, and endocrine glands) in neonates. The VRG receives a greater proportion of the cardiac output in neonates compared with adults because the VRG constitutes 18% of the body weight in the former compared with only 8% in the latter. As a result of the increased blood flow to the VRG, the partial pressures of anesthetics in the VRG equilibrate with those in the alveoli more rapidly in neonates than in adults. Because the uptake of anesthetic by tissues other than those in the VRG in neonates is small, the rapid increase in FA/FI in the VRG and blood suggests that the partial pressure of anesthetic in venous blood returning to the lungs rapidly equilibrates with that in the alveoli. Uptake of anesthetic from the lungs then diminishes. The net effect of the greater cardiac output in neonates is paradoxical in that it speeds the equilibration of anesthetic partial pressures in the VRG and thus speeds the equilibration of FA/FI. This also explains the "downward spiral" that occurs when an excessive concentration of inhaled agent (particularly the soluble anesthetic halothane) is administered to a neonate or infant during controlled ventilation, as discussed later.

Solubility



Inhalational agents partition into two compartments in body fluids and tissues: (1) an aqueous phase and (2) a protein/lipid phase. This partitioning is analogous to the distribution of gases such as oxygen in blood between the aqueous phase (dissolved fraction) and hemoglobin (bound fraction). Because inhaled anesthetics move along partial pressure gradients (and not concentration gradients) within and between fluids and tissues, the rate of increase of FA/FI and, therefore, the anesthetic partial pressure in blood determines how rapidly anesthetics move in and out of tissues and affect organ function (e.g., central nervous and cardiac systems).

The rate of increase of FA/FI of inhalational anesthetics, which varies inversely with the solubility of the anesthetic in blood, follows the order: nitrous oxide > desflurane > sevoflurane > isoflurane > enflurane > halothane > methoxyflurane (see E-Table 7.1 and Fig. 7.14).[294,303] Although the solubilities of nitrous oxide and desflurane are similar, the rate of increase in FA/FI of nitrous oxide is more rapid than that after desflurane because of the concentration effect from administering 70% nitrous oxide. After a stepwise change in the inspired partial pressure of less soluble anesthetics, the alveolar partial pressure equilibrates rapidly with the new inspired partial pressure. Because the wash-out of these anesthetics is equally rapid (see later), the alveolar partial pressure can be adjusted to previous values rapidly by decreasing the inspired partial pressure. Thus anesthetic depth can be adjusted more rapidly with a less soluble (i.e., desflurane or sevoflurane) than with a more soluble inhalational anesthetic (i.e., halothane).

Age is an important determinant of the solubility of inhalational anesthetics in blood. The blood solubilities of halothane, isoflurane,

E-FIGURE 7.5 Effect of alveolar ventilation on the wash-in (F_A/F_I) of more soluble (i.e., halothane) and less soluble (i.e., N_2O) anesthetics. Changes in ventilation speed the wash-in of more soluble anesthetics to a greater extent than do changes in ventilation for less soluble anesthetics. *FA*, fractional alveolar partial pressure of anesthetic; *FI*, fractional inspired partial pressure of anesthetic; *N_2O,* nitrous oxide. E-FIGURE 7.6 Effect of cardiac output on the wash-in (F_A/F_I) of more soluble (i.e., halothane) and less soluble (i.e., N_2O) anesthetics. Decreases in cardiac output from 18 to 2 L/minute speed the wash-in of more soluble anesthetics to a greater extent than it does less soluble anesthetics. See text for explanation. *FA*, fractional alveolar partial pressure of anesthetic; *FI*, fractional inspired partial pressure of anesthetic; *N_2O,* nitrous oxide. (Redrawn from Eger EI 2nd. *Anesthetic Uptake and Action*. Baltimore: Williams & Wilkins; 1974.)

enflurane, and methoxyflurane are 18% less in neonates than in adults (E-Fig. 7.7; see also E-Table 7.1).[304] Serum cholesterol and proteins (including albumin) account for these age-related differences in blood solubilities.[304,305] In contrast, the blood solubility of the less soluble anesthetic sevoflurane is similar in neonates and adults.[305] Factors that do not significantly affect the blood solubility of most inhaled anesthetics include age-related differences in hemoglobin, serum concentration of α_1-acid glycoprotein, and prematurity.[304,305]

The tissue/gas solubilities of the inhaled anesthetics in the VRG in neonates are approximately one-half those in adults (E-Fig. 7.8).[306] The reduced tissue solubilities in neonates are attributable to two differences in the composition of tissues: (1) greater water content and (2) decreased protein and lipid concentrations. In terms of the uptake and distribution of inhaled anesthetics in tissues, the tissue/blood solubilities determine the speed of equilibration of anesthetics in tissues. The reduced tissue solubilities of inhaled anesthetics reduce the time for partial pressure equilibration of anesthetics (see time constant discussion, later). Although the partial pressures of inhaled anesthetics in tissues cannot easily be measured in vivo, they may be estimated by their concentrations in the exhaled or alveolar gases. The solubilities of these anesthetics in the brain of adults vary approximately 50% from desflurane to halothane (see E-Table 7.1). In the case of neonates, the reduced tissue solubilities of inhaled anesthetics speed the rate of increase in FA/FI compared with the rates in adults. In the cases of sevoflurane and desflurane, their respectively small but similar blood solubilities and likely similar tissue solubilities in neonates and adults offer a safety factor in neonates compared with adults, because tissue equilibration of these relatively insoluble inhalational anesthetics should be similar in both age groups. In contrast, the reduced tissue solubility of halothane in neonates leads to a more rapid and unexpected anesthetic effect compared with the time course in adults.

We can estimate the time to equilibration of the partial pressures of inhaled anesthetic in tissues by calculating the time constant for equilibration in tissue. For example, the time constant (tau τ) for equilibration of anesthetic partial pressure in the brain is based on the expression:

$$\tau_{brain} = \frac{\text{Volume of the brain (mL)} \times \text{Brain/blood solubility}}{\text{Brain blood flow (mL/minute)}},$$

Eq. 7.24

where one time constant is the time for 63% equilibration of brain to blood anesthetic partial pressures. If the blood flow to the brain is approximately 50 mL/minute per 100 g of brain tissue and the brain/blood solubility ratio for an inhalational anesthetic is 2.0 (assuming the density of brain tissue is 1 g/mL), then the time constant is:

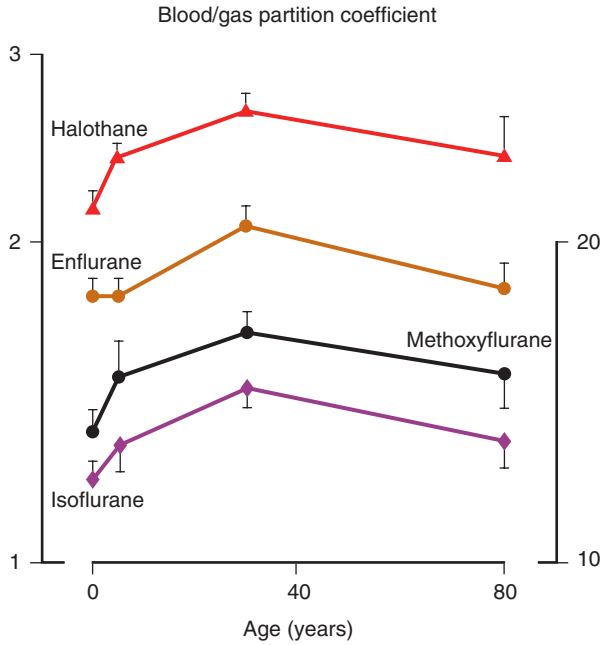
$$\tau_{brain} = \frac{100\ \text{mL} \times 2}{50\ \text{mL/minute}} = 4\ \text{minutes}$$

Knowing that four time constants achieve 98% equilibration, then the time to 98% equilibration is 16 minutes. If the brain/blood solubility ratio were halved to 1.0, as it might be in the case of the neonate, then the time to 95% equilibration would decrease by 50% to 8 minutes. *Thus the time to equilibration of anesthetic partial pressure within the brain of the neonate would be approximately one-half that of the adult but still requires 8 minutes.* This holds true for the more soluble anesthetics, such as halothane, whose tissue solubility in neonates is diminished compared with adults[306] but not for the less soluble anesthetics, such as desflurane and sevoflurane, whose tissue solubilities may be similar in neonates and adults.

Whereas the PK of inhalational anesthetics during the first 15 to 20 minutes depends primarily on the characteristics of the VRG, the PK during the subsequent 20 to 200 minutes depends primarily on the characteristics of muscle.[294] The solubility of inhalational anesthetics in skeletal muscle varies directly with age in a logarithmic relationship.[306] Thus the lower solubility of inhalational anesthetics in the muscle of neonates and the smaller muscle mass speed the increase in FA/FI during this period compared with that in adults. This effect of age on the solubility of anesthetics in muscle has been attributed to age-dependent increases in protein concentration (i.e., muscle bulk) during the first 5 decades of life and in fat content during the subsequent 3 decades of life.[306] Overall, the reduced solubility combined with the reduced muscle mass in neonates (and infants) decreases uptake by the muscle group, leaving the FA/FI to equilibrate more rapidly in neonates compared with adults.

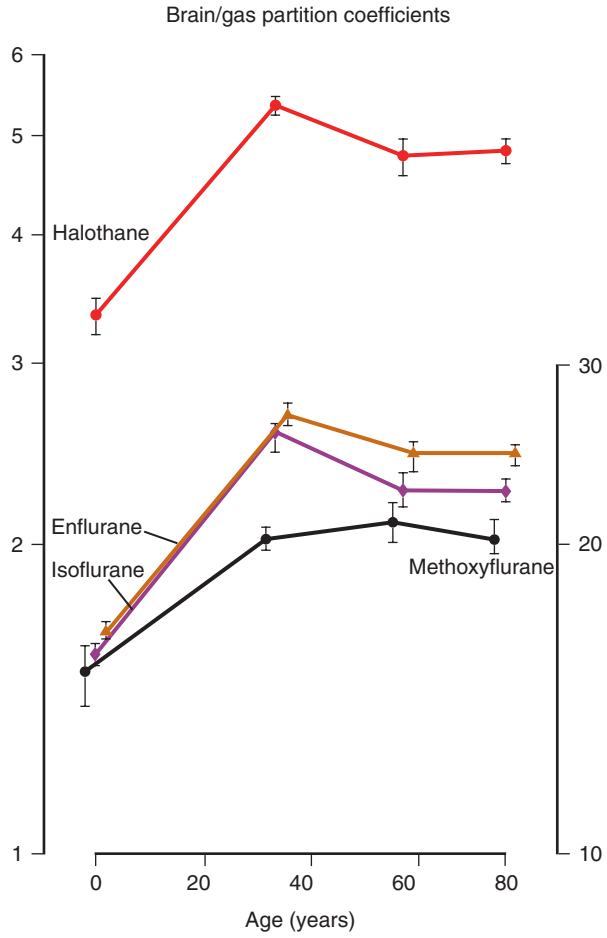
Alveolar to Venous Partial Pressure Gradient

The difference in the anesthetic partial pressures between the alveolar and venous blood returning to the heart is a measure of the driving force of inhalational anesthetics from the alveoli into the bloodstream. As the anesthetic partial pressures in the VRG, muscle group, and others approach equilibration and less anesthetic is taken up by those tissues, the anesthetic partial pressure in the blood returning to the heart is similar to that when it left the alveoli. Thus the driving force for anesthetics to move along a partial pressure gradient from the alveoli to the blood is diminished. This reduces the partial pressure gradient and diminishes the uptake of anesthetic from the alveoli.



Second Gas Effect

When two anesthetics are administered simultaneously, the wash-in of the anesthetic administered in a small concentration may be increased if the uptake of the second anesthetic is relatively large.[294] Nitrous oxide is the only anesthetic for which the uptake may be relatively large compared with that of the potent inhalational anesthetics, as described earlier. There is evidence, however, that casts doubt on the clinical relevance of the second gas effect.[307,308] These data suggest that the concentrating effect, if it exists in humans at all, is a small and weak effect.



Induction

The more rapid increase in FA/FI of insoluble anesthetics compared with soluble anesthetics is generally thought to result in a more rapid induction of anesthesia. However, the speed of induction of anesthesia depends not only on the wash-in (PK) but also on (1) the potency or MAC of the agent, (2) the rate of increase of the inspired concentration, (3) the maximum inspired concentration, and (4) respiration (including airway irritability and the mode of ventilation [spontaneous or controlled]). It is the combination of these four factors that determines the relative rate of induction of anesthesia.

The rate of wash-in of inhalational anesthetics into the lungs varies inversely with their solubilities in blood. Although anesthetics that are less soluble (e.g., sevoflurane and desflurane) wash into the lungs more rapidly than more soluble anesthetics (e.g., halothane), the more rapid increase in FA/FI of less soluble anesthetics is offset by their greater MAC (see E-Table 7.1). To ensure that induction of anesthesia is as rapid with less soluble anesthetics as it is with more soluble anesthetics, two criteria must be satisfied.

E-FIGURE 7.7 Effect of age on the blood/gas partition coefficient of the four inhalational agents, isoflurane, enflurane, halothane (*left axis*), and methoxyflurane (*right axis*). The solubility of all four agents in neonates is 18% less than that in adults. (Redrawn from Lerman J, Gregory GA, Willis MM, Eger EI 2nd. Age and solubility of volatile anesthetics in blood. *Anesthesiology* 1984;61(2):139–143.)

E-FIGURE 7.8 Effect of age on the solubility of isoflurane, enflurane, halothane (*left axis*), and methoxyflurane (*right axis*) in human brain tissue. The solubilities of all anesthetics in neonatal brain tissues are less than those in older adults. (Redrawn from Lerman J, Schmitt-Bantel BI, Gregory GA, et al. Effect of age on the solubility of volatile anesthetics in human tissues. *Anesthesiology* 1986;65(3):307–311.)

First, the inspired concentration of the less soluble anesthetic must be increased in greater increments (based on the relative MAC values and wash-in profile, where the MAC is defined as the minimum alveolar [or end-tidal or end-expiratory] concentrations of anesthetic at which 50% of subjects do not move in response to a noxious stimulus) than the more soluble anesthetic and, second, the maximum inspired concentration of the less soluble anesthetic must provide an alveolar concentration that is equipotent with that of the more soluble anesthetic. Theoretically, the overpressure technique should provide rapid and similar rates of induction of anesthesia with anesthetics of differing solubilities. However, if the maximum inspired anesthetic concentrations from the vaporizers preclude the delivery of equipotent end-tidal concentrations or if airway irritability (as in the case of coughing and breath-holding) interrupts the smooth delivery of anesthetic, induction of anesthesia will not be comparable.

To illustrate this, contrast the steep wash-in of FA/FI for sevoflurane and halothane during the first few minutes of induction of anesthesia (see Fig. 7.14). The FA/FI for halothane in adults reaches 0.35 in the first few minutes, whereas that in children reaches ~0.45.[296] This corresponds with an alveolar concentration in a child of 2.25% or ~2.25 MAC multiples. Contrast this to the wash-in of sevoflurane during the same time frame; the FA/FI for sevoflurane in adults and children both reach ~0.5. This corresponds to an alveolar concentration in children of ~4% or 1.6 MAC multiples, 25% less than that achieved with halothane.

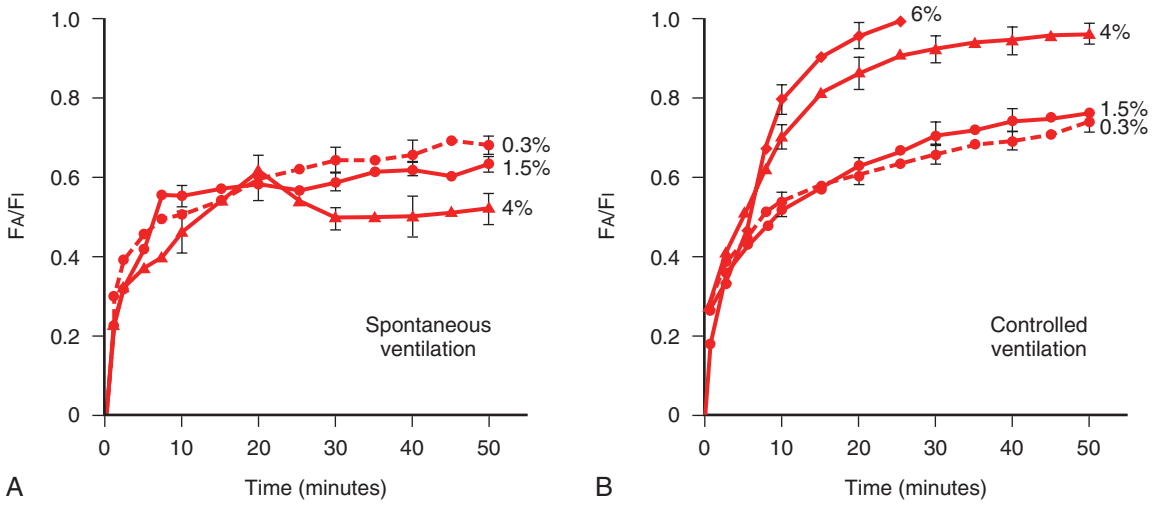
A similar but more clinically important case can be made for neonates with an MAC for halothane of ~0.87% and sevoflurane of 3.3%. With halothane the alveolar concentration reaches 2.9 MAC multiples, whereas with sevoflurane it reaches only 1.2 MAC multiples, 60% less depth of anesthesia. Thus it is difficult to rapidly induce a deep level of anesthesia with sevoflurane in spontaneously breathing neonates and infants but at the same time, more difficult to cause an anesthetic overdose during induction with sevoflurane compared with halothane in a neonate.

These two examples illustrate several extremely important features of the pharmacology of sevoflurane that distinguish it from halothane. First, it may be difficult to rapidly achieve a deep level of anesthesia with sevoflurane in children (as was previously achieved with halothane) when sevoflurane is the sole anesthetic. Hence, inserting an IV catheter or performing laryngoscopy and tracheal intubation or bronchoscopy immediately after induction of anesthesia with sevoflurane may result in a physiologic or motor (withdrawal) response or physiologic sequelae (bronchospasm), even if the inspired concentration remains at 8%. We caution against decreasing the inspired concentration of sevoflurane (and nitrous oxide) as soon as the eyelash reflex is lost or the child appears to have lost consciousness, because a deep level of anesthesia has not been achieved (despite theoretical fears of epileptiform brain activity, see later text). In such cases, supplemental IV anesthetics may be effective to rapidly deepen the level of anesthesia. Second, these examples illustrate an important safety feature of sevoflurane. With the current vaporizer design, anesthetic overdose with sevoflurane is not easily accomplished in neonates and infants because their large MAC values more than offset their reduced solubilities. These insights contribute to the cardiovascular safety profile of sevoflurane and explain why the morbidity and mortality associated with sevoflurane in children appear to be less than with halothane.[309] It should be noted that halothane vaporizers allow administration of many more MAC multiples than sevoflurane vaporizers, and this factor may also contribute to anesthetic ovedose (see later text).

CONTROL OF ANESTHETIC DEPTH

Two feedback responses modulate the depth of anesthesia during inhalational anesthesia: (1) a negative-feedback respiratory response and (2) a positive-feedback cardiovascular response. The feedback responses refer to the relationships between the inspired concentration of anesthetic and depth of anesthesia. After an increase in the inspired concentration, a negative feedback response refers to a decrease in the depth of anesthesia, whereas a positive-feedback response refers to an increase in the depth of anesthesia. Two examples that follow are used to illustrate the importance of these responses in clinical pediatric anesthesia practice.

During spontaneous respirations, as the partial pressure of inhaled anesthetics increases, alveolar ventilation decreases, thereby limiting both the wash-in of anesthetics and the depth of anesthesia achieved (E-Fig. 7.9A).[310] This negative-feedback response is a protective mechanism that permits the safe use of inspired concentrations of inhalational anesthetics that are severalfold greater than MAC (overpressure technique) during spontaneous respirations. Excessive depth of anesthesia cannot normally be achieved during spontaneous respirations (irrespective of the inspired concentrations of anesthetics, even if multiple anesthetics are administered simultaneously) because of the negative-feedback effect such anesthetic concentrations have by depressing minute ventilation. As alveolar ventilation decreases and the wash-in of anesthetics slows, the uptake of anesthetic by blood slows and the delivery of anesthetics to the VRG slows. When the partial pressure of anesthetics in the VRG exceeds that in blood, anesthetics move along their partial pressure gradients from the VRG into blood and other tissues, thus decreasing the depth of anesthesia. As the depth of anesthesia decreases, alveolar ventilation again increases and uptake of anesthetic from the alveoli resumes. *Thus spontaneous ventilation protects against an anesthetic overdose by virtue of its negative feedback effect to decrease respiration.*



In contrast to the negative-feedback response of spontaneous ventilation, the positive-feedback effect of controlled ventilation relentlessly delivers inhaled anesthetic to the alveoli, increasing both FA/FI and the depth of anesthesia, which in turn decreases cardiac output that, if unabated, may lead to cardiac arrest (E-Fig. 7.9B).[310] For a specific minute ventilation in a neonate, the risk of profound cardiovascular collapse occurring is reflected in part by the maximum number of MAC multiples the vaporizer can deliver; halothane and isoflurane ≫ sevoflurane and desflurane (Table 7.5). With sevoflurane and desflurane, the number of MAC multiples that can be administered (~2.5) is less than with halothane (~6), building in a safety margin with these two anesthetics.

The safety of spontaneous versus controlled ventilation during inhalational anesthesia is predicated on the feedback loops. This

TABLE 7.5 Minimum Alveolar Concentration Multiples for a Neonate Allowed by Current Vaporizers

Agent	Maximum Vaporizer Output (%)	MAC (%)	Maximum Possible MAC Multiples
Halothane	5	0.87	5.75
Isoflurane	5	1.20	4.2
Sevoflurane	8	3.3	2.42
Desflurane	18	9.16	1.96

See text for further discussion.
MAC, minimum alveolar concentration.

E-FIGURE 7.9 Effect of the mode of ventilation on the wash-in (F_A/F_I) of halothane in dogs. **A,** F_A/F_I reached a steady-state value independent of the inspired concentration of halothane between 0.3% and 4% inspired concentrations during spontaneous ventilation. All of the dogs survived. **B,** In contrast, F_A/F_I increased rapidly toward equilibration as the inspired concentration of halothane increased with controlled ventilation, reaching alveolar partial pressures after 20 minutes with 6% and after 60 minutes with 4% that resulted in cardiac arrest. This illustrates the negative feedback protection that spontaneous ventilation affords during inhalational anesthesia and the positive feedback depression of the heart that controlled ventilation may precipitate. *F_A*, fractional alveolar partial pressure of anesthetic; *F_I*, fractional inspired partial pressure of anesthetic. (Redrawn from Gibbons RT, Steffey EP, Eger EI 2nd. The effect of spontaneous versus controlled ventilation on the rate of rise of alveolar halothane concentration in dogs. *Anesth Analg*. 1977;56(1):32–34.)

has been illustrated in anesthetized dogs that all survived when they breathed halothane at 4% to 6% spontaneously, but died in a dose response when ventilation was controlled.[310] This concept is of particular importance in neonates and small infants who are more susceptible to the cardiodepressant effects of inhaled agents.[294]

Shunts

Two types of shunts exist in the lungs and heart: left-to-right or right-to-left. Left-to-right shunts refer to conditions in which blood recirculates through the lungs (usually via an intracardiac defect, such as a ventricular septal defect). In general, left-to-right shunts do not significantly affect the PK of inhalational anesthetics (they may affect IV medications), provided cardiac output remains unchanged. In contrast, right-to-left shunts refer to conditions in which venous blood returning to the heart bypasses the lungs as in an intracardiac shunt (cyanotic heart disease) or intrapulmonary shunt (pneumonia or an endobronchial intubation). With these shunts, the equilibration of FA/FI can be markedly delayed. The magnitude of the delay depends on the solubility of the anesthetic: the FA/FI of less soluble anesthetics is delayed to a greater extent than that of the more soluble anesthetics.[294] These effects are independent of the location of the shunt: intracardiac or intrapulmonary.

To understand the effects of right-to-left shunts on the PK of inhalational anesthetics, consider a simplified model of a right-to-left shunt using an endobronchial intubation to mimic the shunt. In this model, each lung is represented by one alveolus and each is perfused by one pulmonary artery (Fig. 7.16). When the tracheal tube is positioned with its tip at the mid-trachea level (Fig. 7.16A), ventilation is divided equally between both alveoli (lungs), thereby yielding equivalent anesthetic partial pressures in both pulmonary veins ($P\bar{v} = 1$). However, if the tip of the tracheal tube is advanced into the right main-stem bronchus (equivalent to a right-to-left shunt) (Fig. 7.16B), all of the ventilation is delivered to one alveoli (lung); that is, the ventilation to that alveoli (lung) is doubled and ventilation to the nonventilated lung is nil. Under these conditions, total ventilation remains unchanged. For the remainder of this discussion, it is important to recognize that with a right-to-left shunt, the end-tidal and blood anesthetic partial pressures will differ, with the magnitude of the difference dependent on the solubility of the anesthetic.

With a more soluble anesthetic (e.g., halothane), when the tracheal tube that is positioned in the right main-stem bronchus (to model a right-to-left shunt) doubling the ventilation to that lung speeds the increase in FA/FI (effect of changes in ventilation on the wash-in of soluble anesthetics) (see E-Fig. 7.5) such that the augmented ventilation increases the FA/FI sufficiently to compensate, for the most part, for the absence of ventilation to the contralateral lung (see Fig. 7.16B).[294] The more soluble the anesthetic, the closer the partial pressure of anesthetic in the combined pulmonary vein that drains both the ventilated and nonventilated lungs approximates the partial pressure from delivering the anesthetic to lungs without a right-to-left shunt. The net effect of a right-to-left shunt on the FA/FI of a more soluble inhalational anesthetic is thus minimal.

In contrast, when a less soluble anesthetic (e.g., sevoflurane or desflurane) is administered in the presence of such a right-to-left shunt, doubling the ventilation to the lung minimally increases the FA/FI, because ventilation has a limited effect on the speed of increase of FA/FI of less soluble anesthetics (see E-Fig. 7.5 and Fig. 7.16C).[294] Consequently, the increase in FA/FI in the ventilated lung is insufficient to offset the lack of anesthetic in the blood draining the nonventilated lung. The *net effect is to almost halve* the anesthetic partial pressure in the combined pulmonary vein. The

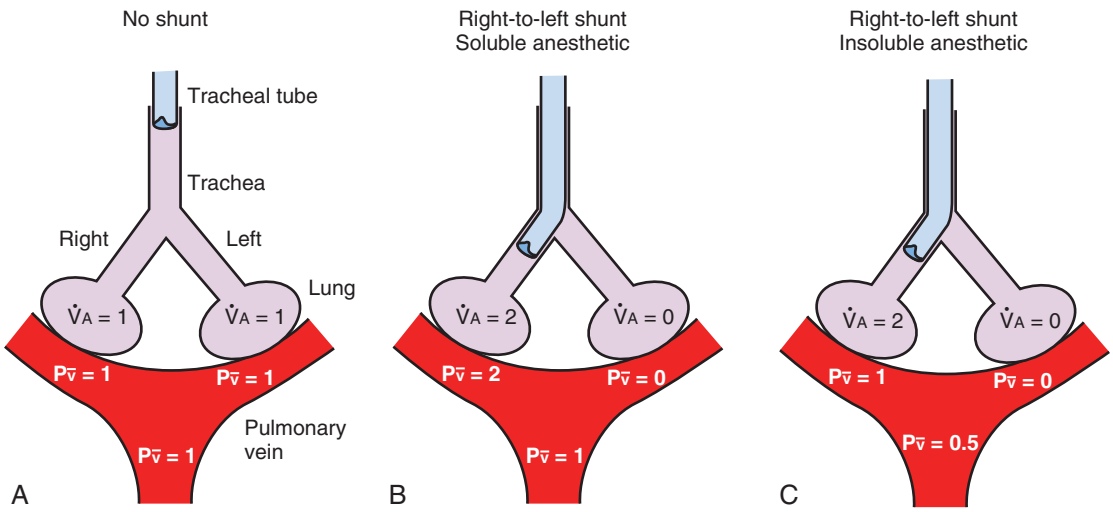


FIGURE 7.16 Effect of a shunt on the rate of increase of anesthetic partial pressure in blood using a model. **A,** Normal situation with no shunt, equal alveolar ventilation ($\dot{V}_A$) to both lungs, and normocapnia. **B,** The effect of a right-to-left shunt (via an endobronchial intubation) with a more soluble anesthetic (e.g., halothane). Ventilation and therefore normocapnia are maintained, and hypoxic pulmonary vasoconstriction is negligible. In this case, the increased ventilation to the ventilated lung speeds the increase in FA/FI (wash-in) and offsets the effect of the shunt. Results in terms of the mixed pulmonary venous partial pressure of the anesthetic ($P\bar{v} = 1$) are similar to those in **A**. **C,** The effect of a shunt with a less soluble anesthetic (e.g., desflurane or sevoflurane). Because the increase in alveolar ventilation does not increase FA/FI in the ventilated lung, there is a dramatic reduction in the anesthetic partial pressure in the blood ($P\bar{v} = 0.5$). *FA*, Fractional alveolar partial pressure of anesthetic; *FI*, fractional inspired partial pressure of anesthetic. (Redrawn from Lerman J. Pharmacology of inhalational anaesthetics in infants and children. *Paediatr Anaesth*. 1992;2:191–203.)

less soluble the anesthetic, the greater the discrepancy between the anesthetic partial pressure in the pulmonary vein that drains the ventilated and nonventilated lungs and the partial pressure when the tube is in the trachea. The overall effect of a right-to-left shunt is to slow induction of anesthesia or even limit the depth of anesthesia that can be achieved with less soluble anesthetics.[311,312]

Few studies have documented the clinical importance of such a shunt.[311,312] Clinical situations that have posed challenges with these shunts include children with right-to-left cardiac shunts and infants with chronic lung disease. In the case of halothane, the most soluble anesthetic available, anesthesia remained quite effective in children with right-to-left shunts even though the ratio of arterial to inspired partial pressures lags behind the ratio when the shunt is closed.[312] The most likely explanation for this is that the 5% inspired concentration of halothane from the vaporizer permitted delivery of a 5 × MAC overpressure effect. Although the ratios of the arterial to inspired partial pressures of sevoflurane and desflurane have not been measured in children with right-to-left shunts, we theoretically expect that they will pose even greater difficulties than halothane, particularly with their limited overpressure effect (i.e., the maximal inspired concentrations of the vaporizers are limited to 3 × MAC or less [see Table 7.5]). Our experience suggests that when we use these less soluble anesthetics in such circumstances (e.g., bronchoscopy for a bronchial foreign body), IV anesthetics may be needed to achieve an adequate depth of anesthesia in infants and younger children.

Wash-Out and Emergence

The wash-out of inhalational anesthetics follows an exponential decay (the inverse of the wash-in curves, see Fig. 7.14) and during emergence, this is achieved by setting the inspired concentration to zero.[303] The speed of the wash-out (and speed of emergence) of the inhalational anesthetics parallels their blood solubilities: desflurane > sevoflurane > isoflurane > halothane > methoxyflurane (see E-Table 7.1).[303,313] For most inhalational anesthetics, metabolism does not contribute substantively to the wash-out. Halothane is the one exception; its wash-out is as rapid as that of isoflurane, likely because its metabolism is 15- to 20-fold greater than that of isoflurane (see later discussion). The order of the wash-out of anesthetics in children should be similar to that in adults, whereas the wash-out in neonates and infants is likely to be more rapid than that in adults for the same reasons the rate of wash-in is more rapid (see Table 7.4).

Although some advocate switching from a more soluble to a less soluble inhalational anesthetic toward the end of surgery for economy and to facilitate a rapid emergence, there is a dearth of data to support such a practice in children. In adults, it has been suggested that switching from isoflurane to desflurane 30 minutes before the end of a 2-hour anesthetic does not speed emergence.[314]

A number of other strategies have been used to speed emergence and recovery from anesthesia. In adults, discontinuing nitrous oxide accelerates the wash-out of and emergence from inhalational anesthesia.[315] Most recently, charcoal filters added to anesthesia breathing circuits adsorb anesthetics and have been shown to speed emergence.[316] Hypercapnic hyperventilation with a charcoal filter to adsorb the inhaled anesthetic has been shown to speed emergence from isoflurane, sevoflurane, and desflurane anesthesia in adults by about 60%.[317,318] Similar data in children are lacking.

When comparing the speed of recovery after anesthesia, the results are heavily influenced by the study design. Studies in which the anesthetic concentration is maintained at a fixed MAC multiple until the end of surgery usually demonstrate a pattern of recovery that parallels the solubilities of the anesthetics in blood, at least during the early recovery period: halothane > isoflurane > sevoflurane > desflurane (see earlier).[319–323]

However, when the inspired concentrations of inhalational anesthetics are tapered toward the end of surgery, this attenuates the differences reported with the fixed MAC technique. Second, differences in the speed of recovery among anesthetics parallels the duration of anesthesia; for example, differences will be less for brief surgery and greater for surgery of greater duration.[320,324–326] Third, failure to prevent or treat pain before emergence will trigger a much more rapid and stormy emergence after less soluble than after more soluble anesthetics.[320,323] A more sophisticated approach to the wash-out of inhalational anesthetics is to use the CSHT, which is a measure of the time required for the anesthetic partial pressure to decrease by 50%. Using a computer model and PK data from adults, the CSHTs of the potent inhalational anesthetics enflurane, isoflurane, sevoflurane, and desflurane were similar (<5 minutes) and were unaffected by the duration of the anesthetic.[327] The 80% decrement times were similar for desflurane and sevoflurane (<8 minutes), whereas those for isoflurane and enflurane were greater (30 and 35 minutes, respectively). However, after 6 hours of simulated anesthesia, the 90% decrement times differed substantially: 14 minutes for desflurane, 65 minutes for sevoflurane, 86 minutes for isoflurane, and 100 minutes for enflurane. These data suggest that the early recovery (up to 80% decrement in partial pressure) after inhalational anesthesia is similar among these four anesthetics (although sevoflurane and desflurane are more rapid), but after 6 hours (i.e., prolonged anesthesia) 90% decrement is achieved much more rapidly with desflurane than with the remainder.

In animal models, recovery of motor function (a metric for more complete recovery than the expired anesthetic concentrations) parallels the speed of wash-out of inhalational anesthetics from fastest to slowest: desflurane > sevoflurane > isoflurane > halothane.[328] Notably, the time to recover increases in parallel with the duration of anesthesia.[328] In pediatric studies in which the recovery times after two or more anesthetics were compared, the end-tidal concentrations of the anesthetics were maintained at approximately 1 MAC until the conclusion of surgery, after which the anesthetics were abruptly discontinued.[319,320,329] In this paradigm, the rates of recovery paralleled the rates of wash-out, which in turn paralleled the solubilities of the inhalational anesthetics, including xenon and desflurane.[330] In clinical practice, however, anesthetic concentrations are gradually tapered as the end of surgery approaches. This practice may attenuate the differences in the speed of recovery among inhalational anesthetics.

PHARMACODYNAMICS OF INHALED ANESTHETICS

Minimum Alveolar Concentration

MAC is defined as the minimum alveolar (or end-tidal or end-expiratory) concentration of anesthetic at which 50% of patients do not move in response to a noxious stimulus. The classic stimulus for MAC in humans is skin incision; throughout the remainder of this chapter, MAC will refer to this stimulus. MAC has also been determined in response to other stimuli, including tracheal intubation, insertion of a laryngeal mask airway, tracheal extubation, and awake responsiveness (see Table 7.6). The MAC response to tracheal intubation during sevoflurane anesthesia in children is

TABLE 7.6 MAC Values in Children

	MAC (%)	References
Tracheal intubation	Halothane: 1.33	2036
	Enflurane: 2.93	2037
	Sevoflurane: 2.69, 2.66, 2.83	341, 357, 2038
Tracheal extubation	Isoflurane: 1.4	2039
	Sevoflurane: 1.70, 2.3	2040, 2041
	Desflurane: 7.7	2042
LMA insertion	Sevoflurane: 2.0	2038
LMA extubation	Sevoflurane 1.84	2043
	Desflurane (with 1–1.3 μμg/kg Fentanyl): 3.56%	2044
Tracheal intubation/skin incision ratio[a]	Halothane, enflurane, sevoflurane: 1.33	Calculated from MAC data
MAC awake	Sevoflurane: 0.66 (2–5 years) and 0.43 (5–12 years)	2045

LMA, Laryngeal mask airway; *MAC*, minimum alveolar concentration.
[a]Calculated using the above MAC data.

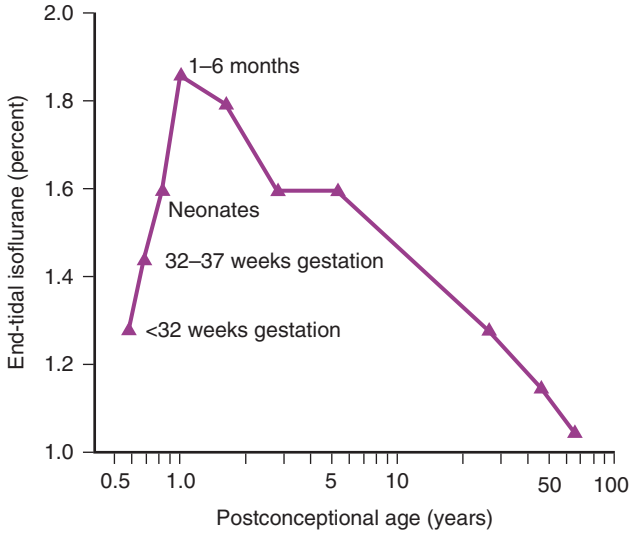

FIGURE 7.17 MAC (minimum alveolar concentration) of isoflurane in preterm and full-term neonates, infants, and children. MAC increased with gestational age in infants younger than 32 weeks gestation (1.3%), reaching a zenith in infants 1 to 6 months of age of 1.87%, and decreased thereafter with increasing age to adulthood. Postconceptional age is the sum of the gestational age and postnatal age in years. (Data from Cameron CB, Robinson S, Gregory GA. The minimum anesthetic concentration of isoflurane in children. *Anesth Analg*. 1984;63(4):418–420 and LeDez KM, Lerman J. The minimum alveolar concentration (MAC) of isoflurane in preterm neonates. *Anesthesiology* 1987;67(3):301–307.)

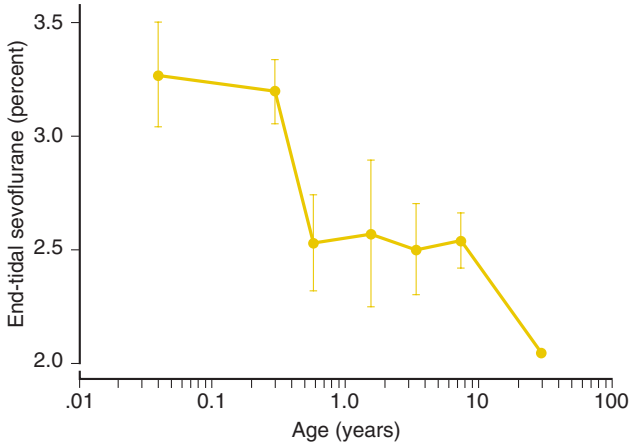

FIGURE 7.18 The MAC (minimum alveolar concentration) of sevoflurane in neonates, infants, and children. MAC is greatest in full-term neonates (3.3%), less in infants 1 to 6 months of age (3.2%), and then decreases 25%, to 2.5%, for all infants and children 6 months to 10 years of age. (The thin vertical yellow bars are standard deviations.) Age is postnatal age in years. The MAC of sevoflurane in adults, 30 years of age, is shown for completeness. All MAC measurements were performed with sevoflurane in 100% oxygen using a single skin incision. (Data from Lerman J, Sikich N, Kleinman S, Yentis S. The pharmacology of sevoflurane in infants and children. *Anesthesiology* 1994;80(4):814–824.)

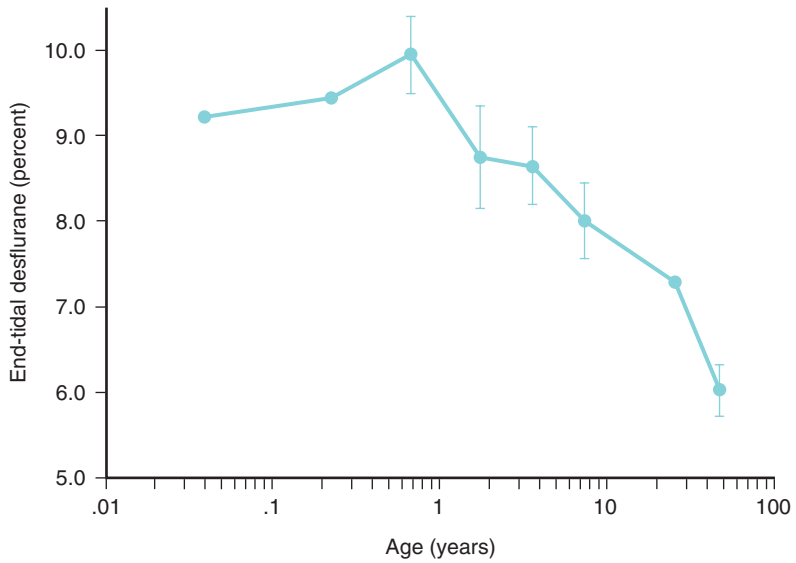
attenuated in the presence of adjuvants, such as clonidine (see E-Table 7.2).[331] Conflicting evidence exists regarding the relative potencies of isomers or enantiomers of chiral inhalational anesthetics.[332–334] Studies in animals suggest that the *S*(+) optical enantiomer may be more potent than the *R*(–) enantiomer, as evidenced by its ability to enhance potassium conductance in neurons.[332,333] In adults, the *R*(–) enantiomer of isoflurane was nominally (17%) more potent than the *S*(+) enantiomer.[334]

The difference in the potency (or MAC) of inhalational anesthetics varies inversely with lipid solubility; that is, as the lipid solubility decreases, the potency decreases in parallel (i.e., MAC increases) (see E-Table 7.1).

In children, MAC varies significantly with age. For example, the MAC of halothane increases as age decreases, reaching a maximum value in infants 1 to 6 months of age (1.20% ± 0.06%) and then decreases by about 30% to (0.87 ± 0.03%) in full-term neonates.[335,336] Similar relationships hold true for isoflurane and desflurane (Figs. 7.17 and E-Fig. 7.10).[337,338] However, the relationship for sevoflurane differs substantively from that of the other inhalational anesthetics in that the MAC of sevoflurane does not increase steadily as age decreases (Fig. 7.18).[339] In fact, the MAC of sevoflurane in neonates and infants younger than 6 months of age is 3.3%, whereas in older infants and children it is 2.5%.[339–341] The explanation for this different relationship for sevoflurane remains unclear.

The MAC of inhalational anesthetics in preterm neonates has been determined only for isoflurane (see Fig. 7.17). The (mean ± standard deviation [SD]) MAC of isoflurane in preterm neonates younger than 32 weeks gestation (1.28% ± 0.17%) is 10% less than it is in neonates of 32 to 37 weeks gestational age (1.41% ± 0.18%), which in turn is 12% less than it is in full-term neonates (1.60% ± 0.03%).[218] The etiology of these age-dependent changes in MAC remains elusive. Several possible causes have been proposed, including maturational changes in the CNS and neurohumoral factors, but none of these have been confirmed.



Several other factors are known to affect MAC. The presence of the melanocortin-1 receptor gene affects the MAC of desflurane. That is, 90% of adults who are either homozygous or heterozygous for mutations of this gene (i.e., redheads) require 20% more anesthesia than those who have no mutations (brunettes).[342] A similar relationship is likely to hold true for children with these mutations. Hypothermia decreases MAC; in children 4 to 10 years, the MAC of isoflurane decreases 5% per degree Celsius.[343]

Cerebral palsy and severe cognitive impairment reduce the MAC of halothane approximately 25% compared with healthy

E-TABLE 7.2 Effects of Adjunctive Therapies on MAC of Sevoflurane

Adjunct	MAC Sevoflurane	References
MAC tracheal intubation in oxygen	2.69%, 2.66%, 3.2%	331, 341, 357
MAC tracheal intubation and 60% N_2O	1.57% (41% decrease), 2.4% (25% decrease)	331, 357
MAC tracheal intubation and oral clonidine (4 μg/kg)	40% decrease	331
MAC tracheal intubation and clonidine (4 μg/kg) and 60% N_2O	56% decrease	331

MAC, minimum alveolar concentration, N_2O, nitrous oxide.

E-FIGURE 7.10 MAC (minimum alveolar concentration) of desflurane in neonates, infants and children. MAC in full-term neonates of 9.2% increased slowly during infancy, reaching a zenith in infants 6 to 12 months of age of 9.9%, and decreased thereafter with increasing age to adulthood. All MAC measurements were performed with desflurane in oxygen using a single skin incision. (The thin vertical blue bars are standard deviations.) (Data from Taylor RH, Lerman J. Minimum alveolar concentration of desflurane and hemodynamic responses in neonates, infants, and children. *Anesthesiology* 1991;75(6):975–979.)

children.[344] Although tetanic stimulation was used to elicit the pain response, this stimulus underestimates the MAC compared with skin incision.[345] Nonetheless, the MAC of halothane in healthy children was similar to published data with skin incision.[336] Chronic anticonvulsant therapy decreased the MAC of halothane in handicapped children by 15%, compared with those without anticonvulsants, from 0.71% ± 0.10% to 0.62% ± 0.03%.[344] Several factors may account for this decrease in MAC, including central sensory impairment, increased pain threshold or insensitivity, and a disequilibrium of inhibitory and excitatory regulatory neurons within the spinal cord in these children.[346,347] Although the acute administration of barbiturates and benzodiazepines decreases MAC,[348,349] chronic administration of similar medications does not.[350] The effects of specific anticonvulsants, such as valproic acid and phenytoin, on the MAC of inhalational anesthetics in children remain unclear.

The MAC for nitrous oxide has been estimated to be 104% in adults[351]; comparable data do not exist in children. The additivity of MAC fractions of nitrous oxide with inhalational anesthetics is well established. The concept of additivity has been confirmed in adults for nitrous oxide with all inhalational anesthetics, including sevoflurane and desflurane,[352,353] although in children, it holds true only for halothane or isoflurane.[354,355] When nitrous oxide is combined with sevoflurane or desflurane in children,[199,200,214] 60% nitrous oxide decreases the MAC of sevoflurane only 20% and that of desflurane 26% (see Table 7.7).[338,339,356] The MAC response to tracheal intubation during sevoflurane anesthesia in children is also attenuated by nitrous oxide.[357] The explanation for the differential additivity effect of nitrous oxide remains unclear.

The MAC for xenon in middle-aged adults is about 70%[358,359]; the MAC of xenon in children has not been determined.

Central Nervous System

All potent inhalational anesthetics depress the central nervous system (CNS), as evidenced by dose-dependent decreases in the cerebral vascular resistance and the cerebral metabolic rate for oxygen ($CMRO_2$). The decrease in vascular resistance causes a reciprocal increase in CBF that begins at approximately 0.6 MAC.[360] The extent of the increase in CBF, however, depends on the inhalational anesthetics: halothane > enflurane ~ desflurane > isoflurane > sevoflurane.[360–363] In adults, the cerebral vasculature remains responsive to CO_2 under general anesthesia but decreases with increasing MAC, disappearing at 1.5 MAC in the case of desflurane.[364] The net effect of inhalational anesthetics is a dose-dependent increase in the ratio of the CBF to $CMRO_2$.

The effects of inhalational anesthetics on the CNS in children have not been fully elucidated. Autoregulation of CBF does not appear to vary with age in children up to 1.5 MAC sevoflurane.[365,366] CBF velocity in children varies directly with the end-tidal CO_2 ($ETCO_2$) during halothane and isoflurane anesthesia.[367] CBF velocity increases as the concentrations of halothane[368] and desflurane[369] increase. Compared with halothane, however, sevoflurane does not increase CBF velocity, suggesting it may be the preferred anesthetic.[370] Based on current evidence, sevoflurane and isoflurane remain the preferred inhalational anesthetics for neuroanesthesia in children at small MAC values (<1 MAC) and in the presence of mild hyperventilation (see Chapter 26).

In children, the EEG activity during halothane anesthesia differs substantially from that of sevoflurane. In the case of halothane, the EEG is characterized by slow waves superimposed on fast rhythms (α and β waves), whereas in the case of sevoflurane, the EEG is characterized by mainly sharp slow waves.[371] Furthermore, the shift of power of the EEG from low (1–4 Hz) to medium frequencies (8–30 Hz) is greater with halothane than it is for sevoflurane. The clinical relevance of these EEG differences remains unclear at this time, but may explain in part the inconsistencies reported with processed EEG monitoring in children anesthetized with various inhalation anesthetics (see later discussion).

Both myoclonic movement of the extremities and transient spike-and-wave complexes on EEGs have been reported during sevoflurane anesthesia in children.[371–375] Diffuse spike-and-wave complexes were noted on EEGs at 5% and 7% inspired concentrations in two children with histories of epilepsy.[373] In a third child without a history of seizures, a 30-second burst of spike-and-wave complexes was recorded during sevoflurane anesthesia but was identified only after the event resolved.[376] The EEG data were analyzed in children who were premedicated with midazolam and then anesthetized with halothane or sevoflurane. There was no evidence of seizure activity.[371] Cortical epileptiform EEG activity has been reported during 1 to 2 MAC sevoflurane in adults with one episode of seizures that occurred with a partial pressure of carbon dioxide (PCO_2) of 34 mm Hg.[377] This prompted some to recommend limiting the depth of anesthesia with sevoflurane to minimize epileptiform EEG activity or even clinically evident seizure activity.[378] However, the coadministration of other anesthetic medications, such as midazolam, nitrous oxide, and opioids, may attenuate epileptiform EEG activity.[377] Furthermore, the notion of limiting the depth of sevoflurane anesthesia by reducing the concentration of sevoflurane as soon as the eyelash reflex is lost has not been shown to benefit children, and may actually increase the risk of awareness and physiologic responses (see later discussion).

The association between myoclonic movement and seizures during induction of sevoflurane anesthesia remains tenuous. To prevent involuntary movements during induction, we recommend increasing the inspired concentration of sevoflurane in a single stepwise manner from 0% to 8% (see Induction, earlier). If apnea occurs, ventilation should be gently assisted, while avoiding hyperventilation.

Awareness during inhalational anesthesia has been reported to occur with an incidence of 0.2% to 1.2% during sevoflurane anesthesia in children,[379–381] which exceeds that in adults. The studies suggest that children who experience awareness did not develop long-term sequelae.[382] However, the reason for this discrepancy remains elusive. Concerns regarding awareness during

TABLE 7.7 Percent MAC Reduced in 2-Year-Olds With 60% Nitrous Oxide

Agent	MAC With Oxygen (%)	MAC With 60% Nitrous Oxide	Percent MAC Reduced
Halothane	0.91	0.37	65
Desflurane	8.67	6.4	26
Sevoflurane	2.5	2.0	20

anesthesia have increased interest in the use of processed EEG monitoring in children.[383] The most widely studied monitor to date is the BIS monitor, which displays the value on a scale between 0 and 100 (see Chapter 52). In adults, BIS readings less than 60 may be associated with a small risk of awareness and recall, whereas readings greater than 70 are associated with a greater risk for awareness. The BIS value has been studied in children to a limited degree to date, but its validity and role in the anesthetic management of infants and children younger than 5 years of age remain in question. One concern is that the EEG algorithm in current BIS software is derived from adult EEG data, not from children. Despite use of an algorithm derived from adults, BIS measurements in older children appear, for the most part, to track the depth of anesthesia, and these values correlate with the end-tidal concentration of the anesthetic. However, several unexplained curiosities have been reported. The BIS readings for halothane in children exceed those for isoflurane, desflurane, and sevoflurane at equal MAC values.[246,247,384] This has been attributed to the differential effects of anesthetics on the EEG. In addition, the BIS values for a specific sevoflurane concentration decrease with increasing ages.[243,246,385] Paradoxically, the BIS values actually increase as the sevoflurane concentration increased between 3% and 4%, an observation that has been attributed to the unique EEG during sevoflurane anesthesia in children.[385]

A further concern is the enormous interindividual variability in processed EEG monitoring, making it difficult to define thresholds for awareness or lack thereof.[385] Interestingly, spontaneous respirations increase the variability in the BIS readings.[386] The issue is further complicated by the fact that ketamine, nitrous oxide, and opioids do not depress the EEG in a dose-dependent manner. Discrepant BIS readings have been reported from the right and left sides of the brain[387] as well as in the prone position.[388] The BIS values in children with cognitive impairment were 28 points less than those who were unaffected at the same anesthetic concentration, although the MAC reduction for cognitive impairment was not accounted for.[389] Had the reduced MAC been accounted for in cognitively impaired children,[344] the BIS readings may not have differed. With the State Entropy monitor, entropy increases in the presence of nitrous oxide, rendering the readings misleading. The aggregate of this evidence undermines the validity of processed EEG monitoring during inhalational anesthesia in children (see Chapter 52).

Cardiovascular System

Inhalational anesthetics (with the exception of xenon) affect the cardiovascular system either directly (by depressing myocardial contractility [calcium channel blockade], altering the conduction system, or by dilating the peripheral vasculature) or indirectly (by affecting the balance of parasympathetic and sympathetic nervous systems and neurohumoral, renal, or reflex responses). The cardiovascular responses to inhalational anesthetics in children are further complicated by maturational changes in the cardiovascular system and responsiveness to these anesthetics. When all of these developmental changes are taken in aggregate, there is a reduced margin of safety between adequate anesthesia and severe cardiopulmonary depression in infants and children compared with adults. The salient features of the immature cardiovascular system in infants and children at both the macroscopic and microscopic levels have been reviewed elsewhere.[390]

Assessment of cardiovascular variables in infants and children presents a challenge for clinicians. Although BP and electrocardiography are standard monitors of hemodynamics in infants and children of all ages, measures of cardiac output and myocardial contractility are much more difficult to quantitate accurately. Two-dimensional echocardiography and impedance cardiometry have been used to estimate cardiac output and myocardial contractility in infants and children,[391–394] although the echocardiographic measurements are subject to variability depending on the preload and afterload. Load-independent–derived echocardiographic variables (stress-velocity and stress-shortening indexes) have improved the accuracy of echocardiographic estimates of myocardial function and are used with increasing frequency.[395] Transesophageal echocardiography is used much more frequently in children, although its use is limited to children with congenital heart disease undergoing cardiac surgery. Future studies using continuous noninvasive cardiac output estimates obtained using bioimpedance may shed further light on this issue in the future.[396–400]

In children, several factors determine the BP responses to inhalational anesthetics, including the particular anesthetic studied, the dose, the administration of a premedication, the level of preoperative anxiety, and the systemic pressure measured: systolic, diastolic, or mean. Most studies demonstrate modest, dose-dependent decreases in BP with all of the inhalational anesthetics, although the magnitudes of the changes vary. In a direct comparison of sevoflurane and halothane, systolic BP decreased 7.5% at 1 MAC sevoflurane and 12.5% at 1 MAC halothane, but returned to awake values at 1.5 MAC with both anesthetics.[395] In children older than 1 year of age, systolic BP decreased 0% to 11% at 1 MAC sevoflurane, and 22% to 28% at 1 MAC desflurane, compared with awake values.[338,339] At 1 MAC, mean BP in children decreased 15% to 25% with isoflurane and sevoflurane.[392,394] All of the inhalational anesthetics (in concentrations up to 1.5 MAC) modestly depress the systolic BP in children.

Myocardial contractility decreases to a greater extent during halothane (up to 1.5 MAC) than during isoflurane or sevoflurane anesthesia, as evidenced by decreases in cardiac output and ejection fraction in healthy children.[393,394,401] Cardiac index decreases to similar extents with halothane and sevoflurane at 1 and 2 MAC: 10% at 1 MAC and 20% to 35% at 2 MAC.[394] Ejection fraction decreases 30% at 0.5 and 1.5 MAC halothane compared with awake values, but is unchanged at equipotent concentrations of isoflurane.[392] The addition of nitrous oxide to halothane or isoflurane in infants and small children depresses myocardial function to a similar extent as equipotent anesthetic concentrations of halothane or isoflurane in oxygen.[401] In children, halothane decreases myocardial contractility in a dose-dependent manner and to a greater extent than the ether anesthetics. Isoflurane and sevoflurane decrease myocardial contractility to a lesser extent than halothane and are preferred for children with limited cardiovascular reserves. IV atropine restores the decrease in myocardial function, in part, associated with halothane anesthesia,[401–404] whereas IV balanced salt solution restores the decrease in myocardial function associated with isoflurane anesthesia.[393]

The mechanism by which inhalational anesthetics depress myocardial function remains controversial. Studies in both animal and human myocardial cells suggest that halothane, isoflurane, and sevoflurane directly depress myocardial contractility by decreasing intracellular calcium ion (Ca^{2+}) flux. Inhalational anesthetics decrease the Ca^{2+} flux by their action on the calcium channels themselves, ion exchange pumps, and the sarcoplasmic reticulum.[390] Evidence suggests that inhalational anesthetics attenuate contractility of ventricular myocytes via voltage-dependent L-type calcium channels (which are responsible for release of large amounts of calcium from the sarcoplasmic reticulum).[405,406]

That neonates and infants are more sensitive to the depressant actions of inhalational anesthetics than are older children is supported by experimental evidence of maturational differences between neonatal and adult rat, rabbit, and feline myocardium.[406–409] Structural differences that may account, in part, for the changes in myocardial sensitivity to inhalational anesthetics with age include a reduction in contractile elements, immature sarcoplasmic reticulum, and functional differences in calcium sensitivity of the contractile elements, calcium channels, and the sodium-calcium pump in the neonatal myocardium.[390,405–407,409–412] The determinants of Ca^{2+} homeostasis in neonatal ventricular myocardial cells depend on transsarcolemmic Ca^{2+} flux to a far greater extent than on the sarcoplasmic reticulum.[390] This is based on a growing body of experimental evidence that includes the finding that the concentration of the Na^{+}-Ca^{2+} exchange protein in the neonatal myocardium, a protein that regulates transsarcolemmic flux of Ca^{2+}, exceeds that in adult cells by 2.5-fold and that its concentration decreases with age as the concentration of L-type voltage-dependent calcium channels increases.[407] Furthermore, halothane reversibly inhibits the Na^{+}-Ca^{2+} exchange protein in immature myocardial cells.[407] The sarcoplasmic reticulum is poorly developed in neonatal myocardial cells, and this finding weighs heavily against the sarcoplasmic reticulum being the major source of Ca^{2+} required for myocardial contractility. Further research is required before the contribution of each aspect of Ca^{2+} homeostasis to myocardial contractility in the neonate can be confirmed.

Ever since the introduction of halothane into clinical practice, clinicians have been aware of a greater incidence of hypotension and bradycardia in neonates who were anesthetized with halothane than in adults. However, this was not the case when *equipotent* concentrations (approximately 1 MAC) of halothane[336,403] were administered to neonates and older infants 1 to 6 months of age. Subsequent studies demonstrated that isoflurane,[413] sevoflurane,[339] and desflurane[338] all decreased systolic pressure in neonates to similar extents as in older infants 1 to 6 months of age. Interestingly, systolic BP decreased 30% in response to 1 MAC sevoflurane in neonates and infants 1 to 6 months of age, which was substantially greater than the 5% decrease in older infants and children up to 12 years of age.[339] In the case of desflurane, systolic BP decreased 30% in response to 1 MAC desflurane across all age groups.[338] These data suggest that systolic BP decreases up to 30% in response to 1 MAC of all inhalational anesthetics in infants and children, and that caution should be exercised when administering these anesthetics to infants and children who are at risk for hemodynamic instability, or in whom greater concentrations of inhaled anesthetics are required. On the basis of echocardiographic determinations, cardiac output and ejection fraction decrease in a dose-dependent fashion from awake to 1.5 MAC halothane and isoflurane in neonates and infants.[391] In a comparison of sevoflurane and halothane up to 1.5 MAC in infants, sevoflurane maintained cardiac index but decreased BP and systemic vascular resistance.[414] Myocardial contractility decreased in a dose-dependent manner with halothane as well as with sevoflurane, although the decrease with the former exceeded that with the latter.

The baroreceptor reflex response is also depressed in infants with either halothane[415] or isoflurane,[416] albeit to a greater extent with halothane. In view of the greater incidence of hypotension in neonates and infants than older children, an intact baroreceptor reflex could offset, in part, the cardiovascular consequences. However, inhalational anesthetics blunt this response, leaving the infant vulnerable to the direct cardiodepressant actions of the anesthetics. Prophylactic anticholinergics augment the cardiac output by increasing the heart rate.

Two studies evaluated the effects of inhalational anesthesia on the hemodynamics of children with congenital heart disease undergoing cardiac surgery.[417,418] Sevoflurane maintained cardiac index and heart rate with less hypotension and negative inotropic effect than halothane. Isoflurane maintained cardiac index and ejection fraction, increased heart rate, and caused less depression of mean arterial pressure than halothane.[417] Sevoflurane was also associated with fewer episodes of severe hypotension and reduced need for vasopressors and chronotropes during emergence than halothane.[418]

Inhalational anesthetics also vary in their effect on cardiac rhythm. Halothane slows the heart rate, in some cases leading to junctional rhythms, bradycardia, and asystole. This response is dose dependent. Three mechanisms have been proposed to explain the genesis of halothane-associated dysrhythmias: a direct effect on the sinoatrial node, a vagal effect, or an imbalance in the parasympathetic and sympathetic tone. It has also been suggested that the etiology of the bradycardia during halothane anesthesia may be a withdrawal of sympathetic tone. Bradycardia is particularly marked in the neonate, presumably because parasympathetic influences predominate over the sparse sympathetic innervation of the myocardium in this age group. Junctional rhythms are also common during halothane anesthesia. Atrial or ventricular ectopic beats and brief episodes of ventricular tachycardia are rare, except in the presence of hypercapnia.[419] In infants and children anesthetized with halothane, 10 μg/kg atropine increases heart rate by 50% or more and promotes sinus rhythm.[420] This dose of atropine also increases BP in infants and children 2 years of age and older.

Sevoflurane has limited effect on heart rate, at 1 MAC and during induction of anesthesia, generally maintaining or increasing the heart rate. The heart rate may slow transiently during the first 3 minutes of induction of anesthesia but the rate usually recovers spontaneously without treatment. Heart rate remained stable during studies with 1 MAC sevoflurane. However, children with Down syndrome are at increased risk for bradycardia during induction of anesthesia. The bradycardia usually resolves by decreasing the inspired concentration of anesthetic. Heart rate is usually unaffected by the administration of desflurane unless the inspired concentration is increased suddenly in the absence of opioids, a phenonmenon reported in adults.

Halothane also sensitizes the myocardium to catecholamines, particularly in the presence of hypercapnia and "light anesthesia."[419] Halothane decreases the threshold for ventricular extrasystoles during epinephrine administration threefold.[421–423] In contrast, isoflurane, desflurane, and sevoflurane maintain or increase heart rate during the early induction period of anesthesia,[a] although a transient slowing of the heart rate, usually preceeded by a nodal rhythm, has been reported during induction of anesthesia with sevoflurane.[427] When bradycardia occurs in an anesthetized child, hypoxia must be considered first before other causes, such as a direct drug effect (i.e., high concentration of halothane). Isoflurane, desflurane, and sevoflurane do not sensitize the myocardium to catecholamines to the same extent as does halothane, and ventricular arrhythmias are rare.[421,422,428] Nonetheless, sevoflurane may cause transient bradycardia during induction of anesthesia. The bradycardia usually resolves spontaneously, without requiring any

[a]References 320, 338, 339, 392, 394, 413, 414, and 424–426.

interventions. In children with Down syndrome, bradycardia during induction of anesthesia with sevoflurane occurs three to four times more frequently than in children without Down syndrome, irrespective of whether a congenital heart defect is present.[429,430] Bradycardias in children with Down syndrome were treated with an anticholinergic twice as frequenty as children who were unaffected.

The mechanism by which the sinus node controls automaticity is incompletely understood but may include potassium ion (K^+) currents, hyperpolarization-activated current, and T and L forms of Ca^{2+} currents.[390] Moreover, developmental changes in these channels likely account, in part, for the differential effects of inhalational anesthetics on heart rate with age.[410]

Recent concerns of a relationship between inhalational anesthetics and prolonged QT interval that progressed to induce cardiac arrest or torsades de pointes have emerged. Although the ether inhalational anesthetics prolong the QTc interval (with >500 milliseconds being abnormal),[431,432] this alone appears to be insufficient to induce torsades de pointes. Torsades de pointes also requires the transmural dispersion of repolarization. This is defined as the variability in the rate of repolarization across the myocardium, from epicardium to endocardium. The rate of repolarization may be estimated by the interval in the peak to end of the T wave on a 12-lead electrocardiogram. Evidence has demonstrated that the risk of torsades de pointes during sevoflurane anesthesia is minimal because the transmural dispersion of repolarization is limited.[433]

Paroxysmal increases in BP (both systolic and diastolic pressures) and heart rate have been reported in adults and observed by one of the authors (CJC) in children after a rapid increase in the inspired concentration of isoflurane or desflurane.[434] This occurs as a result of a massive sympathetic response, mediated by norepinephrine and/or epinephrine, that culminates in tachycardia and hypertension.[435,436] Further increases in the inspired concentration of the inciting anesthetic while attempting to attenuate the tachycardia and hypertension are ineffective and may perpetuate or augment the response. To restore vital signs to normal, the inciting anesthetic should be discontinued and replaced with another anesthetic. Repetitive small increases (1%) in the inspired concentration of the putative anesthetic produce transient but attenuated catecholamine bursts and cardiovascular responses compared with larger increases in concentration.[437,438] Fentanyl (2 μg/kg), esmolol, and clonidine have all been shown to be effective in preventing, attenuating, or eliminating these responses.[439–441] The origin of these responses is unknown, although the rapidity of the response points to the lung.[442] Others, however, dispute this notion, contending that two sites must be responsible for triggering the sympathetic discharge–the lung and the VRG[443]–with the latter mediating the greater response.[443,444] Neuroexcitatory responses have not been reported in children with isoflurane, desflurane, or sevoflurane.[445]

Xenon offers an immense advantage over the ether-based inhalational anesthetics in that it maintains circulatory stability. However, the cardiovascular effects of xenon in children have not been studied. Although the MAC of xenon in adults is very large (see E-Table 7.1), the MAC for xenon in children may be even greater. If the MAC exceeds the adult values, this may limit not only the dose that may be administered to children (e.g., much less than 1 MAC), but it may also limit the inspired concentration of oxygen as well. Notwithstanding the MAC of xenon in children, this anesthetic will certainly be much less effective in children with cyanotic congenital heart disease, as it is the least soluble anesthetic and its large MAC restricts the MAC multiples that may be administered.

Respiratory System

During spontaneous ventilation, both tidal volume and respiratory rate vary with the specific anesthetic, depth of anesthesia, and nociception. The increased respiratory rate during inhalational anesthesia in children has been attributed to sensitization of the stretch receptors within the lung as well as possible central effects. Inhalational anesthetics significantly affect respiration in infants and children in a dose-dependent fashion via effects on the respiratory center, chest wall muscles, and reflex responses. Halothane depresses minute ventilation by decreasing tidal volume and attenuating the response to CO_2.[446–449] This depression is offset, in part, by an increase in the respiratory rate.[446,449] These ventilatory responses to halothane are age dependent; minute ventilation in infants decreases to a greater extent than in children.[448] In infants and young children anesthetized with halothane, intercostal muscle activity is attenuated before the diaphragm.[446,450] This effect is most pronounced in preterm and full-term neonates and infants and when a tracheal tube is used in place of a laryngeal mask airway.[451] The movement of the chest and abdomen during the respiratory cycle is one of synchronized protrusion of the abdomen and collapse of the chest wall during inspiration (with some intercostal indrawing) and indrawing of the abdomen and flattening of the chest wall during expiration. This is commonly referred to as the "rocking horse" movement of the chest (similar to the phenomenon that occurs during upper airway obstruction in infants and children). This results in loss of FRC and is of particular concern in infants younger than 2 years of age who have decreased type I muscle fibers in both the diaphragm and intercostal muscles (see Fig. 14.11). This explains why infants fatigue easily and why positive end-expiratory pressure is useful in this age group. Isoflurane, enflurane, sevoflurane, and desflurane also depress ventilatory drive, decrease tidal volume, and attenuate the response to CO_2.[447,449,452–458] The increase in respiratory frequency that follows respiratory depression (decreased tidal volume) may not restore minute ventilation to preanesthetic levels.

Sevoflurane depresses respiration to a similar extent as halothane up to 1.4 MAC but depresses respiration to a greater extent at concentrations greater than 1.4 MAC.[452] This results from a direct effect of sevoflurane on respiratory frequency.[455] Although respiratory effort may decrease rapidly during sevoflurane or desflurane anesthesia, the low blood solubilities and rapid wash-out profiles of these drugs in part ensure that this is a self-limiting phenomenon during spontaneous respirations. Sevoflurane decreases the tone of the intercostal muscles to a lesser extent than halothane.[450,454] The compensatory changes in respiratory rate differ among the anesthetics; respiratory rate increases at 1.4 MAC or more with halothane, is unchanged with isoflurane, but decreases at 1.4 MAC or less with sevoflurane and enflurane.[447,449] This inadequate compensatory response to respiratory depression with sevoflurane and enflurane suggests that when children are anesthetized with those anesthetics, spontaneous ventilation must be monitored carefully to avoid hypopnea or apnea. Sevoflurane maintains or decreases airway resistance in children with normal airways and those with asthma or a recent upper respiratory tract infection. Insertion of a tracheal tube during sevoflurane anesthesia increases airway resistance without sequelae.[459,460]

Desflurane depresses respiration in children during spontaneous respirations at greater than 1 MAC by decreasing tidal volume.[458] However, desflurane increases airway resistance in children with

asthma and respiratory tract infections to a greater extent than sevoflurane.[460] Desflurane is probably best avoided in these children.

Studies of the upper airway in children anesthetized with inhalational anesthesia have sought to explain the pathophysiology of airway obstruction. Sevoflurane at 1 MAC causes more upper airway obstruction than halothane.[461] In escalating doses between 0.5 and 1.5 MAC, sevoflurane decreased the cross-sectional area of the airway by one-third, predominantly in the anteroposterior dimension.[462] This effect primarily results from pharyngeal wall collapse, which can be easily offset with positive end-expiratory pressure (see Chapter 14).

Renal System

Potent inhalational anesthetics may affect renal function via four possible mechanisms: cardiovascular, autonomic, neuroendocrine, and metabolic. Although the first three mechanisms pose no direct threat to renal function, the fourth mechanism, metabolic, is a serious clinical concern that has resulted in renal dysfunction after inhalational anesthesia.

Inhalational anesthetics are metabolized in vivo by the CYP isozyme system to varying extents (see E-Table 7.3). Metabolism of inhalational anesthetics may release both inorganic and organic fluoride moieties.[463] It is the inorganic fluoride that is released from these ether anesthetics that has stimulated interest in renal dysfunction after inhalational anesthesia.

Isoflurane and desflurane undergo limited metabolism in vivo, resulting in very small plasma concentrations of inorganic fluoride even after 131 MAC hours of isoflurane.[464] In contrast, halothane is metabolized to a substantially greater extent but releases most of the fluoride in an organic form, trifluoroacetate. Trifluoroacetate has, however, been linked to halothane hepatitis (see later discussion). The metabolism of enflurane, sevoflurane, and methoxyflurane yields greater plasma concentrations of inorganic fluoride than isoflurane. The metabolism of sevoflurane yields both inorganic and organic fluoride moieties.[465] The organic form, hexafluoroisopropanol, is rapidly conjugated and excreted by the kidneys[465] and poses no threat to humans. Peak plasma concentrations of inorganic fluoride after exposure to inhalational anesthetics follow an order similar to that in E-Table 7.3: methoxyflurane > sevoflurane > enflurane > isoflurane > halothane ≅ desflurane.[466–470] In the case of methoxyflurane, two metabolites are produced: inorganic fluoride and oxalic acid. Both were implicated in the pathogenesis of renal dysfunction, although clinically, the renal injury was more consistently associated with inorganic fluoride.[471] Subsequent studies demonstrated that subclinical nephrotoxicity occurred after more than 2.5 MAC hours of methoxyflurane, provided the plasma concentration of inorganic fluoride exceeded 50 µmol/L. Nephrotoxicity occurred after more than 5 MAC hours if the concentration of inorganic fluoride exceeded 90 µmol/L.[472] These clinical concerns led to the voluntary withdrawal of methoxyflurane from clinical practice.

That the plasma concentrations of inorganic fluoride in children who were anesthetized with sevoflurane were similar to or greater than those after enflurane[473–475] raised concerns about possible renal dysfunction after prolonged exposure. However, inorganic fluoride concentrations after relatively brief anesthetics in children are similar to those in adults: less than 20 µmol/L after about 1 MAC hour, which decreases to less than 10 µmol/L by 4 hours after discontinuation of anesthesia.[457] Nonetheless, the peak plasma concentrations of inorganic fluoride paralleled the MAC hour exposure to sevoflurane in both children and adults.[475] Concerns regarding the risk of renal dysfunction after sevoflurane were heightened after reports that the peak plasma concentration of inorganic fluoride in some adults exceeded the purported threshold for nephrotoxicity (50 µmol/L).[476] Despite the large plasma concentrations of inorganic fluoride after sevoflurane anesthesia, there was no evidence of renal dysfunction. These reports, together with a dearth of evidence in the toxicology literature, suggest that fluoride-mediated nephrotoxicity may be independent of the plasma concentration of inorganic fluoride.

Kharasch and colleagues postulated that inhalational anesthetic-induced nephrotoxicity might be anesthetic specific. They determined that the primary isozyme responsible for the degradation of enflurane, isoflurane, sevoflurane, and methoxyflurane anesthetics was CYP2E1,[463,477–479] with secondary isozymes including CYP2A6 and CYP3A.[480] Subsequently, they reported large quantities of CYP2E1 not only within the liver but also within the kidneys.[477] They also noted that the affinity of renal CYP2E1 for methoxyflurane was 5-fold greater than it was for sevoflurane.[480] This provided further evidence that the renal dysfunction after ether inhalational anesthetics resulted from the local production of inorganic fluoride within the renal medulla rather than extrarenal production, and that certain anesthetics were more prone to release of inorganic fluoride than others (e.g., methoxyflurane much more so than sevoflurane). Because CYP2E1 has a greater affinity for methoxyflurane than sevoflurane, we now understand why renal dysfunction occurs after methoxyflurane and not after sevoflurane.[480] The lack of an association between sevoflurane, plasma inorganic fluoride concentration, and renal dysfunction in children and adults supports this new understanding of the mechanism of renal dysfunction after inhalational anesthesia. Consequently, the risk of renal dysfunction after sevoflurane is independent of the duration of exposure to sevoflurane. Sevoflurane does not pose any greater risk for perioperative renal disease than other maintenance anesthetics.[481] A second theoretical cause of sevoflurane-associated renal dysfunction is compound A, a product of alkaline hydrolysis of sevoflurane in the presence of CO_2 absorbents (see later discussion).

Hepatic System

In vivo metabolism of inhalational anesthetics varies with age, increasing to adult values within the first 2 years of life. The developmental changes in metabolism may be attributed to several factors, including reduced activity of the hepatic microsomal enzymes, reduced fat stores, and more rapid elimination of inhalational anesthetics in infants and children compared with adults. Halothane, isoflurane, enflurane, sevoflurane, and desflurane have all been associated with postoperative liver dysfunction and/or liver failure in adults, although the relationship between sevoflurane and desflurane and liver dysfunction remains tenuous.[482–485] In children, halothane and sevoflurane have been associated with transient hepatic dysfunction.[486–489] Indeed, several pediatric cases of transient postoperative liver failure and one case of fulminant hepatic failure and death have been attributed to "halothane hepatitis" that was confirmed serologically with antibodies to halothane-altered hepatic cell membrane antigens.[486] The exact mechanism of the hepatic dysfunction after halothane exposure remains unclear, although some clinicians have speculated that it is caused by an immunologic response to a metabolite of halothane. This putative toxic metabolite, a trifluoroacetyl halide compound, is produced during oxidative metabolism of halothane. It is thought that this compound induces an immunologic response in the liver by binding covalently to hepatic microsomal proteins,

E-TABLE 7.3 In Vivo Metabolism of Inhalational Anesthetics

Inhalational Agent	Percent Metabolized	Reference
Methoxyflurane	50	2046
Halothane	20	2047
Sevoflurane	5	477
Enflurane	2.4	2035
Isoflurane	0.2	2048
Desflurane	0.02	2049

thereby forming an immunologically active hapten. A subsequent exposure to halothane then incites an immunologic response in the liver.[490] Hepatic enzymes may also be induced by previous administration of drugs, such as barbiturates, phenytoin, and rifampin. Although some have admonished clinicians for administering repeat anesthetics with halothane in children, it is our opinion that, in view of the millions of uneventful repeat halothane anesthetics in infants and children worldwide, insufficient evidence exists to support such an admonition.

CLINICAL EFFECTS

Induction Techniques

Although the physicochemical characteristics of the ether series of anesthetics would predict that anesthesia could be induced smoothly and more rapidly with these agents than with halothane,[304,306] this has not proved to be the case. All of the ether anesthetics except sevoflurane irritate the upper airway in children, resulting in a high incidence of breath-holding, coughing, salivation, excitement, laryngospasm, and hemoglobin–oxygen desaturation.[424,491–500] Clinical studies with desflurane in children demonstrated a high incidence of breath-holding, laryngospasm, and desaturation during inhalational induction (~50%).[424,500] As a result, a "black box" warning was issued against the use of desflurane for induction of anesthesia in infants and children. Before the introduction of desflurane, some advocated inducing anesthesia in children with isoflurane.[493–497] For example, it has been suggested that the quality and speed of induction of anesthesia with isoflurane in oxygen in infants and children is similar to that with halothane.[494] However, airway reflexes were commonly triggered with isoflurane despite the use of a number of strategies to attenuate them,[498,500,501] including slowly increasing the inspired concentration and using scented masks. Given the smooth induction characteristics, economy, and availability of sevoflurane, there are no reasons to consider other anesthetics for induction of anesthesia in infants and children.

In contrast to the noxious effects of the methyl ethyl ether series of anesthetics on the airway, sevoflurane does not irritate the upper airway and is well tolerated when administered by mask to infants and children at any concentration.[a] The introduction of sevoflurane has challenged and displaced halothane as the induction agent of choice in children in most countries. The incidences of coughing, breath-holding, laryngospasm, and hemoglobin–oxygen desaturation during induction with sevoflurane, whether by slow incremental increases in concentration or a single breath, are similar to those that occur during halothane (there was a significantly greater incidence of breath holding with halothane compared with sevoflurane but a greater incidence of induction excitement with sevoflurane compared with halothane) (see E-Table 7.4). The observation that the airway reflex responses are infrequent after a single-breath induction with 8% sevoflurane or 5% halothane casts doubt on the adage that large concentrations of inhalational anesthetics trigger airway reflex responses.[506–508] In fact, the induction is so smooth with sevoflurane that adjuvants, such as a premedication, concurrent use of nitrous oxide, or other strategies to prevent airway reflex responses, are generally unnecessary.

Induction of anesthesia with xenon has not been studied in children. In adults, inhalational induction with xenon at equi-MAC with sevoflurane resulted in a more rapid induction with stability of respirations.[509] These data suggest that xenon may be an excellent induction anesthetic in children, provided its characteristics are upheld in well-designed clinical trials.

There is no single ideal approach to induce anesthesia by inhalation for all children. However, we advocate empowering children as much as possible to minimize fear. After appropriate preoperative preparation (involving premedication or parental presence or distraction techniques), the child is seated on the bed and encouraged to breathe through a face mask scented with a favorite flavor (to disguise the plastic odor of the mask) that is held over the nose and mouth. A fresh gas composed of 70% nitrous oxide in oxygen is breathed (while the pop-off value is completely open for 1 to 2 minutes). As soon as the child becomes "silly" or ceases to respond verbally, 8% sevoflurane is administered. Induction of anesthesia with halothane was performed with stepwise increments in the inspired concentration of 0.5% to 1.0% every three to four breaths until an adequate depth of anesthesia was achieved. This slow increase in the inspired concentration of halothane was thought to attenuate the incidence of airway reflex responses, although this is not evidence based. In fact, when a single-breath vital capacity induction was performed in children older than 6 years of age with 5% halothane, the incidence of airway reflex responses was surprisingly small.[506] Initially, sevoflurane was also administered in slow increments of 1% to 1.5% until 8%, but this caused transient agitation and involuntary movement of the extremities, frequently and sometimes violently, particularly in adolescents.[339] This was attributed to an exaggerated excitement phase. To minimize the excitement phase, we recommend that the inspired concentration of sevoflurane be increased as rapidly as possible, from 0% to 8% in a single-step increase.[506] This is based on a study of single-breath induction with 8% sevoflurane and 5% halothane in which the incidence of involuntary movement and the need for restraint were significantly less with sevoflurane than with halothane.[506] Recently, induction of anesthesia with 12% sevoflurane was reported to be more rapid than with 8%.[510] This is not a surprising finding, although 12% sevoflurane vaporizers should not be used in clinical practice because inspired concentrations of sevoflurane (in a laboratory setting) of 11% in oxygen and 10% in nitrous oxide support combustion.

Although some studies report more rapid induction of anesthesia with sevoflurane than with halothane, others have not. This inconsistency in the relative speed of induction reflects differences in study design that likely failed to take advantage of the 8% sevoflurane vaporizer and the differences in MAC. For children who are unable to perform a single-breath vital capacity induction, a rapid increase in the inspired concentration of sevoflurane has been a very effective alternative, with results comparable to the single-breath technique.[324,504–506]

Sevoflurane does not trigger airway reflex responses either alone or in combination with other agents, such as nitrous oxide. One study suggested that sevoflurane is the least irritating to the airway of all the inhalational anesthetics.[511] Previous studies suggested that airway irritability and excitement during sevoflurane anesthesia were similar whether nitrous oxide was present or absent, although others have disputed these findings.[506,512] The lack of effect of nitrous oxide on the speed of induction in the single-breath study was attributed to its concentration-reducing effect on sevoflurane.[506]

Although halothane has been the preferred agent for induction of anesthesia because of its lack of airway irritability, arrhythmias occur more frequently during halothane anesthesia than during anesthesia with the ether anesthetics. Halothane-induced arrhythmias occur more frequently during spontaneous ventilation and

in association with high levels of circulating catecholamines or hypercarbia.[419] Most of these arrhythmias are unifocal or multifocal premature ventricular beats, nodal rhythm, bigeminy, or supraventricular arrhythmias.[325,419,499] Despite their appearance, most of these arrhythmias are benign and preserve the BP; ventricular tachycardia, however, may cause hypotension. Management of arrhythmias during halothane anesthesia includes inflating the lungs with large tidal volumes, hyperventilation to decrease the arterial CO_2 tension, increasing the concentration of halothane if there is evidence of "light" anesthesia (i.e., sweating, hypertension), and substituting another inhalational anesthetic for halothane.[419,513] Lidocaine has no role in the treatment of these arrhythmias because the myocardium is not intrinsically irritable. Moreover, a rapid IV bolus of lidocaine (2 mg/kg) may cause profound bradycardia.[514] Arrhythmias are rare during anesthesia with the ether series of anesthetics, but when they occur they are usually nodal in origin.[a] Arrhythmias during anesthesia with the ether anesthetics are usually self-limiting, resolving spontaneously or with parenteral administration of an anticholinergic. If the arrhythmias persist, then a cardiology consultation should be sought, particularly in a child with a history of congenital heart disease. Both IV and inhalational anesthetics have been used for induction and maintenance of anesthesia in children with congenital heart disease. (See the earlier cardiovascular section and Chapter 23 for a more detailed discussion.)

Once an adequate depth of anesthesia has been achieved, it is prudent to maintain spontaneous respirations with the maximal inspired concentration of sevoflurane tolerated until IV access has been achieved. If hypopnea or apnea occurs, then ventilation should be assisted. The reason to recommend this practice is to prevent awareness from occurring in the early induction period.[379,380] Discontinuing or decreasing the inspired concentration of nitrous oxide or sevoflurane individually or together may predispose to awareness, particularly if the child is stimulated at a light plane of anesthesia. This may occur in situations when anesthesia is induced in one location (induction room) and the child is then transferred to another (OR) without continuously supplying sevoflurane. Appreciating the limited solubility of nitrous oxide and sevoflurane will help to understand how rapidly these anesthetics egress from the body, particularly after a brief exposure. Once IV access is established, some practitioners administer propofol or another IV anesthetic before discontinuing the nitrous oxide to facilitate insertion of a laryngeal mask airway or tracheal intubation. The concentration of sevoflurane can then be decreased.

Emergence

Emergence or recovery has been arbitrarily divided into early (extubation, eye opening, following commands) and late (drinking, discharge time from postanesthesia care unit or hospital). Although most studies have demonstrated a more rapid early recovery after less soluble anesthetics,[321–323,326,329] few have demonstrated a more rapid late recovery.[320,329,515,516]

The speed of emergence and recovery from anesthesia are discussed in earlier text. The incidence of complications, such as airway reflex responses and vomiting during emergence from anesthesia, after mask anesthesia or tracheal intubation, are similar with most inhalational agents.[b] However, the incidence of airway responses of any severity after desflurane was significantly greater than after isoflurane. Moreover, the incidence of airway adverse responses after removing a laryngeal mask airway (LMA) deep during desflurane anesthesia was significantly greater than was the incidence after removal of an LMA after recovery from desflurane (awake) or after isoflurane anesthesia.[518]

Emergence Delirium

Emergence delirium (ED) is defined as a dissociated state of consciousness in which children are inconsolable, irritable, uncompromising, and/or uncooperative (see Videos 47.1 and 47.2).[519,520] Children who experience ED often demand that all monitors, IV lines, and bandages be removed and that they be dressed in their own clothing. Many of these children fail to recognize and respond appropriately to their parents. Parents who witness this transient state usually volunteer that this behavior is unusual and uncustomary for their child. The core behaviors identified in association with ED after anesthesia in children include nonpurposeful action and averting eyes or staring.[521]

ED is not a new phenomenon; it was first reported in 1961[522] and was reported repeatedly after the introduction of almost every new anesthetic, including most inhalational anesthetics,[c] as well as IV agents, including midazolam, remifentanil, and propofol.[525,526] The incidence of ED after inhalational anesthesia in children ranges from 2% to 80%.[321,323,326,516,519]

The incidence of ED is greatest in children 1 to 5 years of age, similar after all inhalational anesthetics except halothane, reduced in the presence of adjuvant medications (e.g., opioids), increased in the presence of pain, and quite variable when a non-validated assessment scale is used.[519,520,527–530] These episodes have an average duration of 10 to 20 minutes and resolve spontaneously without sequelae. The mechanism by which ED occurs remains unknown.

ED has been reported in adults as well as infants, although the incidence is much less in both age groups than in children. Diagnosing ED after anesthesia and surgery has been complicated by our inability to distinguish it from pain. In one study, ketorolac decreased the incidence of ED 3-fold to 4-fold after myringotomy with either halothane or sevoflurane anesthesia.[517] Because ketorolac does not sedate children, it is likely that pain was confused with ED. Subsequent studies in children demonstrated that ED occurs after sevoflurane anesthesia even in the presence of neuraxial blocks.[519,530] The frequency of ED is independent of the speed of awakening from anesthesia,[531,532] the duration of a deep level of anesthesia,[533] the duration of general anesthesia,[534] and the presence of parents.[529]

The definitive study regarding the incidence of ED was undertaken in healthy children who required anesthesia for magnetic resonance imaging (MRI) and who did not undergo surgery.[529] The incidence of ED was 2-fold greater after sevoflurane than it was after halothane.

However, in most published studies, the metric used to diagnose ED had not been validated. To address this deficiency, the **P**ediatric **A**nesthesia **E**mergence **D**elirium (PAED) scale was developed (see Table 47.4).[520] The threshold PAED score to diagnose ED was thought to be greater than 10, but more recently a value greater than 12 was suggested.[535] When the PAED scale was compared with two nonvalidated scales,[535] the three appeared to be comparable, although the comparison was biased because the PAED scale was assessed first, followed by the other two scales (Table 7.8).

TABLE 7.8 Development and Psychometric Evaluation of the Pediatric Anesthesia Emergence Delirium Scale

1. The child makes eye contact with the caregiver.
2. The child's actions are purposeful.
3. The child is aware of his or her surroundings.
4. The child is restless.
5. The child is inconsolable.

Items 1, 2, and 3 are reverse scored as follows: 4 = not at all, 3 = just a little, 2 = quite a bit, 1 = very much, 0 = extremely. Items 4 and 5 are scored as follows: 0 = not at all, 1 = just a little, 2 = quite a bit, 3 = very much, 4 = extremely. The scores of each item were summed to obtain a total Pediatric Anesthesia Emergence Delirium (PAED) scale score. Emergence delirium is diagnosed if the total score is ≥10 or ≥12.

From Sikich N, Lerman J. Development and psychometric evaluation of the pediatric anesthesia emergence delirium scale. *Anesthesiology* 2004;100(5):1138–1145.

Pharmacologic interventions to prevent and treat ED have been summarized (see Table 47.6).[527,536] Effective treatment included fentanyl,[537] ketamine,[538] a propofol infusion or a bolus at the end of anesthesia, clonidine,[539,540] and dexmedetomidine.[541] In contrast, a single dose of propofol at induction of anesthesia, midazolam, and flumazenil were all ineffective.[536,542–546] Additional studies using assessment with a validated delirium scale are needed to clarify the contribution of anesthetics to ED during pain-free surgery.

Neuromuscular Junction

All inhalational anesthetics potentiate the actions of nondepolarizing muscle relaxants[547–549] and decrease neuromuscular transmission[550]; the latter, however, occurred only at increased concentrations. The mechanism of the reduced neuromuscular transmission is unknown but is likely attributable to actions of these anesthetics at the synaptic junction rather than PK or CNS effects. The potentiation of action of nondepolarizing relaxants follows the following order: isoflurane ~ desflurane ~ sevoflurane > enflurane > halothane > nitrous oxide–opioid technique.[547,551] However, this potentiation may depend on the type of nondepolarizing relaxant studied (longer-acting relaxants are affected to a greater extent than intermediate-acting relaxants),[547,548,552] and the concentration of anesthetic (reduced concentrations may yield small or no differences between anesthetics, whereas greater concentrations may demonstrate substantive differences).[548] In two parallel studies of atracurium infusions in children,[552,553] halothane and isoflurane decreased the atracurium requirements similarly in the first, whereas enflurane markedly decreased the requirements compared with halothane in the second. These observations suggest that inhalational anesthetics potentiate both intermediate-acting and long-acting NMBDs.

Malignant Hyperthermia

All potent inhalational anesthetics, except xenon,[554] trigger malignant hyperthermia (MH) reactions in susceptible adults and children.[555–564] Studies indicate that the relative capabilities of the four inhalational anesthetics to augment caffeine-induced contractures in MH-susceptible muscle in vitro are halothane > enflurane > isoflurane > methoxyflurane.[565] Using the surrogate marker of the time interval from administration of anesthesia until a reaction was detected to estimate the relative potency of the modern anesthetics to trigger MH, the order was halothane > sevoflurane > isoflurane ~ enflurane.[566] Currently, all inhalational anesthetics should be avoided in children who are MH susceptible (see Chapter 41).

The wash-out of inhalational anesthetics from anesthetic machines before anesthetizing a child with MH requires an understanding of the PK of these anesthetics in the specific anesthetic workstation. See Chapter 41 for a full discussion.

Stability and Toxicology of Breakdown Products

Inhalational anesthetics may be degraded via several pathways in the presence of most CO_2 absorbents to form several potentially toxic by-products. Enflurane, isoflurane, and desflurane (but not halothane and sevoflurane) react with desiccated soda lime to produce carbon monoxide. Halothane and sevoflurane react with soda lime to yield several organic compounds that are potentially organ toxic. In contrast, xenon is completely inert with CO_2 absorbents, thereby posing no risk from the genesis of metabolites or degradation products in humans.

Two strategies to address the clinical risks associated with the degradation of ether inhalational anesthetics are molecular sieves[567] and new CO_2 absorbents.[568–572] While molecular sieves were thought to have great promise, they have not reached the market for clinical use. In contrast, a number of new CO_2 absorbents have been developed to absorb CO_2 from the breathing circuit without degrading inhalational anesthetics to carbon monoxide and compound A (E-Table 7.5).[568,569] The previous generation of CO_2 absorbents differed in their composition and, therefore, in their affinity to degrade inhalational anesthetics. Soda lime contained 95% calcium hydroxide, either sodium or potassium hydroxide, and the balance as water. Baralyme, which is no longer available, contained 80% calcium hydroxide, 20% barium hydroxide, and the balance as water. E-Table 7.5 compares the compositions of the older with the newer CO_2 absorbents, which do not contain a strong base. Most recently, Amsorb Plus (Armstrong Medical, Coleraine, UK), Drägersorb Free (Dräger, Lubeck, Germany), and Yabashi lime (Yabashi product, Gifu, Japan) were formulated for minimal degradation of inhalational anesthetics, as well as to address efficient CO_2 absorption.[573]

Carbon monoxide may be produced when a methyl ethyl ether inhalational anesthetic is incubated with a desiccated CO_2 absorbent (most commonly soda lime or Baralyme). The absorbent within a CO_2 canister may become desiccated if dry fresh gas flows through the canister at a rate sufficient to remove most of the moisture (i.e., >5 L/minute continuously through the absorbent canister for 24 hours or longer while it is not in service). If the circuit reservoir bag is detached from the canister while fresh gas is flowing, then fresh gas may flow retrograde through the canister and exit primarily where the reservoir bag is normally placed. This cannot occur in anesthetic machines in which the fresh gas enters distal to the inspiratory flow valve. If the fresh gas flows retrograde through the canister for a sufficient time, it desiccates the absorbent and increases the risk of degradation of subsequently administered inhalational anesthetics. If one of the methyl ethyl ether inhalational agents (desflurane, isoflurane, or enflurane) is administered through a desiccated absorbent, carbon monoxide may be generated.[572,574,575] The magnitude of the carbon monoxide CO_2 production for a specific absorbent follows the order: desflurane = enflurane > isoflurane ≫ halothane = sevoflurane. Other factors that determine the magnitude of the carbon monoxide concentration produced include the concentration of the inhalational agent, the dryness of the absorbent, the type of absorbent (Baralyme > soda lime > newer absorbents), and the temperature of the absorbent.[574] The newer absorbents remove the strong alkalis, sodium hydroxide (NaOH) and potassium hydroxide (KOH), which are essential for the production of carbon monoxide, virtually eliminating this risk (E-Table 7.5).[576]

E-TABLE 7.5 Composition of Carbon Dioxide Absorbents Tested

CO_2 Absorbent	$Ca(OH)_2$ (%)	KOH (%)	NaOH (%)	LiOH (%)	H_2O (%)
Drägersorb 800 Plus	82	0.003	2	—	16
Medisorb	81	0.003	3	—	16
Spherasorb	84.5	0.003	1.5	—	14
Amsorb	83.2	—	—	—	14.4
Loflosorb	84	—	—	—	16
Superia	79.5	—	—	—	17.5
Lithium hydroxide	—	—	—	99	1

Absorbents obtained from Dräger, Lubeck, Germany (Drägersorb 800 Plus); Datex-Ohmeda, Hoevelaken, The Netherlands (Medisorb, Superia); Intersurgical, Uden, The Netherlands (Spherasorb, Loflosorb); Armstrong, Coleraine, Northern Ireland (Amsorb); and Chem2000, Delft, The Netherlands (lithium hydroxide). Amsorb contains 2.4% other chemicals, such as polyvinylpyrrolidine, calcium chloride, and calcium sulfate. Superia contains 3% other chemicals, such as magnesium chloride and aluminosilicates.

Reproduced with permission from Keijzer C, Perez RS, de Lange JJ. Compound A and carbon monoxide production from sevoflurane and seven different types of carbon dioxide absorbent in a patient model. *Acta Anaesthesiol Scand.* 2007;51(1):31–37.

Small concentrations of carbon monoxide (up to 18 ppm) have been detected in children who were anesthetized with desflurane or sevoflurane using fresh CO_2 absorbent that included KOH and NaOH.[577] Carbon monoxide concentration correlated closely with the fresh gas flow to minute ventilation ratio (<0.68) and weakly with the type of anesthetic agent (desflurane) and age.[577] Carbon monoxide has been detected in concentrations up to 3 ppm during and after anesthesia, even spinal anesthesia.[578] One may question whether a minimum fresh gas flow with desflurane and other nonsevoflurane anesthetics is warranted. The presence of carbon monoxide in the exhaled breath has been attributed to heme metabolism, inflammation, and sepsis, although the authors did not use fresh soda lime in their breathing circuits.[578]

Carbon monoxide is not detectable by any freestanding anesthetic agent analyzer, pulse oximetry, or blood gas analyzer (with the exception of co-oximeters), although it is detectable by mass spectrometry. A carbon monoxide analyzer is currently marketed for use during anesthesia. The solution to this problem is prevention: turn off the anesthetic machine at the end of the day, disconnect the fresh gas hose to the absorbent canister, always have the reservoir bag connected to the canister, and avoid passing desflurane, enflurane, and isoflurane through a desiccated absorbent. Others have suggested that high-flow anesthesia should be avoided whenever a circle circuit is used to prevent inadvertent desiccation of absorbent. If the absorbent is desiccated, some have suggested "rehydrating" the absorbent, although this, too, is fraught with potential problems (including clumping of the absorbent).[579] If there is suspicion that the absorbent is desiccated, we strongly recommend replacing the absorbent before introducing an inhalational anesthetic. Alternatives to conventional absorbents, such as the molecular sieve and the newer absorbents, may very well obviate degradation of the ether anesthetics, provided the absorbent is not dessicated.[568,569,571,572] When methyl ethyl ether anesthetics are incubated with desiccated Amsorb, carbon monoxide is not produced, although it may be produced with other desiccated absorbents (E-Table 7.6).[568,569,572] The incidence of carbon monoxide poisoning during anesthesia remains extremely rare even when soda lime is used as the absorbent. In contrast, the potential for carbon monoxide poisoning is zero if Amsorb or one of the absorbents that does not include strong metal alkali is used.

Halothane is degraded in the presence of CO_2 absorbents to the unsaturated vinyl compound, 2-bromochloroethylene, which is lethal in mice.[580] Although 2-bromochloroethylene is potentially nephrotoxic, it poses very little risk in humans, even under low-flow conditions, because its maximal concentration in the circuit is less than 3% of its lethal concentration (LC_{50}).[581]

Sevoflurane is both absorbed and degraded via the Cannizzaro reaction in the presence of absorbent, resulting in five degradation products.[582,583] Although the degradation of sevoflurane by the absorbent was initially posited to delay its wash-in, evidence suggests that this effect is trivial.[584] Of the five degradation products produced when sevoflurane is degraded in either soda lime or Baralyme, compounds A and B appear in the greatest concentrations. Compound A, fluoromethyl-2,2-difluoro-1-(trifluoromethyl) vinyl ether, is nephrotoxic in rats at concentrations of 100 ppm or greater and has an LC_{50} of 1100 ppm. Compound B, a methoxyethyl ether compound that is minimally volatile at room temperature, is present in closed circuits at less than 5 ppm and poses no serious risk to animals or humans. The remaining three metabolites, compounds C, D, and E, are present in such low concentrations in the breathing circuit that they are inconsequential. In a low-flow closed-circuit model with an inspired concentration of 2.5% sevoflurane, the concentration of compound A peaks at 20 to 40 ppm after several hours of anesthesia.[584–588] In children, compound A concentrations reach 16 ppm after 5.6 MAC hours of sevoflurane in a semi-closed circuit with 2-L/minute fresh gas flow.[589] Factors that are known to increase the production of compound A include an increase in the inspired concentration of sevoflurane, Baralyme greater than soda lime, and an increase in the temperature of the absorbent.[583,584] The newer formulation of CO_2 absorbents degrade sevoflurane to a lesser degree compared with the previous absorbents (see E-Tables 7.5 and 7.6). As in the case of carbon monoxide production, monovalent bases are important ingredients for the degradation of sevoflurane to compound A and their absence reduced the extent of degradation of sevoflurane.[570,576,590] In rats under low-flow conditions, compound A is nephrotoxic.[591–593] In contrast, studies in humans have been far from conclusive.[585–587,594] Commonly used indicators, such as albuminuria, have yielded inconsistent evidence of renal dysfunction.[585–588,594] One mechanism to explain compound A–induced nephrotoxicity is the β-lyase–dependent metabolism to nephrotoxic fluorinated compounds. However, this has been the subject of intense debate.[595,596] If compound A–associated nephrotoxicity were proven to depend on the β-lyase metabolic pathway, the limited concentration of this enzyme system in the renal cytoplasm and mitochondria of humans would make nephrotoxicity an unlikely outcome. Indeed, the inconsistency in the evidence of nephrotoxicity associated with compound A between rats and humans has been attributed to an 8- to 30-fold greater concentration of β-lyase in rats compared with humans.[597] To date, there have been no reported complications related to compound A and kidney damage in humans.

At the present time, sevoflurane is the only inhalational agent for which some federal authorities have recommended a minimum fresh gas flow when it is administered in a closed circuit with soda lime or Baralyme. The minimum fresh gas flow is 1–2 L/minute for 2 MAC-hours in the USA, although this limitation has not been universally adopted.

NITROUS OXIDE

Nitrous oxide confers several properties that differ substantively from the potent inhalational anesthetics that merit consideration. Nitrous oxide has a very limited solubility in blood, with a blood/gas partition coefficient ($\lambda_{blood/gas}$) value of 0.47. The MAC for nitrous oxide is 104% in adults; MAC has not been determined in children. Its chemical structure is N–N–O.

Nitrous oxide diffuses into gas cavities that are filled with nitrogen more rapidly than nitrogen egresses because it is 34 times more soluble in blood than nitrogen ($\lambda_{blood/gas}$ for nitrogen 0.014). Consequently, the volume of the cavity expands. However, the magnitude of the increase in the volume of the cavity depends, in part, on the concentration of nitrous oxide administered, as determined by the formula $100/(100 - \%N_2O$ [nitrous oxide]). The rate at which the cavity expands also depends on the source of the blood supply: those cavities in which the blood supply decreases as the volume of the cavity increases (e.g., a loop of obstructed bowel) will expand slower and to a smaller overall volume than a cavity in which the blood supply is independent of the cavity volume (e.g., a pneumothorax). By using a model of these conditions the time to double the volume of a loop of obstructed bowel with nitrous oxide was estimated to be 120 minutes, whereas the time to double the volume of a pneumothorax

E-TABLE 7.6 AUCs (ppm min) of CA and CO Based on the Mean Concentrations From the Duplicate Experiments of Each Desiccated and Normally Hydrated CO_2 Absorbent Used in Combination With Sevoflurane 0.8%

CO_2 Absorbent	AUC-CA-d	AUC-CA-f	AUC-CO-d	AUC-CO-f

was 12 minutes.[598] Any gas-filled cavities within the body are vulnerable for expansion if nitrous oxide is administered; expansion can occur with obstructed bowel,[598] pneumothorax, gas cavities within the eye, endotracheal tube cuffs,[599] laryngeal mask airways,[600,601] bubbles in veins,[602] and pneumoencephalography.[603] Theoretically, nitrous oxide should be avoided during laparoscopic surgery to avoid expanding CO_2 bubbles that reach the venous circulation (see Chapter 29).

Inhalational anesthetics confer a low risk for postoperative nausea and vomiting. In contrast, nitrous oxide is considered to be an emetogenic anesthetic. In a large meta-analysis of the impact of nitrous oxide on the incidence of postoperative nausea and vomiting in adults, the authors determined that for emetogenic surgery, eliminating nitrous oxide was salutary (number needed to treat of six), whereas for nonemetogenic surgery there was no benefit from omitting nitrous oxide.[604] Hence, avoiding nitrous oxide in surgery that is emetogenic is reasonable. At the same time, the authors of that study noted that the number needed to harm, in the form of intraoperative awareness when nitrous oxide was omitted from the anesthetic, was 46, or more than 2%. A recent Cochrane review failed to establish whether the presence of nitrous oxide has an impact on the incidence of awareness in adults after general anesthesia.[605]

A number of studies have investigated the contribution of nitrous oxide to postoperative vomiting in children. Although there is some evidence that avoiding nitrous oxide reduces the incidence of postoperative vomiting in children,[606] the preponderance of evidence fails to show any benefit.[607–611] In part, this may be attributed to the multiplicity of factors that contribute to postoperative vomiting, as well as the salutary effects of other factors, such as the use of propofol and/or antiemetics. Evidence from adults indicates that the contribution of nitrous oxide to postoperative vomiting increases with the duration of exposure.[612] Similar data in children have not been forthcoming. In none of the studies in children where nitrous oxide was omitted was awareness reported.

The inclusion of nitrous oxide in remifentanil-propofol anesthesia in children has been associated with a reduction in postoperative hyperalgesia.[613]

ENVIRONMENTAL IMPACT

The National Institute for Occupational Safety and Health (NIOSH) recommendations currently limit the chronic exposure to nitrous oxide to 25 ppm and to inhalational anesthetics to 10 ppm. The basis for these recommendations is uncertain but may be attributed to the risk of teratogenicity and end-organ dysfunction. In pediatric anesthesia, mask anesthesia and/or uncuffed tracheal tubes and laryngeal mask airways in children leak inhalational anesthetics into the environment. As a result, there is local exposure to inhaled anesthetics during anesthesia in children that should be considered.

Concern over the pollution of the stratosphere and ozone layer depletion by polyhalogenated anesthetics has raised further questions for the long-term use of these agents and the need to fully recycle or adsorb the waste gases.[614] The polyhalogenated anesthetics are produced in extremely low concentrations and although they have a large molecular weight, atmospheric winds likely facilitate their transfer up to the stratosphere, where they cause global warming and decrease the ozone layer. However, the most compelling data of their limited impact on the environment relate to their half-lives. The half-lives of these polyhalogenated anesthetics in the stratosphere are approximately 5 years. Contrast these to nitrous oxide, a compound with a very small molecular weight, which is administered in large concentrations (50%–70%) and has a half-life in the stratosphere of 120 years. Nitrous oxide is a known greenhouse gas that also depletes the ozone layer. The case for banning the polyhalogenated anesthetics pales in comparison with the enormous potential environmental impact of nitrous oxide. Although nitrous oxide is a serious greenhouse pollutant, agriculture and industry account for the vast majority of the nitrous oxide released into the atmosphere, with medical sources accounting for a trivial, unidentified fraction.[615] To preserve the ozone layer, all anesthetic providers should strive to limit the fresh gas flow and concentrations of inhalational anesthetics and nitrous oxide.

Oxygen

The concentration of oxygen for each anesthetic should be carefully titrated to the child's needs. Requirements are monitored by inspired oxygen concentration measurement, oxygen-hemoglobin saturation (pulse oximetry), and arterial blood gas determinations. Oxygen is often liberally administered in excess of the child's metabolic needs. However, potential dangers in this excess should be noted,[616] particularly in two areas. (1) Pulmonary oxygen toxicity is well documented; despite the fact that it develops slowly, general recommendations are to use an air/oxygen combination for prolonged procedures when nitrous oxide is contraindicated.[617] (2) Of additional concern is the remote possibility of adverse effects on the immature neonatal retina leading to retinopathy of prematurity (ROP).[618–629] Several cases of ROP have been reported in infants whose only known exposure to supplemental oxygen occurred in the OR; it should be noted that no new cases related to OR management have been reported since 1981![630,631] Many factors contribute to the development of ROP; it has been reported in children with cyanotic congenital heart disease, infants not exposed to exogenous oxygen, and even in stillborn infants.[632,633] A possible relationship of the development of ROP to arterial CO_2 variations, hypercarbia, hypotension, candida sepsis, inflammatory response, red blood cell transfusions, corticosteroid therapy, duration of ventilation, elevated blood glucose values, low gestational age, chronic lung disease, a deficiency of insulin-like growth factor, and vascular endothelial growth factor, as well as hypoxemia and fluctuating levels of oxygen, have all been suggested.[634–654] Other factors, such as exogenous bright light, maternal diabetes, maternal chorioamnionitis, and maternal antihistamine use within 2 weeks of delivery, are risk factors; the evidence for vitamin E deficiency is less convincing.[655–658] The possibility of a genetic predisposition–that is, a genetic polymorphism altering control of neovascularization–has also been proposed.[648,659–661] The use of continuous transcutaneous oxygen tension monitoring was not found to reduce the risk of ROP in infants weighing less than 1000 g, compared with controls.[662] It appears the major risk factor for developing ROP is extreme prematurity; *oxygen therapy represents only part of this complex problem.*[621,622,624] The incidence of ROP is predominantly limited to infants weighing 1000 g or less, but it is a concern in infants with a birth weight less than 1500 g born at less than 28 weeks gestation.[663–665] It should be noted that new treatments may involve systemic administration of propranolol (which improves neovascularization) and intravitreal injections of anti–vascular endothelial growth factors; both of these treatments may have anesthetic implications.[666,667] The evidence implicating hyperoxia as contributing to the development of ROP must be recognized but placed

in perspective. Although it was thought that tight control of oxygen saturation and minimizing exposure to exogenous oxygen would reduce the incidence of ROP,[668] a multicenter study, the **S**upplemental **T**herapeutic **O**xygen **P**rethreshold for **R**etinopathy of **P**rematurity study (STOP-ROP), failed to support that hypothesis.[669] In fact, the conclusion reached stated, *"Although the relative risk–benefit of supplemental oxygen for each infant must be individually considered, clinicians need no longer be concerned that supplemental oxygen, as used in this study, will exacerbate active prethreshold ROP."*[669] This study suggests that anesthesiologists should take practical precautions to protect an infant's retinas from hyperoxemia without unnecessarily endangering the infant. No comprehensive epidemiologic studies have yet examined anesthetic risk factors, but given the many cofactors that are associated with this entity, it appears that anesthesia management, although very important, is a small piece of this puzzle.

Bearing in mind the possible role of hyperoxia and hypercarbia, intraoperative management must include careful monitoring of inspired oxygen and expired CO_2 concentrations. Maintaining the oxygen saturation at 93% to 95% results in an arterial partial pressure of oxygen (PaO_2) of approximately 70 mm Hg, with values exceeding 80 mm Hg on occasion.[623,670,671] Unfortunately, individual oximeters may vary considerably in terms of their accuracy, so practitioners must be familiar with their equipment.[672] The use of air blended with oxygen can be used to further reduce the inspired oxygen concentration. A transport system equipped with an air–oxygen blender is desirable to continue the titration of oxygen therapy from the OR to the ICU. (When using portable oxygen tanks, a good rule of thumb to determine the capacity of an E-cylinder is as follows: the minutes of oxygen delivery left in the tank = pounds of pressure [in pounds per square inch] × 0.3 divided by gas flow [in liters per minute].) While avoiding hyperoxia, one must never lose sight of the importance of *avoiding hypoxemia; hypoxemia is life-threatening whereas hyperoxia is not.* One cannot be faulted if ROP should occur, provided a reasonable and safe approach to oxygen administration and ventilation has been made.

Intravenous Anesthetic Agents

The anesthetic effects of IV agents are primarily reflected by brain concentrations (the effect site). To achieve anesthesia, it is necessary to obtain an adequate cerebral blood concentration that equilibrates with the effect size. Each drug administered is rapidly redistributed from vessel-rich well-perfused areas (brain, heart, lung, liver, kidneys, and endocrine glands) to muscle, and finally to vessel-poor less well-perfused areas (bone, fat). Thus termination of the effect of a single drug dose is primarily determined by redistribution. The much slower tertiary distribution to relatively underperfused tissues of the body is noted with long-term drug infusions. Protein binding, body composition, cardiac output, distribution of cardiac output, metabolism, and excretion all alter the PK and PD of IV drugs. Anesthetic depth may be altered if a constant cerebral blood concentration is not maintained. The changes in body composition and the BBB that occur during maturation may also greatly affect the duration of action of IV drugs, especially in neonates. In addition to perinatal circulatory changes (e.g., ductus venosus, ductus arteriosus), there are maturational differences in relative organ mass and regional blood flow while a symptomatic patent ductus arteriosus (PDA) may also result in differences in distribution. Blood flow, as a fraction of the cardiac output, to the kidney and brain increases with age, whereas that to the liver decreases through the neonatal period.[673] Cerebral and hepatic mass, as proportions of body weight in the infant, are much greater than in the adult.[96] Whereas onset times are generally faster for neonates than adults (a size effect), reduced cardiac output and cerebral perfusion in neonates means that the expected onset time after an IV induction is slower in neonates, although reduced protein binding may counter this observation for some drugs. Offset time is also delayed because redistribution to well-perfused and deep underperfused tissues is more limited.

BARBITURATES

Methohexital

Methohexital (Brevital) is a short-acting barbiturate for IV induction of anesthesia (1–2 mg/kg). Administered intravenously as a 1% solution (10 mg/mL), it produces pain at the injection site; hiccups, apnea, and seizure-like activity may also be occasionally observed.[674,675] Methohexital has minimal effects on cardiovascular function (increased heart rate) in children.[676] Methohexital may be contraindicated in children with temporal lobe epilepsy.[674] Slow IV titration averts apnea. A possible advantage of methohexital (clearance 0.76 L/minute per 70 kg) over thiopental (clearance 0.24 L/minute per 70 kg) is that its mature rate of metabolism is greater while the volumes of distribution at steady state are similar (170 L/70 kg),[677] suggesting a more rapid recovery when large doses have been administered.[678–680] Anesthesia is achieved at plasma concentrations of 3.12 ± 0.99 mg/L.[681]

Rectal methohexital in a 10% solution (20–30 mg/kg) is a safe and atraumatic method of induction with an acceptably small incidence of undesired adverse effects (hiccups 13%, defecation 10%),[682] although this technique is no longer commonly used. It was particularly suited for brief radiologic procedures in children 3 months to 6 years of age, such as computed tomography (CT) scans, with a single rectal administration of a 10% solution given through a well-lubricated catheter.[683,684] Absorption by this route is quite variable and may account for an occasional child with slow or rapid onset of sedation.[678,685] It is also an alternative for children who are still in diapers and who are not candidates for other premedicants, such as midazolam (e.g., a child taking erythromycin).[686,687]

Oxygen desaturation occurs in approximately 4% of cases and is usually related to airway obstruction, which is readily corrected by repositioning the head[682,688]; methohexital should be administered only under the supervision of a physician trained in airway management to ensure adequacy of the airway because airway obstruction, seizures, or apnea may rarely occur.[689] *Children must not be left unobserved after administration.*

THIOPENTAL

The most likely anesthetic mechanism of action of thiopental is via binding to $GABA_A$ receptors, which increases the duration of GABA-activated chloride channel opening. The median effective dose (ED_{50}) of thiopental varies with age: 3.4 mg/kg in neonates, 6.3 mg/kg in infants, 3.9 mg/kg in children aged 1 to 4 years, 4.5 mg/kg in children 4 to 7 years, 4.3 mg/kg in children 7 to 12 years, and 4.1 mg/kg in adolescents aged 12 to 16 years.[690,691] The ED_{95} in children is 5 to 6 mg/kg and further increased to 7–8 mg/kg in children recovering from burn injuries.[692–694] Children aged 13 to 68 months given rectal thiopental (44 mg/kg) 45 minutes before surgery were either asleep or adequately sedated with plasma concentrations above 2.8 mg/L.[695] The effect-site concentration of thiopental for induction of anesthesia in neonates may be less than that in infants because the neonate has relatively immature

cerebral cortical function, rudimentary dendritic arborization, and relatively few synapses.[696]

The hypotensive response in neonates given thiopental appears not as dramatic as that associated with propofol, although it still may occur with reversion to fetal circulation.[697,698] Thiopental has little direct effect on vascular smooth muscle tone. Cardiovascular depression is centrally mediated by inhibition of sympathetic nervous activity and direct myocardial depression through effects on transsarcolemmic and sarcoplasmic reticulum calcium flux. Although doses of 6 mg/kg have been given before intubation in term infants without physiologic consequences,[699] the mean dose required for satisfactory induction in neonates is less, at 3.4 ± 0.2 mg/kg.[690]

The duration of the clinical effect of thiopental depends primarily on redistribution rather than metabolism (10% per hour). As a result, repeated doses of thiopental may accumulate, causing prolonged sedation. Children 5 months to 13 years of age, however, metabolize thiopental almost twice as rapidly as adults when expressed as per kilogram (see E-Fig. 7.3).[700–702] The elimination half-life of thiopental in neonates is greater than that in adults and children[703,704] because of reduced clearance. Clearance, expressed using a ¾ allometric model, at 26 weeks PMA was 0.015 L/minute per 70 kg and increased to 0.119 L/minute per 70 kg by 42 weeks PMA.[182] Maturation of the CYP2C19 pathway increases rapidly after birth in term neonates,[705] and the mature clearance of 0.24 L/minute per 70 kg is achieved within 3 months of age.

Acute tolerance to thiopental may occur.[706] A total IV dose of 10 mg/kg is generally the upper limit; however, with this dose it is common to have a prolonged period of sedation after brief procedures. Thiopental is a weak vasodilator and a direct myocardial depressant; both of these effects may cause significant systemic hypotension in the *hypovolemic* state (e.g., dehydration resulting from prolonged fasting or trauma).[707]

Thiopental in a 10% solution (20–30 mg/kg) may also be used for induction of anesthesia by rectal instillation when methohexital is contraindicated (temporal lobe epilepsy).[674] The period of sedation may be greater for thiopental than for methohexital, partly because of the reduced rate of metabolism.[708]

Thiopental has also been used in the pediatric critical care setting as a continuous high-dose infusion (~2–4 mg/kg per hour) to control intracranial hypertension. Monitoring the blood concentration of thiopental may be useful during such therapy to avoid depressing myocardial function. The elimination of thiopental after a continuous infusion may be markedly prolonged compared with that after a single bolus (11.7 vs, 6.1 hours) because of zero-order elimination (Michaelis-Menten kinetics).[701,702] The maximum rate of metabolism (V_{max}) increased from 11 mg/hour per 70 kg at 25 weeks PMA to 172 mg/hour per 70 kg at term. The adult estimate for V_{max} was 402 mg/hour per 70 kg with a Michaelis constant of 28.3 mg/L.[182,709] Slower elimination reported in neonates may, in part, be attributed to the underlying illness (e.g., hypoxic insult) and intercurrent drug treatment.

PROPOFOL

Propofol (Diprivan) is a sedative-hypnotic agent useful for both the induction and maintenance of anesthesia.[710] Diprivan is formulated with 1% propofol, 10% soybean oil, 1.25% egg yolk phosphatide (ovolecithin), 2.25% glycerol, EDTA (ethylenediaminetetraacetic acid), and sodium hydroxide to maintain a pH of 7.0 to 8.5. This formulation has a white milky appearance because it is a lipid macroemulsion with average droplet size of 0.15 to 0.3 µmol/L (where 5 to 7 µmol/L is required to pass through capillaries).[711] These droplets remain distinct in suspension owing to the negative surface charges on the phosphate moieties in the ovolecithin phospholipids in the aqueous outer layer. These droplets may coalesce if the negative surface charges on the emulsion droplets dissipate, which is a slow, naturally occurring process, but which may also be precipitated by physical maneuvers (freeze-thawing, high temperatures, or agitation) or by changes in the chemical composition of the emulsion, such as by decreasing pH or the addition of electrolytes (i.e., sodium, potassium, calcium, or magnesium) or medications (i.e., lidocaine [see later discussion]).[711] Soybean oil is composed of long-chain triglycerides (LCT), defined by the 12 to 22 carbon atoms in their skeletons: linoleic acid (54%), oleic acids (26%), linolenic acid (7.8%), and stearic acid (2.6%). EDTA was added to Diprivan after 1998 as an antimicrobial agent. Generic formulations of propofol are available; these contain sulfites or metabisulfite as the antimicrobial agent.

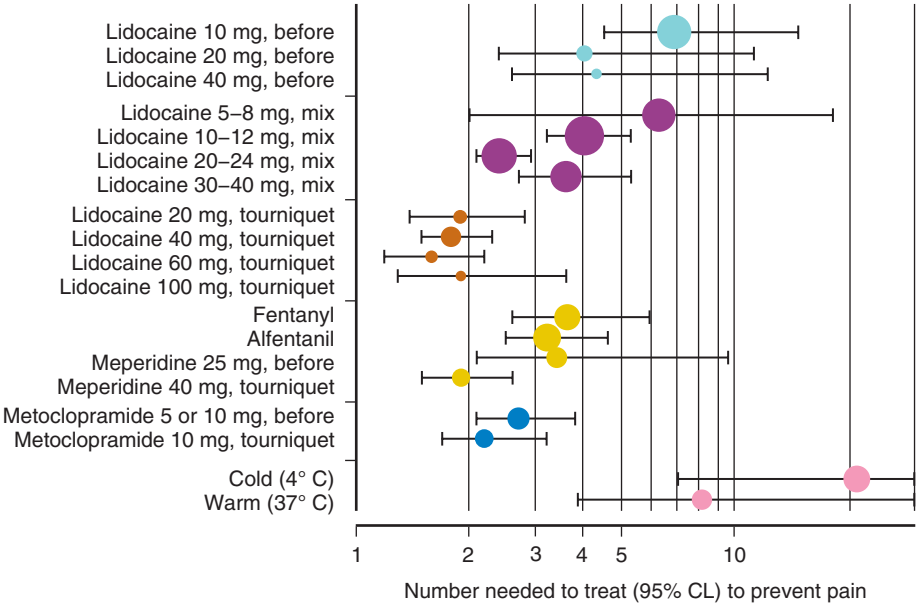
Propofol is a very lipophilic drug that is rapidly distributed into vessel-rich organs, accounting for its rapid onset and usefulness as an induction agent. Termination of this effect is achieved by the combination of rapid redistribution and rapid hepatic and extrahepatic clearance.[712–714] The rapidity of the redistribution from vessel-rich organs accounts for its brief action and the need for repeated small boluses or a constant infusion to maintain a stable plane of anesthesia and sedation. PK studies demonstrated a larger Vdss (9.7 L/kg) in children compared with adults, and more rapid redistribution, but a clearance (34 mL/minute per kilogram) similar to or greater than that reported in adults (see Chapter 8 for a review of PK parameter sets used to describe propofol disposition).[715–718] Clearance, standardized to a 70-kg person using allometry, is immature in preterm neonates (0.4 L/minute per 70 kg at 30 weeks PMA); there is rapid maturation around term (1 L/minute per 70 kg), achieving 90% of mature clearance (1.8 L/minute per 70 kg) by 5 months postnatal age (see Fig. 7.11).[174,719–722] Clearance is limited by hepatic blood flow and is consequently reduced in children in low cardiac output states.[723] Although interindividual variability in the PK in neonates is large, the reduced clearance suggests that recovery after propofol in neonates may be prolonged and that repeat doses may not be required as frequently as in older children and adults. Propofol is conjugated to a water-soluble glucuronide in the liver and excreted in the urine.[715] Propofol also undergoes extrahepatic metabolism (in lung, kidney), as evidenced by the similar PK in infants with biliary atresia and healthy controls.[724]

Integrated PK–PD studies in neonates are lacking, partly because of a lack of consistent effect measures. However, studies in children are increasing (see Chapter 8).[55–57] The equilibration half-time ($T_{1/2}keo$) for the effect compartment is smaller (< 2 minutes) than in adults (3 minutes).[725,726] Reduced $GABA_A$ receptor numbers in the neonatal brain may contribute to a reduced target concentration, but this hypothesis remains untested. A circadian night-rhythm effect has been noted in an investigation of infant propofol sedation after major craniofacial surgery,[727] but such an effect is unlikely in neonates who do not have established day–night sleep cycles.[728]

Although measuring the concentration of propofol in blood has been the sole means to assess its disposition in vivo, alternate noninvasive techniques have been sought to provide online measurements. Mass spectrometry of the exhaled breath from adults and children, a technique similar to end-tidal gas monitoring of inhalational anesthetics, has proven to provide stable estimates of the concentration of propofol in blood.[729,730] It may soon be

possible to guide administration of propofol in the OR by the measurement of expired propofol.[731–734]

In children who have not been premedicated, the dose of propofol (per kilogram) required for loss of the eyelash reflex generally increases with decreasing age.[735–739] The ED_{50} for loss of the eyelash reflex in infants (1–6 months) is 3 ± 0.2 mg/kg, which decreases in children (1–12 years) to 1.3 to 1.6 mg/kg, and increases in older children (10–16 years) to 2.4 ± 0.1 mg/kg. A more linear decrease in propofol dosing with increasing age between infants and children 12 years of age was determined in Chinese children.[738] A 10% decrease in the propofol dose for the ED_{95} between children younger than age 2 years, 2 to 5 years, and 6 to 12 years was noted. The $ED_{90\text{-}95}$ for loss of eyelash reflex for all age groups is 50% to 75% greater than the ED_{50}.[735,736] Larger doses may be required for acceptance of the face mask.[736,740] The dose of propofol in neonates has not been clearly established but appears to be slightly less on the first day of life; the mean dose was 3.3 ± 1.2 mg/kg with 15% of neonates requiring additional medication.[741] In one study, a dose of 2.5 mg/kg permitted tracheal intubation in the majority of neonates, although the exact dose used was not specified.[742] In neonates, the ED_{50} for tracheal intubation ranged from 0.72 to 1.3 mg/kg, although only 58% were successfully intubated on the first attempt.[743] In infants 1 to 4 months, the intubating conditions 1 minute after a (median) propofol dose of 3 mg/kg and remifentanil 2 μg/kg were poor in almost one-third[744]; the addition of rocuronium 0.2 mg/kg did not improve their success rate. After induction of anesthesia with sevoflurane and nitrous oxide, excellent conditions for tracheal intubation are achieved with 1.5 to 2 mg/kg in children.[745–748] In contrast to the propofol doses needed for tracheal intubation with inhalation agent, successful insertion of a laryngeal mask airway (LMA) in unpremedicated children requires an even larger dose of propofol (5.4 mg/kg [4.7–6.8 mg/kg, 95% confidence interval (CI)]).[749]



Propofol is widely used as a continuous infusion or in intermittent doses in children undergoing brief radiologic procedures, during medical procedures such as oncology and gastroenterology, and for children with MH.[24,750–753] Although early evidence suggested that 100 μg/kg per minute propofol was required after a halothane induction to maintain immobility during MRI,[750] subsequent studies showed that much larger doses are required in unpremedicated children or after sevoflurane inductions.[24] Specifically, initial infusion rates of propofol of 200 to 250 μg/kg per minute (12–15 mg/kg per hour) or even greater may be required (up to 500 μg/kg per minute for the first 15 minutes and then tapered) to prevent nonpurposeful limb movement during scans. The initial rate may have to be increased for younger children (e.g., infants)[754] and for those who are cognitively impaired, but there is no difference for children with attention deficit disorder.[755] Midazolam premedication may reduce the propofol requirements, but it delays emergence after brief procedures. Once movement has abated, the infusion rate of propofol may be titrated approaching 200 μg/kg per minute in infants and 150 μg/kg per minute in older children. If minor movement can be tolerated (e.g., medical procedures), then intermittent boluses may be preferred for brief procedures, whereas if immobility is required (radiation oncology and radiologic procedures), then infusions are preferred. Repeated sedation with propofol over a prolonged period such as radiation oncology has not demonstrated the development of tolerance.[756] Propofol may offer advantage over dexmedetomidine sedation for MRI in terms of rapidity of onset, emergence, and parental satisfaction.[757]

Propofol affects a number of organ system responses in vivo. Systolic BP decreases approximately 15% in children,[716,740,758,759] which is similar to what occurs in adults.[760] Most studies reported similar decreases in BP after propofol and thiopental in children.[759,761] A study of preterm infants (29–32 weeks gestational age) enrolled in the **IN**tubation **SUR**factant **E**xtubation (INSURE) study found unacceptable hypotension after low-dose propofol (1 mg/kg) 10 minutes after propofol administration (mean arterial pressure 38 mm Hg reduced to 24 mm Hg); the authors concluded that *"propofol should be used with caution in very preterm infants with respiratory distress during the first hours of life."*[697] The incidence of apnea after an induction bolus of either propofol or thiopental is similar.[740,758,759,761] The major clinical disadvantage of propofol in children is pain when it is injected intravenously into a small vein.[762] This pain can be diminished by using any one of a number of strategies, including injecting propofol into a large vein; pretreatment with IV lidocaine (0.5 mg/kg), meperidine, nitrous oxide, metoprolol, dexmedetomidine, low-dose ketamine or tramadol; and combining a small dose of lidocaine (0.5–1.0 mg/kg) with the propofol.[a] The most effective method to eliminate pain in adults is to apply a "mini-Bier block" by manually occluding the IV flow by squeezing the extremity proximal to the IV site for 45 to 60 seconds and injecting IV lidocaine (0.5–1.0 mg/kg).[762] As soon as the Bier block is released, the desired dose of propofol is administered painlessly (E-Fig. 7.11). The average number of patients who need to be treated to benefit from this maneuver to prevent pain *(number needed to treat)* in adults is less than two,[766] indicating that this technique is extremely effective.[762] Some advocate that the use of IV lidocaine should be routine practice,[771] but the tourniquet may cause discomfort in some children. In children, IV lidocaine 2 mg/kg before propofol (without a tourniquet) dramatically reduced the pain.[771] In a meta-analysis, IV lidocaine effectively reduced pain before propofol although in most of the studies, lidocaine (10–20 mg) was admixed with the propofol immediately before administration.[772] Pretreatment of lidocaine with a tourniquet may be of greater benefit to prevent injection pain of propofol LCT/medium-chain triglycerides (MCT) compared to a premixed injection with lidocaine (see Chapter 8).[773]

The mechanism by which IV propofol causes pain has been attributed to the nociceptive effects of trace concentrations of propofol (15–20 μg/mL) in the outer aqueous layer of the Diprivan soybean-oil micelles. When the concentration of propofol in the outer layer was reduced (i.e., by increasing the concentration of MCT in the formulation or IV lidocaine), irritation of the nociceptive nerve endings in the veins and the severity of the pain during injection were attenuated.[774]

Indicators for recovery from anesthesia, such as time to eye opening and time to extubation, are more rapid in children when anesthesia was induced with propofol compared with thiopental.[775–780] Recovery of psychomotor function is more rapid after a propofol induction and maintenance of anesthesia compared with thiopental–isoflurane anesthesia.[781] Recovery room stay and time to hospital discharge are reduced with propofol.[775,777] ED rarely occurs after propofol anesthesia in children, and small doses at the end of inhalation anesthesia have been shown to reduce ED.[782–784] Propofol reduces the incidence of nausea and vomiting when used as an induction agent or when used for the maintenance of anesthesia.[777,785–791] However, there have been conflicting results for particular procedures, such as strabismus repair and

tonsillectomy, and when the drug is combined with opioids.[792–795] Nausea and vomiting may be considered surrogate endpoints for serious adverse outcomes after surgery in children. No studies have demonstrated clinically important abbreviated times to discharge or decrease in overnight admission rate for vomiting and/or dehydration in children treated with propofol. Short-term infusions of propofol for surgical or medical procedures have shown that the depth of sedation is easily controlled by adjusting the infusion rate while still ensuring rapid and complete recovery.[796–800] Propofol compromises airway patency and respiration in children; the upper airway narrows particularly in the hypopharyngeal region, but it does remain patent.[801] If airway obstruction occurs, the chin lift maneuver augments the patency of the upper airway.[802,803] Theoretically, collapse of the upper airway increases in parallel with the dose of propofol by direct inhibition of genioglossus muscle activity, as well as an inhibition of centrally mediated airway dilatation and airway reflexes.[804] All of these upper airway changes are reversed on emergence from anesthesia.[805] When propofol is given as an IV bolus, transient apnea may occur.[738,745,759]

Diprivan and the current lipid-based generic formulations of propofol must be handled with aseptic techniques because the lipid is a culture medium.[806] Propofol 1% can support the growth of at least four well-known organisms: *Staphylococcus aureus, Pseudomonas aeruginosa, Escherichia coli,* and *Candida albicans*.[807–809] When Diprivan was first introduced, it was prepared (as are all lipid emulsions) under strict aseptic conditions, with a layer of nitrogen above the liquid emulsion in each vial.[711] Once opened, external contamination of the vials, however, resulted in severe sepsis and several deaths before bacteriostatic or bacteriocidal agents were mandated to be included in the propofol formulations to prevent or retard bacterial growth. In very small concentrations, EDTA inhibits bacterial growth by chelating vital trace metals without affecting the emulsion droplet size or stability. Other formulations of propofol contain sulfite or metabisulfites, which release sulfur dioxide that prevents bacterial growth. Sulfites are more effective at reduced pH values, but there is a limit to how acidic the emulsion can become because this destabilizes the emulsion droplets. To further prevent any risk of bacterial contamination, all opened vials of propofol should be discarded after 12 hours.

Long-term propofol infusions were used extensively for sedation in ICUs after recognizing that its favorable PK would facilitate a rapid wake-up.[712] However, a report of five deaths in infants and children (4 weeks to 6 years of age) who were sedated with Diprivan raised serious doubts about the safety of such a practice.[810] The syndrome, now known as propofol infusion syndrome (PRIS), occurs primarily, but not exclusively, in children who are sedated for prolonged periods in ICUs.[810–814] Clinical experience indicates that PRIS is most common when propofol is infused continuously at more than 5 mg/kg per hour (70 μg/kg per minute) for more than 48 hours. Manifestations of PRIS include the insidious onset of lipemia, metabolic acidosis, hyperkalemia, and rhabdomyolysis that may precipitously transform into profound myocardial instability and cardiovascular collapse refractory to all resuscitative efforts. Manifesting signs may be subtle, with the sudden onset of bradycardia refractory to the usual interventions. PRIS was suspected in a 5-year-old undergoing an arteriovenous malformation resection when an unexplained metabolic acidosis was detected after a 7-hour infusion of propofol.[815] When propofol was discontinued, the signs of PRIS abated. In an adult neurosurgical ICU where propofol sedation was used, a retrospective review determined that for every 1 mg/kg per hour that the propofol infusion exceeded 5 mg/kg per hour, the odds ratio of death was 1.93.[816] After a total of at least 28 deaths in children and 14 adults, the FDA cautioned against the use of propofol for long-term sedation. Predisposing risk factors include concomitant catecholamine inotrope infusions or high-dose corticosteroids and sepsis. In addition, some have cautioned against using propofol for extended periods of time in children with mitochondrial disorders.[817] Mortality currently ranges from 30% to 80%; institution of hemodialysis, partial exchange transfusion, and extracorporeal membrane oxygenation may improve survival.[818,819]

Despite PRIS risk, infusion at rates greater than 5 mg/kg per hour continue to be used in the ICU.[820] Unraveling factors that predispose to PRIS has proved to be difficult. Early investigations noted that during PRIS, the blood concentrations of malonylcarnitine and C5-acylcarnitine increased. These compounds are known to inhibit carnitine palmitoyl transferase and the transfer of LCT into mitochondria.[821,822] Propofol may also directly inhibit carnitine palmitoyl transferase to impede flux of LCT into mitochondria. Within the mitochondria, propofol uncouples the β-oxidation spiral at complex II in the respiratory chain, which in turn inhibits transmembrane flux of LCT into mitochondria, strangling the mitochondria from a much needed source of energy. One trauma center reported their experience with adult patients and correlated PRIS with duration of infusion and increasing triglyceride levels and suggested that the latter might be a useful biomarker for PRIS.[823]

The safety of propofol in the neonatal period has raised concerns after reports of profound episodes of cardiorespiratory collapse in neonates.[824,825] In these cases, precipitous and severe decreases in systolic BP, heart rate, and oxygenation were observed after a single induction dose of propofol (1–7 mg/kg) in neonates without evidence of congenital heart defects or cardiomyopathy. Resuscitation was extremely difficult in all cases despite intervention with both inotropic and chronotropic agents. A myriad of causes of bradycardia associated with propofol administration have been proposed.[826] In a comprehensive review of bradycardia after propofol in children and adults, the authors concluded that "propofol carries a finite risk for bradycardia with potential for major harm."[827] Whether these responses reflect acute right-to-left shunting, a return to fetal circulation, or another, as yet undisclosed cause in neonates has not been confirmed; caution should be exercised when propofol is used to induce anesthesia in neonates.[698]

Although anaphylactoid reactions have been reported after propofol administration in children, specific causes for the allergic reaction have not been identified.[828] In some instances, the "reactions" were primarily respiratory and attributed to preservatives, such as metabisulfites.[829] However, 13 of 14 adults who developed anaphylactoid reactions after their first exposure to propofol displayed a hypersensitivity response to propofol with at least one test during immunologic testing.[830] Similar findings in children have not been reported. It has been proposed that first-exposure reactions suggest a previous sensitization, possibly arising from isopropyl epitopes similar to propofol in cosmetics, detergents, and cough medicines.

Some clinicians avoid propofol in patients with egg, soy, or peanut allergies out of concern that cross-sensitivity with trace components in propofol may trigger perioperative anaphylactoid reactions. Both a case series and a recent review concluded that there is no evidence to eschew propofol in patients with egg, soy, or peanut allergies.[831,832]

The package insert for Diprivan cautions against its use in all patients with "egg allergy." However, children with egg allergy (including severe allergy) have received the measles-mumps-rubella vaccine, which is derived from eggs, without untoward experience,[833–835] although isolated reactions have been reported. In the past 2 decades, no immunologically verified anaphylactic reactions have been reported in children with egg allergy who received Diprivan.[832] In fact, Diprivan contains egg lecithin, which is derived from heated egg yolk. Egg lecithin is a phospholipid and has not been reported to trigger allergic reactions, although trace concentrations of egg yolk, of which only 2 of 9 proteins present (Gal d 5 and Gal d 6) are possibly immunogenic. When propofol was given 43 times to 28 children with egg allergy, only one experienced a mild nonanaphylactoid reaction, which led to the recommendation to avoid propofol only in children with documented anaphylaxis to eggs.[832] There is little evidence for present practice of choosing alternatives to propofol in patients with egg allergy.[831]

Soy protein allergy is primarily a gastrointestinal allergy that dissipates by 5 to 6 years of age because most foods consumed contain soy protein, resulting in natural desensitization. Very rarely is soy allergy a systemic disease. Although propofol is a soy-based emulsion, the AstraZeneca website states that all protein moieties are removed during the manufacturing process, rendering soy an exceedingly unlikely epitope to trigger an immunologically based anaphylactic reaction, although one case has been reported[836] in an adult not known to be soy-allergic. The reader should note that there is an approximately 5% cross-reactivity between soy and peanut allergy.[837] In children with both soy allergy and peanut anaphylaxis, it may be prudent to avoid propofol, especially if administering generic formulations. However, there is little evidence for the present practice of choosing alternatives to propofol in patients with peanut or soy allergy.[831]

In an effort to divest propofol of its lipid carrier and pain during IV administration, alternate formulations of propofol have been under development for parenteral use. New formulations of propofol must satisfy a number of conditions: easy to administer, stable formulation, no or minimal pain on injection, no infectious risk, no adverse organ effects including anaphylaxis and rapid PK. Unfortunately, most formulations to date have failed in one or more of the previous criteria.

Some have recommended replacing LCT in propofol with MCT to reduce the risk of PRIS and pain during injection. When 1% propofol with LCT was compared with the same with MCT, both with 1 mL of 2% lidocaine, the frequency of pain and its intensity during injection were similar.[838]

KETAMINE

Ketamine (Ketalar) is a derivative of phencyclidine that similarly antagonizes the *N*-methyl-D-aspartate (NMDA) receptor.[839] Its action is related to central dissociation of the cerebral cortex, and it also causes cerebral excitation. The latter property may be responsible for precipitating seizures in susceptible children and the reason that processed EEG monitoring devices do not work with ketamine sedation or anesthesia.[254–256,840,841]

Ketamine is available as a mixture of two enantiomers; the *S*(+) enantiomer has four times the potency of the *R*(–) enantiomer. *S*(+)-ketamine has approximately twice the potency of the other enantiomer. The metabolite norketamine, has a potency that is one-third that of its parent compound. Plasma concentrations associated with anesthesia are approximately 3 μg/mL,[842] whereas concentrations for hypnosis and amnesia during surgery are reported to be 0.8 to 4 μg/mL; awakening usually occurs at concentrations

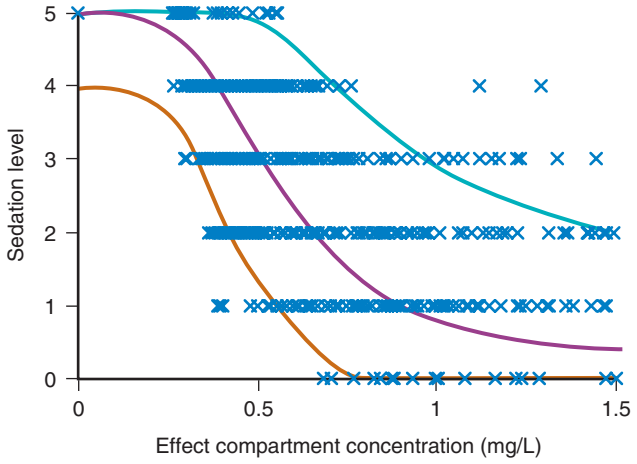

FIGURE 7.19 The relationship between effect compartment concentration and level of ketamine sedation (*purple line*). The concentration producing 50% of the maximum effect (EC_{50}) was 0.562 mg/L. Categorical data are shown as crosses. The *brown* and *blue lines* demonstrate the 5% and 95% confidence intervals. (Reproduced with permission from Herd DW, Anderson BJ, Keene NA, Holford NH. Investigating the pharmacodynamics of ketamine in children. *Paediatr Anaesth.* 2008;18(1):36–42.)

less than 0.5 μg/mL. Pain thresholds are increased at 0.1 μg/mL.[843] The concentration-response curve for ketamine sedation is steep.[66,844] This means that small serum concentration changes will have dramatic effect on the degree of sedation observed (Fig. 7.19).

Ketamine is very lipid soluble with rapid distribution and the onset of anesthesia after IV administration is approximately 30 seconds. This is usually heralded by horizontal or vertical nystagmus (Video 7.1).[845,846] Studies separating equivalent anesthetic doses of ketamine isomers identified a reduced incidence of adverse effects, more potent analgesia and rapid onset, and fewer cardiovascular effects with the dextro isomer rather than the levo isomer[113,845,847–849]; acute tolerance has been reported.[850] Children require greater doses of ketamine (per kilogram) than adults because of greater clearance (per kilogram); however, there is considerable patient-to-patient variability.[253,843,845,847]

Ketamine undergoes *N*-demethylation to norketamine. It is metabolized mainly by CYP3A4, although CYP2C9 and CYP2B6 also have a role. Elimination of racemic ketamine is complicated by the *R*(–)-ketamine enantiomer, which inhibits the elimination of the *S*(+)-ketamine enantiomer.[851] Clearance is immature in neonates but matures to reach adult rates (80 L/hour per 70 kg; that is, liver blood flow) within the first 6 months of life, when described using allometric size models.[852] Clearance in neonates is reduced (26 L/hour per 70 kg),[853–855] while Vdss is increased (3.46 L/kg at birth, 1.18 L/kg at 4 years, 0.75 L/kg at adulthood).[853] This larger Vdss in neonates contributes to the observation that neonates require a 4-fold greater dose than 6-year-old children to prevent gross motor movement.[856]

Bioavailability after IM administration is approximately 93% in adults and even greater in children.[843,857,858] There is a high hepatic extraction ratio, and the relative bioavailability of oral, nasal, and rectal formulations is 20% to 50% (Table 7.9).[128,858,859] Children presenting for burn surgery had slow absorption (absorption half-time [$T_{1/2}$abs] of 59 minutes) with large between-subject variability.[128]

Ketamine is an excellent analgesic and amnestic; the recommended dose for induction of anesthesia is 1 to 3 mg/kg

TABLE 7.9 Ketamine Equivalency by Route of Administration[a]

Route	Approximate Bioequivalence (mg/kg)
Intravenous	2
Intramuscular	2.15
Nasal	4
Rectal	8
Oral	11.75

[a]Note that these are estimates and that there is extreme patient-to-patient variability.
Extrapolated from data from Grant IS, Nimmo WS, McNicol LR, Clements JA. Ketamine disposition in children and adults. *Br J Anaesth*. 1983;55(1):1107–1111; Grant IS, Nimmo WS, Clements JA. Pharmacokinetics and analgesic effects of i.m. and oral ketamine. *Br J Anaesth*. 1981;53(8):805–810; Clements JA, Nimmo WS, Grant IS. Bioavailability, pharmacokinetics, and analgesic activity of ketamine in humans. *J Pharm Sci*. 1982;71(5):539–542.

intravenously or 5 to 10 mg/kg intramuscularly.[849,860] The duration of action of a single IV dose is 5 to 8 minutes, with an α-elimination half-life of 11 minutes and a β-elimination half-life of 2.5 to 3.0 hours.[861–863] Further supplementary doses of 0.5 to 1.0 mg/kg are administered when clinically indicated. Atropine or another antisialagogue accompanying the initial dose diminishes the production of copious secretions that may occur with ketamine.[864–866] Ketamine may also be administered in very low doses intravenously (0.25–0.5 mg/kg) or intramuscularly (1–2 mg/kg), either alone or in combination with low-dose midazolam (0.05 mg/kg [50 μg/kg]), along with atropine (0.02 mg/kg) for sedation, for a variety of procedures, such as oncology evaluations, suture of lacerations, or radiologic interventions.[849,860,867–872] If an antisialagogue is not administered, there is a greater risk for laryngospasm,[873] although guidelines for emergency departments suggest that supplementation with atropine or a benzodiazepine may not be necessary with doses of 1 to 1.5 mg/kg.[874–876] Larger doses of ketamine will produce a state of general anesthesia.[877–879] Even after small doses there is potential for apnea or airway obstruction, particularly when combined with other sedating medications.[877,880,881]

Ketamine has also been administered orally, nasally, and rectally, both as a premedication before general anesthesia and for procedural sedation.[882–900] Oral ketamine administered as a premedicant has also been reported to reduce ED; there is conflicting evidence regarding the efficacy of ketamine to reduce pain scores after tonsillectomy.[901–904]

There are concerns regarding both rectal and nasal drug administration. Rectal administration can result in very irregular and less predictable times of onset and peak sedation, just as with rectal barbiturates. Nasal drug administration may result in drug entering directly into the CNS by tracking along neurovascular tissue of the nasal mucosa (E-Fig. 4.2),[905–909] although this remains unproven in humans. Because the preservative in ketamine has been shown to be neurotoxic, there is the theoretic possibility of CNS toxicity because of the preservative.[910,911] These theoretical concerns have not been evident in clinical practice. The bioavailability of both *S*(+)-ketamine and racemic ketamine administered by nasal spray was ~36% with a peak blood level occurring at ~8.5 minutes.[113,118] A ketamine-sufentanil combination nasal administration provided rapid onset of analgesia for a variety of painful procedures with few adverse effects and has promising features for use in pediatric procedural pain management.[118]

Ketamine has also been administered as a means of providing caudal epidural analgesia.[860,912–917] There is risk of neurotoxicity during neuraxial administration of ketamine: *epidural ketamine must not be administered unless it is preservative free.*

The use of ketamine is increasing for postoperative pain management when administered in small doses as an opioid-sparing drug.[849,860,918–921] Although a recent meta-analysis documented reduced pain scores and nonopioid-sparing effects, it failed to substantiate its efficacy in opioid-sparing (see later discussion). Ketamine has also been used topically to treat mucositis and other painful conditions.[287,922–928] Ketamine increases heart rate, cardiac index, and systemic BP; it also increases pulmonary artery pressure in adults but has a small effect on respiration.[845,929] In children, there is apparently no effect on pulmonary artery pressure provided that ventilation is controlled.[930] If a child is sedated with ketamine but allowed to breathe spontaneously, increases in $ETCO_2$ could increase pulmonary artery pressures.[931] Ketamine sedation has been shown to maintain peripheral vascular resistance, thus affecting intracardiac shunting less than propofol in children sedated for cardiac catheterization.[932] However, the combination of ketamine and propofol[933,934] might be superior to either drug alone in this circumstance.[935,936] Ketamine has negative inotropic effects in those who depend on vasopressors.[937] The effect of ketamine on the musculature of the upper airway differs from that of midazolam; in adults, ketamine does not cause airway obstruction, whereas midazolam does.[938] Ketamine has one of the best safety profiles of any anesthetic agent. After unintended overdoses as great as 56 mg/kg IM and 15 mg/kg IV,[939] the duration of sedation persisted for 3 to 24 hours; respiratory depression occurred in four children, whereas tracheal intubation was required in two. When the children who received an overdose were monitored and their airways were maintained, recovery occurred without incident. This report, combined with the minimal effect of ketamine on airway patency, may explain, in part, the successful widespread use of this anesthetic by nonanesthesiologists. However, there remains a small but consistent incidence of adverse airway-related events, such as laryngospasm, apnea, and airway obstruction associated with ketamine, underscoring the need to ensure that the personnel responsible for administering ketamine are trained in advanced airway management. Ketamine also relaxes the smooth musculature of the airway stimulated by histamine[940]; treatment of acute asthma with subanesthetic doses has yielded mixed results.[941–946]

The most common adverse reaction to ketamine is postoperative vomiting, which occurs in up to 33% of children depending on the route of administration.[846,882] Intraoperative and postoperative dreaming and hallucinations occur more commonly in older than in younger children.[846] The incidence of these latter adverse effects may be reduced when ketamine is supplemented with a benzodiazepine.[947,948] One clinical report described 2 children, each 3 years of age, who had recurrent nightmares and abnormal behavior persisting for 10 months after a single ketamine administration.[949] A soporific environment may reduce the incidence of emergence phenomena.[950]

Ketamine is useful for children who are developmentally delayed or those who become combative because they are too frightened to come to the OR. IV ketamine can be used in very low doses (0.25–0.5 mg/kg) for short-term procedures, such as diagnostic spinal punctures and bone marrow aspiration, and in larger doses for angiography and cardiac catheterization. Ketamine may be particularly valuable for changes of burn dressings, suture removal, induction of anesthesia in hypovolemic children, children for whom application of a face mask may prove hazardous (such as

those with epidermolysis bullosa), and children who require invasive monitoring before induction of general anesthesia.[845,847,951–953] Ketamine has been successfully used even in neonates with less apparent cardiovascular depression than occurs with halothane or isoflurane.[954] Oral ketamine given to children suffering burns is slowly absorbed owing to delayed gastic emptying. However, formation of the active metabolite (norketamine) contributes to analgesia and facilitates IV cannulation for subsequent IV administration in the OR.[128]

The role of ketamine for postoperative pain has been reviewed in a meta-analysis. Administration of ketamine in the OR was associated with decreased postoperative pain intensity and nonopioid analgesic requirement in the postoperative care unit, but it failed to exhibit a postoperative opioid-sparing effect in the subsequent 6 to 24 hours.[955,956] While postoperative low-dose infusion (0.02–0.25 mg/hour per kilogram) is ineffective in reducing opioid consumption after pediatric spinal surgery, it has been shown effective after adult abdominal surgery.[957]

Ketamine may produce increases in intracranial pressure (ICP) as a result of cerebral vasodilation; it also increases $CMRO_2$. Ketamine may be contraindicated in children with intracranial hypertension.[958,959] This concern regarding ICP has been challenged[960,961]; adult patients whose lungs were mechanically ventilated and who were sedated with a ketamine infusion demonstrated a decrease in ICP after bolus doses of 1.5, 3.0, and 5.0 mg/kg.[962] The caveat is that the tracheas were already intubated, ventilation was controlled, and they were sedated. There may be a use for ketamine sedation in the ICU, where there is meticulous attention to airway management and control of ventilation.[961]

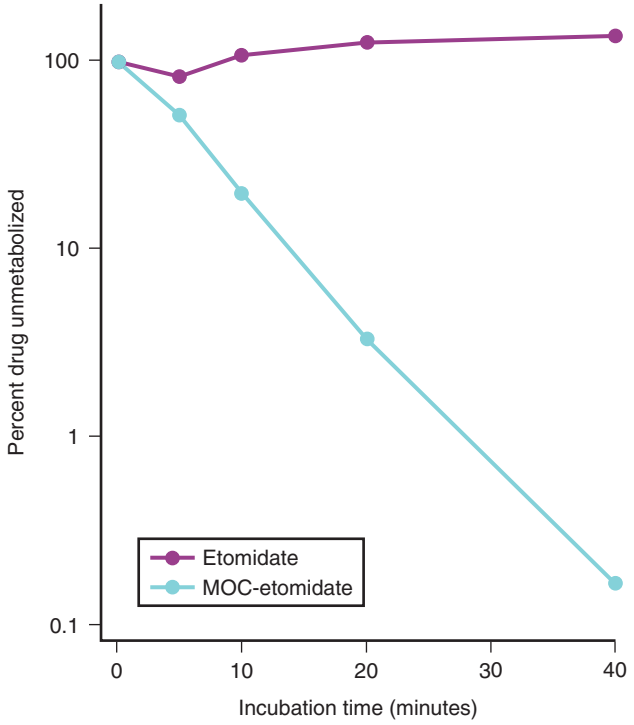
A 30% increase in intraocular pressure (IOP) has also been noted; thus ketamine may be potentially dangerous in the presence of a corneal laceration.[963] In children with active upper respiratory tract infections, copious secretions caused by ketamine may well exacerbate an already irritable airway and result in laryngospasm.[864,873] Ketamine may cause an incompetent gag reflex and thus should not be administered in anesthetic induction doses to children with a full stomach without appropriate airway management. Ketamine may not be useful as the sole anesthetic agent in any surgical procedure in which total control of the child's position is necessary, because purposeless movements frequently occur. Ketamine may be inappropriate in any child with a history of psychiatric or seizure disorder because of its psychotropic and epileptogenic effects.[840,845]

In addition, studies in newborn rodents and nonhuman primates correlated ketamine treatment with increased neuronal apoptosis during rapid synaptogenesis.[839,964,965] Infusions of ketamine (20–50 μg/kg per hour) to neonatal rhesus monkeys yielded apoptosis after 24 hour but not after 3-hour infusions.[966] The clinical importance of these findings is unclear since it is unknown if these data can be extrapolated from animals to developing humans (see Chapter 25).

Although the administration of ketamine appears simple, its adverse side effects are potentially dangerous. *Ketamine must be administered only by physicians experienced with managing a compromised airway.* We urge that it not be used as a premedication unless given in the presence of continuous supervision by properly trained personnel.

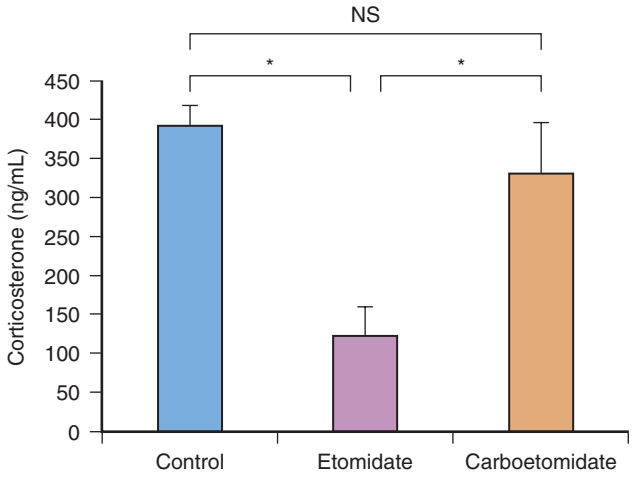
ETOMIDATE

Etomidate (Amidate) is a steroid-based hypnotic induction agent metabolized principally by hepatic esterases. Concentrations associated with anesthesia are 300 to 500 μg/L. As with most induction agents, offset of effect is by redistribution. Etomidate PK have been studied in children with a median age of 4 years (range 0.53–13.21 years) and weight 15.7 kg (7.5–52 kg). The estimates of PK parameter (standardized to a 70-kg adult) for typical 4-year-old children were CL 1.50 L/minute per 70 kg; Q2 1.95 L/minute per 70 kg; Q3 1.23 L/minute per 70 kg; V1 9.51 L/70 kg; V2 11.0 L/70 kg; and V3 79.2 L/70 kg.[967] Similar to propofol, younger children require a larger bolus dose of etomidate than older children to achieve equivalent plasma concentrations.[968] Etomidate clearance is reduced in neonates and infants (postnatal age 0.3–11.7 months) with congenital heart disease. A two-compartment model with allometric scaling to a 70-kg adult revealel a CL 0.624 L/minute per 70 kg and Q2 0.44 L/minute per 70 kg; central (V1) and peripheral distribution volume (V2) were 9.47 L/70 kg and 22.8 L/70 kg, respectively. Children also require a 30% increased bolus dose because of an increased V1.[969]



Etomidate is painful when administered intravenously. However, concerns regarding the risks of anaphylactoid reactions and suppression of adrenal function (which lasts for ~24 hours)[970,971] have resulted in most anesthesiologists avoiding this agent in routine cases.[972] Etomidate is useful in children with head injury and those with an unstable cardiovascular status, (e.g., cardiomyopathy) because of its lack of effect on cardiac function.[973,974] It is often used by emergency physicians for management of the airway.[975–978] Usual doses include 0.2 to 0.3 mg/kg before administration of a low-dose opioid and a muscle relaxant. Etomidate is often used to facilitate tracheal intubation in critically ill children—that is, those in whom it would seem to offer the most advantage. Because a very large proportion of critically ill children, particularly those resistant to vasopressors, suffer from relative adrenal insufficiency, corticosteroid supplementation may be indicated in such patients in whom etomidate is deemed necessary for their airway management.[979,980]

New etomidate formulations that are very short-acting and not associated with adrenal suppression are in development (Fig. 7.20).[981–985] An additional ester group on methoxycarbonyl-etomidate (MOC-etomidate) rendered this compound vulnerable to nonspecific esterases. MOC-etomidate showed very rapid degradation in vitro as well as in animals (E-Fig. 7.12). In animals, the righting reflex recovers more rapidly after MOC-etomidate treatment than after treatment with the parent compound. Adrenal suppression was addressed by substituting a pyrrole group in place of the imidazole group to preclude the binding of etomidate to 11-β-hydroxylase in the synthesis of adrenal hormones. As a consequence, carboetomidate did not bind well to 11-β-hydroxylase and therefore did not suppress adrenal hormone synthesis (E-Fig. 7.13). However, the slow onset of action of MOC-carboetomidate has not led to clinical trials.



Neuromuscular Blocking Drugs

NEUROMUSCULAR MONITORING

The measurement of evoked responses after an electrical stimulus is the standard method for evaluating neuromuscular function. This method allows nearly instantaneous evaluation of the degree of neuromuscular blockade in the unconscious individual. The force of contraction of the thumb, the accelerometer, or the electromyogram may be used to make this assessment.[986] Twitch tension measurements use the force of contraction of the adductor pollicis. This muscle is the only thumb muscle supplied by the ulnar nerve; measurements therefore approach the single-muscle precision of the experimental nerve muscle preparation.[547] The

(With permission from Cotten JF, Forman SA, Laha JK, et al. Carboetomidate: a pyrrole analog of etomidate designed not to suppress adrenocortical function. *Anesthesiology* 2010;112(3):637–644.)

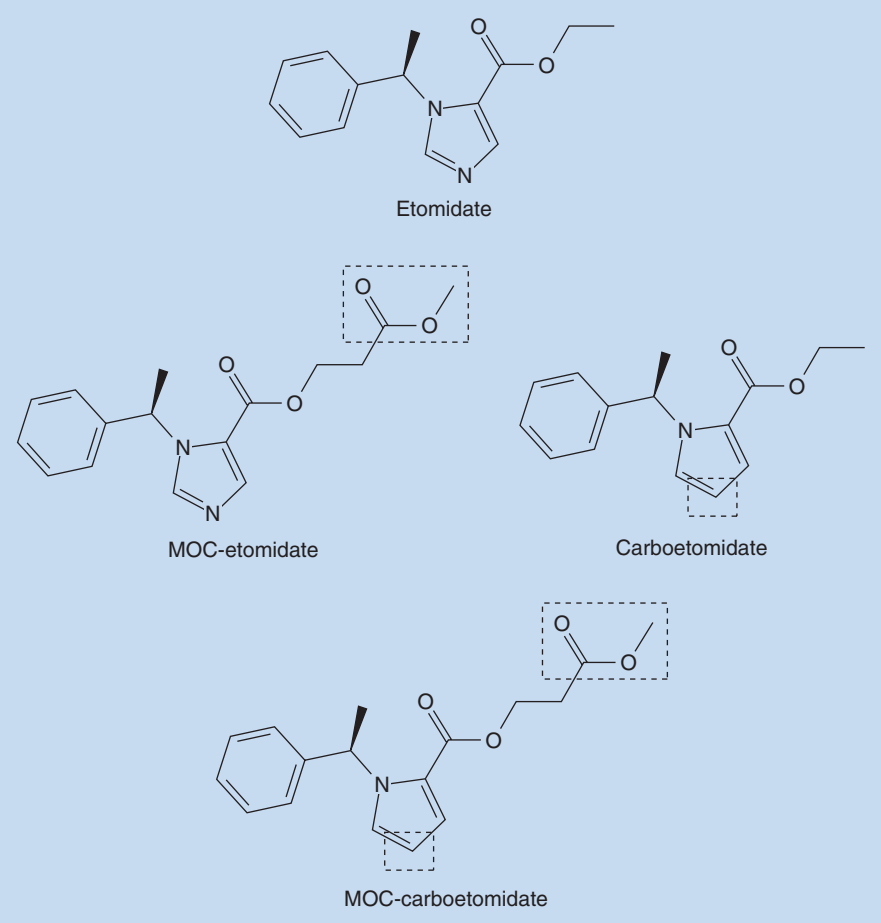

FIGURE 7.20 Molecular structures of etomidate (parent compound), methoxycarbonyl-etomidate *(MOC-etomidate)* (the doubly substituted ester side chain), carboetomidate (the imidazole ring has been replaced by a pyrrole ring), and MOC-carboetomidate (in which both the double ester and the pyrrole-for-imidazole ring substitutions are present). MOC-carboetomidate has a brief duration of action, does not suppress adrenal hormone synthesis, and appears to share similar potency with etomidate. (Reproduced with permission from Pejo E, Cotton JF, Kelly EW, et al. In vivo and in vitro pharmacological studies of methoxycarbonyl-carboetomidate. *Anesth Analg*. 2012;115(2):297–304.)

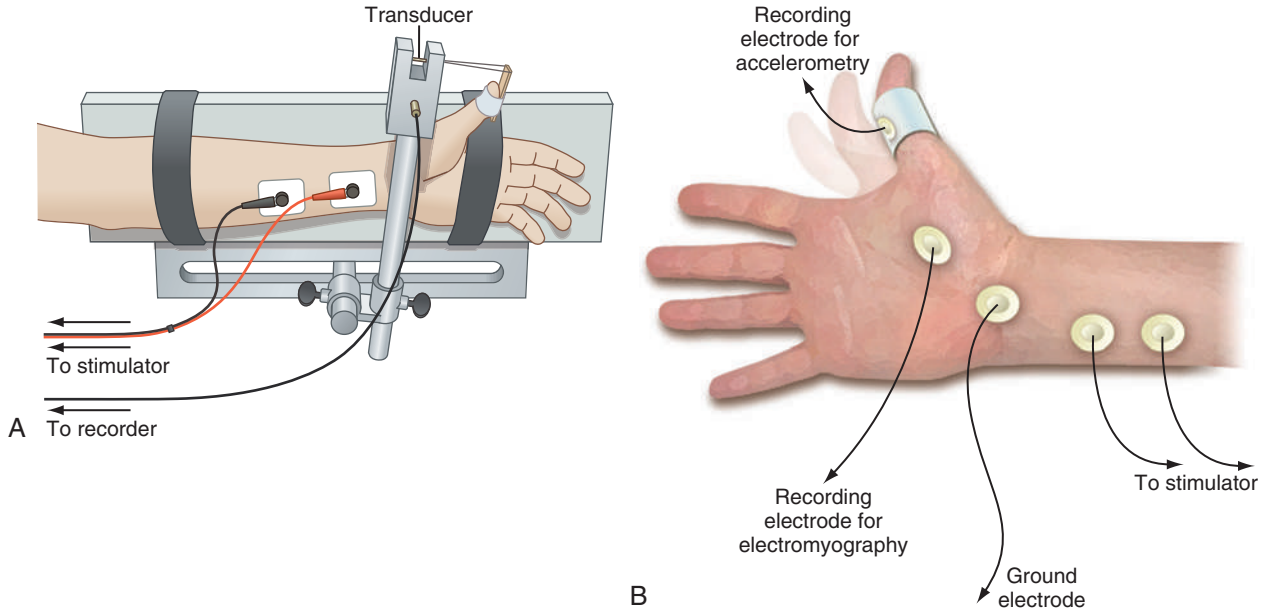
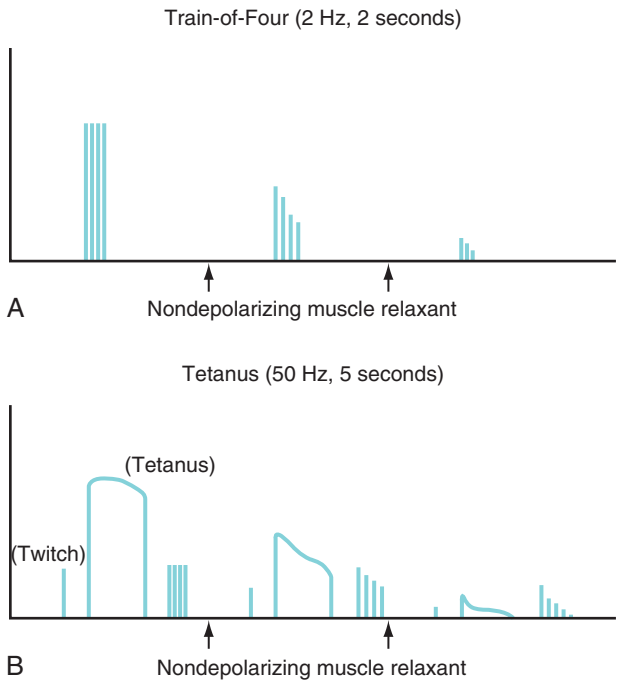
evoked tension of the adductor pollicis in response to stimulation of the ulnar nerve can be recorded by a force displacement transducer (E-Fig. 7.14A). With the electromyogram, the compound muscle action potential is recorded by surface or needle electrodes applied to any muscle, usually the adductor pollicis brevis, the abductor digiti minimi, or the first dorsal interosseous muscle of the hand (see E-Fig. 7.14B). To achieve reproducibility and to ensure full activation of all stimulated nerve and muscle fibers, the stimuli should be supramaximal in intensity, square wave in nature, and no longer than 0.2 milliseconds in duration.



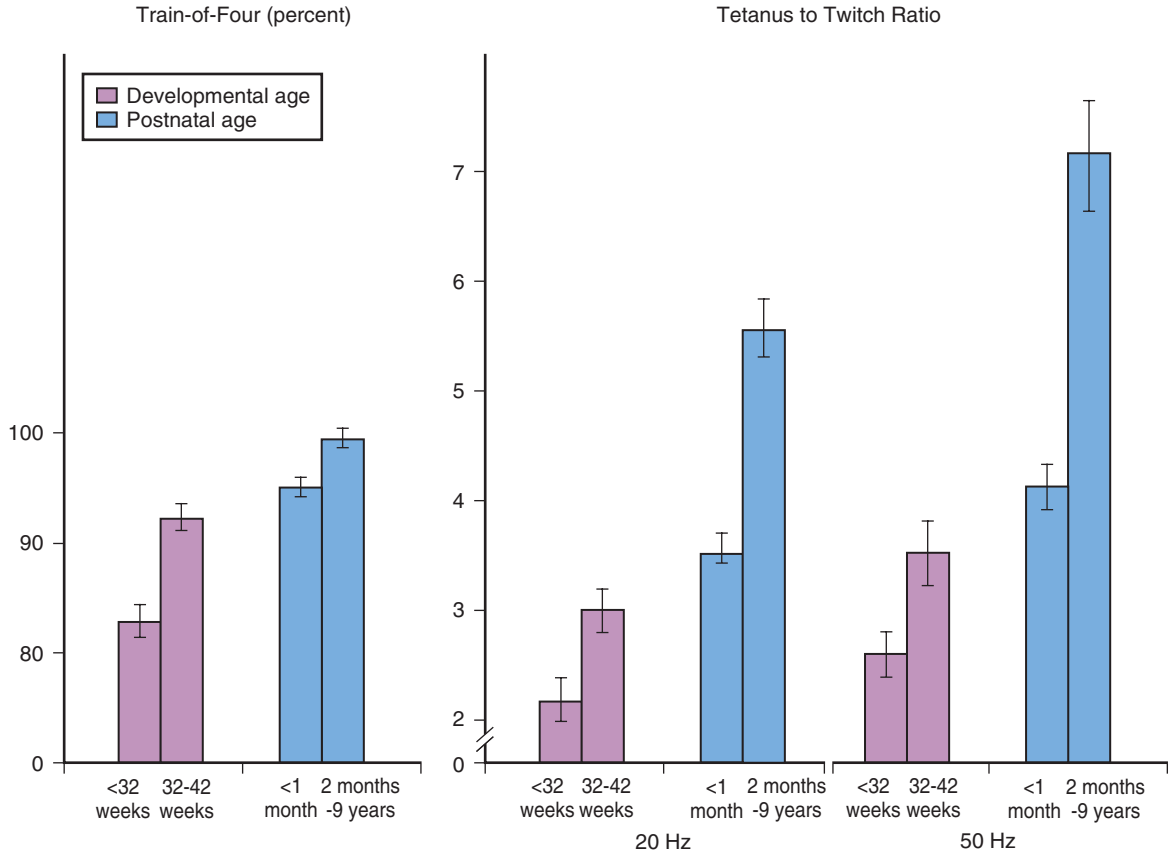
Clinically, three types of stimulation are used (E-Fig. 7.15):

1. Single twitch (0.1 to 0.25 Hz [cycles/second])
2. Train-of-four (2 Hz for 2 seconds)
3. Tetanus (50 Hz, usually for 5 seconds)



Single-twitch rates are useful whenever there is an observable control response. By comparing the percentage change of twitch tension before and after administration of the neuromuscular blocking agent, one can assess the degree of paralysis. Single stimuli detect relatively profound degrees of neuromuscular blockade. In fact, depression of the twitch response can be observed only if more than three-fourths of the postsynaptic receptors are blocked.[987]

The *train-of-four* is the most commonly used method for assessing nondepolarizing neuromuscular blockade. It consists of four supramaximal stimuli applied to the ulnar nerve at a frequency of 2 cycles/second. The ratio of the amplitude of the fourth twitch to the first is an indicator of the degree of neuromuscular blockade. The main advantage of the train-of-four is that it does not require a control measurement. Furthermore, the train-of-four technique can be repeated every 10 seconds, thus allowing rapid changes in neuromuscular blockade to be closely monitored.[547] In general, when the train-of-four is zero, the conditions for tracheal intubation are satisfactory (excellent or good).[988] Preterm infants younger than 32 weeks PCA have reduced train-of-four fourth-response values (83% ± 2%) compared with more mature neonates (E-Fig. 7.16).[989] In full-term infants younger than 1 month of age, the height of the fourth evoked response of the train is about 95%.[990] The change to the greater value during the first month of life probably indicates maturation of the myoneural junction. In children 2 months of age and older, all components of the train-of-four are nearly equal (100%).[989]



Tetanic stimulation is usually obtained by supramaximally stimulating the nerve for 5 seconds or more. During tetanic

E-FIGURE 7.14 **A,** Arrangement used for studying evoked tensions in infants and children. **B,** Position of electrodes for recording an evoked electromyogram. In a clinical setting and in the absence of recording apparatus, feeling the twitch response is adequate.

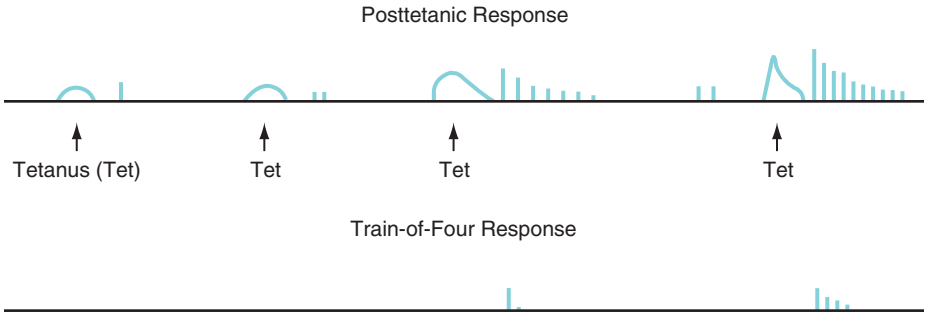
E-FIGURE 7.15 Idealized recording of the effect of nondepolarizing muscle relaxants on the train-of-four and tetanic stimulation. Note in **A** the four equal twitches before the administration of a nondepolarizing muscle relaxant (*arrows*). After curare, the fourth twitch is less in amplitude than the first (train-of-four). The last sequence indicates greater neuromuscular blockade because only three of the four twitches are observed. **B,** Corresponding single twitch, train-of-four, and tetanus observations at a lower amplification. Note the marked fade and posttetanic facilitation after the second dose of nondepolarizing muscle relaxant (*arrows*).

E-FIGURE 7.16 The train-of-four values and tetanus to twitch ratios of critically ill infants younger than 42 weeks developmental age in the neonatal intensive care unit and term infants anesthetized with halothane. Note the evidence of maturation of the myoneural junction in the older children. (Redrawn from Goudsouzian NG, Crone RK, Todres ID. Recovery from pancuronium blockade in the neonatal intensive care unit. *Br J Anaesth*. 1981;53(12):1303–1309.)

stimulation, synthesis of acetylcholine increases; however, this increase is limited. If the duration of stimulation is too prolonged or the frequency of stimulation is too great, fade occurs—that is, a decrement in the height of tetanus is noted. The usual explanation for the occurrence of fade is that during repetitive stimulation, the acetylcholine output-per-impulse wanes. Under normal circumstances, the diminution of acetylcholine output does not affect transmission because of the continuing excess of both acetylcholine and receptors at the myoneural junction (safety factor). During partial receptor blockade with a nondepolarizing relaxant, the progressive diminution of acetylcholine output eventually results in a decreased number of stimulated receptors and a consequent decrease in the amplitude of contraction. Alternatively, fade may not be simply the consequence of a spontaneously occurring decrease in the transmitter action but, in fact, a different and separate action of the drug. This suggests that the relaxant has a prejunctional effect.[991] In infants and children anesthetized with halothane, the percent of fade during tetanic stimulation for 5 seconds at 20 cycles/second is 5% and at 50 cycles/second it is 9%.[990] These values are comparable to those for adults.[992] If the duration of stimulation is prolonged, an even greater degree of fade may be noted. In small infants, a more than 50% decrement in the height of tetanus has been observed during 15 seconds of tetanic stimulation; this decrement is even more marked in preterm infants.[993,994] These findings suggest that small infants can indeed sustain short periods of tetanic stimulation, but their musculature becomes fatigued more quickly than that of older children.

The integrity of the myoneural junction can also be analyzed by evaluation of posttetanic facilitation. The increased synthesis and release of acetylcholine that occur during tetanic stimulation continue for a short interval after the stimulation has stopped. This increased production normally does not result in facilitation because all the muscle fibers are excited by the stimulus. In the presence of nondepolarizing (competitive) neuromuscular blockade, however, the increased posttetanic acetylcholine release stimulates a greater number of muscle fibers, producing the characteristic posttetanic facilitation.[992]

The posttetanic count has been used to evaluate intense neuromuscular blockade in children.[995,996] This is a measure obtained by applying a 50-cycle/second tetanic stimulus to the ulnar nerve for 5 seconds, followed by single-twitch stimulation at 1 cycle/second; the number of twitches observed in the posttetanic period is known as the posttetanic count (E-Fig. 7.17). Because tetanus and posttetanic responses are indicators of deep neuromuscular blockade, they can usually be elicited during recovery before the reappearance of the train-of-four. At very deep levels of blockade, no tetanus or posttetanic effect can be seen; as the patient recovers, a single posttetanic response eventually manifests itself. The number of posttetanic counts increases as recovery proceeds until, at posttetanic counts of six to seven, the first twitch of the train-of-four reappears. It has been shown that during recovery, the first posttetanic response precedes the first response of the train-of-four by 5 to 10 minutes with intermediate relaxants and by 20 to 30 minutes with long-acting relaxants.[995,996] In a clinical situation in which neuromuscular recording instruments are not available, the number of contractions during train-of-four are counted. This technique depends on the fact that the number of twitches in the train-of-four usually correlates well with the degree of blockade. When the height of the first twitch is about 21% of control, three contractions are usually detected during train-of-four stimulation; at a single-twitch height of 14% of control, two contractions are in evidence; when the single-twitch height is about 7%, only one contraction is detected.[997] During procedures in which a child's hand is covered by surgical drapes, palpating the number of contractions provides a satisfactory alternative. The number of contractions during train-of-four stimulation thus yields a practical assessment of neuromuscular blockade. For more profound blockade, the posttetanic counts can be used intermittently. However, repeated tetanic stimulation is not ideal because it is painful and can lead to posttetanic exhaustion.



Although twitch monitoring is the standard method of evaluating neuromuscular blockade, the neuromuscular blockade in one group of muscles can differ substantively from that in another. For example, 1.7 times more relaxant is required to block the diaphragm and the vocal cords than the adductor pollicis.[998,999] Nonetheless, recovery of the twitch response is also approximately 50% more rapid in these central muscles. Accordingly, it is conceivable that children could cough or react during intubation in the absence of the twitch response when it is measured peripherally. Perhaps more importantly, when the peripheral twitch response has recovered at the end of the procedure, it is a clear indication that the diaphragm and the vocal cords are in a more advanced stage of recovery. Monitoring the orbicularis oculi contraction (as an estimate of the relaxation of central muscles) to predict whether the conditions for tracheal intubation are suitable is preferred because it occurs before the twitch response of the adductor muscle of the thumb.[1000]

Another method for monitoring neuromuscular blockade is acceleromyography, which uses a piezoelectric sensor to quantitate the movement of the thumb, converting this to an electrical signal. There is considerable disagreement in the published literature as to which of these techniques is most accurate.[1001–1003] Monitors based on acceleromyography are becoming more commonly available; however, these are not "user friendly" and are difficult to use in infants because of the small arc of the displaced thumb. Some consider this monitor to be more accurate than standard mechanomyography-based train-of-four monitors.[1004,1005] Others think that mechanomyography is more accurate because it is "less influenced by external disturbances"—that is, it does not go out of calibration.[1006] Therefore at present, for clinical purposes in infants and children, mechanomyography still seems to be the simplest and most helpful clinical monitor during the use of nondepolarizing competitive blockers.

NEUROMUSCULAR JUNCTION

Adult postjunctional acetylcholine receptors possess five subunits—two α and one β, δ, and ε subunits. Preterm neonates (<31 weeks PMA) have a γ subunit instead of an ε subunit in their neuromuscular receptor.[1007] Fetal receptors have a greater opening time than adult receptors, allowing more sodium to enter the cell, with a consequent larger depolarizing potential. The resulting increased sensitivity to acetylcholine is at odds with the observed increased sensitivity to NMBDs, but may compensate for reduced acetylcholine stores in the terminal nerve endings.[1008]

Neuromuscular transmission is immature in neonates and infants until the age of 2 months.[990,1009] Neonates deplete acetylcholine vesicle reserves more quickly than do infants older than 2 months, in response to tetanic nerve stimulation.[990] Data from phrenic nerve–hemidiaphragm preparations from rats aged 11 to 28 days suggest this is the result of a low quantal content of acetylcholine in neonatal endplate potentials.[223] Neonates display an increased sensitivity to NMBDs. An alternative proposal to explain this increased sensitivity is based on NMBD synergism

E-FIGURE 7.17 The recovery pattern of train-of-four and posttetanic response after treatment with a nondepolarizing muscle relaxant. Note that despite deep neuromuscular blockade (absent train-of-four) the posttetanic response is evident. The less intense the neuromuscular blockade, the greater the number of posttetanic counts (see text).

observations.[1010,1011] Neonates display poor synergism and this has been explained on the basis that NMBDs occupy only one of the two α-subunit receptor sites in neonates as opposed to two in children and adults.[1011] If this is true, then neonates may use NMBDs more efficiently than children.

Preterm infants tolerate respiratory loads poorly. The diaphragm in the preterm neonate contains only ~10% of the slowly contracting type I fibers (see Fig. 14.11). This proportion increases to ~25% at term and to ~55% by 2 years of age.[225] A similar maturation pattern has been observed for the intercostal muscles.[225] Type I fibers tend to be more sensitive to NMBDs than type II fibers, and consequently the diaphragmatic function in neonates may be better preserved and recover earlier than peripheral muscles.[999,1012–1014]

Total body water and extracellular fluid (ECF)[1015] are greatest in preterm neonates and decrease throughout gestation and postnatal life, whereas fat as a percentage of body weight increases with postnatal age. Muscle contributes only ~10% of body weight in neonates and ~33% by the end of childhood. Polar drugs, such as depolarizing and nondepolarizing NMBDs, distribute rapidly into the ECF, but enter cells more slowly. Consequently, a larger initial dose of such drugs is required in infants compared with children or adults. Increasing the muscle bulk contributes new acetylcholine receptors. This greater number of receptors requires a greater amount of drug to block activation of receptor ion channels.

PHARMACODYNAMICS

There is age-related variability in the dose required to achieve a predetermined level of neuromuscular blockade during balanced thiopental–N_2O–fentanyl anesthesia. The ED_{95} of vecuronium was 47 ± 11 μg/kg in neonates and infants, 81 ± 12 μg/kg in children between 3 and 10 years of age, and 55 ± 12 μg/kg in children aged 13 years or older (Fig. 7.21).[1016]

Similar profiles have been reported for other NMBDs.[335,999,1017–1019] In addition, duration of neuromuscular blockade is greater in neonates than in children.[1020] The reduced dose requirement in neonates is attributable to immaturity of the neuromuscular junction. The increased Vd from an expanded ECF in neonates means a similar initial dose (per kilogram) is given to neonates and teenagers. Children tend to require larger doses than adults; the reason for the larger dose requirement in children is unclear but it may be the result of increased muscle bulk.

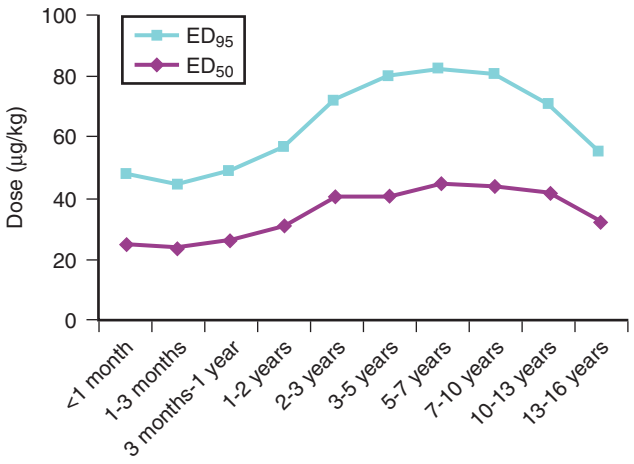


FIGURE 7.21 Dose changes with age for vecuronium during balanced anesthesia. *ED_{50}* is the dose that achieves 50% of the maximum response; *ED_{95}* is the dose that achieves 95% of the maximum response. (Data extracted from Meretoja OA, Wirtavuori K, Neuvonen PJ. Age-dependence of the dose-response curve of vecuronium in pediatric patients during balanced anesthesia. *Anesth Analg*. 1988;67(1):21–26.)

Investigation of concentration–response relationships is more revealing. The plasma concentration required in neonates to achieve the same level of neuromuscular block as in children or adults is 20% to 50% less, consistent with immaturity of the neuromuscular junction.[86,1021–1024] Plasma concentration requirements are reduced by inhaled anesthetic agents.[552,1025,1026]

The onset time for NMBDs in neonates is faster than it is in older children and adults. Onset time (time to maximal effect) after vecuronium 70 μg/kg was most rapid for infants (1.5 ± 0.6 minutes) compared with that for children (2.4 ± 1.4 minutes) and adults (2.9 ± 0.6 minutes).[1020] These observations are similar to those reported for other intermediate- and long-acting NMBDs.[1014] The more rapid onset of these drugs in neonates has been attributed to a greater cardiac output seen with the per-kilogram model.[1014]

Cardiac output is used as a surrogate measure for muscle perfusion. Onset time is a function of size. An onset time standardized to a 70-kg person using an allometric ¼-power model is around 3 minutes for most long-acting NMBDs. In children with low cardiac output or decreased muscle perfusion, onset times are prolonged. The onset time of neuromuscular paralysis is proportional to $T_{1/2}$keo. An old study demonstrated an increase in the $T_{1/2}$keo of *d*-tubocurare with increasing inspired halothane concentrations[257]; a possible explanation for the delayed action of tubocurarine may be that halothane is a negative inotrope[258] and decreases muscle blood flow.[259]

PHARMACOKINETICS

The dose of NMBDs at different ages depends on the complex interweaving of PD and PK factors. The Vd mirrors ECF changes and can be predicted using either an allometric ¾-power model or the surface area model (⅔-power model), both of which approximate ECF changes with weight.[68]

The clearance of *d*-tubocurarine, standardized to an allometric or surface area model, is reduced in neonates and infants compared with older children and adults.[86] These age-related clearance changes follow age-related maturation of glomerular filtration in the kidney,[171] which is the elimination route of *d*-tubocurarine. Total plasma clearance of other nondepolarizing muscle relaxants cleared by renal (alcuronium) and/or hepatic pathways (pancuronium, pipecuronium, rocuronium, and vecuronium) are all reduced in neonates.[1021,1023,1027–1029] In contrast, the clearances of atracurium and cisatracurium are neither renal- nor hepatic-dependent but rather depend on Hofmann elimination, ester hydrolysis, and other unspecified pathways.[1030] Clearance of these drugs is increased in neonates when expressed as per kilogram.[1031–1033] When clearance is standardized using allometric ¾-power scaling, the clearances for atracurium and cisatracurium are similar throughout all age groups. The clearance of succinylcholine, expressed as per kilogram, also decreases as age increases.[189,190] Succinylcholine is hydrolyzed by butyrylcholinesterase. These observations are consistent with that observed for the clearance of remifentanil,[39] which is also cleared by plasma esterases. These clearance pathways are mature at birth.[40]

Conversion of *d*-tubocurarine half-times from chronologic time to physiologic time is revealing. $T_{1/2}\alpha$ increases with age in chronologic time, but in physiologic time it is the same at all ages, as we would expect from a distribution phase standardized by allometry. $T_{1/2}\beta$ decreases with age in physiologic time, consistent

with reduced clearance related to the greater Vd in the very young. The $T_{1/2}$keo is large in neonates and infants, reduced in children, and further reduced in adults, possibly because of increased muscle bulk and concomitant increased muscle perfusion in children and young adults.

Depolarizing Neuromuscular Blocking Drugs

SUCCINYLCHOLINE

Succinylcholine is the only depolarizing relaxant used in children. Infants are more resistant to its neuromuscular effects than adults.[1034] Early studies demonstrated that the degree of neuromuscular blockade achieved by 1 mg/kg IV in infants is about equal to that produced by 0.5 mg/kg in older children.[1035] The increase in dose requirement in younger children is thought to result, in part, from the drug's rapid distribution into the infant's large ECF volume (E-Table 7.7 and Table 7.10).

Succinylcholine remains the NMBD with the most rapid onset. The onset time of a paralyzing dose (1.0 mg/kg) of succinylcholine is 35 to 55 seconds in children and adolescents; the onset time after 3 mg/kg in neonates is faster (30–40 seconds).[1036] Onset time is dependent on both age and dose; the younger the child and the greater the dose, the shorter the onset time.

As in adults, administration of a continuous infusion of succinylcholine in infants and children can result in tachyphylaxis (increased requirement). In addition, Phase II block may be produced, as evidenced by a train-of-four less than 50% (blockade similar to that produced by nondepolarizing muscle relaxants). In children, tachyphylaxis generally develops after administration of about 3 mg/kg of succinylcholine, and Phase II block develops during tachyphylaxis after 4 mg/kg.[190,1037]

Succinylcholine is effective when administered by the IM route; in this instance, complete paralysis is achieved in 3 to 4 minutes. Evidence of relaxation of the respiratory muscles, as manifest by decreased positive pressure required to ventilate by face mask, can be detected before the abolishment of the twitch response. A dose of 2 mg/kg IM does not achieve satisfactory relaxation in all children, whereas the larger dose of 3 mg/kg IM produces a mean twitch depression of 85%; 4 mg/kg produces profound relaxation in all children, but its effects may last up to 20 minutes.[1038] In infants younger than 6 months of age, a dose of 5 mg/kg IM is required to achieve profound relaxation; maximal twitch depression occurred a mean of 3.3 ± 0.4 minutes.[1039] Recovery from the neuromuscular effect of IM succinylcholine is faster in infants than in children. Changes in the heart rate after IM succinylcholine are not pronounced. Consequently, routine IM administration of atropine with IM succinylcholine is not generally indicated.[1040] Succinylcholine has also been administered intralingually.[1041,1042] One study examined the time to clinical apnea in 60 children younger than 10 years of age. Succinylcholine (1.1 mg/kg) resulted in apnea in 75 ± 4 seconds when administered intralingually, in 35 ± 1 seconds when administered intravenously, and in 210 ± 17 seconds when administered intramuscularly.[1042] In that study, 8 of 10 children given intralingual succinylcholine who did not receive concomitant atropine developed an arrhythmia (primarily bradycardia).

In an emergency, an alternate route for administration of succinylcholine (3 mg/kg) when an IV line is not in place should offer a fairly rapid onset of relaxation. Intralingual administration with an onset of 133 seconds, is significantly more rapid than after IM injection, 295 seconds.[1041] Caution should be exercised, however, when administering sublingual or intralingual medications. To preclude an intralingual hematoma, it is advised that a 25-gauge needle be used and the blood vessels on the undersurface of the tongue identified to minimize the risk of puncture. Sublingual succinylcholine is an alternative to the IV route, but it should be preceded by a vagolytic agent to avoid arrhythmias. The submental approach would seem to avoid the potential for causing bleeding from the tongue.

TABLE 7.10 Suggested Standard Intubating IV Doses of Commonly Used Relaxants in Infants and Children

	Infants (mg/kg)	Children (mg/kg)
Succinylcholine	3	1.5–2
Cisatracurium	0.1	0.1–0.2
Atracurium	0.5	0.5
Rocuronium[a]	0.25–0.5	0.6–1.2
Pancuronium	0.1	0.1
Vecuronium	0.07–0.1	0.1

See text for source data.
[a]Low-dose rocuronium (0.3 mg/kg) allows tracheal intubation after 3 minutes during inhalational anesthesia in children, but then is easily antagonized in about 20 minutes. Large-dose rocuronium (1.2 mg/kg) may be used as a substitute for succinylcholine for rapid intubation in children in less than one minute.

Cholinesterase Deficiency

Plasma cholinesterase (pseudocholinesterase) is a circulating glycoprotein that metabolizes succinylcholine into succinylmonocholine. The activity of plasma cholinesterase may be increased or decreased as a result of genetic inheritance (see Chapter 6).

Activity of plasma cholinesterase may decrease as a result of a congenital enzyme variant or an acquired cause. This enzyme codes at the E1 locus of the long arm of chromosome 3. Ninety-six percent of the population is homozygous for the "usual" cholinesterase enzyme and 4% are homozygous or heterozygous for the variant alleles.[1043] Five alleles code for the majority of cholinesterase enzyme: (1) normal cholinesterase enzyme, which is designated by "usual" (E^u); (2) decreased cholinesterase activity or quantity, which is designated as atypical (E^a) (homozygote in 1:3000–1:10,000); (3) fluoride-resistant allele (E^f) (homozygote in 1:150,000); (4) silent allele (E^s) (homozygote 1:10,000); and (5) the Cynthiana (C_5) or Neitlich variant, which is associated with an increase in (or rapid) cholinesterase activity.[1044] Variations on the silent gene have been detected in Eskimo populations with three variants labeled: S for silent, T for trace, and R for residual. The duration of succinylcholine in children who are homozygous for the silent gene may be up to 6 to 8 hours. Additional genetic variants of pseudocholinesterase have been identified, including types H, J, and K, which represent a 60%, 66%, and 30% reduction in enzyme activity, respectively.[1043] Evidence suggests that the K variant occurs in 13% of the population and that the K/K homozygous variant may be present in 1:63, one of the most common variants with a duration of prolonged blockade of less than 1 hour. Moreover, the K variants have occurred in the presence of other mutations suggesting that multiple mutations may be present in the same patient.

Heterozygote atypical (E^uE^a), which occurs in 1:30 of the population, may prolong neuromuscular blockade by only a few minutes and may go undetected. In contrast, homozygote atypical (E^aE^a), which occurs in approximately 1:3000 population, may

E-TABLE 7.7 Effective Doses[a] of Commonly Used Relaxants in Neonates, Infants, Children, and Adults

	Neonates	Infants	Children	Adults
Succinylcholine	620	729	423	290
Atracurium	120	156–175	170–350	110–280
Vecuronium	47	42–47	56–80	27.56
Rocuronium	ND	251	409	350
Cisatracurium	ND	150	41	32–50
Pancuronium	ND	55–92	55–81	50–70

See text for details.
ED_{95}, dose that achieves 95% of the maximum response; *ND*, no published data at the time of writing this chapter.
[a]The ED_{95} is measured in micrograms per kilograms (μg/kg).

cause paralysis for up to 1 hour after a single dose of succinylcholine. Of the genetic variants of cholinesterase, the silent gene (E^s) confers the least plasma cholinesterase activity and therefore the most prolonged duration of paralysis. Homozygote (E^sE^s) occurs in 1 : 10,000 population and may result in 8 hours of paralysis.

Plasma cholinesterase activity is more often diminished when a genetic variant is present, but a number of clinical conditions may also reduce its activity. These include severe liver disease, malnutrition, organophosphate poisoning, severe burns, renal failure, plasmapheresis, and medications (cyclophosphamide, echothiophate iodide, oral contraceptives).[1043,1045,1046] Several conditions are associated with increases in plasma cholinesterase activity, including thyroid disease, obesity, nephrotic syndrome, and cognitively challenged children.[1043,1047–1049]

Plasma cholinesterase activity is determined by the percent inhibition of benzyl choline degradation by the amide local anesthetic dibucaine when it is incubated with a sample of plasma. With the homozygous normal allele (E^uE^u), dibucaine profoundly inhibits plasma cholinesterase activity (approximately 80%), whereas with the homozygous atypical allele (E^aE^a), it inhibits the activity by only 20%. When fluoride is added to the plasma, fluoride inhibits E^uE^u by 60% but inhibits E^fE^f by only 36%. Thus a low dibucaine number indicates a deficiency of plasma cholinesterase.

Adverse Effects of Succinylcholine

Temporomandibular Joint Stiffness

IV succinylcholine is infrequently associated with an increase in masseter muscle tone that limits mouth opening (trismus), particularly when given during halothane anesthesia. The incidence of isolated trismus when IV succinylcholine is administered during halothane anesthesia is 0.3% to 1%; it is severalfold greater than that after IV thiopental and succinylcholine, 0/4457 (upper 95% confidence interval of 7/10,000).[1050,1051] The increase in masseter muscle tone after succinylcholine is transient, lasting for only a few minutes and occurring despite abolition of the evoked twitch response in the masseter and peripheral muscles. The increase in masseter muscle tone is usually mild and can be overcome by manually distracting the mandible.[1052] However, on rare occasions, the increase in muscle tone may be so severe that mouth opening is impossible, thus interfering or preventing tracheal intubation. Whether this marked increased tone is related to the so-called "jaws of steel" (see Fig. 41.2) encountered in children with MH remains a matter of debate.[1053] Prospective studies designed to evaluate masseter muscle tone have failed to demonstrate a child with a marked increase in masseter tone who later developed evidence of MH.[1054,1055] In several retrospective reports, however, a number of children experienced severe trismus and did develop or have a positive test response for MH.[1056–1058] These studies failed to clarify how best to proceed when severe trismus occurs. Some advocate canceling the surgical procedure, treating the child as susceptible to MH, and recommending a muscle biopsy.[1058,1059] This recommendation is based on a 50% incidence of positive muscle biopsies for MH in children who developed severe trismus after succinylcholine. Others advocate continuing the procedure, avoiding further exposure to triggering agents by changing the anesthetic technique to one that is free of triggers, observing for signs of MH (e.g., increased CO_2 production or tachycardia), and, if indicated, initiating arterial and central venous blood gas sampling, as well as early treatment.[1060,1061] Finally, others have advocated continuing with the original triggering anesthetic while monitoring for signs of MH.[1050] For the most part, this entire issue has become moot because sevoflurane has supplanted halothane as the primary inhaled anesthetic in children, and the FDA issued a black box warning regarding the routine use of succinylcholine for tracheal intubation in children. Curiously, the now widespread use of nondepolarizing relaxants has generated several purported reports of masseter muscle rigidity after use of these agents. Whether these cases actually represent nondepolarizing relaxant–induced masseter spasm or a combination of light anesthesia and incomplete muscle relaxation is unclear.[1062–1064]

Arrhythmias

The molecular structure of succinylcholine resembles that of two acetylcholine molecules joined by an ester linkage. The consequent stimulation of cholinergic autonomic receptors can be associated with cardiac arrhythmias, increased salivation, and bronchial secretions. Changes in heart rate are frequently observed after treatment with succinylcholine. Heart rate usually increases transiently, and this response appears to be more pronounced in the presence of sevoflurane than halothane.[1065] Succinylcholine-associated arrhythmias are rarely a result of ventricular irritability. Prior IV administration of a vagolytic agent (e.g., atropine) markedly decreases, but does not completely abolish, the incidence of these arrhythmias.[1066] As in adults, the incidence and severity of these irregularities in heart rate increase after a second dose.[1042,1067] Of greater concern is the occasional bradycardia and asystole after a single dose in children.[1066] Accordingly, it is recommended that a vagolytic agent precede the IV administration of succinylcholine unless there is a contraindication to such medications.

Hyperkalemia

Succinylcholine-induced muscle fasciculation is also associated with mild hyperkalemia, increased intragastric and intraocular pressures, and skeletal muscle pains; rhabdomyolysis and myoglobinemia may occur in patients with neuromuscular disorders. These disorders are not always diagnosable in neonates. Congenital myotonic dystrophy, for example, may present with mild respiratory dysfunction or feeding difficulty in the neonate. The response to succinylcholine in these neonates, however, remains dramatic, with sustained muscle contraction.[1068]

The serum potassium concentration increases 1 mEq/L or less after IV succinylcholine in normal children; this increase does not cause arrhythmias.[1069] However, life-threatening hyperkalemia can occur after a single IV dose of succinylcholine in children with burns (>8% body surface area), those who are immobile, or who have chronic infections (including intraabdominal sepsis and *Clostridium*), upper motor neuron lesions (e.g., paraplegia, encephalitis), lower motor neuron lesions (e.g., tetanus, neuropathy complicating nephropathy), crush injuries, and neuromuscular diseases (including Werdnig-Hoffmann disease).[1070–1077] In these situations, direct denervation injury or a pseudo-denervation state (immobilization) leads to a proliferation of extrajunctional normal acetylcholine receptors, as well as proliferation of immature (containing γ subunits) and nicotinic (neuronal) acetylcholine receptors, along the muscle membrane such that the entire muscle becomes capable of releasing potassium during depolarization.[1077] These immature and nicotinic acetylcholine receptors release more intracellular potassium, and for a longer period after the channels open, than do the usual acetylcholine receptors. The presence of extrajunctional receptors has been documented within several hours of injury, although clinically significant hyperkalemia does

not seem to occur until 1 to 3 days after injury. Thus administration of succinylcholine to children with these injuries may result in a massive efflux of intracellular potassium, leading to a cardiac arrest.[1078] In contrast to these acquired conditions, children who are born spastic quadriparetic from cerebral palsy or those with a myelomeningocele respond with a normal increase in serum potassium concentration (<1 mEq/L) after IV administration of succinylcholine.[1078–1080] Another recent concern is the possible fatal interaction of β-blockade–induced hyperkalemia and succinylcholine.[1081,1082]

The definitive treatment of succinylcholine-induced hyperkalemia is IV calcium (10 mg/kg calcium chloride or 30 mg/kg calcium gluconate or more). This restores the gap between the resting membrane potential of the cardiac cells and the threshold potential for depolarization. Repeated doses of calcium may be required, together with cardiopulmonary resuscitation, epinephrine, sodium bicarbonate, hyperventilation, inhaled albuterol (salbutamol) (or the IV formulation), or glucose and insulin, until the arrhythmias abate. Defibrillation of the heart has no role in this circumstance. Successful treatment of hyperkalemia might require a very prolonged resuscitation. Sodium polystyrene sulfonate by nasogastric or rectal administration may be required for leaching potassium after acute redistribution between extracellular and intracellular spaces by the above measures (see Chapters 9, 12, 28, and 40).

Biochemical Changes

Serum creatine kinase concentrations were reported to increase after administration of succinylcholine in the presence of inhalational agents, especially halothane,[1083] an effect that was more pronounced in children with neuromuscular diseases.[1084] After an MH reaction, creatine kinase reaches its peak 12 to 18 hours after the onset of the reaction. It may also be found in association with a jaws of steel response to succinylcholine.

Rhabdomyolysis

Rhabdomyolysis can occur after halothane or sevoflurane,[1085] even in the absence of succinylcholine as in the case of Duchenne and Becker muscular dystrophy.[1086,1087] Isolated rhabdomyolysis or rhabdomyolysis in combination with hyperkalemia, as in the case of Duchenne muscular dystrophy, requires hyperhydration and osmotic diuresis with alkalinization of the urine to prevent acute tubular necrosis from deposition of myoglobin.

Myoglobinemia

Myoglobinemia, another sensitive indicator of muscle injury, may occur after succinylcholine treatment but rarely leads to myoglobinurea (i.e., "cola"-colored urine).[1088] If it occurs, it should be aggressively treated as described previously for rhabdomyolysis.

Fasciculations

Fasciculations are usually observed in adolescents and children but rarely in infants; in children 1 to 3 years old they are described as gross muscle movements.[1083,1089] Pretreatment with small doses of succinylcholine (100 μg/kg), pancuronium (20 μg/kg), fentanyl (1–2 μg/kg), or alfentanil (50 μg/kg) may decrease the frequency and intensity of the fasciculations and the resulting increase in intragastric pressure.[1083,1089–1092] This increase in intragastric pressure, however, is more than offset by the increase in skeletal muscle tone of the crura of the diaphragm, with a net effect of increasing the barrier to regurgitation.

Intraocular Pressure

Intraocular pressure increases transiently in children after IV succinylcholine independent of the presence of fasciculations.[1093] The exact mechanism of this increase in IOP is not clear. Initially, the increase in IOP was attributed to tonic contractions of extraocular muscles, but it is probably because of the cycloplegic action of succinylcholine, with deepening of the anterior chamber and increased outflow resistance. The IOP usually increases by about 10 mm Hg, peaks in 2 to 3 minutes, and then returns to baseline in 5 to 7 minutes.[1093] It is advisable to perform applanation tonometry before succinylcholine or to wait at least 7 minutes after succinylcholine before performing tonometry in children. Although the use of succinylcholine in children with open-eye injuries has not resulted in further damage to the eye,[1094] it is nonetheless prudent to refrain from its use in situations of penetrating ocular wounds unless the eye is not salvageable. High-dose rocuronium (1.2 mg/kg) is a reasonable substitute for succinylcholine rapid-sequence intubation in these circumstances.[1095]

Clinical Uses of Succinylcholine

The use of succinylcholine for routine surgical procedures in children has been abandoned, primarily because of the rare but life-threatening possibility of cardiac arrest in male children with undiagnosed muscular dystrophy.[1096,1097] On the other hand, succinylcholine does have the most rapid onset and the briefest duration of action of all currently available muscle relaxants. Consequently, succinylcholine is desirable for rapid-sequence tracheal intubation for brief procedures and for the treatment of laryngospasm.[1036,1098,1099] Because the rapidity of onset is dose related, 1.5 to 2.0 mg/kg IV succinylcholine should be administered to children to depress the neuromuscular twitch 95% within 40 seconds; the smaller dose of 1.0 mg/kg would achieve the same degree of depression in about 50 seconds.[1036,1098] In infants younger than 1 year of age, 3 mg/kg IV would be an appropriate dose because of the larger Vd. These doses provide excellent intubating conditions in all children.[1036] To decrease the incidence of arrhythmias after succinylcholine (particularly after a second dose), atropine 0.01 to 0.02 mg/kg IV should precede the succinylcholine.

In 1993 the FDA issued a black box warning against the routine use of succinylcholine in children and adolescents except for emergency airway management. This was based on several case reports of hyperkalemic cardiac arrests, primarily in children with undiagnosed Duchenne muscular dystrophy.[1100] The disturbing observation about this complication was the staggering mortality rate of 55%. Almost all of these cases, however, occurred in male children 8 years old and younger. In many instances the arrhythmias were misdiagnosed as MH and not treated with IV calcium in a timely manner. Subsequently, the FDA and the manufacturer revised the product label (package insert) to read as follows:

> *"Since there may be no signs or symptoms to alert the practitioner to which patients are at risk, it is recommended that the use of succinylcholine should be reserved for emergency intubation or in instances where immediate securing of the airway is necessary, e.g., laryngospasm, difficult airway, full stomach, or for intramuscular use when a suitable vein in inaccessible."*

In cases in which the child has a full stomach and is at risk for a hyperkalemic response to succinylcholine, a standard rapid-sequence intubation with equivalent intubation conditions may

be performed using high-dose rocuronium (1.2 mg/kg)[1095] or a large dose of propofol with an opioid (e.g., propofol/remifentanil).[1101] The main disadvantage of using a large dose of nondepolarizing relaxant is that the duration of blockade may exceed the duration of the planned procedure. Less likely is the disadvantage of an ensuing "cannot intubate, cannot ventilate" situation in which the dose of the relaxant cannot be antagonized. The availability of sugammadex allows rapid intubation with rocuronium, even for brief emergency procedures, while avoiding the need to use succinylcholine (see later discussion).[1102–1105] In an emergency, the cost of sugammadex may be tolerated, but it is currently too expensive to use routinely for antagonizing nondepolarizing relaxants.

Intermediate-Acting Nondepolarizing Neuromuscular Blocking Drugs

ATRACURIUM

Chemically, atracurium (Tracrium) is an imidazoline bisquaternary compound that undergoes spontaneous decomposition into inactive metabolites. At physiologic (alkaline) pH, it undergoes enzymatic hydrolysis independent of plasma cholinesterase (Hofmann elimination), ester hydrolysis, and other unspecified pathways.[1030] In blood and other tissue fluids, the quaternary ammonium compound breaks down primarily into laudanosine and a related quaternary acid (methylacrylate). The elimination half-life of atracurium is similar in infants and children (14–20 minutes). The steady-state plasma concentration resulting in 50% neuromuscular block (EC_{50}) does not differ between infants, children, or adults (363, 444, or 436 ng/mL, respectively).[1022]

For intubating purposes, two to three times the ED_{95} (300–600 µg/kg) is given to produce effective blockade in most children.[1106,1107] Such doses provide satisfactory conditions for intubation within 2 minutes. The period of absence of twitch response after an intubating dose of atracurium usually lasts 15 to 30 minutes. Hence, in clinical situations an intubating dose should provide complete neuromuscular blockade for such an interval, followed by another 20 minutes of intermediate blockade (twitch height 5%–25%); complete recovery usually occurs within 40 to 60 minutes. Comparison of data from children and adults demonstrates that children require more atracurium per kilogram and generally recover faster. This difference, however, is relatively small and is masked in most cases by the wide range of individual patient responses.

Because atracurium is degraded spontaneously and its metabolites do not have neuromuscular blocking properties, it can be easily administered by continuous infusion. The infusion requirement to maintain 90% to 99% twitch depression in children is 6 µg/kg per minute during isoflurane anesthesia, 7 to 8 µg/kg per minute with halothane, and 9 µg/kg per minute with an N_2O:O_2 opioid technique.[552,553] No significant differences in the Vd, clearance, or half-lives have been detected for atracurium between normal infants and children with impaired hepatic function.[1031] Plasma laudanosine concentrations tend to be greater in children with hepatic impairment than in children with normal hepatic function.[1031]

The side effects of atracurium are minimal; at doses of up to 600 µg/kg, there are no significantly changes in the heart rate or BP in children. Mild cutaneous flushing reactions are sometimes observed.[1106] Extremely rare instances of anaphylactoid reactions or bronchospasm have been reported.

CISATRACURIUM

Cisatracurium (Nimbex) is one of the 10 stereoisomers of atracurium (1*R-cis*, 1′*R-cis*). Cisatracurium is three times more potent than atracurium, with the same duration of action.[1108] Similar to other nondepolarizing relaxants, its onset can be accelerated by increasing the dose (see E-Table 7.7 and Table 7.10); as with the other relaxants, this will increase the duration of the action. Cisatracurium, like atracurium, is a noncumulative agent with recovery occurring during the elimination phase rather than during the distribution phase.

Cisatracurium has a slightly slower onset of action than atracurium, consistent with its relative potency. Twice the ED_{95} dose (80 µg/kg) of cisatracurium leads to complete suppression of the twitch response in 2.5 minutes. The recovery to 25% and 95% of control response occurs in 31 and 53 minutes, respectively.[1108–1111] Its histamine-releasing effects are minimal; its duration and recovery profile are similar to atracurium.

The distribution and elimination half-lives of cisatracurium in children are 3.5 and 23 minutes, respectively. The Vdss and the total body clearance of most drugs in children are greater (expressed as milligrams per kilogram; see the example of dexmedetomidine Fig. 7.5) than in adults, thus explaining the faster recovery in children.[1032] In adults with renal failure, the clearance of cisatracurium is reduced by 13%; plasma laudanosine levels were greater but were only about 10% of those reported with atracurium.[1112] The duration of action of cisatracurium in patients with renal failure is not significantly prolonged.[1113] It should be noted that patients receiving chronic anticonvulsant therapy (carbamazepine or phenytoin) can develop a moderate resistance to the action of cisatracurium.[1114]

VECURONIUM

Vecuronium is the monoquaternary homologue of pancuronium in which the methyl group of the 2β-nitrogen atom is absent. The Vd is greater in infants than in children (357 ± 70 vs. 204 ± 116 mL/kg), whereas plasma clearances are similar (5.6 ± 1.0 vs. 5.9 ± 2.4 mL/kg per minute).[1021]

Its primary advantage is the absence of any adverse cardiovascular effects even in doses several times greater than the usually recommended clinical doses (see E-Table 7.7 and Table 7.10).[1115] Vecuronium is primarily metabolized by the liver and excreted in bile.[1116] Dose requirements according to age groups are much more pronounced (>50%), with a biphasic distribution of the dose requirement and duration of action; infants younger than 1 year of age are significantly more sensitive to the action of vecuronium than older children. As adolescence is reached, the requirement diminishes to that of adults.[1016,1020,1117,1118] However, on rare occasions there may be resistance to vecuronium in neonates.[1119]

Neuromuscular blockers are often administered to critically ill children. Vecuronium has been popular because of the absence of cardiovascular side effects and because its metabolites do not seem to have CNS effects. However, adult and pediatric patients in ICUs have had residual weakness after the discontinuation of vecuronium, possibly contributed by active 3-OH metabolite or its steroid-like structure.[1120–1122] In one study in which the rate of infusion was adjusted by accelerometry, all children recovered within 1 hour. Of note in these children, the requirements of neonates and small infants were 45% less than those of older children.[1123] In this respect, cisatracurium may offer advantage because its recovery from prolonged infusion is faster than vecuronium.[1124]

ROCURONIUM

Rocuronium (Zemuron) is a monoquaternary steroidal muscle relaxant similar to vecuronium. It has the fastest onset of action of the intermediate-acting nondepolarizing relaxants because of its low potency and greater dose requirements.[1125] The onset time of rocuronium is 1 to 1.5 minutes after a dose of $2 \times ED_{95}$; this is 20 to 70 seconds faster than vecuronium, although its duration of action is similar.[1126] Rocuronium is eliminated primarily by the liver; the kidney excretes about 10%.[1127–1132] Renal failure does not affect the onset of rocuronium-induced neuromuscular blockade in adults or children. However, it may prolong the duration of action of rocuronium in adults, a finding not shared for children older than 1 year of age.[1127,1129,1132]

Rocuronium has an ED_{95} of 303 μg/kg in children during halothane anesthesia,[1133] with slightly greater doses required during N_2O:O_2 opioid anesthesia.[1134–1136] After the administration of 600 μg/kg rocuronium ($2 \times ED_{95}$), 90% and 100% neuromuscular block occurred in 0.8 and 1.3 minutes, respectively (see E-Table 7.7 and Table 7.10). At this dose, heart rate increased by approximately 15 beats/minute in children. The mean time to recover to 25% of control was approximately 28 minutes, and recovery to 90% of control was 46 minutes.[1136]

For brief cases in which children are anesthetized with 8% inspired sevoflurane, 0.3 mg/kg rocuronium yields satisfactory intubating conditions within 2 to 3 minutes.[1137] This dose of rocuronium can be antagonized within approximately 20 minutes of administration.[1132] The intubating conditions after rocuronium (600 μg/kg) have been compared with those after vecuronium (100 μg/kg), atracurium (500 μg/kg), and succinylcholine (1 mg/kg). It was found that tracheal intubation could be performed within 60 seconds in all the children who had received rocuronium or succinylcholine, but not until 120 seconds after vecuronium and 180 seconds after atracurium.[1138,1139] The time for intubating conditions is shortened by increasing the dose[1140]; at a dose of 1.2 mg/kg (3 to $4 \times ED_{95}$), the intubating conditions are similar to those after treatment with succinylcholine.[1095,1136] At the larger doses, heart rate increases transiently, while systolic and diastolic pressures are unchanged.[1133,1141] It is unclear whether this increase in heart rate after rocuronium is the result of pain on injection or an inherent chronotropic effect.[1104] Dosing studies in infants 2 to 11 months of age demonstrated a slightly faster onset of neuromuscular blockade than in older children with the same dose (600 μg/kg). The times to 90% and 100% twitch depression were 37 and 64 seconds, respectively. In infants, the rate of onset of neuromuscular blockade 60 seconds after rocuronium is comparable to that after succinylcholine.[1133,1142] Neonates appear to be more sensitive to rocuronium than older infants.[1143] In neonates, the duration of action of 600 μg/kg is approximately 90 minutes, and there is marked patient-to-patient variability. Consequently, 450 μg/kg rocuronium provides adequate intubating conditions, with a duration of action of approximately 1 hour.[1143]

In a PK study, the clearance of rocuronium in infants was less than in children (4 vs. 7 mL/kg per minute), whereas the Vd was greater in infants. The mean residence time was 56 minutes in infants versus 26 minutes in children, thus explaining the prolonged duration of action of rocuronium in infants compared with children. In a steady-state target-controlled infusion study, the potency of rocuronium was greatest in infants, least in children, and intermediate in adults.[1144] The greater plasma clearance and smaller Vd of rocuronium in children compared with infants and adults result in a markedly smaller mean residence time and a decreased duration of neuromuscular blockade.[1023] Consistent with the dose-response effects of curare and vecuronium in infants, smaller plasma concentrations of rocuronium are required in the effect compartment in infants than in children to produce the same degree of neuromuscular blockade.[86] Sevoflurane markedly potentiates the effects of rocuronium.[1145]

If an IV route is unavailable, the IM route for rocuronium is a reasonable alternative; IM rocuronium (1.8 mg/kg, 3 × the IV intubating dose) provided poor intubating conditions 4 minutes after administration in most children. Neuromuscular blockade (>98%) was achieved in 6 to 8 minutes.[1146] The bioavailability of IM rocuronium at these doses is approximately 80%.[1147] IM rocuronium appears to be a viable alternative to IM succinylcholine, although the time of onset of neuromuscular blockade is very slow and would not be appropriate for emergent situations. The duration of IM rocuronium effect (approximately 80 ± 22 minutes) is much greater than that after IM succinylcholine.[1146]

CLINICAL IMPLICATIONS WHEN USING SHORT- AND INTERMEDIATE-ACTING NEUROMUSCULAR BLOCKING DRUGS

Short- and intermediate-acting NMBDs have great utility in infants and children because of the large number of brief surgical procedures performed. Because of their short duration of action, these drugs can be given in one intubating dose (atracurium [500 μg/kg]; cisatracurium [200 μg/kg]; vecuronium [100 μg/kg]; rocuronium [600 μg/kg]), and a light anesthetic level is maintained throughout the procedure. If more than 45 minutes elapse after the last dose of these neuromuscular blockers, one may reasonably assume that neuromuscular function has nearly recovered, but safe practice would recommend confirming *recovery of neuromuscular integrity by clinical signs or by assessment with a neuromuscular blockade monitor. We recommend antagonism in all neonates and infants despite clinical signs of recovery.*

The benzylisoquinoliniums and organosteroidal NMBDs are acidic compounds (pH 3–4) that can precipitate thiopental (pH 10–11) if admixed.[1148] Consequently, when these drugs are administered in tandem, the IV tubing should be thoroughly flushed between the thiopental and these relaxants. Vecuronium and rocuronium are painful when administered intravenously in a small vein during the light stages of anesthetic. This pain is usually demonstrated by withdrawal of the hand. Pain can be attenuated by deepening the level of anesthesia or pretreating with fentanyl, lidocaine, or ketamine.[1149,1150]

Long-Acting Nondepolarizing Neuromuscular Blocking Drugs

For almost half a century the mainstay of NMBDs was curare (*d*-tubocurarine). After the development of intermediate-acting NMBDs, its use diminished because its duration of action was too great for most surgeries, and large doses released histamine. Curare is no longer available.

After the introduction of curare, several long-acting NMBDs with minimal adverse effects were developed. These included metocurine, pipecuronium, and doxacurium, which are 2, 4, and 10 times as potent as curare, respectively. The only long-acting relaxant that is still used in some institutions is pancuronium.

PANCURONIUM

Pancuronium bromide (Pavulon) is a bisquaternary ammonium steroidal compound with nondepolarizing neuromuscular

blocking properties. Pancuronium undergoes partial (15%–20%) hepatic deacetylation to produce 3-OH, 17-OH, and 3,17-di-OH metabolites. A prolongation of effect can be expected in patients with renal or hepatic failure because a major proportion of pancuronium is excreted in the urine (40%–60%) and in the bile (11%). Vd (203 ± 36 mL/kg) and plasma clearance (1.7 ± 0.2 mL/kg per minute) of pancuronium are associated with a prolonged elimination half-life (103 ± 23 minutes) in children (3–6 years) under halothane anesthesia.[1151] It induces mild tachycardia by blocking presynaptic noradrenaline uptake (increased cardiac output in infants) but has no histamine-releasing properties, so systolic BP tends to increase.[1152] Pancuronium (100 µg/kg) provides satisfactory conditions for tracheal intubation in 70% to 90% of infants and children within 150 seconds of administration. Increasing the initial dose to 150 µg/kg provides satisfactory intubating conditions in all children within 80 seconds (see E-Table 7.7 and Table 7.10).[1098,1153]

Pancuronium is frequently advocated for cardiac surgery and other high-risk procedures in infants and children. The anesthetic technique of combining a high-dose opioid with air–oxygen–pancuronium is well tolerated by infants, from a cardiovascular perspective. The vagolytic effect (tachycardia) of pancuronium counteracts the vagotonic effect (bradycardia) of potent opioids, and its relaxant properties counteract opioid-induced chest wall and glottic rigidity.[1154] Pancuronium has been used to facilitate ventilation in preterm infants in neonatal ICUs.[1155] Because pancuronium increases the heart rate, BP, and plasma epinephrine and norepinephrine levels in neonates, there is some concern that it may contribute to the risk of an intracerebral hemorrhage.[1156] Accordingly, it would seem prudent to administer pancuronium with either general anesthesia or with adequate sedation to blunt adverse cardiovascular responses. Vecuronium may offer an advantage over pancuronium because it does not significantly increase the BP.[1157–1161] Nasotracheal intubation or intratracheal suctioning in neonates who are paralyzed with pancuronium results in smaller increases in intracranial pressure than in neonates who are not paralyzed.[1161,1162] By abolishing fluctuations in CBF through the use of muscle relaxants, the incidence and severity of intraventricular hemorrhages should theoretically be reduced.

Antagonism of Neuromuscular Blocking Drugs

GENERAL PRINCIPLES

In children and especially infants, oxygen consumption is greater than in adults. Therefore a slight diminution in respiratory muscle power may lead to hypoxemia and CO_2 retention. Consequently, it is very important that neuromuscular function is returned to normal at the end of the surgical procedure. Neonates are at greater risk for residual neuromuscular blockade than adults for several reasons, including (1) immaturity of the neuromuscular system, (2) greater elimination half-life of relaxants, (3) the reduced number of type I muscle fibers in the ventilatory musculature (thus being more susceptible to fatigue [see Chapter 14, Fig. 14.11]),[225] and (4) the closing lung volume of a neonate overlaps with the tidal volume (i.e., airway closure occurs at the end of expiration) (Fig. 2.5).[1163] If respiration is mildly impaired as a result of residual muscle paralysis, even more alveoli will collapse. The result may be hypoxemia as well as hypercarbia and acidosis, which may potentiate and prolong the duration of action of the muscle relaxant, thus creating a vicious cycle.

When monitoring neuromuscular blockade in infants and children, train-of-four monitoring of the adductor pollicis overestimates the degree of neuromuscular blockade in the diaphragm.[999] Larger doses of muscle relaxants are required to block the diaphragm than the adductor pollicis train-of-four would suggest. Therefore if the train-of-four of the adductor has fully recovered, one can assume that the diaphragm has fully recovered.

Clinical evaluation of the adequacy of antagonism in infants is more difficult than in children or adults. Neither grip strength nor voluntary head lifting can be elicited; rather, it is important when working with infants to observe the clinical conditions preoperatively (muscle tone, depth of respiration, vigor of crying) and to aim for a comparable level of activity in the postantagonism period. Useful clinical signs that the neuromuscular blockade has been antagonized include the ability to flex the hips, flex the arm, lift the legs, and the return of abdominal muscle tone.[1164] Inspiratory force may be measured; a negative force of –25 cm H_2O or greater indicates adequate antagonism.[1165] A crying vital capacity greater than 15 mL/kg indicates an adequate respiratory reserve. The train-of-four is a valuable aid because it can be used in the smallest of infants in whom the force of contraction can easily be palpated (four equal contractions indicating adequate antagonism).

Although edrophonium may establish a faster onset of effect, final recovery is invariably greater with neostigmine, which is why the latter is recommended for routine pediatric practice.[1166,1167] The distribution volumes of neostigmine are similar in infants (2–10 months), children (1–6 years), and adults (Vdss 0.5 L/kg), whereas the elimination half-life is less in children.[1168] Clearance decreases as age increases (13.6, 11.1, 9.6 mL/minute per kilogram in infants, children, and adults 29–48 years, respectively).[1168] The dose requirement of anticholinesterase agents to antagonize neuromuscular blockade in children is less than in adults.[1168] However, the speed of antagonism depends on the extent of neuromuscular blockade at the time of the antagonism, as well as the type and dose of antagonizing agent. In the presence of train-of-four responses with fade, 20 to 25 µg/kg of neostigmine, preceded by 10 to 20 µg/kg of atropine or 5 to 10 µg/kg of glycopyrrolate, is sufficient to achieve full recovery of muscle strength. This dose of neostigmine can be repeated if required (up to 70 µg/kg). Doses of neostigmine in excess of 100 µg/kg may induce a paradoxical weakness from excessive acetylcholine at the neuromuscular junction. The dose of edrophonium for children is greater than it is for adults; at least 0.3 mg/kg is needed, but 0.5 to 1.0 mg/kg is most common.[1167,1169–1172]

Some have suggested that it is not necessary to antagonize intermediate-acting NMBDs, particularly if a lengthy time interval has elapsed since the last dose. With the advent of reliable neuromuscular monitors and their use in conjunction with clinical observations and measurements of respiratory adequacy, clinicians are more confident that antagonism is not always required. This may be appropriate for the short- and intermediate-acting NMBDs, particularly atracurium or cisatracurium, which are hydrolyzed in plasma. Children have the additional advantage of recovering from neuromuscular blockade more rapidly than adults.[1171,1172] In infants, the elimination of all muscle relaxants might be delayed, necessitating antagonism of any NMBD; if there is any concern that some degree of neuromuscular blockade persists, then the blockade must be antagonized.

Hypothermia potentiates the action of most nondepolarizing muscle relaxants and delays their elimination.[1173] This effect can create a special problem at the end of a surgical procedure when

the children attempt to resume spontaneous respirations. Shivering increases oxygen consumption and augments the load on the respiratory system. If the respiratory muscles are unable to match this increased load, hypoxemia and CO_2 retention may occur, which in turn may lead to acidosis, which, again, may potentiate the relaxant. To avoid the extra cardiorespiratory load in a postsurgical infant, it is reasonable to warm the infant if the temperature is less than 35°C (95°F). Once the core temperature is above this level, antagonism of neuromuscular blockade may be attempted.

Theoretically, all antibiotics have neuromuscular depressing properties when administered in association with relaxants.[1174] Among the antibiotics, aminoglycoside derivatives, such as gentamicin, tobramycin, and neomycin, have the greatest effect. A single clinical dose of antibiotic will likely have minimal effect on the neuromuscular blockade.[1175] This factor alone does not rule out the possibility that large concentrations of antibiotics, especially in the presence of other potentiating factors, may augment the neuromuscular blockade. The clinical importance of the interaction of antibiotics with NMBDs to prolong neuromuscular blockade has diminished with the introduction of intermediate-acting NMBDs.

Magnesium also relaxes muscles and may also potentiate neuromuscular blockade. When magnesium was administered after paralysis from rocuronium was antagonized by sugammadex in an adult, plasma magnesium concentrations of 2.67 mM caused recurarization that resolved after 45 minutes.[1176]

SUGAMMADEX

Sugammadex (Org 25969), a member of the cyclodextrin family, is a cyclic oligosaccharide[1177] with hydrophobic molecules within the center (Fig. 7.22).[1178,1179] This compound encapsulates rocuronium, and vecuronium to a lesser degree, and forms a stable complex that prevents further action of the relaxants; the complex is then excreted unchanged by the kidneys. The chemical encapsulation decreases the plasma concentration of rocuronium, thus promoting the dissociation of rocuronium from the acetylcholine receptor, speeding recovery of muscle strength. Three minutes after 0.6 mg/kg rocuronium produced profound neuromuscular block in adult volunteers, a single dose of sugammadex, 2 mg/kg or greater, reversed the neuromuscular block within 2 minutes.[1180] An early sugammadex study in children suggested that sugammadex, at 2 mg/kg, reverses a rocuronium-induced moderate neuromuscular blockade in infants, children, and adolescents.[1103] The average time to recover a train-of-four ratio of 0.9 at the time of appearance of the second twitch response was ~1.2 minutes in children, adolescents, and adults. Recent studies have demonstrated much more rapid times to extubation and recovery after sugammadex compared with neostigmine in children with similar side effects.[1181,1182] Clinical trials confirm the safety and efficacy of this new concept, and studies in children demonstrate safety and efficacy.[1182a,1182b] Sugammadex may be effective in antagonizing large doses of rocuronium rapidly, efficiently, and soon after the onset of neuromuscular blockade in children.[1183–1187] Sugammadex rapidly antagonizes even intense neuromuscular blockade in adults, in whom no twitches were observed.[1184,1188] The rapidity of the reversal depends on both the intensity of the block and the dose of sugammadex.[1102,1104,1189] Under these circumstances, rocuronium might then supplant succinylcholine in many circumstances, including rapid-sequence intubations for brief procedures in children.[1105,1190] Sugammadex is cleared through the renal system, and the elimination kinetics of rocuronium are known to be prolonged in renal failure.[1127] Although GFR is immature in neonates, this is unlikely to be of consequence. Sugammadex has been used in patients with end-stage renal failure [1191–1193] with reversal characteristics similar to those with normal renal function.

Two impediments delayed the introduction of sugammadex in the United States. First, there was some evidence that sugammadex may trigger allergic or anaphylactic reactions.[1194] Second, sugammadex is exceedingly expensive. The expense of sugammadex has put this medication out of financial practicality for routine use in nearly every health care facility in the world (E-Table 7.8).[1195] This renders sugammadex a rescue drug only. Data suggest that this drug could be used for rescue of a cannot intubate–cannot ventilate situation after administration of a rapid intubating dose of rocuronium (1.2 mg/kg) within 2 minutes, compared with the time for the effects of succinylcholine to abate.[1105,1184] This great expense is quite unfortunate, as the incidence of hyperkalemia or MH induced by succinylcholine would likely have decreased to near zero if we could routinely substitute high-dose rocuronium for succinylcholine without fear of prolonged neuromuscular blockade.

If neuromuscular blockade must be reinstituted after administration of sugammadex, the dose of rocuronium that would be required for neuromuscular blockade is unclear[1151]; it would seem prudent to switch to a benzylisoquinolinium muscle relaxant that is unaffected by the presence of sugammadex.

Neuromuscular Blocking Drugs in Special Situations

Of the many drug combinations possible, that of succinylcholine after a halothane induction seems to be most likely to trigger MH[1196] (see Chapter 41). The use of depolarizing neuromuscular

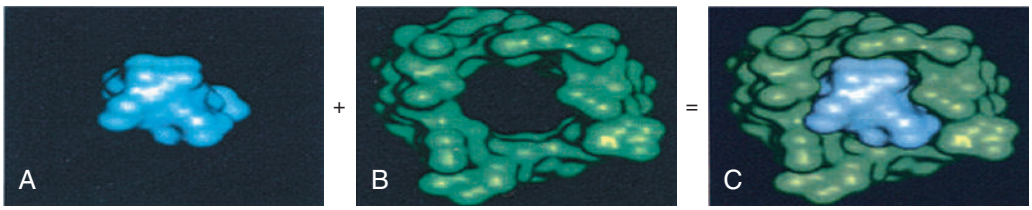

FIGURE 7.22 X-ray crystallography of **(A)** the rocuronium molecule (shown in *blue*) and **(B)** sugammadex (*green ring*). **C,** The 3-D conformation of the rocuronium molecule complements the conformation of the inner ring of sugammadex. The rocuronium–sugammadex complex is stable, without a dissociation constant, and is excreted unchanged via the kidneys. (Redrawn from Gijsenbergh F, Ramael S, Houwing N, van Iersel T. First human exposure of Org 25969, a novel agent to reverse the action of rocuronium bromide. *Anesthesiology* 2005;103(4):695–703.)

E-TABLE 7.8 Approximate Cost[a] for Sugammadex Reversal of Rocuronium by Weight and Density of Block

	WEIGHT (kg)			
Depth of Block	**3**	**10**	**20**	**70**
Mild (4 twitches with fade) 2 mg/kg	$2.70	$9.00	$18.00	$63.00
Moderate (1–2 twitches) 4 mg/kg	$5.40	$18.00	$36.00	$126.00
Profound (no twitches) 8 mg/kg	$10.80	$36.00	$72.00	$252.00
Wasted drug (single patient use; profound blockade)	$79.20	$54.00	$18.00	$20.25[b]

[a]Costs are listed as U.S. dollars (USD).
[b]Assumes three 200-mg vials at ~$90 USD each.
Personal communication with Cynthia Brown RPH, Women and Children's Hospital of Buffalo. Sept 28, 2017.

blocking agents in combination with halogenated agents should be avoided in children at risk for this syndrome.[1197] The safest general anesthetic technique for children at risk for MH is an opioid plus N_2O plus O_2 combination, together with benzodiazepines, propofol, and a nondepolarizing relaxant. Nondepolarizing agents devoid of cardiovascular side effects may offer an advantage in not causing tachycardia, an early sign of MH.[1198,1199] There has been some concern of the potential association between mitochondrial disease and MH. A major review, along with evidence from pathology specimens from patients who had a family member with MH, suggest that this is not at all clear and may be a case of "fortuitous association."[1200] Because many of these children are bedridden, it would seem prudent to avoid succinylcholine, although there are *"inadequate data to support the recommendation … that the anesthetic plan for patients with mitochondrial disease should routinely include MH precautions."*[1201]

The use of NMBDs in children with neuromuscular and mitochondrial diseases has been the subject of debate.[1199,1202,1203] Rhabdomyolysis has been reported after succinylcholine in children with Duchenne and Becker muscular dystrophy (see Chapters 24 and 41). It is prudent to avoid succinylcholine in any child with a suspicious neuromuscular or mitochondrial disease (see earlier). The response of children with neuromuscular disease to nondepolarizing relaxants is variable. Most are relatively sensitive to the NMBDs, particularly those with muscular dystrophy, because of muscle wasting.[1199,1204,1205] The duration of neuromuscular blockade is often prolonged. Rarely, resistance may be evident as a result of chronic immobilization. Of all the nondepolarizing relaxants, we recommend cisatracurium because of its multiple sites of degradation that are independent of organ function.[1206–1208] The dose requirement of atracurium in children with Duchenne muscular dystrophy is similar to that in unaffected children, although the duration of action may be prolonged.[1206] The dose response of rocuronium in children with Duchenne muscular dystrophy shows marked prolongation of both the onset and recovery times (two to three times normal).[1209] Thus NMBDs should be administered with caution in children with severe preexisting respiratory dysfunction, because even a small dose of a NMBD may cause profound muscle weakness and the need for ventilatory support. Similarly, it is important to antagonize any residual neuromuscular blockade at the end of surgery. *If there is any doubt about the competence of the neuromuscular junction, the trachea should remain intubated until muscle strength has recovered.*

Succinylcholine can cause hyperkalemia in children with burns, which may cause a cardiac arrest.[1210] The more extensive the burn, the more likely and the greater the hyperkalemic response. An 8% burn is the smallest burn that has been associated with hyperkalemia. Although most instances of cardiac arrest have occurred 20 to 50 days after the burn injury, exaggerated increases in the plasma concentration of potassium after succinylcholine can occur within a few days of the burn. However, hyperkalemia after succinylcholine has not been reported in the first 24 hours after a burn. Hyperkalemia is thought to result from the upregulation of acetylcholine receptors along the surface of the muscle membrane in the postburn phase (see Chapter 36).[1211]

Children with burns may require two to three times the usual IV dose of nondepolarizing relaxants. This resistance peaks about 2 weeks after the burn, persists for many months in those with major burns, and decreases gradually as the burns heal. The degree of resistance appears to correlate with both the extent of the burn and the period of healing. The resistance can be explained, in part, by an increase in the Vd of the relaxant (including binding to an increased plasma concentration of α_1-acid glycoprotein) and an increase in number, sensitivity, and type of extrajunctional acetylcholine receptors (see Chapter 36).

Opioids

MORPHINE

Morphine is the most frequently used opioid to treat postoperative pain in children and is the standard against which all other opioids are compared. Morphine's main analgesic effect is by supraspinal μ_1-receptor activation. The μ_2-receptor in the spinal cord plays an important analgesic role when the drug is administered by the intrathecal or epidural route.[1212] Morphine is soluble in water, but poorly soluble in lipids compared with other opioids.

Pharmacodynamics

Target analgesic plasma concentrations are thought to be 10 to 20 ng/mL after major surgery in neonates and infants.[1213,1214] No concentration-response relationship has been described in children.[1215] The large PK and PD variability suggests that morphine be titrated to effect using small incremental IV doses (0.02 mg/kg) in neonates and infants with postoperative pain.[1216,1217] Both sex and genetics have major impacts on PD.[1218] There is polymorphism A118G of the human mu-opioid receptor gene controlling response.[1219] Inflammatory cytokines, mood and adrenergic response also impact on PD (see Chapter 6).[1220]

Morphine's low oil–water partition coefficient of 1.4 and its pKa of 8 (10%–20% un-ionized drug at physiologic pH) contribute to its delayed onset of peak action, with slow CNS penetration. The $T_{1/2}$keo for morphine is approximately 17 minutes in adults[1221] but is estimated to be 8 minutes in the full-term neonate.[1222]

Pharmacokinetics

Morphine is primarily metabolized by the hepatic enzyme UGT2B7 to morphine-3-glucuronide (M3G) and morphine-6-glucuronide (M6G); both have pharmacologic activity. Sulfation and renal clearance are minor pathways in adults but are more dominant in neonates. Contributions to both the desired effect (analgesia) and the undesired effects (nausea, respiratory depression) of M6G are the subject of clinical controversy.[1223] It has been suggested that M3G antagonizes morphine and contributes to the development of tolerance.[1224]

Clearance increases from 3.2 L/hour per 70 kg at 24 weeks PMA to 19 L/hour per 70 kg at term, reaching adult values (80 L/hour per 70 kg) at 6 to 12 months (see Fig. 7.11).[45,48,1225] These developmental factors for morphine metabolism explain in part the prolonged duration of action in neonates. The maturation profile also suggests that older infants are able to exceed the reported clearance (in liters per hour per kilogram) of morphine in adults. Clearance is perfusion-limited, with a high hepatic extraction ratio. Oral bioavailability is approximately 35% because of this first-pass effect.[1226] The metabolites are cleared by the kidney and, in part, by biliary excretion. Impaired renal function leads to M3G and M6G accumulation.[1227] Clearance is reduced in critically ill neonates compared with healthier cohorts and in those undergoing cardiac surgery (Fig. 7.23).[45–47,1213]

Morphine PK parameters show large interindividual variability contributing to the range of morphine serum concentrations observed during constant infusions.[1228] A large number of covariates contribute to PK variability. For example, African America children have a more rapid clearance of morphine than Caucasian children after tonsillectomy.[1229] Variability in clearance is influenced by

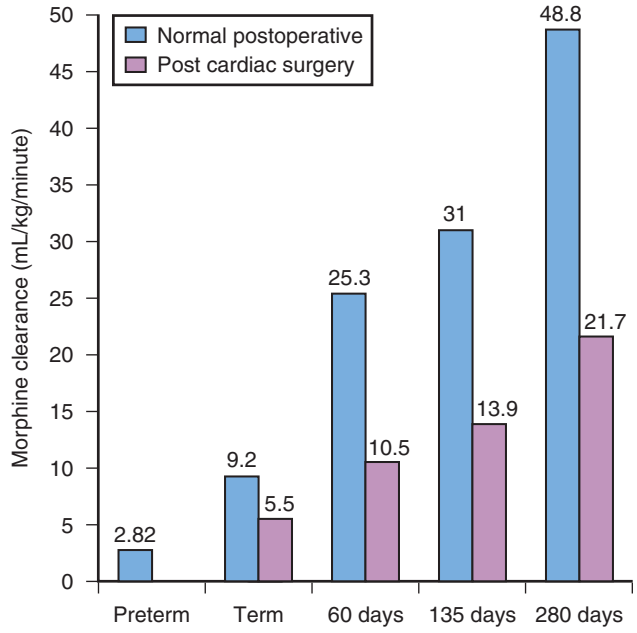

FIGURE 7.23 Morphine clearance versus postconception age in normal postoperative infants and infants undergoing cardiac surgery. Note that there is a rapid increase in an infant's ability to metabolize morphine in the first several weeks of life and that some infants achieve adult values by 1 month of age. Also note that after cardiac surgery infants have a marked impairment of morphine metabolism, which may reflect the use of vasopressors and/or decreased cardiac output to the liver. There is extreme patient-to-patient variability at all ages; preterm infants have the lowest clearance of any age group. (Data from Lynn A, Nespeca MK, Bratton SL, et al. Clearance of morphine in postoperative infants during intravenous infusion: the influence of age and surgery. *Anesth Analg*. 1998;86(5):958–963 and Mikkelsen S, Feilberg VL, Christensen CB, Lundstrøm KE. Morphine pharmacokinetics in preterm and mature newborn infants. *Acta Paediatr*. 1994;83(10):1025–1028.)

genetic factors controlling the UGT enzyme system[1220]; even the patient's domicile (e.g., high altitude) could have an impact (see also Chapter 6).[1230,1231]

Routes of Administration

Although morphine is usually administered intravenously to neonates, other routes have been used. A large variability in the analgesic effect of morphine has been observed after rectal administration[1232]; however, delayed absorption with multiple doses causing respiratory arrest has been reported so **this route is not recommended**.[108] Morphine administered orally also has considerable absorption variability (F 0.3, coefficient of variation [CV] 36%; absorption half-time [$T_{1/2}$abs] 0.71 hour; CV 55%), contributing to wide prediction intervals for observed concentrations.[1233] Morphine (25–50 µg/kg) can also be given via the caudal route and subarachnoid spaces (see Chapters 42 and 44). Although systemic absorption is slow, morphine spreads within the CSF to the brainstem, where it may cause respiratory depression lasting from 6 to more than 18 hours.[1223]

Morphine may be administered IV by intermittent bolus, continuous infusion, or patient-controlled analgesia (see Chapter 44).[1234–1236] The usual initial IV dose is 0.05 to 0.2 mg/kg. A reduced dose is indicated in neonates, children who are critically ill, those who are receiving supplemental analgesics or hypnotics, and/or those who have nocturnal hemoglobin desaturation (<85%) during obstructive sleep apnea (OSA).[1237–1239]

Adverse Effects

The major risk associated with opioid use in infants and children is respiratory depression.[99,1205] Morphine infusion rates of 10 to 30 µg/kg per hour provide adequate postoperative analgesia without respiratory depression in children.[1240] Postoperative analgesia is achieved at reduced infusion rates in infants 4 weeks of age or older (~5 µg/kg per hour for neonates, ~8.5 µg/kg per hour at 1 month, ~13.5 µg/kg per hour at 3 months, ~18 µg/kg per hour at 1 year, and slightly less than 16 µg/kg per hour for 1- to 3-year-olds).[213] Respiratory depression may occur at plasma concentrations of 20 ng/mL in infants and children,[211] but concentration-response relationships in neonates, particularly in preterm neonates who are prone to physiologic apnea, are unknown. When respiratory depression from morphine occurs, it results from both diminished tidal volume and respiratory rate. Whether morphine causes a parallel shift in the CO_2 response curve or a change in the slope, as well as a parallel shift, has not been clearly established. Morphine appears to depress respirations in neonates to a greater extent than meperidine,[1241] although the mechanism behind this is uncertain and may relate to altered PK, an immature BBB,[203] altered regional blood flow, or an increased cerebral uptake. In neonatal rats, the brain uptake of morphine is two to three times that in adult rats.[203] This may explain the 5-fold reduced LD_{50} of morphine in neonatal versus adult animals.[201–203] This immaturity of the BBB may account, in part, for the increased sensitivity of the premature neonate to morphine compared with meperidine or fentanyl; because of their lipophilicity, the latter two opioids rapidly cross an adult's or infant's BBB—that is, there is essentially no BBB.[1242]

Alternatively, reduced clearance could lead to drug accumulation in some infants given repeat doses of morphine.[167] Another possibility is a maturation of the PD effects on respiration rather than altered PK—that is, a maturation of the sensitivity of the respiratory center to morphine, rather than a change in brain equilibrium.[1243] Whether one or more of these mechanisms is relevant, morphine must be used with caution in preterm infants and in infants younger than 1 year of age. Significant histamine release may follow a rapid IV bolus of morphine and, on rare occasions, result in systemic hypotension.[1244] Urticaria over the course of the vein in which morphine was infused is a local, not systemic, allergic reaction.

M6G can also contribute to respiratory depression in children with renal failure. M6G has a $T_{1/2}$keo of 6.7 hours (range 4–8 hours) for both analgesic effect and for respiratory depression. The EC_{50} for morphine and M6G of 16.9 ng/mL (range 10–18 ng/mL) and slope parameter (n = 2.35) are also similar.[1245]

The incidence of postoperative nausea and vomiting (PONV) is related to the morphine dose; doses in excess of 0.1 mg/kg are associated with a greater than 50% incidence of vomiting in children.[1246,1247] For unclear reasons, Latino children have a 4-fold greater incidence of pruritus and a 7-fold greater incidence of vomiting with similar morphine and morphine metabolite values.[1248] Gender may also be a factor as another study of children undergoing tonsillectomy found a significantly greater incidence of PONV in Caucasian females compared with Caucasian males (P = 0.001) as well as a prolonged stay in the postanesthesia care unit (P = 0.01).[1249]

Withdrawal symptoms may be observed in neonates after cessation of a continuous morphine infusion for more than 2 weeks, and after infusion periods less than 2 weeks if the morphine infusion rate is greater than 40 µg/kg per hour. Strategies to prevent withdrawal from morphine include the use of neuraxial analgesia, nurse-controlled sedation management protocols, ketamine or

TABLE 7.11 Relative Comparison of Commonly Used Oral and Parenteral Opioids in an Adult

Drug	Parenteral Dose (mg)	Oral Dose (mg)	Half-Life (Hours)
Morphine	10	30–40	2.0–3.5
Hydromorphone	1.5–2.0	6.0–7.5	2–4
Oxycodone		15–30	2–4
Methadone	7.5–10.0	15	22–25
Meperidine	75–100	300	3–5
Codeine	120–130	200	3
Fentanyl	0.1	0.1	0.5

naloxone mixed with morphine infusion, and the use of alternate agents (e.g., methadone) with lower potential for tolerance.[1250,1251] Table 7.11 summarizes the relative doses of opioids administered to adults via the parenteral and oral routes.

The use of oral morphine for tonsillectomy pain and other chronic painful conditions is increasing after the safety issues regarding codeine were promulgated by the FDA and the American Academy of Pediatrics.[1226,1252–1254] There are limited data available in children.[1234,1255] A starting dose of 1.5 to 2 mg/kg per day has been suggested for children with chronic pain.[1256] These doses may be excessive for children with acute pain, particularly those sensitized by OSA. Conversion from IV to oral morphine is estimated at 3 to 6 mg equivalent to 1 mg IV and oral morphine solutions are available in multiple concentrations. Extended-release tablets are also available again with limited pediatric data and are likely only useful for teenagers with chronic pain.

MEPERIDINE

Meperidine (pethidine, Demerol) has been traditionally considered a potent opioid to treat severe pain; meperidine is no longer indicated as an analgesic (because of its adverse effects and metabolites). Because repeated doses of meperidine may result in the accumulation of normeperidine, which causes seizures,[1257,1258] this drug has been removed from the formulary in many children's hospitals. We do not recommend the use of this opioid other than for a single-dose administration. Meperidine is a weak opioid, primarily a μ-receptor, agonist that has a potency approximately one-tenth that of morphine. The analgesic effects are detectable within 5 minutes of IV administration, and peak effect is reached within 10 minutes in adults ($T_{1/2}$keo of approximately 7–8 minutes).[1259,1260] Meperidine is metabolized by *N*-demethylation to meperidinic acid and normeperidine. Meperidine clearance in infants and children is approximately 8 to 10 mL/minute per kilogram.[1261,1262] Elimination in neonates is greatly reduced, and elimination half-time in neonates who have received meperidine by placental transfer may be 2 to 7 times greater than that in adults.[1263] The elimination half-life of meperidine in children after IV administration is approximately 3 ± 0.5 hours,[1261] with a very variable half-life in neonates between 3.3 and 59.4 hours.[1262] The Vdss in infants, 7.2 (3.3–11) L/kg,[1262] is greater than that in children 2 to 8 years (2.8 ± 0.6 L/kg).[1261]

In children, meperidine is indicated only to stop shivering, not for analgesia. Although its onset time is more rapid than morphine, the risk of seizures after repeated dosing in children has all but removed it from routine clinical use. The dose of meperidine is 1 to 2 mg/kg (see Table 7.11), although reduced doses should be used in critically ill children. Peak plasma values after IV, IM, and rectal administration are 5 minutes, 10 minutes, and 60 minutes, respectively.[1264,1265] Rectal administration of meperidine in children results in wide variations in systemic bioavailability (32%–81% of administered dose) and **is not recommended**.[1261]

In infants, respiratory depression after meperidine is less than that after morphine; the larger Vd of meperidine may contribute.[1241] The LD_{50} of meperidine in the neonatal animal is only 20% less than in the adult animal, corresponding with the human clinical response.[201] This is consistent with the reduced respiratory depression with meperidine compared with the equivalent dose of morphine. As with any opioid, the use of meperidine in very young infants must be accompanied by careful observation for respiratory depression and airway obstruction because the PK vary considerably.[1262] Meperidine was used for a number of years as a component of various "lytic cocktails" that provided sedation. The safety of these admixtures is dubious, and its use in sedation mixtures is not indicated.[1266]

HYDROMORPHONE

Hydromorphone (Dilaudid) is a semisynthetic congener of morphine with a potency of around 5 to 7.5 times that of morphine.[1267] The IV and IM dose is 10 to 20 μg/kg with a continuous IV infusion of 1 to 4 μg/kg per hour. Its bioavailability is about 55% after nasal and oral (30–80 μg/kg every 3 to 4 hours) administration and about 35% after rectal administration (not recommended)[1268–1270]; there is extensive first-pass metabolism.[1271] A clearance of 51.7 (range, 28.6–98.2) mL/minute per kilogram is reported in children, with a half-life of 2.5 ± 0.9 hours.[1268,1272] Hydromorphone is metabolized to hydromorphone-3-glucuronide (95%) and to other metabolites and does not appear to present added risk caused by polymorphisms.[1273]

Hydromorphone is commonly used when prolonged analgesia is required.[1274–1277] Morphine is often changed to hydromorphone to reduce the adverse effects or because of concern of accumulation of morphine metabolites, particularly in the presence of renal failure.[1278] Hydromorphone is commonly administered intravenously, orally, epidurally, and intranasally.[1267,1274,1275,1279–1282] Hydromorphone is used for chronic cancer pain, and plasma concentrations of around 4.7 ng/mL (range 1.9–8.9 ng/mL) relieve mucositis in children given patient-controlled analgesia devices.[1267,1272] Some may require greater plasma concentrations (10–30 ng/mL) to control severe pain. Oral extended-release formulations are available, and a pediatric trial of children 7 to 17 years of age is in progress (FDA.gov).

OXYCODONE

Oxycodone (OxyContin) is a long-acting semisynthetic opioid that is usually administered orally and is available in controlled-release formulations.[1283–1285] Metabolism is through CYP3A-mediated *N*-demethylation to noroxycodone and CYP2D6 *O*-demethylation to oxymorphone and noroxymorphone; these pathways are immature in neonates.[1286,1287] Extremely preterm neonates have a median elimination half-life of 8.8 hours (range 6.8–12.5 hours); the half-life in preterm neonates is 7.4 hours (4.2–11.6 hours) and in older neonates it is 4.1 hours (2.4–5.8 hours). Infants aged 6 to 24 months have a smaller half-life of 2.0 hours (1.7–7.2.6 hours). Median renal clearance is fairly constant in all age groups, whereas nonrenal clearance increases markedly with age.[1286–1289]

Clearance matures within the first year of life. Maturation aspects of clearance in children 6 months to 7 years are adequately described using allometric models; $CL/F = 55 \times (Wt/70)^{0.87}$ L/hour/70 kg, $Vd/F = 86 \times (Wt/70)^{1.16}$ L/70 kg.[1288] Clearance is similar in children 5.4 years (range 2–9 years) given oxycodone hydrochloride (0.1 mg/kg) by IV bolus after ophthalmic surgery. Mean values of drug clearance and volume of distribution (Vdss) are 46 L/hour per 70 kg and 147 L/70 kg.[1290] As with many medications, interindividual variability in the elimination half-life of oxycodone in the neonate is extreme.[1288] In children, the elimination half-life after IV, buccal, IM, or orogastric administration is 2 to 3 hours.[1289] Clearance may be decreased in patients with liver dysfunction.[1291]

The relative bioavailability in adults of intranasal, oral, and rectal formulations is approximately 50% that of the IV route. The buccal and sublingual absorption of oxycodone is similar in young children.[1272] The bioavailability after various routes is IM, 68%; buccal, 55%; and orogastric, 37%.[1289,1292] Oxycodone may also be administered rectally, with a similar bioavailability, although absorption can be prolonged; **this route is not recommended**.[1293] The IV formulation of oxycodone significantly depresses respiration; 0.1 mg/kg in children after ophthalmic surgery caused greater ventilatory depression than other opioids.[1288,1290,1294,1295] Maximum mean $ETCO_2$ concentration and minimum mean ventilatory rate occurred 8 minutes after administration of oxycodone IV in children, but the minimum mean peripheral arteriolar oxygen saturation occurred at 4 minutes.

CYP2D6 catalyzes *O*-demethylation producing oxymorphone, which accounts for 10% of the circulating oxycodone metabolites and is 14 times more potent than oxycodone because of its 40-fold greater affinity for the mu-opioid receptor compared with oxycodone. Consequently, "fast metabolizers" who are breastfeeding mothers may expose their infants to excessive opioids.[1290,1296] Clearance may also be decreased in patients with liver dysfunction.[1291] This opioid is commonly used to transition from patient-controlled analgesia and to treat chronic painful conditions (see Chapters 44 and 45).[1290] The therapeutic concentration range is broad: 10 to 100 ng/mL.[54,1297]

HYDROCODONE

Hydrocodone is also metabolized by the CYP2D6 enzyme system to the active metabolite hydromorphone (see also Chapter 6). One study of adult females after cesarean section found that 60% were extensive metabolizers, 30% intermediate, 3% poor, and 7% ultrarapid. This genotypic variability can have profound effects on effectiveness and the potential for toxicity with ultrarapid metabolism.[1298] A pediatric study of African American children treated for sickle cell disease found a similar distribution of metabolic conversion from hydrocodone to hydromorphone.[1299] Thus caution is advised as both inadequate analgesia and potential overdose are possible with this opioid.[1300–1302] This drug is frequently provided in combination with acetaminophen in fixed doses (e.g., Lortab elixir); therefore it is essential to avoid adding other acetaminophen-containing analgesics when it is prescribed. The dose should be based on ideal body weight.[1303] The dose should be reduced by 33%–50% for children at risk for OSA. The therapeutic concentrations are 10 to 40 ng/mL.[1304]

METHADONE

Methadone is a synthetic opioid with an analgesic potency similar to that of morphine but with a more rapid distribution and a slower elimination. Methadone is used as a maintenance drug in opioid-addicted adults to prevent withdrawal. Methadone might have beneficial effects because it is a long-acting synthetic opioid with a very high bioavailability (80%) by the enteral route. It also has NMDA receptor antagonistic activity and this may be beneficial in chronic pain treatment because agonism of this receptor is associated with opioid tolerance and hyperalgesia. Methadone is a racemate, and clinical effect is a result of the *R*-methadone isomer. Methadone is 2.5 to 20 times more analgesic than morphine.[1305]

The primary indication for methadone in children is to wean from long-term opioid infusions to prevent withdrawal, and to provide analgesia when other opioids have failed or have been associated with intolerable side effects.[1306] Oral administration has been recommended as the first-line opioid for severe and persistent pain in children.[1307] It seems also to be a safe enteral alternative for IV opioids in palliative pediatric oncologic patients.[1308]

IV methadone has been shown to be an effective analgesic for postoperative pain relief. The minimum effective analgesic concentration of methadone in opioid-naïve adults is 58 μg/L,[1309] while no withdrawal symptoms were observed in neonates suffering opioid withdrawal if plasma concentrations of methadone exceeded 60 μg/L.[1310] The racemate of methadone, which is commonly used in pediatric and anesthetic care, is metabolized to EDDP (2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine) and EMDP (2-ethyl-5-methyl-3,3-diphenylpyrroline).

Methadone is cleared by the cytochrome P450 mixed oxidase (CYP3A4, CYP2B6, and CYP2D6) enzyme systems, all of which are immature at birth. CYP3A7 may contribute to clearance in the neonate.[1311,1312] Methadone has high lipid solubility with a large Vd of 6 to 7 L/kg in children and adults.[1313,1314] Pharmacokinetic parameters, standardized to a 70-kg adult using allometry, have been estimated using a three-compartment linear disposition model. Population parameter estimates (CV, between subject variability) were central volume (V1) 21.5 (29%) L/70 kg; peripheral volumes of distribution V2 75.1 (23%) L/70 kg; V3 484 (8%) L/70 kg; clearance (CL) 9.45 (11%) L/hour per 70 kg; and intercompartment clearances Q2 325 (21%) L/hour per 70 kg, Q3 136 (14%) L/hour per 7 kg. EDDP formation clearance was 9.1 (11%) L/hour per 70 kg; formation clearance of EMDP from EDDP was 7.4 (63%) L/hour per 70 kg; elimination clearance of EDDP was 40.9 (26%) L/hour per 70 kg; and the rate constant for intermediate compartments was 2.17 (43%) per hour.[1315] These parameter estimates in children and neonates are consistent with those reported by others in neonates,[1251] children,[1314] adolescents,[1316] and adults.[1317] There was no clearance maturation with age. Neonatal enantiomer clearances were also similar to those described in adults.[1315]

An IV regimen of 0.2 mg/kg 8 hourly in neonates achieves a target concentration of 60 μg/L within 36 hours. Infusion, rather than intermittent dosing, should be considered if this target is to be achieved in older children after cardiac surgery. Analgesic responses in adults on chronic methadone programs suggests a steep concentration-response relationship for pain relief (Hill = 4.4 ± 3.8) with very rapid equilibration between plasma methadone concentrations and the sites mediating pain relief. Consequently, the drug rapidly loses effect as concentrations decrease to less than EC_{50}. A single dose of 0.2 mg/kg will contribute little analgesia after a few hours. An infusion (Fig. 7.24) has been suggested for analgesia in adolescents after spinal instrumentation surgery,[1316] and consideration could be given to this technique after cardiac surgery in children. It should be noted that methadone, like other opioids, has large between-subject PK variability that could result in drug accumulation and possible fatal outcomes with long-term administration.[1318]

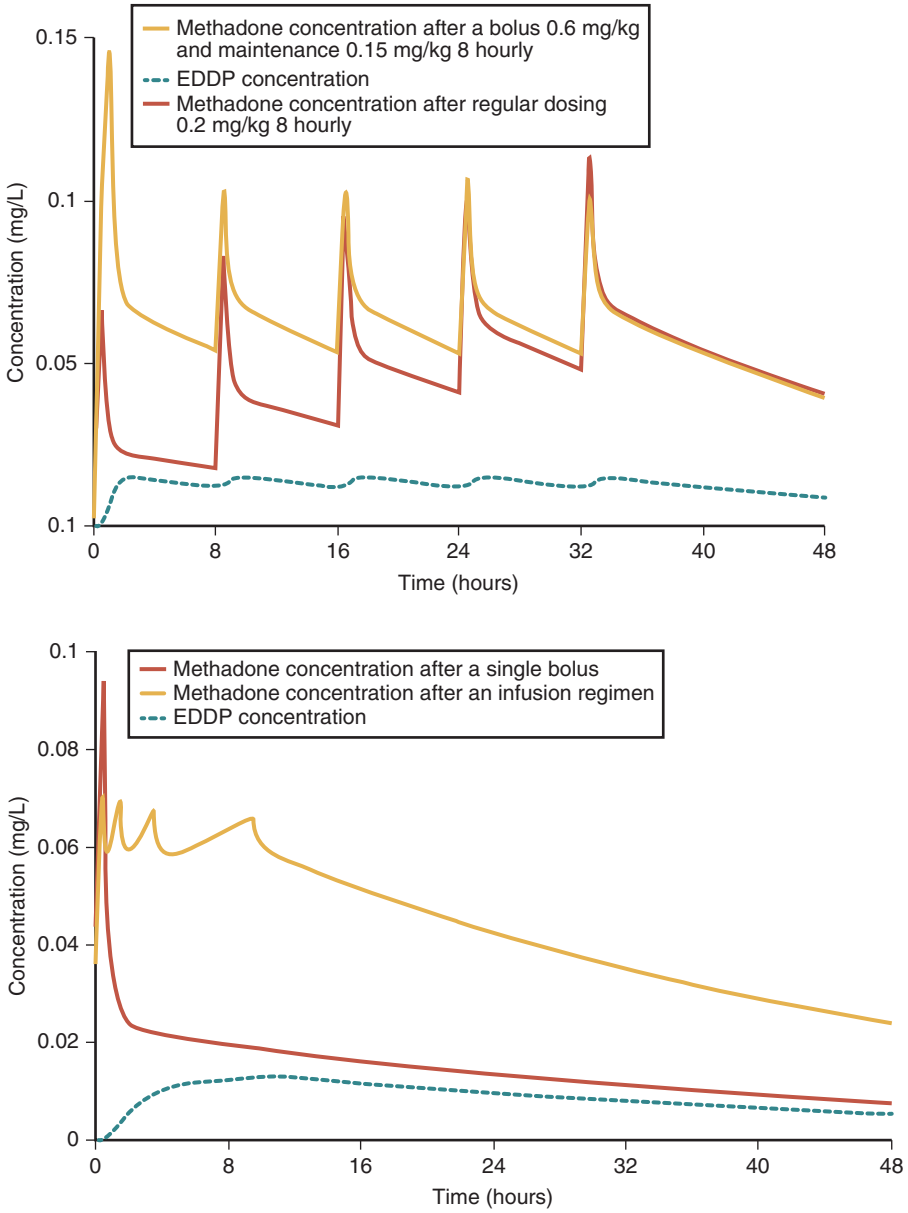

FIGURE 7.24 The upper panel shows a simulation for a 3.5-kg neonate given a methadone loading dose of 0.6 mg/kg followed by a maintenance dose of 0.15 mg/kg 8 hourly. EDDP concentrations track parent drug concentrations. The methadone target concentration of 0.06 mg/L is achieved rapidly compared with the neonate given 0.2 mg/kg 8 hourly without a loading dose. A single dose of methadone 0.2 mg/kg given for postoperative analgesia in a child is unlikely to achieve long duration of analgesia because concentrations are below 0.03 mg/kg within 1.5 hours (lower panel). An infusion may be a better option. A regimen consisting of a methadone bolus of 0.15 mg/kg followed by 0.15 mg/kg per hour for 1 hour, 0.075 mg/kg per hour for 2 hours, and 0.025 mg/kg per hour for 6 hours maintains a concentration of 0.06 mg/L. EDDP concentrations after this infusion regimen are also shown. *EDDP,* 2-ethylidene-1,5-dimethyl-3,3-diphenylpyrrolidine. (From Ward RM. The pharmacokinetics of methadone and its metabolites in neonates, infants, and children. *Paediatr Anaesth.* 2014;24(2):591–601, with permission.)

FENTANYL

Fentanyl (Sublimaze) offers greater hemodynamic stability than morphine, a rapid onset ($T_{1/2}$keo of 6.6 minutes in adults), and a short duration of effect. Its relative increased lipid solubility and small molecular conformation enables efficient penetration of the BBB and redistribution. It is the most commonly used opioid during general anesthesia in infants and children. It is particularly effective in the care of high-risk preterm and term neonates, as well as in infants and children during cardiac surgical procedures. High doses of fentanyl (10–100 μg/kg) are often administered to maintain cardiovascular homeostasis.[1154,1319–1329] Fentanyl may be administered intravenously, intramuscularly, intranasally, as a supplement to epidural analgesia, orally, oral transmucosal absorption, and transdermally–both passively and by iontophoresis.[1330–1337]

Fentanyl is metabolized by oxidative *N*-dealkylation (CYP3A4) into norfentanyl and hydroxylated. All metabolites are inactive and a small amount of fentanyl is eliminated via the kidneys

unchanged. Compared with term neonates, the clearance of fentanyl in preterm infants is markedly reduced (mean elimination half-life is 17.7 ± 9.3 hours), contributing to prolonged respiratory depression in preterm neonates. Clearance matures with gestational age; 7 mL/minute per kilogram at 25 weeks PMA, 10 mL/minute per kilogram at 30 weeks PMA, and 12 mL/minute per kilogram at 35 weeks PMA.[1338] The clearance of fentanyl is 70% to 80% of adult values in term neonates and, when standardized to a 70-kg person, reaches adult values (~50 L/hour per 70 kg) within the first 2 weeks of life.[852] Clearance of fentanyl in older infants (>3 months of age) and children is greater than that in adults when expressed per kilogram (30.6 mL/kg per minute vs. 17.9 mL/kg per minute, respectively), resulting in a reduced elimination half-life (68 minutes vs. 121 minutes, respectively).[1319,1322,1339–1341]

The Vdss of fentanyl is approximately 5.9 L/kg in term neonates and decreases with age to 4.5 L/kg during infancy, 3.1 L/kg during childhood, and 1.6 L/kg in adults.[1342] This increased Vdss results in a smaller blood concentration after bolus administration in neonates and infants.[1343] Administration of fentanyl 3 µg/kg by slow IV push in term infants (1–7 months of age) intraoperatively neither depressed respiration nor caused hypoxemia in placebo-controlled trials.[1344,1345] Slow administration and both an increased Vdss and an increased clearance (per kilogram) in this age group contributed to these results. Fentanyl clearance may be impaired with decreased hepatic blood flow (e.g., from increased intra-abdominal pressure in neonatal omphalocele repair), although a maldistribution of blood away from regions of concentrated cytochrome enzyme activity in the liver may also play a role.[1346]

Infants with cyanotic heart disease had reduced Vdss and greater plasma concentrations of fentanyl with infusion therapy.[1321] These greater plasma concentrations resulted from a reduced clearance (34 L/hour per 70 kg), which was attributed to hemodynamic disturbance and consequent reduced hepatic blood flow.[1347] Hypothermia also reduces fentanyl clearance.[1348] Profound hypotension has been reported after a bolus of midazolam in neonates in whom fentanyl was infused and vice versa.[1349] Other drugs metabolized by CYP3A4 (e.g., cyclosporine, erythromycin) may compete for clearance and result in increased fentanyl plasma concentrations.

Fentanyl is a potent µ-receptor agonist with a potency 70 to 125 times greater than that of morphine. A plasma concentration of 15 to 30 ng/mL is required to provide total IV anesthesia in adults, whereas the EC_{50}, based on EEG evidence, is 10 ng/mL.[1350,1351] Fentanyl has been shown to effectively prevent preterm neonates from surgical stress responses and to improve postoperative outcomes.[1352] Single doses of fentanyl (3 µg/kg) can reduce the physiologic and behavioral measures of pain and stress associated with mechanical ventilation in preterm infants.[1353] Fentanyl has similar respiratory depression in infants and adults when plasma concentrations are similar.[1354]

The PK of fentanyl in critically ill children receiving long-term infusions is also quite variable, with a mean terminal elimination half-life of 21 hours and a range of 11 to 36 hours.[1355,1356] The infusion rates of fentanyl that are required to achieve a similar level of sedation and analgesia may vary as much as 10-fold.[1355] This variability in PK and PD strongly reinforces the need to titrate the dose to effect and to be prepared to provide postoperative ventilatory support as needed. Children receiving a long-term infusion of fentanyl are at risk of rapidly developing tolerance with a doubling of opioid dose more likely to occur after 7 days[1357]; on discontinuance of the infusion, these children may demonstrate signs of withdrawal. Continuous infusions of fentanyl in mechanically ventilated preterm infants combined with intermittent boluses have been shown to reduce acute pain compared with bolus dosing alone.[1358] All long-term infusions should be tapered slowly over days rather than discontinuing them abruptly.[1340,1359,1360]

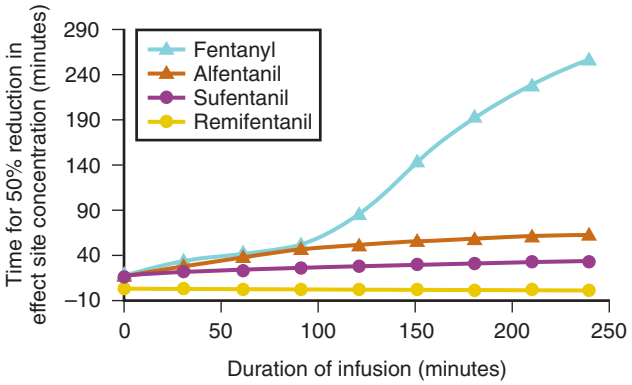

FIGURE 7.25 This figure is a simulation of the time required for a 50% reduction in the effective site concentration of remifentanil (*yellow circles*), sufentanil (*purple circles*), alfentanil (*brown triangles*), and fentanyl (*blue triangles*) after an infusion (duration of 240 minutes) designed to maintain a constant effect-site concentration. Note that there is a completely flat curve for remifentanil, suggesting that a plateau effect is rapidly reached with remifentanil compared with the other opioids, such that even after a long infusion, the time to 50% reduction in effect-site concentration is still less than 4 minutes. (Redrawn and modified with permission from Westmoreland CL, Hole JF, Sebel PS, Hug CC Jr, Muir KT. Pharmacokinetics of remifentanil [GI87084B] and its major metabolite [GI90291] in patients undergoing elective inpatient surgery. *Anesthesiology* 1993;79(5):893–903.)

With low-dose fentanyl, the termination of action is primarily a combination of redistribution and rapid clearance by the liver.[1340,1361] The CSHT after a 1-hour infusion of fentanyl is approximately 20 minutes, which increases to 270 minutes after an 8-hour infusion in adults (Fig. 7.25).[23] Although the CSHT is reduced in children, there are no data in neonates.[1341] High-dose fentanyl, accumulates in muscle and fat and is therefore released (recirculated) more slowly, thus accounting in part for the prolonged respiratory depression after large doses. There is no evidence of dose-dependent kinetics–that is, there is no tissue or enzyme saturation in the clinically used ranges.[1361] In some respects, the pharmacology of opioids is very similar to that of barbituates: at low doses their clinical effect is terminated by redistribution, whereas at large doses their clinical effect is terminated by metabolism.[1354,1361–1364]

The usual initial dose of fentanyl is 1 to 3 µg/kg, a dose that may be supplemented as clinically indicated. Fentanyl is very lipid soluble and rapidly crosses the BBB. This characteristic may, in part, explain why the LD_{50} for fentanyl in neonatal animals is 90% of that in adult animals. Continuous intraoperative and postoperative infusions of fentanyl are common in children of all ages.[1321,1364,1365] Fentanyl is also used to provide patient-controlled analgesia (see Chapter 44).[1366,1367]

Chest wall and glottic rigidity have been reported after IV administration of opioids, although most often after fentanyl. The reason for this is not clear.[1368–1373] Glottic rigidity may account for the inability to ventilate by bag and mask after IV fentanyl.[1373,1374] This adverse response can be minimized by administering the opioid slowly, and it can be reversed by administering either a muscle relaxant or naloxone.[1374] Another concern is the rare association of increased vagal tone with bolus administration;

bradycardia may have profound effects on the cardiac output of neonates. Additionally, fentanyl markedly depresses the baroreceptor reflex control of heart rate in neonates.[1375] It is for these reasons that pancuronium (with its vagolytic effect) is often combined with high-dose fentanyl and why atropine is administered before a fentanyl-succinylcholine combination for neonatal intubation.[1376]

Oral transmucosal fentanyl (Fentanyl Oralet) was approved by the FDA for premedication of children but is no longer marketed. A new formulation (Actiq) has been approved for adults and children 16 years of age or older, but it has been used off-label in children for the treatment of cancer breakthrough pain.[1377–1379] This route of administration provides more rapid onset of analgesia than buccal immediate-release tablets but is slower in onset than nasal administration.[1379] Fentanyl is rapidly absorbed through the oral mucosa, which bypasses the liver.[794,1331,1332,1380–1384] Nonetheless, approximately half the absorption is gastrointestinal. The bioavailability of this formulation in children (33%) is less than that in adults (50%).[1331,1332] Uptake continues for a period of time after consumption, which potentially can provide analgesia for several hours.[794,1331,1332]

The fentanyl patch was developed to provide an extended release of fentanyl similar to that provided with a continuous IV infusion.[1330,1385–1394] *This formulation was not designed to be administered to treat postsurgical pain, but rather for those who require opioids chronically.* This fentanyl transdermal therapeutic system (TTS) is available with a drug release rate of 12.5 μg/hour and matches the smaller dosing requirements of cancer pain control in children.[1395] An approximate conversion factor of 45 mg/day oral morphine to 12.5 g/hour fentanyl TTS is used for initial dose estimation in children receiving long-term morphine therapy. This is conservatively low to avoid respiratory depression. In adults, uptake of fentanyl begins within 1 hour and achieves therapeutic levels within 6 to 8 hours and peak levels at 24 hours.[1391,1394,1396] In children, the peak occurs earlier, at about 18 hours.[1397] The skin acts as a reservoir, and even after removal of the patch, uptake continues for several hours, with a consequent apparent elimination half-life of 14.5 ± 6 hours.[1397] Fentanyl uptake is markedly affected by skin blood flow, skin thickness, location of the patch, and adherence to the skin.[1395,1398–1400] Alterations in skin blood flow (e.g., fever) may increase absorption.[1401] Alterations to skin blood flow caused by warming devices (increased absorption) or hypothermia (decreased absorption) during anesthesia should be considered in children with chronic pain who present with TTS fentanyl.

The use of TTS medication should be limited to pain specialists who are familiar with the unusual PK of this drug delivery system.[1402] One study suggests that the PK of fentanyl by this route in children and adult patients are similar.[1397] A multicenter study in children 2 to 16 years of age reported satisfactory long-term analgesia. However, it should be noted that the data submitted to the FDA revealed plasma concentrations of fentanyl in children 1.5 to 5 years of age that were twice those in adults.[1403] These data are consistent with another study that found a negative correlation between fentanyl concentrations and age—that is, greater concentrations in younger children.[1397] Children may be particularly vulnerable to the rapid drug absorption compared with adults because they have thinner skin and better skin blood flow.[905] Accordingly, it seems prudent to begin with the smallest size patch and gradually increase as indicated (see Chapters 44 and 45). All patches, including those that have already been used, contain large amounts of fentanyl that may cause a fatal intoxication if accidentally or intentionally ingested or improperly applied.[1404–1406] Proper disposal of these opioid-containing patches is required.

Epidural fentanyl is often combined with an amide local anesthetic for provision of postoperative analgesia; pruritus, nausea, and vomiting may be exacerbated by the addition of fentanyl. Spread beyond the site of administration is dose dependent but limited, and respiratory depression is uncommon.[1283,1407] It should be noted, however, that plasma concentrations may increase for a period of time after cessation of epidural fentanyl, thus prolonging the potential for respiratory depression for several hours.[1337]

ALFENTANIL

Alfentanil (Alfenta) is a fentanyl analog whose main advantage is its reduced lipid solubility and smaller Vd compared with fentanyl.[1408] It has a rapid onset ($T_{1/2}$keo of 0.9 minutes in adults), a brief duration of action, and one-fourth the potency of fentanyl. A target plasma concentration of 400 ng/mL is used in anesthesia. Metabolism is through oxidative *N*-dealkylation by CYP3A4 and *O*-dealkylation and then conjugation to metabolites that are excreted renally.[1409] Studies indicate that brain concentrations of alfentanil are 7-fold to 9-fold less, the Vd is four times less, and protein binding is greater than fentanyl.[1410]

Alfentanil is more rapidly eliminated from the body than fentanyl, thus necessitating more frequent dosing. Clearance in neonates (20–60 mL/minute per 70 kg) is one-tenth that in adults (250–500 mL/minute per 70 kg) with rapid maturation.[68] In preterm neonates, the half-life is as long as 6 to 9 hours.[1411,1412] The Vd in children and adults are similar but are increased in preterm neonates (Vd 1.0 ± 0.39 vs. 0.48 ± 0.19 L/kg). Clearance is greater in children, expressed as per kilogram (11.1 ± 3.9 mL/kg per minute vs. 5.9 ± 1.6 mL/kg per minute). As a result, the elimination half-life in children is less (63± 24 vs. 95 ± 20 minutes).[1413–1416] The Vd and elimination half-life in infants 3 to 12 months of age and older children are similar.[1415] Because clearance is markedly diminished in children with hepatic disease, clinical effects are prolonged in those with reduced hepatic blood flow (e.g., children with increased intraabdominal pressure, children receiving vasopressors, and those with some forms of congenital heart disease).[1408,1417,1418] Renal failure has little effect on its elimination.[1419] Because less alfentanil is bound to α_1-acid glycoprotein in preterm infants (65%) than in term infants (79%), an increased unbound fraction of alfentanil is available for biologic effect in the former.[80]

The PK and PD of alfentanil suggest potential applications for the rapid control of analgesia and awakening from anesthesia. Alfentanil (10 μg/kg) has been combined with propofol (2.5 mg/kg) for tracheal intubation without an NMBD.[1420] High-dose alfentanil is also used for cardiac procedures. Alfentanil should be used with caution without NMBDs in neonates because of the frequency of chest wall or glottic rigidity.[1262,1421]

SUFENTANIL

Sufentanil (Sufenta) is a potent synthetic opioid that in many respects is similar to fentanyl and alfentanil. Sufentanil is 5 to 10 times more potent than fentanyl, with a $T_{1/2}$keo of 6.2 minutes in adults.[1422] A concentration of 5 to 10 ng/mL is required for total IV anesthesia, and 0.2 to 0.4 ng/mL for analgesia. PD differences are suggested in neonates. The plasma concentration of sufentanil at the time of additional anesthetic supplementation to suppress hemodynamic responses to surgical stimulation was 2.51 ng/mL in neonates, significantly greater than the concentrations of 1.58, 1.53, and 1.56 ng/mL observed in infants, children, and adolescents, respectively.[1423]

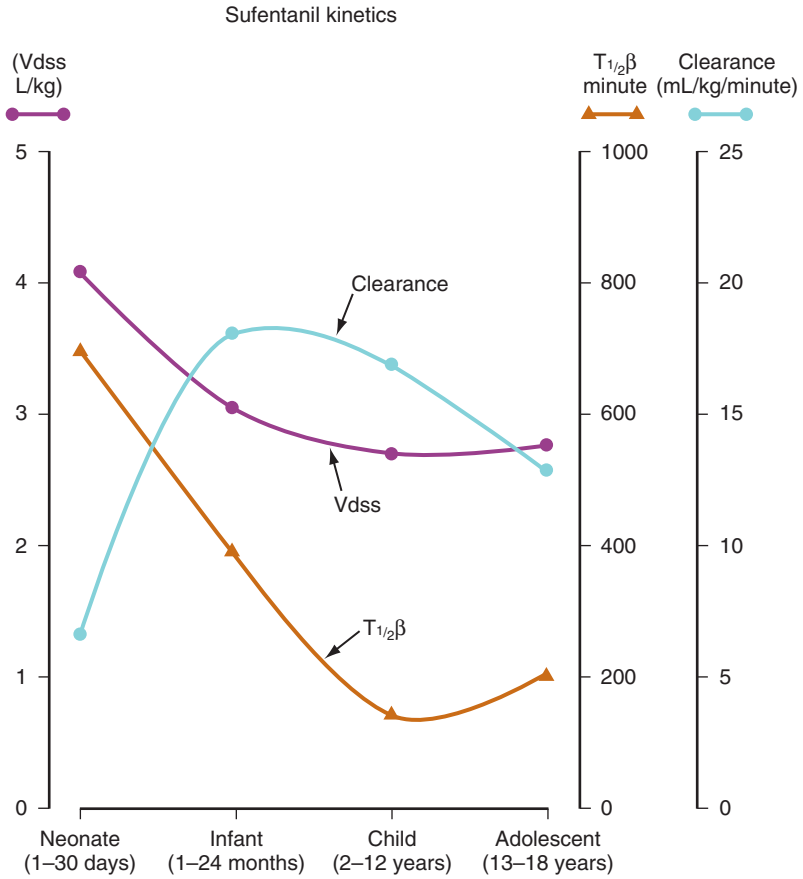
Elimination of sufentanil is by *O*-demethylation and *N*-dealkylation in animal studies. As with fentanyl and alfentanil, the CYP3A4 enzyme is responsible for the *N*-dealkylation.[1424] The majority of studies of IV sufentanil in children have focused on those undergoing cardiac surgery. Evidence has shown age-dependent PK in which neonates have a larger Vdss, reduced clearance, and a greater and more variable elimination half-life than older children and adults (E-Fig. 7.18).[1423,1425,1426] Clearance in neonates undergoing cardiovascular surgery (6.7 ± 6.1 mL/kg per minute) is reduced compared with values of 18.1 ± 2.7, 16.9 ± 3.2, and 13.1 ± 3.6 mL/kg per minute in infants, children, and adolescents, respectively,[1423] which is consistent with rapid development of hepatic metabolic pathways.[1425] Clearance maturation standardized to a 70-kg person using allometry is similar to that of other drugs that depend on CYP3A4 for metabolism (e.g., levobupivacaine, fentanyl, alfentanil) (see Fig. 7.11).[1427] Clearance rates in infants (27.5 ± 9.3 mL/kg per minute) were greater, expressed per kilogram, than those in children (18.1 ± 10.7 mL/kg per minute) in another study of children undergoing cardiovascular surgery.[1426]

Clearance in healthy children (2–8 years) was greater (30.5 ± 8.8 mL/kg per minute) than in those undergoing cardiac surgery.[1428] Decreased hepatic blood flow reduces clearance.[1428] The elimination of sufentanil is unaffected by renal failure but markedly altered by factors that influence hepatic blood flow; cirrhosis apparently has little effect on its elimination.[1408,1429,1430] The Vdss was 4.15 ± 1.0 L/kg in neonates, greater than the values of 2.73 ± 0.5 and 2.75 ± 0.5 L/kg observed in children and adolescents, respectively.[1423,1428]

Bradycardia and asystole have been observed after a bolus administration of sufentanil, suggesting that pretreatment with a vagolytic agent (atropine, glycopyrrolate, or pancuronium bromide) may be sensible.[1431,1432]

Nasal sufentanil may have a role for sedation/analgesia in children undergoing painful procedures,[118] although data in neonates are lacking and there are concerns about the risk of respiratory depression.[1433–1438] Several studies demonstrated that children are more likely to accept nasal sufentanil compared with nasal midazolam, although there was a greater incidence of vomiting after sufentanil and several children experienced decreased chest wall compliance after or during induction of anesthesia. The dose of sufentanil that is most effective when administered intranasally is 2 to 3 μg/kg.[1434,1436] Epidural sufentanil (0.7–0.75 μg/kg) has been effective in children, lasting more than 3 hours, although pruritus can be bothersome.[1439–1441] If administered as a continuous epidural infusion, it should be noted that sufentanil is slowly eliminated. Plasma concentrations may continue to increase even after discontinuation, which could potentially lead to respiratory depression.[1442] Nasal sufentanil 0.5 μg/kg had a maximum plasma concentration (C_{max}) of 0.042 μg/L at 13.8 minutes.[118]

REMIFENTANIL



Remifentanil (Ultiva) is the newest in the family of synthetic opioids.[1443,1444] Its brief elimination half-life of 3 to 6 minutes requires that it be given as an infusion.[185,1445–1447] This opioid is unique because blood and tissue esterases rapidly terminate its action by degrading an ester linkage in the molecule to a carboxylic acid metabolite.[1448] Metabolism is unaffected by hepatic or renal function.[1449] The active metabolite of remifentanil that is eliminated by the kidneys has approximately 1/300th to 1/1000th the opioid activity of the parent compound and, theoretically, could accumulate and cause clinical manifestations in children with impaired renal function.[1450] One study in adults failed to demonstrate any residual opioid effects after a 12-hour infusion in patients with renal failure.[1451] Perhaps the most important characteristic of remifentanil is its very brief half-life and the associated rapid recovery within about 10 minutes. Clearance in patients with butyrylcholinesterase deficiency is unaffected. The nonspecific blood esterases that metabolize remifentanil are mature at birth.[40]

A target plasma concentration of 2 to 3 μg/L is adequate for laryngoscopy, 6 to 8 μg/L for laparotomy, and 10 to 12 μg/L might be sought to ablate the stress response associated with cardiac surgery (see Chapter 8 for remifentanil use in total IV anesthesia).[1452] Analgesic concentrations are 0.2 to 0.4 μg/L. The $T_{1/2}$keo is 1.16 minutes in adults,[184] but the neonatal $T_{1/2}$keo has not been reported. Analgesic alternatives should be available when the short-duration analgesic effects from remifentanil are dissipating. Reports of a rapid development of μ-receptor tolerance with remifentanil are in conflict; activity at δ-opioid receptors may contribute.[1453] Remifentanil clearance can be described in all age groups by simple application of an allometric model.[39] This standardized clearance of 2790 mL/minutes per 70 kg is similar to that reported by others in children[185,1454] and adults.[184,1444] The smaller the child, the greater the clearance when expressed as milliliters per minute per kilogram. Clearance decreases with increasing age, with rates of 90 mL/kg per minute in infants younger than 2 years of age, 60 mL/kg per minute in children 2 to 12 years of age, and 40 mL/kg per minute in adults (Fig. 7.26 and Table 7.12).[39,185,1454]

The Vdss was greatest in infants younger than 2 months of age (452 mL/kg) and decreased to 308 mL/kg in children 2 months to 2 years, and to 240 mL/kg in children older than 2 years of age.[185] The elimination half-life appears to be constant, approximately 3 to 6 minutes, independent of dose or duration of the infusion,[185,1445] and the CSHT is constant (see Fig. 7.25).[1450] For example, when the infusion rates of remifentanil differed as much as 20-fold, the time to return to spontaneous respirations varied by only 1 to 3 minutes.[1449,1455] As an opioid, the effect of remifentanil on respiration is an excellent reflection of its PD effects.[1456] After 3-hour infusions of alfentanil and remifentanil in adults, the elimination half-lives were 47.3 ± 12 minutes for alfentanil, compared with 3.2 ± 0.9 minutes for remifentanil. The time to recover 50% of the minute ventilation, a PD effect of opioids, was 54.0 ± 48.1 minutes for alfentanil, compared with 5.4 ± 1.8 minutes for remifentanil.[1456]

Although covariate effects, such as cardiac surgery, appear to have a muted effect on PK, cardiopulmonary bypass (CPB) does have an impact. Remifentanil dosage adjustments are required during and after CPB because of marked changes in its Vd.[1457] Other PK changes during CPB are consistent with adult data in which a decreased metabolism occurred with a reduced temperature[1458] and with reports of greater clearance after CPB (increased metabolism) compared with during CPB.[1454]

Respiratory depression is concentration dependent.[1459,1460] Vocal cord closure, commonly interpreted as muscle rigidity, remains a concern with bolus doses above 3 μg/kg used for intubation in neonates.[1461] Induction with propofol (4 mg/kg) and either remifentanil (3 μg/kg) or succinylcholine (2 mg/kg) for intubation was similar, with no bradycardia, hypotension, or chest wall rigidity.[1462] The initial loading dose of remifentanil may cause hypotension and bradycardia,[1463] prompting some to target the plasma rather than effect-site concentration when initiating an infusion. This hypotensive response has been quantified in children undergoing cranioplasty surgery. A steady-state remifentanil

E-FIGURE 7.18 Pharmacokinetics for sufentanil versus age. Note that the β-elimination half-life ($T_{1/2}\beta$) and volume of distribution at steady state (*Vdss*) are inversely related to age; clearance is the smallest in neonates. Children and adolescents have sufentanil pharmacokinetics similar to those of adults. (Data from Greeley WJ, de Bruijn NP, Davis DP. Sufentanil pharmacokinetics in pediatric cardiovascular patients. *Anesth Analg*. 1987;66(11):1067–1072.)

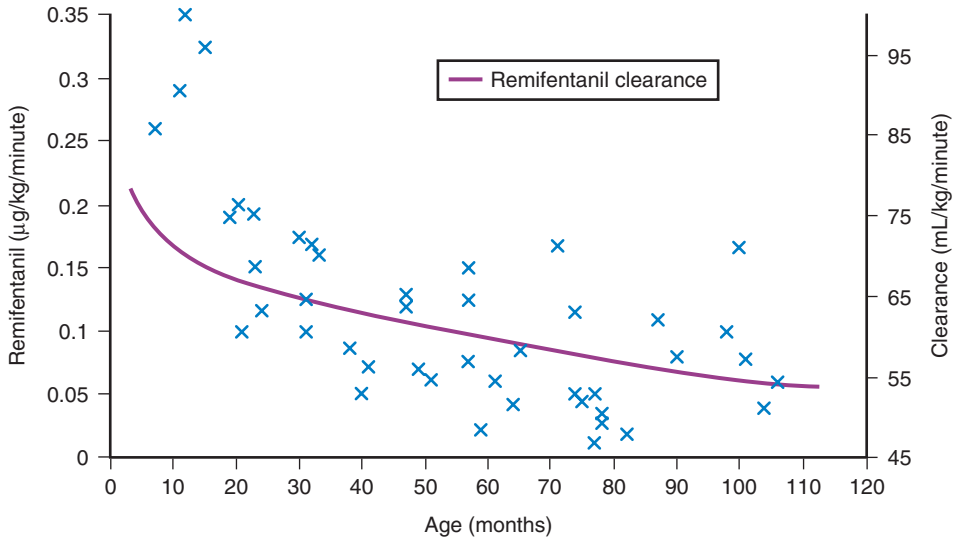


FIGURE 7.26 The effect of age on the dose (infusion rate) of remifentanil tolerated during spontaneous ventilation under anesthesia in children undergoing strabismus surgery.[248] Superimposed on this plot is the estimated remifentanil clearance determined using an allometric model.[76] There is a mismatch between clearance and infusion rate for those individuals still in infancy. The larger infusion rates recorded in those infants can be attributed to greater suppression of respiratory drive in this age group than with the older children during the study; a respiratory rate of 10 breaths/minute in an infant is disproportionately slow compared with the same rate in a 7-year-old child, suggesting excessive dose. (Reproduced with permission from Anderson BJ. Pediatric models for adult target-controlled infusion pumps. *Paediatr Anaesth*. 2010;20(3):223–232; Rigby-Jones AE, Priston MJ, Sneyd JR, et al. concentration of 14 µg/L would typically achieve a 30% decrease in mean arterial pressure. This concentration is twice that required for laparotomy but is easily achieved with a bolus injection. The $T_{1/2}$keo of 0.86 minutes for this hemodynamic effect[58] is less than remifentanil-induced spectral edge frequency changes described in adults ($T_{1/2}$keo of 1.34 minutes).[184,1464]

One theoretical concern associated with the long-term administration of remifentanil is the development of acute tolerance. In a study of adult volunteers, the analgesic threshold was one-fourth of the peak values within 3 hours.[1465] A study of adolescents undergoing spinal instrumentation for scoliosis has also demonstrated acute tolerance.[1466] Another prospective randomized trial in children 1 to 5 years of age undergoing laparoscopic procedures that compared three remifentanil infusions of 0, 0.3, 0.6, and 0.9 µg/kg per minute found that those who received 0.6 or 0.9 µg/kg per minute required more postoperative fentanyl at 24 hours than those who received 0 or 0.3 µg/kg per minute, suggesting that large doses of remifentanil may cause tolerance.[1467]

Remifentanil has an important role in providing safe analgesia to children of all ages, but particularly in very sick preterm infants and children.[1468–1472] Its main advantage is the ability to provide an intense opioid effect with cardiovascular stability during the procedure, and then transition to a less intense opioid effect, allowing for early extubation.[1468,1473] *Remifentanil is the only opioid for which there is a greater rather than a reduced clearance (per kilogram) in neonates (see Fig. 7.26)*, and the reason that it is so valuable in this age group.[1474–1481] These pharmacologic differences have important clinical implications because they translate into the ability to rapidly titrate the opioid effect, without regard to prolonged sedation. *This opioid should be administered only by continuous infusion. If an IV line becomes interrupted, kinked, or disconnected, the opioid effect will rapidly dissipate and the child will show evidence of pain.* Therefore this drug should be "piggybacked" into a continuous infusion carrier as close to the IV cannula as possible to provide smooth constant drug delivery. In neonates, a more dilute concentration is useful (e.g., 5 µg/mL). This also means that at the

end of a procedure, the anesthetic plan must include a transition to some other form of analgesia, including another longer acting opioid or a regional block.[1482]

Although remifentanil can be administered as a loading dose, 0.1 to 0.25 μg/kg, the risk of hypotension and the rapidity of achieving steady-state analgesia (0.05–0.15 μg/kg per minute) with an infusion renders a loading dose unnecessary. However, if a loading dose is used, then the plasma concentration, rather than effect-site concentration, is commonly targeted.[733] The infusion may be titrated to effect with little fear of producing an "overdose" because of the very favorable PK. As with many synthetic opioids, severe bradycardia and hypotension may occur after bolus administration, especially at large doses.[185,1483] Remifentanil may have a direct negative chronotropic effect; therefore the concomitant use of a vagolytic or pancuronium may prevent this adverse cardiac response.[1484,1485] The negative chronotropic effect and the concomitant decrease in BP at large concentrations (e.g., 15–20 ng/mL) may also be used to induce controlled hypotension.[1486,1487]

Remifentanil would seem to be the ideal opioid to provide a deep analgesic effect that allows spinal cord–evoked motor and sensory monitoring.[1488,1489] Nonetheless, anesthesia is not produced by opioids alone. An anxiolytic must be administered to ensure that amnesia occurs. The half-lives of all anxiolytics exceed that of remifentanil, and this needs to be considered during recovery.

Remifentanil has also been used to supplement propofol to facilitate endotracheal intubation without the use of an NMBD.[1490] Several dose-response studies found that about 3 μg/kg of remifentanil combined with ~3 to 4 mg/kg of propofol provided the best intubating conditions, similar to those with an NMBD. Remifentanil 2 μg/kg did not produce satisfactory intubating conditions.[744] Resumption of spontaneous respirations after a remifentanil–propofol combination was similar to that after succinylcholine.[1462,1491,1492] This combination is a reasonable alternative to succinylcholine to facilitate tracheal intubation in children.

BUTORPHANOL AND NALBUPHINE

Butorphanol (Stadol) and nalbuphine (Nubain) are synthetic opioid agonist-antagonist analgesics that are equianalgesic.[1493–1496] They are effective through κ-receptor agonism and partial μ-receptor antagonism, have 0.5 to 0.7 times the potency of morphine, and an antagonist effect 25 times weaker than naloxone. An appealing PD effect is sedation, particularly when compared with midazolam.[1493,1496–1499] The elimination half-life of nalbuphine is significantly smaller in children 1.5 to 5 years of age (0.9 hours) than in children 5 to 8.5 years of age (1.9 hours) and in adults (2.3 hours). A half-life of 4 hours has been reported in neonates, reflecting immaturity of hepatic glucuronide metabolism. The half-life of butorphanol is similar to that of nalbuphine at about 3 hours in adults.[1496,1500–1502] Nalbuphine PK have been reported using allometric scaling in children 1 to 10 years: CL 130 L/hour per 70 kg, Q 75.6 L/hour per 70 kg, V1 210 L/70 kg, and V2 151 L/70 kg.[1502]

Both of these drugs can be administered orally with bioavailability in young adults of 12% to 17%, but this dramatically increases to about 80% when administered to the nasal mucosa.[1501,1503–1505] The claimed advantage of this family of drugs is adequate analgesia with a ceiling on respiratory depression[1493,1494,1506–1508]; thus there is some popularity for use in children,[1509–1515] although a systematic review reported that quantitative analysis of nalbuphine compared with other analgesics for postoperative pain management was lacking.[1516] The administration of butorphanol by the nasal route may offer particular advantage for children without IV access.[1509,1517–1520] One report suggested that the frequency of postoperative vomiting after butorphanol was less than with morphine.[1510] Another describes the use of rectal administration; as expected, the authors found irregular absorption, but peak blood levels were relatively rapidly achieved (25 ± 11 minutes), and the elimination half-life was 2.7 ± 0.7 hours.[1521] **We do not recommend the rectal route of administration.** What must be remembered is that these agents may reverse μ-receptor–mediated analgesic effects of the more potent opioids and should therefore be used as the initial or the sole opioid.

This family of drugs has had mixed results in reversing or preventing opioid-induced pruritus.[1522,1523] Nalbuphine does not reverse respiratory depression after morphine,[1524] but may be effective after fentanyl.[1525] Butorphanol has also been administered by the caudal epidural route (25 μg/kg).[1526,1527]

CODEINE

Codeine, or methylmorphine, is a morphine-like opioid with 10% of the potency of morphine. It is mainly metabolized by glucuronidation, but minor pathways are by N-demethylation to norcodeine and O-demethylation to morphine. However, a full accounting of the metabolism of codeine has remained elusive. Approximately 10% of codeine is metabolized to morphine. As the affinity of codeine for opioid receptors is very low, the analgesic effect of codeine is a result of its morphine metabolite.[1528] Evidence suggests that up to 11% of codeine is metabolized to hydrocodone,[1529] which may provide an alternate mechanism of analgesia to its metabolism to morphine. The continued use of this minor opium alkaloid for pediatric analgesia remains baffling because it is effectively a prodrug analgesic and is highly subject to genomic variations resulting in either no analgesia or potential drug overdose (see further text and Chapters 6 and 33); most children's hospitals have removed this drug from their pharmacy because of safety concerns.[1157,1530–1533] The American Academy of Pediatrics recommended a better understanding of the dangers of this drug and the need for alternative methods for analgesia, particularly in obese children with the potential for OSA.[1534] In 2013 the U.S. FDA issued a black box warning against the use of codeine in children after tonsillectomy and adenoidectomy (T&A) surgeries after a number of deaths were attributed to overdoses associated with undiagnosed ultrarapid polymorphisms; this has resulted in a sharp reduction in the prescriptions of codeine after T&A surgery (see Chapters 6 and 33). The FDA recently extended this warning to obese children and those with OSA or lung disease who are less than 18 years of age undergoing T&A.[1534a] St. Jude's Research Hospital, however, addressed the CYP2D6 polymorphism issue by identifying the CYP2D6 polymorphisms in hundreds of children with sickle cell disease and obviating the use of codeine in those with the poor and ultrarapid polymorphisms.[1535] The remainder of the children were successfully managed with codeine for their sickle cell disease.

The primary routes for delivery of codeine are the oral and IM routes, although the rectal route has also been advocated.[1536] The dose of codeine by all three routes is similar, 0.5 to 1.5 mg/kg. IV codeine was used in the past, but serious life-threatening adverse effects, including transient but severe cardiorespiratory depression[1537–1539] and seizures,[1540] led to proscription of this route of delivery.

Codeine's popularity as a perioperative analgesic in children is based in part on its favorable PK. When given orally, it is rapidly and completely absorbed, with 50% undergoing first-pass

hepatic metabolism. Bioavailability after oral codeine is 90%, although after surgery the bioavailability may be quite variable.[1528,1541] Blood concentrations after oral codeine reach a peak by 1 hour. Its terminal elimination half-life is 3 to 3.5 hours. When given by the IM and rectal routes, peak blood concentrations are achieved rapidly, within 0.5 hours, with the blood concentrations after the rectal route being less than after the IM route. The duration of action after these two routes of administration is 1 to 2 hours. The elimination half-life after rectal administration in children is approximately 2.6 hours in children, but 4.6 hours in infants,[1542] suggesting the need for a much greater interval between subsequent doses in infants. A Vd of 3.6 L/kg and a CL of 0.85 L/hour have been described in adults, but there are few data detailing the developmental changes in children.

In vivo, 5% to 15% of codeine is excreted unchanged in the urine. The remaining 85% to 95% undergoes metabolism in the liver by one of three routes: glucuronidation (principal route), *O*-demethylation, and *N*-demethylation.[1528] Five percent to 15% of codeine undergoes *O*-demethylation to morphine. This metabolic pathway depends on CYP2D6, an enzyme responsible for the metabolism of more than 20% of prescribed medications. The *N*-demethylation pathway depends on the CYP3A enzyme system.

The wide array of CYP2D6 polymorphisms of codeine may be summarized into three broad categories: poor metabolizers (PM, negligible morphine produced), extensive metabolizers (EM, normal), and ultrarapid metabolizers (UM, rapid production and large amounts of morphine produced). Up to 10% of Caucasians and 30% of Hong Kong Chinese are PM, rendering codeine an ineffective analgesic for these children.[1528] Alternately, 29% of the Ethiopian and 1% of Swedish, German, and Chinese populations are UM.[1528] Recent evidence suggested that the frequency of CYP2D6 polymorphisms, particularly in children who are PM, may be more common and more varied than previously thought. Children with these polymorphisms who also have upregulated opioid receptors as a result of long-term intermittent nocturnal hypoxia may be particularly vulnerable to a mishap after a usual or subclinical dose of codeine.[1253,1254] Consequently, the wide clinical response to a standard (or less than standard) dose of codeine necessitates careful monitoring in those with compromised cardiorespiratory status or with obesity and possible OSA. Several deaths or near-deaths have been reported with "standard" doses of oral codeine in children later found to be UM.[1253,1532,1543–1545]

Codeine may be effective for pain control, although its limited conversion to morphine likely makes it suitable for only mild and moderate forms of pain. The limited conversion to morphine and fewer adverse effects of codeine have made it popular for infants and young children, particularly when a single dose is involved. There is some evidence that codeine is associated with less nausea and vomiting than morphine.[1546] Codeine is often used in combination with acetaminophen or NSAIDs. The addition of codeine to acetaminophen has been shown to improve postoperative pain relief in infants.[1547] One study found that the analgesic effect of the combination of acetaminophen (10–15 mg/kg) and codeine (1–1.5 mg/kg) was comparable to that of ibuprofen (5–10 mg/kg) in children after tonsillectomy.[1548]

In PM, codeine confers little or no analgesia, although adverse effects persist.[1549] In ultrarapid metabolizers on the other hand, a large incidence of adverse effects might be expected, including apnea, because of large plasma morphine concentrations. Administration (especially of codeine preparations with an antihistamine and a decongestant) in the neonate may cause intoxication.[1252,1534,1550] A mother who ingested codeine while breastfeeding is thought to have transferred morphine in the breast milk, resulting in a fatality in her neonate. The mother, an UM, produced morphine more rapidly from the codeine, which resulted in respiratory depression in the neonate.[1543,1551] Because of the unpredictable variability in converting codeine to morphine, we recommend alternative medications.[1552] We no longer recommend codeine unless the child's blood is tested for CYP2D6 polymorphisms; if the child is a PM, he or she will receive very little analgesia with codeine. If a child is an UM, he or she could sustain a life-threatening event because of increased conversion to morphine.[1553]

TRAMADOL

Tramadol (Ultram) is a weak opioid with minimal effects on respiration and causes monoaminergic spinal cord inhibition of pain.[1554–1557] This formulation is structurally related to morphine and codeine.[1557] Two enantiomers provide analgesia; one is a opioid μ-receptor agonist, and the other inhibits neuronal reuptake of serotonin and inhibits norepinephrine uptake, thus producing "multimodal antinociception."[1557] It is primarily metabolized into *O*-desmethyltramadol (M1) by CYP2D6. PM have both reduced analgesia and reduced nausea.[1558,1559] Unfortunately, the identification of genotype does not predict phenotype. Those classed as PM may have normal clearance (see Fig. 6.2). The active M1 metabolite has a μ-receptor affinity approximately 200 times greater than tramadol. Tramadol provides analgesia both from the parent compound (target concentration 100 ng/mL) and from its M1 metabolite (target concentration 15 ng/mL).[1560]

Tramadol clearance increases from 25 weeks PCA (5.52 L/hour per 70 kg) to reach 84% of the mature value (8.58 L/hour per 70 kg) by 44 weeks PMA.[1561] A target concentration of 300 μg/L is achieved after a bolus of tramadol hydrochloride of 1 mg/kg, and can be maintained by an infusion of tramadol hydrochloride at 0.09 mg/kg per hour at 25 weeks, 0.14 mg/kg per hour at 30 weeks, and 0.18 mg/kg per hour at 40 weeks PMA.[1561] CYP2D6 activity was observed as early as 25 weeks PCA.[1561] Clearance in children is similar to that in adults, using standardized allometric models.[1562] Tramadol has been shown to be effective for moderate to severe pain in a variety of pediatric populations and may offer some advantage for the treatment of pain after tonsillectomy in children with OSA.[1563–1571] Because of the metabolism by CYP2D6 polymorphisms, the FDA has issued a similar contraindication for use in children <18 years of age undergoing T&A.[1534a] Apnea is associated with a 10-fold dosing error in children (>9 mg/kg).[1572] One formulation is prescribed in drops rather than in milliliters and this can confuse caregivers and result in an accidental overdose.[1573]

Tramadol (1.5–2 mg/kg) has been administered rectally with peak plasma concentrations occurring at approximately 2 hours.[1574] Tramadol has also been administered in the caudal epidural space[1277] with longer-lasting analgesia than when administered intravenously.[1575] Caudal epidural tramadol (5%, 2 mg/kg) was also compared with caudal epidural bupivacaine (0.25%, 2 mg/kg) and found to provide superior analgesia.[1576] *Caudal administration is not recommended until further clarification of potential neurotoxicity.*[1563,1577] Tramadol has also been very useful as a transition to oral analgesics after IV therapy (see Chapter 44). The low incidence of respiratory depression and constipation, fewer controls on use, and similar frequency of nausea and vomiting (10%–40%) compared with other opioids make tramadol an attractive alternative.[1578]

TAPENTADOL

Tapentadol (Nucynta, Palexia, and Tapal) is an oral opioid analgesic in the benzenoid class with a dual mechanism of action that is

similar to tramadol; it is a μ-opioid receptor agonist and also inhibits the reuptake of norepinephrine. Its advantage over tramadol is that it has only weak effects on the reuptake of serotonin and is a more potent opioid with no known active metabolites.[1579] We might anticipate better analgesia than following tramadol in those children who are PM of CYP2D6. It is generally regarded as a weak-moderate strength opioid that can be reversed with naloxone.

Tapentadol is cleared by glucuronide conjugation in the liver and, although not reported, it is anticipated that clearance maturation will be similar to other drugs cleared by this route (acetaminophen, morphine). Experience in children is limited. Adverse effect profiles (nausea, dizziness, vomiting, and somnolence) appear similar to those described for tramadol.[1580] Tapentadol produces both nociceptive and neuropathic pain relief, but there are concerns about abuse and dependence. Caution with the use of tapentadol within 14 days after cessation of monoamine oxidase inhibitors is advised because of fear that serotonin syndrome could occur.[1581]

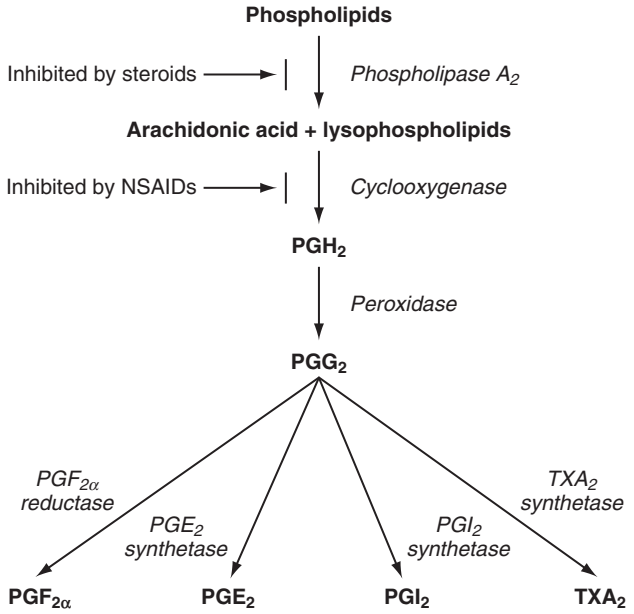
Acetaminophen

Acetaminophen (Tylenol, paracetamol) is widely used in the management of pain, but lacks antiinflammatory effects. Prostaglandin H_2 synthase (PGHS) is the enzyme responsible for metabolism of arachidonic acid to the unstable prostaglandin H_2. The two major forms of this enzyme are the constitutive PGHS-1 (COX-1) and the inducible PGHS-2 (COX-2). PGHS has two sites, a cyclooxygenase (COX) site and a peroxidase (POX) site. The conversion of arachidonic acid to prostaglandin G_2, the precursor of the other prostaglandins (E-Fig. 7.19), depends on a tyrosine-385 radical at the COX active site. Acetaminophen acts as a reducing cosubstrate on the POX site. Alternatively, acetaminophen effects may be mediated by an active metabolite (*p*-aminophenol). *p*-Aminophenol is conjugated with arachidonic acid by fatty acid amide hydrolase and exerts its effect through cannabinoid receptors.[1582]

The ED_{50} for rectal acetaminophen to reduce the need for supplemental opioids after day-stay surgery is 35 mg/kg.[1583] Further studies are required before regular doses greater than 40 mg/kg can be recommended because of concerns about hepatotoxicity,[1583–1585] which can occur after single doses of 250 mg/kg.[1586] Time delays of approximately 1 hour between peak concentration and peak effect have been reported.[1587,1588] An estimate of a maximum effect was 5.17 (the greatest possible pain relief [Visual Analog Scale (VAS) 0 to 10] would equate to an Emax of 10 out of 10 pain units) and an EC_{50} of 9.98 mg/L. The $T_{1/2}$keo of the analgesic effect compartment was 53 minutes.[1587,1589] A target effect compartment concentration of 10 mg/L was associated with a pain reduction of 2.6/10.[1589]

The relative bioavailability of rectal to oral acetaminophen formulations (rectal/oral) is approximately 0.5 in children but the relative bioavailability is greater in neonates and approaches unity.[106] There are two IV acetaminophen formulations available, and caution must be exercised with the choice of formulation.[1590] One is an acetaminophen formulation,[1591] whereas the other, propacetamol (*N*-acetyl-*para*-aminophenoldiethyl aminoacetic ester), is a water-soluble prodrug of acetaminophen that can be administered intravenously over 15 minutes. It is rapidly hydroxylated into acetaminophen (1 g propacetamol = 0.5 g acetaminophen).[1592]

The $T_{1/2}$abs of acetaminophen from the duodenum is rapid (4.5 minutes) in children who were given acetaminophen as an elixir.[1593] The $T_{1/2}$abs in infants younger than 3 months was delayed (16.6 minutes), consistent with delayed gastric emptying in young infants.[106,1593] In contrast, rectal absorption is slow and erratic with large variability. For example, absorption parameters for the triglyceride base were a $T_{1/2}$abs of 1.34 hours (CV = 90%) with a lag time before absorption began of 8 minutes (CV = 31%). The $T_{1/2}$abs for rectal formulations was prolonged in infants younger than 3 months (1.51 times greater) compared with older children.[1594]



Sulfate metabolism is the dominant route of elimination in neonates, whereas glucuronide conjugation (via UGT1A6) is dominant in adults. A total body clearance of 0.74 L/hour per 70 kg at 28 weeks PMA and 4.9 L/hour per 70 kg (CV = 38%) in full-term neonates after enteral acetaminophen has been reported using an allometric ¾-power model.[1594,1595] Clearance increases over the first year of life (see Fig. 7.11) and reaches 80% of that in older children (16 L/hour per 70 kg) by 6 months postnatal age.[106,169] Similar clearance estimates are reported in neonates after IV formulations of acetaminophen.[1595,1596] The relative bioavailability of the oral formulation is 0.9.

The Vd for acetaminophen is 49 to 70 L/70 kg. The Vd decreases exponentially, with a TM_{50} of 11.5 weeks, from 109.7 L/70 kg at 28 weeks PCA to 72.9 L/70 kg by 60 weeks PMA, reflective of fetal body composition and water distribution changes over the first few months of life.[106]

The toxic metabolite of acetaminophen, *N*-acetyl-*p*-benzoquinone imine (NAPQI), is formed by CYP2E1, 1A2, and 3A4. This metabolite binds to intracellular hepatic macromolecules to produce cell necrosis and other damage. Infants younger than 90 days postnatal age have decreased expression of CYP2E1 activity in vitro compared with older infants, children, and adults,[1597] CYP3A4 appears during the first week after birth, whereas CYP1A2 appears later.[1] Neonates can produce hepatotoxic metabolites (e.g., NAPQI), but the reduced activity of CYP in neonates may explain the rare occurrence of acetaminophen-induced hepatotoxicity in neonates.[1598,1599] Nonetheless, two massive 10-fold overdoses of acetaminophen were reported in infants and underscore the need for extreme care when administering IV forms of acetaminophen.[1600] Neither infant progressed to acute liver necrosis and both recovered fully.

Acetaminophen is useful as an adjunct to spare opioids.[59,1583,1601–1606] Acetaminophen can be administered orally before induction of anesthesia to achieve a therapeutic blood concentration at the time of emergence, even after brief surgery, such as myringotomy and tube insertion. For procedures of greater duration, rectal administration of acetaminophen at the beginning of surgery provides therapeutic blood concentrations at the time of emergence and before the child would be likely to tolerate oral medications.[1607] The current maximum 24 hour dosing of oral acetaminophen varies around the world between 75 and 90 mg/kg per day in hospitalized children, although the total daily dose should be reduced in neonates.[1608] Suppository doses of 35 to 40 mg/kg followed by 20 mg/kg every 6 hours have been proposed for children for the first 24 hours,[1608] consistent with reduced bioavailability and slower absorption of rectal formulations.[1609]

A review of acetaminophen-associated toxicity revealed 76 children with hepatic injury and 26 deaths after repeated administration in children younger than 6 years of age; no deaths or injury occurred when the total daily dose was less than 75 mg/kg in children.[1610] It is difficult to assess those prone to hepatotoxicity after routine dosing. Liver function changes during therapy are commonly transitory and may not reflect hepatotoxicity.[1611]

E-FIGURE 7.19 The conversion of arachidonic acid to prostaglandin G_2 (*PGG_2*), the precursor of the prostaglandins, is controlled by prostaglandin H_2 synthetase. Prostaglandin H_2 synthetase consists of two sites, a cyclooxygenase site and a peroxidase site. *PGE_2*, prostaglandin E_2; *$PGF_{2\alpha}$*, prostaglandin $F_{2\alpha}$; *PGH_2*, prostaglandin H_2; *PGI_2*, prostaglandin I_2; *TXA_2*, thromboxane A_2.

Nonsteroidal Antiinflammatory Agents

The NSAIDs are a heterogeneous group of compounds that share common antipyretic, analgesic, and antiinflammatory effects. NSAIDs act by reducing prostaglandin biosynthesis through inhibition of the COX site of the PGHS enzyme (see E-Fig. 7.19).

The prostanoids produced by the COX-1 isoenzyme protect the gastric mucosa, regulate renal blood flow, and induce platelet aggregation. NSAID-induced gastrointestinal toxicity, for example, is likely mediated through blockade of COX-1 activity, whereas the antiinflammatory effects of NSAIDs are likely mediated primarily through inhibition of the inducible isoform, COX-2.

The NSAIDs are commonly used in children for antipyresis and analgesia. The antiinflammatory properties of the NSAIDs have, in addition, been used in such diverse disorders as juvenile idiopathic arthritis, renal and biliary colic, dysmenorrhea, Kawasaki disease, and cystic fibrosis. The NSAIDs indomethacin and ibuprofen are also used to treat delayed closure of PDA in preterm infants.[1612–1616] One prospective study found paracetamol to be as effective as indomethacin and ibuprophen for ductal closure, but conferring fewer side effects on renal function, platelet count, and bleeding events.[1617]

NSAID-associated analgesia has been compared with analgesia from other analgesics or analgesic modalities (e.g., caudal blockade, acetaminophen, or morphine) in children. These data confirm that NSAIDs in children are effective analgesic drugs, improving the quality of analgesia, but the effects are poorly quantified.[1618] Data from adults given ibuprofen after dental extraction suggest a similar Emax to that described for acetaminophen (1.54 on a scale 0 to 3), with an EC_{50} of 10.2 mg/L.[1619] The $T_{1/2}$keo of 28 minutes was less than the 53 minutes reported for acetaminophen.[1589] In addition, the slope (reflected by the Hill coefficient, see Fig. 7.6) of the concentration-response curve was steeper than that for acetaminophen (Hill = 2 for ibuprofen, Hill = 1 for acetaminophen), indicating a more rapid onset of analgesia. Parameter estimates for acetaminophen and some common NSAIDs using a sigmoid Emax model are shown in Table 7.13.

NSAIDs are rapidly absorbed in the gastrointestinal tract after oral administration in children. The relative bioavailability of oral preparations approaches unity. The rate and extent of absorption after rectal administration of NSAIDs, such as ibuprofen, diclofenac, flurbiprofen, indomethacin, and nimesulide, are less than after the oral routes.

Diclofenac, 2-[(2,6-dichlorophenyl) amino] benzene acetic acid, has an approximate relative COX-1/COX-2 specificity ratio of 1. Formulations may be administered orally, topically, intraocularly, intraarticularly, intravenously, intramuscularly, and rectally. Diclofenac is metabolized by P450 (CYP2C9, 3A4, and 3A5) phase I hydroxylation and phase II conjugation. The principal metabolite in humans is the 4′-hydroxyl derivative of diclofenac (D4OH), metabolized by CYP 2C9. The 4′-hydroxyl metabolite has 30% of the antiinflammatory and antipyretic activity of diclofenac.[1620] Diclofenac is rapidly absorbed when administered rectally; the $T_{1/2abs}$ of the suppository formulations is 35 minutes, with a lag time (T_{LAG}) of 11 minutes.[1621]

TABLE 7.13 Parameter Estimates for the Sigmoid Emax Equation for Some Common NSAIDs and Paracetamol

Parameter	Paracetamol	Ibuprofen	Ketorolac	Diclofenac
Emax (0–10)	5.2	5.1	8.5	4.89
EC_{50}	9.8 mg/L	10.2 mg/L	0.37 mg/L	1.2 mg/L
N	1	2	1	1
$T_{1/2}$keo	53 minutes	28 minutes	24 minutes	14 minutes

From Anderson BJ, Hannam JA. Considerations when using PKPD modeling to determine effectiveness of simple analgesics in children. *Expert Opin Drug Metab Toxicol*. 2015;11(9):1393–1408, with permission

There are few IV NSAID formulations available. Parecoxib sodium is an IV NSAID with increased use in pediatric practice despite limited data concerning PK and PD in this population.[1622–1624] Parecoxib is a prodrug that is rapidly and completely converted to valdecoxib (the active metabolite) within 0.5 to 1 hour. Valdecoxib acts by specifically inhibiting COX-2–mediated prostaglandin synthesis. Onset of analgesia in adults was 7.14 minutes with a peak effect within 2 hours and duration of analgesia that ranged from 6 to 24 hours. Valdecoxib is extensively metabolized by the liver through the cytochrome P450 pathways (CYP3A4 and CYP2C9). The Vd of most NSAIDs is small in adults (<0.2 L/kg) but larger in children. Preterm neonates (22–31 weeks gestational age) given IV ibuprofen had a Vd of 0.62 ± 0.04 L/kg.[1625] One paper reported a dramatic reduction in ibuprofen central volume after closure of the PDA in preterm neonates (0.244 vs .0.171 L/kg).[1626] The NSAIDs, as a group, are weakly acidic, lipophilic, and highly protein bound. The impact of altered protein binding is probably minimal with routine dosing, because NSAIDs cleared by the liver have a low hepatic extraction ratio.[82]

NSAIDs undergo extensive phase I and phase II enzyme biotransformation in the liver, with subsequent excretion into urine or bile. Renal elimination is not an important elimination pathway for the commonly used NSAIDs. PK parameter variability is large, in part attributable to covariate effects of age, size, and pharmacogenomics. Ibuprofen, for example, is metabolized by the CYP2C9 and CYP2C8 subfamily. Considerable variation exists in the expression of CYP2C activities among individuals, and functional polymorphism of the gene coding for CYP2C9 has been described.[1627] CYP2C9 activity is low immediately after birth (21% of adult values), subsequently increasing progressively to reach a peak activity within 3 months, when expressed as milligrams per hour per kilogram.[1628]

Clearance (liters per hour per kilogram) is generally greater in children than it is in adults, as we might expect when the linear per-kilogram model is used. Ibuprofen clearance maturation follows the similar pattern to other drugs (e.g., Fig. 7.5). Clearance increases from 2.06 mL/hour per kilogram in extreme preterm neonates 22 to 31 weeks PMA,[1625] to 9.49 mL/hour per kilogram in preterm neonates 28 weeks PMA,[1626] peaking at 140 mL/hour per kilogram in preschool children, before decreasing again during late childhood and adolescence (71 mL/hour per kilogram).[1629] Similar data exist for indomethacin.[1612,1630,1631]

Many NSAIDs exhibit stereoselectivity.[1632] Ibuprofen stereoselectivity is reported in preterm neonates (<28 weeks gestation). *R*- and *S*-ibuprofen half-lives were about 10 hours and 25.5 hours, respectively. The mean clearance of *R*-ibuprofen (12.7 mL/hour) was about 2.5-fold greater than that of *S*-ibuprofen (5.0 mL/hour).[1633]

During pregnancy, there is relatively little transfer of NSAIDs from maternal to fetal blood. Very small quantities of NSAIDs are secreted into breast milk. Similarly, infant exposure to ketorolac via breast milk is estimated to be only 0.4% of maternal exposure.[1634]

NSAIDs undergo drug interactions through altered clearance and competition for active renal tubular secretion with other organic acids. A large fractional protein binding has been proposed to explain drug interactions between NSAIDs and oral anticoagulant agents, oral hypoglycemics, sulfonamides, bilirubin, and other protein-bound drugs. The classic example is that of the coadministration of warfarin and phenylbutazone (an NSAID). Both the plasma warfarin concentration and the prothrombin time were increased.[1635] However, even though phenylbutazone displaces warfarin from its albumin binding sites in vitro, this observation does not explain the changes in prothrombin time. The increased prothrombin time has been attributed to increased serum warfarin concentrations, which stems from its reduced clearance, and not from changes in protein binding.[82] Both warfarin and phenylbutazone compete for similar protein binding sites; they also compete for similar clearance pathways. NSAIDs have the potential to cause gastrointestinal irritation, blood clotting disorders, renal impairment, neutrophil dysfunction, and bronchoconstriction, effects attributed to COX-1/COX-2 ratios, although this concept may be an oversimplification.

Ibuprofen reduces the GFR by 20% in preterm neonates, affecting aminoglycoside clearance, an effect that appears to be independent of gestational age.[1636] No significant difference in the change in cerebral blood volume, change in cerebral blood flow, or tissue oxygenation index was found between administration of ibuprofen or placebo in neonates.[1637] The risk of acute gastrointestinal bleeding in children given short-term ibuprofen was estimated to be 7.2/100,000 (CI 2–18 per 100,000), a prevalence not different from children given acetaminophen.[1638,1639] The incidence of clinically significant gastropathy in children with juvenile arthritis given NSAIDs is comparable to that in adults given long-term NSAIDs, but the prevalence of gastroduodenal injury may be greater, depending on the assessment criteria applied (e.g., abdominal pain, anemia, endoscopy).[1640,1641] Aspirin- or NSAID-exacerbated respiratory disease (ERD) occurs more frequently in adults, although instances in children and teenagers have been reported.[1642] These cases are countered by reports that the symptoms of asthma improved when ibuprofen was administered for antipyresis. One study concluded that a benefit is likely to occur in younger children with mild episodic asthma and that aspirin-ERD is a concern in one in three teenagers with severe asthma and coexistent nasal disease.[1643] COX-2 inhibitors are reported to be safe in NSAID-ERD.[1643]

The commonly used NSAIDs have reversible antiplatelet effects, which are attributable to the inhibition of thromboxane synthesis. Bleeding time is usually slightly increased, but remains within normal limits in children with normal coagulation systems. Neonates given prophylactic ibuprofen to induce PDA closure did not have an increased frequency of intraventricular hemorrhage.[1644] A Cochrane review has established that even after tonsillectomy, NSAIDs did not cause any increase in bleeding that required a return to the operating room in children. There was significantly less nausea and vomiting with NSAIDs compared with alternative analgesics, suggesting their benefits outweigh their negative aspects.[1645,1646] Recent concerns with OSA-associated deaths from opioids for postoperative pain management have resulted in several studies examining alternating doses of ibuprofen and acetaminophen; this regimen provided adequate analgesia with no increase in the incidence of posttonsillectomy bleeding requiring surgical intervention.[1647,1648] Combination therapy achieves the same maximal response (Emax), but this response is achieved using smaller doses of each drug, and the duration of effect is greater.[262,1649]

KETOROLAC

Ketorolac (Toradol) is an NSAID with very potent analgesic properties.[1650–1653] The analgesic properties of ketorolac are similar to those of low-dose morphine for posttonsillectomy analgesia.[1653,1654] Its major use in pediatric anesthesia is as an adjuvant to opioid analgesia or for the treatment of mild to moderate pain where there is a desire to reduce the potential for respiratory depression or for nausea and vomiting.[1652,1655–1660] It is an important adjuvant to the treatment of postoperative pain, especially for children who require prolonged pain management or those at risk for OSA.[1661] It is particularly useful for the transition from IV to oral therapy. Ketorolac may also be administered nasally, although pediatric perioperative data are limited.[117,1662,1663] Data from adult patients (n = 522) given a single oral or IM administration of 10, 30, 60, or 90 mg ketorolac for postoperative pain relief after orthopedic surgery, revealed an Emax of 8.5/10 (VAS 0-10), EC_{50} 0.37 mg/L, and $T_{1/2}$keo 24 minutes.[1664] This Emax (see Fig. 7.6) is greater than that of acetaminophen or ibuprofen (see Table 7.13) and may be attributed to the population cohort of adult women suffering pain from bone fractures.

The PK, standardized using allometry, are similar in adults and children (E-Table 7.9). The terminal elimination half-life in children 4 to 8 years of age is approximately 6 hours, although there is considerable variability.[1665–1667] PK may also be influenced by chronobiology,[728] and many NSAIDs exhibit stereoselectivity. Ketorolac is supplied and administered as a racemic mixture that contains a 1 : 1 ratio of the *R*(+) and *S*(–) stereoisomers. Pharmacologic activity resides almost exclusively with the *S*(–) stereoisomer.[1632,1668] Clearance of the *S*(–) enantiomer was four times that of the *R*(+) enantiomer (6.2 vs. 1.4 mL/minute per kilogram) in children 3 to 18 years.[1669] Terminal half-life of *S*(–)-ketorolac was 40% that of the *R*(+) enantiomer (107 vs. 259 minutes), and the Vd of the *S*(–) enantiomer was greater than that of the *R*(+) form (0.82 vs. 0.50 L/kg). Recovery of *S*(–)-ketorolac glucuronide was 2.3 times that of the *R*(+) enantiomer. Because of the greater clearance and shorter half-life of *S*(–)-ketorolac, PK predictions based on racemic assays may overestimate the duration of pharmacologic effect.[1669]

One of the major concerns with ketorolac is the inhibition of platelet function through inhibition of cyclooxygenase, and the consequent potential for postsurgical bleeding. Ketorolac has been shown to have minimal effect on prothrombin and partial thromboplastin times but has been shown to cause modest increases in the bleeding time.[1652,1670–1673] Unlike aspirin, the ketorolac antiplatelet effect is reversible and, therefore, the effect depends on the presence of ketorolac within the body.[1674] This effect on platelet function has been of most concern in children undergoing adenotonsillectomy.[1675–1678] In the studies reporting posttonsillectomy bleeding, most involved administration of the ketorolac during or at the beginning of the surgical procedure, before hemostasis was achieved. In addition, the increased incidence of bleeding appears to be primarily during the first 24 hours, which corresponds to the several half-lives it would take to eliminate ketorolac from the body. The incidence of bleeding after the first 24 hours does not appear to be different.[1679] It would therefore be reasonable to not administer this medication until the end of surgery, after hemostasis is achieved. Some practitioners eschew this issue altogether and administer ketorolac only when the potential for a life-threatening hemorrhage is less.[1519] Concerns

E-TABLE 7.9 Ketorolac Age-Related Pharmacokinetic Changes[2053]

Age (Years)	Weight (kg)	Vdss (SD) (L/kg)	CL (SD) (L/minute per kg)	CL_{std} (SD) (L/minute per 70 kg)
1–3	12	0.111 (0.025)	0.6 (0.2)	27.0 (9.0)
4–7	20	0.128 (0.047)	0.61 (0.22)	31.2 (11.3)
8–12	30	0.099 (0.014)	0.54 (0.15)	30.6 (8.5)
12–16	50	0.116 (0.040)	0.51 (0.12)	32.8 (7.7)

regarding the possibility of postoperative hemorrhage appear to be valid, but the true frequency of life-threatening bleeding exclusively the result of ketorolac administration is quite small.[1659,1680–1683] There is a dose-response relationship for this bleeding propensity; the risk associated with the drug was larger and clinically important when ketorolac was used in larger doses, in older subjects, and for more than 5 days.[1684] A systematic review found an increased risk for bleeding in adults but not in children younger than 18 years of age after tonsillectomy.[1685] Safety assessment showed no changes in renal or hepatic function tests, surgical drain output, or continuous oximetry between groups given placebo, 0.5 mg/kg, or 1 mg/kg ketorolac at 6 to 18 hours after surgery.[1632,1668] Many clinicians discuss the possible use of ketorolac with the surgeon before administering it and document the conversation in the anesthesia record. Ketorolac can be used to treat pain after congenital heart surgery without an increased risk of bleeding complications.[1681] A retrospective report of 1451 pediatric neurosurgical patients reported no increase in the incidence of bleeding with short-term therapy.[1686] Ketorolac has been safely used to provide analgesia for preterm and term infants, but the PK in this age group has not been described.[1687]

Another concern is the potential for adverse effects on bone healing, particularly spinal fusion.[1688,1689] Evidence suggests that nonunion of the spine is associated only with large-dose and not small-dose ketorolac. However, ketorolac has been used safely to provide analgesia for other types of orthopedic conditions with no evidence of delayed union or nonunion of fractures.[1690–1693] One other concern is the report of sudden and profound bradycardia after rapid IV administration of ketorolac.[1694] Although the mechanism of this response is unclear, ketorolac should be administered slowly when given intravenously.

Benzodiazepine Sedatives

These drugs produce anxiolysis, amnesia, and hypnosis. They are commonly used as adjuncts to both local and general anesthesia. Benzodiazepines bind to $GABA_A$ receptors, resulting in increased cellular chloride entry. This renders these receptors resistant to excitation because they are hyperpolarized.

MIDAZOLAM

Midazolam (Versed) is a water-soluble benzodiazepine that offers significant clinical advantages over diazepam. It is not painful when administered intravenously or intramuscularly. Midazolam is only one of a few medications that are approved as premedicants in children, and it is the only benzodiazepine approved by the FDA for use in neonates including preterms.

PK–PD relationships have been described for IV midazolam in adults. When an EEG signal is used as an effect measure, the EC_{50} is 35 to 77 ng/mL, with a $T_{1/2}$keo of 0.9 to 1.6 minutes.[67,1695,1696] Duration of effect persists despite decreasing plasma concentrations (Fig. 7.27). The $T_{1/2}$keo is increased in the elderly and in low cardiac output states. PK–PD relationships are more difficult to describe after oral midazolam because the active metabolite, 1-hydroxymidazolam, has approximately half the activity of the parent drug.[1697]

Sedation in children is more difficult to quantify. No PK–PD relationship was established in children, age 2 days to 17 years, who were given a midazolam infusion in the ICU. Midazolam dosing could, however, be effectively titrated to the desired level of sedation, assessed by the COMFORT distress scale (see Table 44.5).[1698] Consistent with this finding, desirable sedation in children after cardiac surgery was achieved at mean serum concentrations between 0.1 and 0.5 mg/L.[1699–1701] Plasma concentrations of 0.3 to

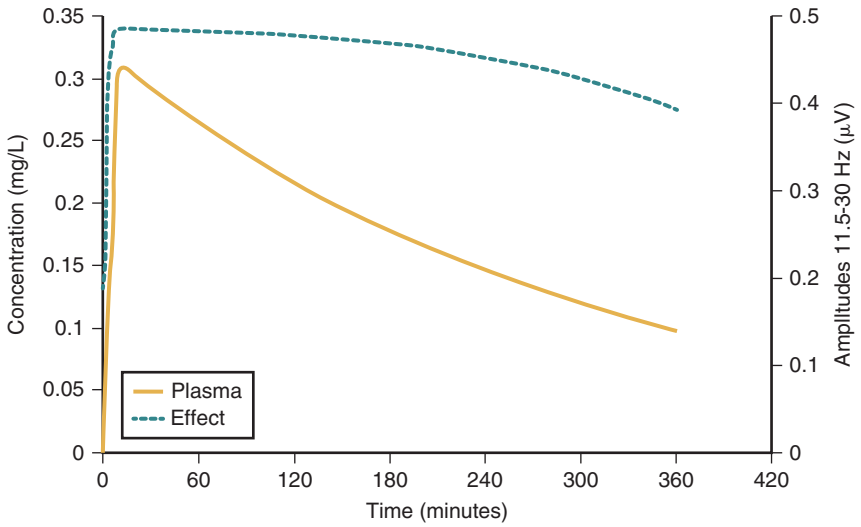

FIGURE 7.27 Plasma concentrations and effect in a neonate given midazolam bolus (0.1 mg/kg) on two early occasions (5-minute interval) to achieve sedation. Plasma concentration declines slowly because of immature clearance. Sedation recovery lags way behind the decline in plasma concentration even though a maintenance infusion was not even given. (Pharmacodynamic parameter estimates are from Mandema J, Tuk B, van Steveninck AL, Breimer DD, Cohen AF, Danhof M. Pharmacokinetic-pharmacodynamic modeling of the central nervous system effects of midazolam and its main metabolite alpha-hydroxymidazolam in healthy volunteers. *Clin Pharm Ther.* 1992;51(6):715–728.) (From Wolf A, Blackwood B, Anderson BJ. Tolerance to sedative drugs in PICU: can it be moderated or is it immutable? *Intensive Care Med.* 2016;42(2):278–281.)

0.4 mg/L are associated with anesthesia in adults.[1702,1703] A target concentration for sedation (arouses to command) in adults is 0.1 mg/L.[170]

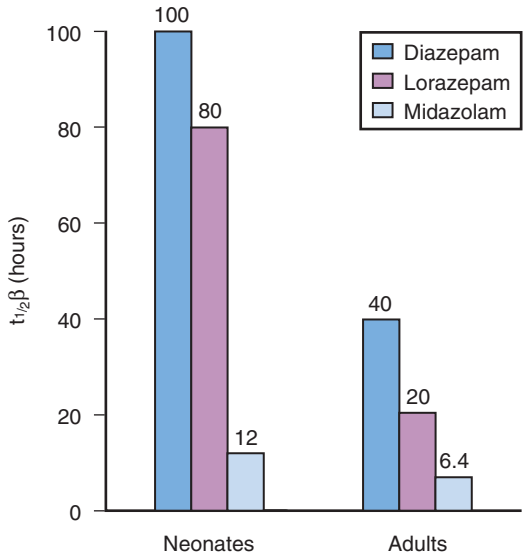
Midazolam is metabolized mainly by hepatic hydroxylation (CYP3A4).[1704] These hydroxylated metabolites are glucuronidated and excreted in the urine. CYP3A7 is the dominant CYP3A enzyme in utero and in the neonate; it is expressed in the fetal liver and appears to have activity from as early as 50 to 60 days after conception. CYP3A4 expression increases dramatically after the first week of life, reaching 30% to 40% of adult expression by 1 month.[1427] Midazolam has a hepatic extraction ratio in the intermediate range of 0.3 to 0.7. Metabolic clearance depends on both liver perfusion and enzyme activity.

Clearance is reduced in neonates (0.8–2.2 mL/minute per kilogram, 60 mL/minute per 70 kg) (E-Fig. 7.20),[1705–1712] but increases rapidly (Hill coefficient = 3) after 39 weeks PMA,[1709] to reach 90% mature clearance at 1 year of age.[1712] Mature clearance was 523 mL/minute per 70 kg. The TM_{50} was 73.6 weeks.[1710,1712] Central Vd is related to weight (V1 = 0.591 ± 0.065 L/kg), whereas peripheral Vd remained constant (V2 = 0.42 ± 0.11 L) in 187 neonates weighing 0.7 to 5.2 kg.[1709] It has been suggested that midazolam induces its own clearance.[1699] The latter observation, from infants after cardiac surgery, likely results from the improved hepatic function after the insult of CPB. Neonates have an increase in Vdss during extracorporeal membrane oxygenation therapy (0.8 L/kg–4.1 L/kg), caused by sequestration of midazolam by the circuitry, although clearance (1.4 ± 0.15 mL/minute per kilogram) was unchanged.[1713]

Clearance may be reduced in the presence of clinical illness.[1714,1715] A reduced clearance of midazolam has been reported after circulatory arrest for cardiac surgery.[1716] Covariates, such as renal failure, hepatic failure,[1701] and concomitant administration of CYP3A inhibitors,[686,687] are important predictors of altered midazolam and metabolite PK in pediatric intensive care patients.[1717] The clearance of midazolam was reduced by 30% in neonates receiving sympathomimetic amines, probably as a consequence of the underlying compromised hemodynamics.[1709]

The suggested infusion rate of midazolam is 0.5 µg/kg per minute for preterm infants younger than 32 weeks gestational age and 1.0 µg/kg per minute for infants more than 32 weeks gestational age. Any factor that impairs hepatic blood flow (e.g., CPB, vasopressors) may decrease midazolam elimination, although cirrhosis only minimally affects its elimination in adults.[1716–1719] Midazolam offers the best PK profile for neonates because the active metabolite has a half-life similar to the parent compound, but with minimal clinical activity.[1341] *Bolus administration to preterm and term neonates has been associated with profound hypotension; the likelihood may be greater if fentanyl is also administered.*[1350] *Likewise, a neonate who is receiving a midazolam infusion is more likely to suffer profound hypotension with a bolus of fentanyl.* Rapid IV and nasal administration have also been associated with myoclonic activity.[1720] Midazolam has been administered as a continuous infusion, both in the OR as an adjunct to general anesthesia and in the ICU.[854,1721–1723] Prolonged administration leads to tolerance, dependency, and benzodiazepine withdrawal.[1724,1725] Long-term infusions, particularly in neonates, should be tapered over days while carefully monitoring for signs of withdrawal (vomiting, agitation, sweating, bowel distention, seizures, change in neurologic status).[1360,1726,1727] A theoretical concern associated with midazolam is benzyl alcohol toxicity with the development of metabolic acidosis and gasping respirations.[1728,1729] The 24-hour dose of benzyl alcohol in midazolam when administered according to recommended dosing guidelines should not cause toxicity.

Midazolam is the most commonly used benzodiazepine in pediatric anesthesia. It is administered orally, nasally, buccally, rectally, intravenously, and intramuscularly. Buccal and sublingual administration (0.3 mg/kg [maximum 10 mg]), like the nasal route, offer ease of administration, rapid systemic absorption, and avoidance of hepatic first-pass metabolism. The buccal route is popular for emergency seizure control. It is better than rectal diazepam (relative risk 1.14; 95% CI, 1.06–1.24).[120]



The desired clinical effects for anesthesia include antegrade amnesia (approximately 50%),[1730–1732] as well as sedation and anxiolysis before induction of anesthesia or a medical procedure.[899,1733–1739] One study suggested that its amnestic properties may be superior to those of diazepam.[1740] The clinical endpoint with midazolam may differ somewhat when compared with diazepam. Midazolam produces a general calming effect with minimal sedation and little effect on speech. In contrast, diazepam frequently causes obvious sedation and slurring of speech.

When midazolam was first introduced, a number of deaths were attributed to respiratory depression. These deaths were probably the result of combining large doses of midazolam with other medications, particularly opioids. An important pharmacologic difference between the benzodiazepines is that the time to achieve peak CNS effect with IV midazolam, 4.8 minutes, is almost 3-fold greater than with diazepam, 1.5 minutes (see Fig. 48.7).[67,1741] This is because of the greater fat solubility of diazepam and therefore a more rapid transit into the CNS.[1742] **Accordingly, one must wait sufficient time between doses of midazolam (3–5 minutes) to achieve the peak CNS effects before considering supplemental doses or other medications**.[1743] IV midazolam depresses the response to hypoxemia, an effect that is exaggerated in the presence of a potent opioid, such as fentanyl. This combination (0.1 mg/kg midazolam and 6 µg/kg fentanyl IV) has been associated with a respiratory arrest in an infant.[1744,1745] Children with sleep-disordered breathing who were premedicated with oral midazolam (0.5 mg/kg) experienced only a small incidence (1.5%) of transient desaturation.[1746] However, IV midazolam (0.1 mg/kg) has been shown to cause both central apnea as well as upper airway obstruction, the latter by reducing pharyngeal muscle tone.[1747] In addition, the combination of oral midazolam (0.5 mg/kg) and nitrous oxide (50%) may cause partial upper airway obstruction four times more frequently in children with large tonsils than in those with normal-sized tonsils.[1748] Interestingly, mouth opening may increase upper airway collapse, thus increasing the airway obstruction in children sedated with midazolam for dental procedures.[1749]

One final concern relates to the administration of drugs that interfere with the cytochrome isoforms that metabolize midazolam (CYP3A4). Examples of such drugs and foods are grapefruit juice, erythromycin, calcium channel blockers, and protease inhibitors.[a] The net effect is to prolong the duration of action of midazolam.

Midazolam has been used as an induction agent, but it is not as satisfactory as other agents.[1750,1752] One author (CJC) has administered as much as 1.0 mg/kg intravenously to a child without producing unconsciousness. The same dose given orally produces rapid onset of sedation and anxiolysis.[1753] Commonly used doses and routes of administration are presented in Table 7.14. The nasal route has some proponents[1733]; with an onset of sedation that may be more rapid than the oral route.[1754] There is a direct

TABLE 7.14 Dosing and Onset Times of Midazolam in Infants and Children (Excluding Neonates)

Route	Dose (mg/kg)	Time of Onset (Minutes)	Time to Peak Effect (Minutes)
Intravenous	0.05–0.15	~1	3–5
Intramuscular	0.1–0.2	3–5	10–20
Oral	0.25–0.75	5–30	10–30
Nasal	0.1–0.2	3–5	10–15
Rectal	0.75–1.0	5–10	10–30

See text for details.

connection with the CNS at that level (see E-Fig. 4.2),[905] and because the preservative in midazolam is neurotoxic when applied directly to neural tissue,[911] there is the theoretical risk of CNS toxicity.[905] In addition, 85% of children who receive nasal midazolam cry and complain of a bitter aftertaste.[125,1438] It would seem prudent to avoid this route of administration because the oral route appears to be equally effective and without risk.

DIAZEPAM

Diazepam (Valium) (0.2–0.3 mg/kg) is rapidly absorbed after oral administration, with peak plasma concentrations at 30 to 90 minutes; the absorption rate is more rapid in children than in adults.[1755,1756] It has been used extensively as a premedication, as an adjunct to balanced anesthesia, and for sedation, amnesia, and control of seizures. IM administration is painful and results in irregular absorption; plasma concentrations are only 60% of those obtained with a similar oral dose.[1757–1759] Rectal diazepam (0.2–0.5 mg/kg) is used for prehospital treatment of pediatric status epilepticus. The recommended IV dose is 0.1 to 0.2 mg/kg. Diazepam has been administered rectally to children for sedation in doses ranging from 0.3 to 1.0 mg/kg with satisfactory results.[1760–1763] One study found a more rapid uptake during the first 2 hours after administration when given in liquid rather than suppository form.[1760] Bioavailability after nasal administration in adults is 70% to 90% with maximal blood concentrations at ~45 minutes.[1764]

Diazepam is highly plasma bound, with a serum half-life varying from 20 to 80 hours. Its half-life is reduced in younger adults and children (~18 hours).[1760] Hepatic disease may also decrease the elimination of diazepam.[1765] Studies in neonates who received diazepam transplacentally just before delivery demonstrate prolonged drug effects and serum half-lives (40–100 hours) a result of immature hepatic excretory mechanisms and reduced hepatic blood flow (see E-Fig. 7.20).[1755,1766,1767] Diazepam undergoes oxidative metabolism by demethylation (CYP 2C19). Its active metabolite, desmethyldiazepam, has potency similar to the parent compound and a half-life as great or greater than the parent compound, thus emphasizing that caution is required when administering this benzodiazepine to neonates.[1755,1768,1769]

The preservative benzyl alcohol is present in many formulations of diazepam. This preservative should be avoided in neonates because it is difficult to metabolize, is associated with kernicterus, and can cause a metabolic acidosis.[1770–1772] The amount of benzyl alcohol that accompanies a usual dose of diazepam would likely be insufficient to cause harm to the neonate.[1773] Diazepam has respiratory depressant effects that are quite variable, especially when combined with opioids.[1774]

Diazepam is useful as an oral premedication, although midazolam has overshadowed this role. Its main disadvantage when given intravenously is pain. Administering IV lidocaine before the diazepam and administering the diazepam slowly through a rapidly flowing IV catheter minimizes this pain. Diazepam is avoided in neonates and infants because of the prolonged half-life of the drug and its metabolites. Finally, diazepam should not be administered intramuscularly because of the pain and erratic absorption.

Other Sedatives

CLONIDINE

Clonidine is also commonly used in pediatric anesthesia practice as a premedicant, as an adjunct to anesthesia and analgesic agents, to reduce ED, as an antiemetic, to prevent postoperative shivering, to supplement regional blockade, and to reduce the stress response secondary to tracheal intubation and surgery.[1775] Clonidine can be administered by the IV, IN, IM, transdermal, oral, rectal, and epidural routes.[127,1776,1777]

The clonidine target concentration depends on the effect sought. A plasma clonidine concentration range of 0.3 to 0.8 µg/L has been estimated as satisfactory for preoperative sedation in children 1 to 11 years.[1778] Fifty percent of children achieve a modified Ramsay sedation score of 3 (appears asleep, purposeful responses to verbal commands at conversation level) at a concentration of 0.79 µg/L, and 90% of children achieve this at 0.95 µg/L. The concentration required for 50% of children to achieve a sedation scale of 4 (appears asleep, purposeful responses to verbal commands but at louder than usual conversation level or requiring light glabellar tap) is slightly more at 0.85 µg/L, and 90% of children achieve this at 1.15 µg/L.[1779] A BIS of less than 60 in adults is associated with adequate anesthesia, and this is achieved with a concentration of 4 µg/L[1780]; the target concentration for analgesia in adults is greater than that for sedation. Reduction of morphine use of up to 30% is reported when clonidine is added to analgesic regimens[1780,1781] with a plasma clonidine concentration of 1.5 to 2 µg/L.[1782,1783] The biphasic hypotensive/hypertensive BP response, reported with dexmedetomidine (see later text[1784]), has also been demonstrated with clonidine. Decreases in BP were related to plasma concentration of 1.5 to 2 µg/L, but at greater concentrations the hypotensive effect was attenuated.[1785]

Approximately 50% of clonidine is eliminated unchanged by the kidney. The exact amount of clonidine that undergoes hepatic biotransformation is uncertain, but has been reported to be between 40% and 60% after IV administration.[1785–1788] The major metabolite of clonidine is *p*-hydroxyclonidine, formed by hydroxylation of the phenol ring, which accounts for less than 10% of the concentration in the urine.[1786] Cytochrome P450 2D6 is involved in this process.

Clearance estimates in children who are not infants are similar to those described in adults when standardized for size using allometric scaling (CL 12.8–16.7 L/hour per 70 kg). Population parameter estimates (between subject variability) for a two-compartment model were CL 14.6 (CV 35.1%) L/hour per 70 kg; central Vd (V1) 62.5 (71.1%) L/70 kg; intercompartment clearance (Q) 157 (77.3%) L/hour per 70 kg; and peripheral Vd (V2) 119 (22.9%) L/70 kg. Clearance at birth was 3.8 L/hour per 70 kg and matured with a half-time of 25.7 weeks to reach 82% of the adult rate by 1 year of age. Clearance in neonates is approximately one-third that described in adults, consistent with immature elimination pathways.[1777] The volumes of distribution, but not clearance, were increased after cardiac surgery (V1 123%, V2 126%). There was a lag time (T_{LAG}) of 2.3 (CV 73.2%) minutes before absorption

began in the rectum. The absorption half-life (Tabs) from the epidural space was slower than that from the rectum (0.98 hours CV 24.5% vs. 0.26 hours CV 32.3%). The relative bioavailability of epidural, nasal, and rectal clonidine was unity (F = 1).[1776,1777] Oral bioavailability is reduced in children (F = 0.55).[127]

DEXMEDETOMIDINE

Dexmedetomidine (Precedex), the *dextro* optical isomer of medetomidine, is a pharmacologically selective α_2-agonist with sedative, anxiolytic, and analgesic properties. Dexmedetomidine is in the same class as clonidine but differs from clonidine in its eightfold greater affinity for α_2- compared with α_1-receptors than with clonidine. In anesthesia and intensive care, dexmedetomidine is currently being administered for procedural sedation and as an anesthetic adjunct.

Dexmedetomidine exerts its effects on numerous organ systems via α-adrenoceptors. These sympathetic adrenoceptors are categorized as either α_1- or α_2-receptors, based on receptor selectivity.[1789] The latter are further subdivided into three subtypes: α_{2A}-, α_{2B}-, and α_{2C}-adrenoceptors according to ligand binding. The α_2-agonists, such as dexmedetomidine, bind all three receptor subtypes, although the receptor subtype binding may vary with the dose of dexmedetomidine. The α_2-adrenoceptors trigger responses by activating G proteins. The common path for the effector response to dexmedetomidine is sympatholysis (suppression of the sympathetic nervous system). Depending on the specific receptor that is activated, α_2-agonists may cause hypotension, bradycardia, sedation, analgesia, attenuation of shivering, and a number of other physiologic responses. Consequently, dexmedetomidine use in neonates and children has expanded to include prevention of ED, postoperative pain management, invasive and noninvasive procedural sedation, and the management of opioid withdrawal.[751,1790–1798]

The α_2-adrenoceptors are located ubiquitously throughout the body. In the CNS, they are located primarily in the locus coeruleus, spinal cord, and autonomic nerves. The CNS manifestations of α_2-agonists include sedation and anxiolysis, both of which are mediated through the locus coeruleus. Sedation may also be mediated by α_2-agonist inhibition of the ascending norepinephrine pathways. Analgesia is mediated primarily via the spinal cord, although there is evidence that supraspinal and peripheral nerves may contribute to this effect as well. Cardiovascular manifestations of α_2-adrenoceptors include actions on the heart and on peripheral vasculature. The primary action of α_2-adrenoceptors on the heart is a chronotropic effect in which it slows heart rate by blocking the cardioaccelerator nerves as well as by augmenting vagal activity. In infants, dexmedetomidine-induced bradycardia may be exacerbated by the coadministration of digoxin. Decreasing the dose of dexmedetomidine restores the heart rate to normal values.[1799] The α_2-agonist action on the autonomic ganglia includes decreasing sympathetic outflow, which can lead to hypotension and bradycardia. Actions on the peripheral vasculature depend on the dose of dexmedetomidine: vasodilatation is the result of sympatholysis, which occurs at low doses, and vasoconstriction is the result of direct action on smooth muscle vasculature at large doses (Fig. 7.28).

In the peripheral nervous system, α_2-adrenoceptors are located at both the presynaptic and postsynaptic junctions.[1789] The presynaptic and postsynaptic effects of α_2-agonists diminish norepinephrine release and inhibit sympathetic activity. Other manifestations of α_2-adrenoceptors include inhibition of shivering as well as promotion of diuresis, although their mechanisms remain elusive.[1789,1800]

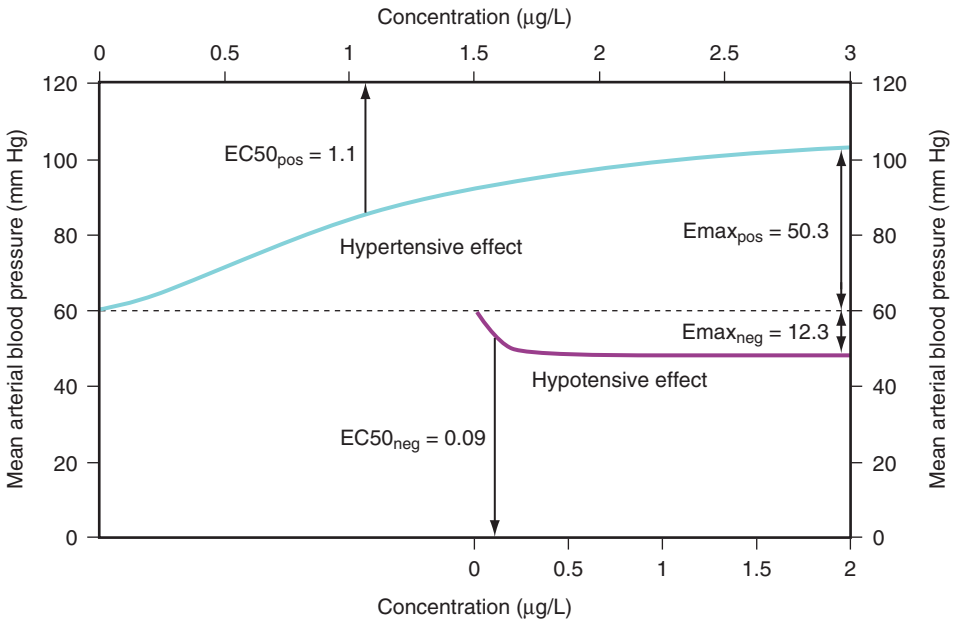

FIGURE 7.28 Composite Emax model showing the hypertensive and hypotensive effect of dexmedetomidine on mean arterial blood pressure in children after cardiac surgery. The vasoconstrictor effect occurred with minimal time delay, whereas an equilibration half-time ($T_{1/2}$keo) of 9.66 minutes was estimated for the sympatholytic response.[2035] *EC50*, concentration that produces half the maximal effect. (Reproduced with permission from Potts AL, Anderson BJ, Holford NH, Vu TC, Warman GR. Dexmedetomidine hemodynamics in children after cardiac surgery. *Pediatr Anesth*. 2010;20(5):425–433.)

A plasma concentration in excess of 0.6 μg/L is estimated to produce satisfactory sedation in adult ICU patients,[1801] and similar target concentrations are estimated in children who require sedation in the ICU after cardiac surgery.[1802] Hypotension has been described in children after cardiac surgery[1784] and in children presenting for sedation during radiologic procedures. In infants and children sedated with large-dose dexmedetomidine, the incidence of hypertension was 5%, affecting a larger fraction of those younger than 1 year of age and those who required an additional bolus dose to maintain sedation.[1803] These adverse cardiovascular effects of dexmedetomidine generate some concern. Dexmedetomidine also decreases heart rate in a dose-dependent manner in children.[1792,1804–1807] This effect is attributed to a centrally mediated sympathetic withdrawal, which results in unregulated cholinergic activity. With large doses of dexmedetomidine (2–3 μg/kg over 10 minutes followed by 1.5–2 μg/kg per hour), 12 children younger than 6 years of age experienced heart rates less than 50 beats/minute although their BPs were maintained.[1807] Administration of anticholinergics or other medications to increase the heart rate during dexmedetomidine-induced bradycardia has not been required, but it should be noted that severe and persistent hypertension has been reported when glycopyrrolate was used to treat large-dose dexmedetomidine-induced bradycardia.[1808] Dexmedetomidine 0.5 μg/kg IV has resulted in several episodes of bradycardia 30 seconds or longer with an unrecordable systolic BP in two children during strabismus surgery (without anticholinergic pretreatment) when the surgeon pulled gently on the extraocular muscle (personal communication, JL, 2017). Vital signs were restored after administration of ephedrine 0.1 to 0.2 mg/kg IV.

Less favorable results have been noted in the electrophysiology laboratory. Heart rate decreased and arterial BP increased significantly after 1 μg/kg IV over 10 minutes followed by a 10-minute continuous infusion of 0.7 μg/kg per hour. Both sinus and atrioventricular node function were depressed. The use of dexmedetomidine may not be prudent during electrophysiology studies and may be associated with adverse effects in patients at risk for bradycardia or atrioventricular nodal block.[1809] However, dexmedetomidine did not interfere with the conduct of pediatric electrophysiologic studies for supraventricular tachycardia and the successful ablation of such arrhythmias, this despite a greater need for isoproterenol when dexmedetomidine was used.[1810] Conduction delay caused by dexmedetomidine has been used to decrease the incidence of junctional ectopic tachycardia after tetralogy of Fallot repair.[1811]

Population parameter estimates for a two-compartment model were clearance of 42.1 L/hour per 70 kg (CV = 30.9%), central Vd of 56.3 L/70 kg (CV 61.3%), intercompartment clearance of 78.3 L/hour per 70 kg (CV 37.0%), and peripheral Vd of 69.0 L/70 kg (CV 47.0%).[1802] Clearance increases from 18.2 L/hour per 70 kg at birth in a full-term neonate to reach 84.5% of the mature value by 1 year postnatal age (see Figs. 7.4 and 7.11). The clearance of dexmedetomidine after an infusion after cardiac surgery was reduced (83.0%) compared with the clearance after a bolus in a noncardiac surgical population.[1802] Similar parameter estimates, including a reduced clearance in children who received a dexmedetomidine infusion after cardiac surgery, have been described by others[1812]; this trait has also been described for morphine, fentanyl, and midazolam.

The preferred route of administration of dexmedetomidine is the IV route, although others have been studied. The PK of dexmedetomidine have also been studied after parenteral (IM), buccal, and oral administration.[1813] Parenteral delivery yielded kinetics similar to the IV route, buccal administration yielded an 82% bioavailability, and orogastric delivery yielded only a 16% bioavailability. Data from adults indicate limited effects of renal failure on the kinetics of dexmedetomidine.[1814] Dexmedetomidine is metabolized extensively in the liver (UGT enzymes), with 40% metabolized by CYP2D6 isozyme.[1800] After metabolism to methyl and glucuronide conjugates, 95% of dexmedetomidine is eliminated via the kidneys.[1815] There appears to be no evidence that dexmedetomidine interferes with the PK of other medications that are substrates for CYP2D6 metabolism.[1815] Dexmedetomidine is 93% protein-bound in children.[1800,1806]

Dexmedetomidine is formulated as a concentrated solution in a 2-mL vial (100 μg/mL). After diluting it with normal saline, lactated Ringer's solution, or 5% dextrose in water to an appropriate concentration, dexmedetomidine can be delivered by syringe pump. Current dosing recommendations for dexmedetomidine begin with a loading dose followed by an infusion, although some skip the loading dose during general anesthesia and administer only an infusion.[1792,1806,1816] The recommended loading dose is 1 μg/kg dexmedetomidine infused over 10 minutes, although loading doses between 0.5 and 3.0 μg/kg have been reported.[751,1792,1803,1816–1818] The purpose of infusing the loading dose over 10 minutes (as opposed to a rapid IV bolus) is to attenuate the severity of the hypertension that can occur with bolus dosing. After completing the loading dose, dexmedetomidine should be infused at 0.5 to 1 μg/hour per kilogram.[751,1792,1816–1818] (*Note:* dexmedetomidine is infused in *micrograms per kilogram per hour, not micrograms per kilogram per minute*.) In the United States, dexmedetomidine is approved only for infusion up to 24 hours, although data exist attesting to hemodynamic stability even after infusions of greater duration.[1819] One reservation concerning dexmedetomidine is the fear of a withdrawal from dexmedetomidine itself after prolonged use (>24 hours). Up to 80% of children (0–17 years) in intensive care experienced withdrawal symptoms after infusion (0.42 ± 0.17 μg/kg per hour).[1820,1821]

When compared with propofol for sedation during MRI, dexmedetomidine provides adequate sedation during the scan but has a slower onset and recovery profile.[1819,1822] It is our experience, and that of others, however, that sedation with the recommended maximal doses of dexmedetomidine generally require the addition of other sedatives, such as midazolam, for a child to remain motionless for a procedure such as an MRI.[751,1823,1824]

One of the major advantages of dexmedetomidine over other sedatives is its minimal respiratory depression in adults and children.[1804–1806,1816,1825–1827] Although dexmedetomidine blunts the CO_2 response curve,[1828] it does not lead to extreme hypoxia or hypercapnia. Indeed, respiratory rate, CO_2 tension, and oxygen saturation are generally maintained during dexmedetomidine sedation in children.[751,1806,1817] In children without OSA, increasing doses of dexmedetomidine (1–3 μg/kg) result in small changes in the upper airway and are not associated with clinical signs of airway obstruction. Even though these changes are small, all precautions to manage airway obstruction should be taken when dexmedetomidine is used for sedation.[1829] In children with suspected OSA, significantly less frequent artificial airway support was required when dexmedetomidine (2 μg/hour per kilogram) was used for sedation for MRI sleep studies, compared with propofol for sedation.[1830]

Quantifying the MAC-sparing effect of dexmedetomidine has proven difficult. Three studies have estimated the MAC of isoflurane or sevoflurane in adults at two concentrations of

dexmedetomidine–high (0.6–0.7 ng/mL) and low (0.36–0.3 ng/mL).[1805,1831,1832] The MAC-sparing effect of large-dose dexmedetomidine concentration ranged from 17% to 50% and that of low-dose dexmedetomidine concentration from 0% to 35%. Accordingly, it is difficult to predict the exact MAC-reducing effect of dexmedetomidine on sevoflurane and isoflurane in adults. Similar data in children have not been forthcoming.

Dexmedetomidine provides an interesting quality of sedation that permits arousal with gentle stimulation.[1806] The lack of respiratory depression distinguishes this sedative from opioids, benzodiazepines, and other sedatives. It has been studied for sedation in children for a number of different purposes, including radiologic procedures such as MRI.[751,1792,1816,1817]

Dexmedetomidine provides a modest degree of analgesia, reducing the need for, but not totally supplanting, opioids and other analgesics. Several studies demonstrated that it spares opioid requirements during surgery.[1800,1833,1834]

The CNS effects of dexmedetomidine have been addressed in animals and, in part, in humans.[1835] The data suggest that dexmedetomidine decreases CBF directly by vasoconstricting the smooth muscle of the cerebral blood vessels, and indirectly through a reduction in arterial BP and cardiac output. In humans, dexmedetomidine decreases CBF by 30%, as determined by positron emission tomography, as well as Doppler measurements of the middle cerebral artery. Interestingly, using Doppler measurements of the cerebral blood vessels in adult volunteers, both the CO_2 response and autoregulation of CBF were preserved. When dexmedetomidine was infused before introducing an inhalational anesthetic, dexmedetomidine attenuated the cerebral vasodilatation induced by the inhalational anesthetic.

Dexmedetomidine depresses sensory-evoked potentials but, for the most part, the potentials are adequate for evaluations.[1836] Similarly, motor-evoked potentials are reduced in a dose-dependent manner during dexmedetomidine infusion but are measurable nonetheless.[1837] There are contrasting reports about the degree of evoked potential suppression, but most report successful spinal cord monitoring during scoliosis surgery.[1838–1841]

ED occurs in 15%–30% of children after most inhalational anesthetics particularly in the 3–5 year age range.[1825] A number of medications attenuate the incidence of delirium after anesthesia, including dexmedetomidine.[1795] Dexmedetomidine decreases the incidence of ED after sevoflurane anesthesia: after an infusion of dexmedetomidine (0.2 μg/kg per hour), recovery was not prolonged,[1842] whereas after a single dose of 0.5 μg/kg administered 5 minutes before the end of surgery, emergence was prolonged.[1843] Further studies are required to assess the cost/benefit ratio for this indication.

The interaction between dexmedetomidine and neuromuscular blockade has been studied during balanced anesthesia with propofol and alfentanil.[1844] In adults, dexmedetomidine decreased the twitch response after sevoflurane 7%, although this was not deemed to be clinically important. Current evidence does not substantiate any clinically significant interaction between dexmedetomidine and neuromuscular blockade.

At present, this medication seems to offer specific advantages for awake fiberoptic intubation, awake craniotomy, sedation in the ICU (opioid-sparing), and perhaps for reducing the incidence of ED.[1796,1845–1848] However, high-dose dexmedetomidine is associated with adverse effects on the heart rate and BP, and unpredictable effects with anticholinergics.[1808,1849] Additional research in children is required before recommendations can be made regarding appropriate dosing and drug interactions.[1809,1850,1851] There are conflicting data regarding its safety in children with congenital heart disease.[1809,1852–1854]

CHLORAL HYDRATE

Chloral hydrate is one of the oldest and, in the past, most widely used sedatives in infants and children, exerting its sedation effect by enhancing the GABA receptor complex. Like many other sedatives, it has no analgesic properties. Its primary use in pediatrics is for sedation for noninvasive procedures and as a premedication. Its principal advantage is that it may be administered orally or rectally, with excellent absorption and relatively good sedation, within 30 to 45 minutes, and the infrequent need to supplement the sedation with other sedatives. The usual dose is 20 to 75 mg/kg orally or rectally, although total doses up to 100 mg/kg (maximum 2 grams) have been used alone or in combination with other sedatives.

Chloral hydrate used to be the most commonly used sedative for infants undergoing a variety of nonpainful procedures[1855–1859]; however, chloral hydrate liquid production ceased in the United States in May 2012 (https://www.drugs.com/drug-shortages/chloral-hydrate-oral-solution-and-capsules-902 [accessed September 29, 2017]). Since this drug is no longer commercially available in the United States, individual hospital pharmacies must reformulate it with reconstituted crystals. One study reported that the duration of sedation was less, the frequency of supplemental sedatives greater, and the incidence of sedation failures greater with compounded chloral hydrate compared with the commercial preparation.[1860]

Chloral hydrate has minimal effects on respiration[1861]; however, it has caused airway obstruction and desaturation, particularly in children with enlarged tonsils.[1862–1864] In addition, apnea, airway obstruction, bradycardia, and hypotension have been reported in a series of infants younger than 6 months of age who were sedated for echocardiograms; this report emphasized that this is not the benign drug that many previously thought.[1865] Indeed, arrhythmias have been reported after chloral hydrate, attributed to its primary metabolite, trichloroethanol. After a single dose of 30 mg/kg, sedation was evident for up to 12 hours after administration in former premature nursery graduates. Bradycardia (as slow as 60 beats/minute) was also observed in these neonates.[1866] Deaths after chloral hydrate overdose when given for sedation have also been reported.[1257,1867,1868]

Chloral hydrate has several disadvantages. It has a bitter taste and is known to cause vomiting.[1869] This drug should not be administered for long periods of time because theoretically (1) its metabolites may be carcinogenic, (2) it may cause severe gastritis (possibly related to its metabolism to trichloroacetic acid), and (3) drug metabolites may accumulate.[1870,1871] In addition, it may interfere with the binding of bilirubin to albumin and toxic metabolites may accumulate, leading to metabolic acidosis, renal failure, and hypotonia in neonates.[1872]

Chloral hydrate is metabolized in the liver and erythrocytes by alcohol dehydrogenase to an active metabolite, trichloroethanol, which has a half-life of 9.7 ± 1.7 hours in toddlers but 39.8 ± 14.3 hours in preterm infants (see Fig. 48.3).[1873] Trichloroethanol is cleared by UGT (see the sections on morphine, acetaminophen, and dexmedetomidine), which is immature in neonates. These very long half-lives imply that residual drug effect will be present long after any procedure requiring sedation.[1874–1876] Because of the long half-life, there is a real risk for prolonged sedation, resedation after leaving medical supervision, and death.[1868,1877–1880] It is for this reason that *chloral hydrate is not generally recommended for premedication before surgery* and that a prolonged period of observation is recommended after sedation for a procedure. If nitrous oxide

is administered to children who have received chloral hydrate, a state of deep sedation or general anesthesia may occur.[1881]

Antihistamines

DIPHENHYDRAMINE

Antihistamines are often used in pediatric anesthesia both for their histamine 1 (H_1)-receptor inhibition and for their sedative properties. Diphenhydramine (Benadryl) is one of the more commonly used antihistamines. It is rapidly absorbed when administered orally (at a dose of 1.25 mg/kg) with a duration of effect that lasts anywhere from 3 to 6 hours. Clearance is through CYP2D6 (see the section on codeine and Chapter 6). It is often administered as a premedicant or as an in-hospital sedative. Caution is advised for children with respiratory problems because diphenhydramine dries secretions, causing difficulty expectorating. The IV dose to treat an allergic reaction is 0.5 mg/kg.

CIMETIDINE, RANITIDINE, AND FAMOTIDINE

Cimetidine (Tagamet) was the first generation of potent, very hydrophilic, competitive inhibitors of H_2-receptor–mediated histamine reactions, which was later followed by ranitidine and famotidine. This class of drugs increases gastric-fluid pH and reduces gastric fluid residual volume.[1882] Indications for an H_2-receptor antagonist include a history of gastroesophageal reflux, hiatus hernia, previous esophageal surgery, obesity, or an anticipated difficult intubation that will require prolonged laryngoscopy, as well as, perhaps, high-risk patients (American Society of Anesthesiologists classes 3 and 4). Cimetidine is likely the most studied of this category of drugs, but its use has diminished because of serious drug interactions through its effects on the cytochrome oxidase system. Cimetidine partially inhibits numerous CYP enzymes (CYP1A2, CYP2C9, CYP2C19, CYP2D6, CYP2E1, and CYP3A4), which prolongs the half-lives of many drugs, including phenytoin, phenobarbital, theophylline, cyclosporine, carbamazepine, benzodiazepines that do not undergo glucuronidation, calcium channel blockers, propranolol, quinidine, sulfonylureas, mexiletine, warfarin, and tricyclic antidepressants, such as imipramine.[1883] The elimination half-life of cimetidine is prolonged in neonates and infants compared with older children.[1884] The kidney is the primary clearance organ in children. Renal clearance in children 4 to 13 years constituted 70% of total body clearance, more than double that of adults. As expected, children have a greater total body clearance (11.6 mL/minute per kilogram) than do adults (7.0 mL/minute per kilogram), a larger Vd (1.24 vs. 0.80 L/kg), and a shorter elimination half-life (83 vs. 122 minutes).[1885]

Although ranitidine (Zantac) also weakly reduces CYP activity, *it does not increase the half-life of other medications significantly* when administered at the usual therapeutic doses.[1886–1889] Ranitidine has been administered by intermittent bolus (2–4 mg/kg in four divided doses), or as a loading dose (0.5 mg/kg) followed by an infusion of 0.05 mg/kg per hour.[1890–1892] The peak effect occurs between 2 and 4 hours after administration.[1495] The elimination half-life of ranitidine is 3 ± 1.35 hours. When a dose of 1.5 mg/kg per 8 hours was administered, ranitidine maintained the gastric fluid pH greater than 4.[1891] Reduced doses have met with less success in controlling the gastric fluid pH.[1890]

Famotidine (Pepcid) is about eight times more potent than ranitidine and about 40 times more potent than cimetidine.[1893] Famotidine has been well studied, including in neonates. Because famotidine is primarily excreted by the kidneys, dosing depends on the maturity of the renal function. Infants younger than 3 months of age have reduced clearance and require 24 hours between doses (0.25 mg/kg IV or 0.5 mg/kg orally), whereas infants older than 3 months are similar to older children and adults and require 12 hours between doses.[1884,1894,1895] There is some evidence to suggest decreased responsiveness to famotidine (a weaker effect in altering gastric acid pH and volume) with long-term administration.[1896] Famotidine increases gastric fluid pH, although it does not reduce gastric residual volumes when administered before anesthesia.[1897]

Antiemetics

METOCLOPRAMIDE

Metoclopramide (Reglan) has been used in children for its antiemetic and gastric emptying properties.[1898] The antiemetic properties result from its direct effects on the chemoreceptor trigger zone. Gastric emptying is a result of the antagonism of the neurotransmitter dopamine, which stimulates gastric smooth muscle activity.[1899,1900] A dose of 0.15 mg/kg at the end of surgery effectively reduces emesis after strabismus surgery and tonsillectomy, although the magnitude of its effectiveness may be limited.[1901] Metoclopramide is less effective than 5-hydroxytryptamine type 3 (5-HT_3) receptor inhibitors, but does offer an alternative rescue medication.[1902] As with many other medications cleared by sulfate and glucuronide conjugation, the elimination half-life in neonates is prolonged compared with older children, thus necessitating a 6-hour interval between oral doses (0.15 mg/kg).[1903] Clearance in infants (0.9–5.6 months) was 0.67 ± 0.13 L/hour per kilogram with Vdss 4.4 ± 0.6 L/kg.[1904]

5-HYDROXYTRYPTAMINE TYPE 3–RECEPTOR ANTAGONISTS

Antagonists to the 5-HT_3 receptor include ondansetron (Zofran), granisetron (Kytril), dolasetron (Anzemet), tropisetron (Navoban), and palonosetron (Aloxi). These agents have proven to be an effective preventive and therapeutic measure for PONV. Notwithstanding their widespread usage, these drugs have been the subject of much debate regarding which is the most effective, which has the better side-effect profile, which lasts the longest, which is best combined with other agents, which costs too much, and so on.[1905–1917] Because ondansetron was the first in this class of serotonergic receptor antagonists that effectively reduced the incidence of nausea and vomiting in children, it forms the basis for discussion of measures to prevent PONV after pediatric surgery.[1918–1927] Some studies report that ondansetron (0.1 mg/kg) is superior to metoclopramide (0.15 mg/kg) for the prophylactic control of postoperative vomiting in children undergoing tonsillectomy.[1928] Most pediatric anesthesiologists limit their routine use to children undergoing procedures known to have a substantial incidence of PONV, such as strabismus repair, tonsillectomy, or middle ear surgery, and to children with a known history of motion sickness or previous nausea and vomiting after surgery.[1929–1937] Ondansetron is effective in preventing nausea and vomiting, as well as in reducing the severity of established nausea and vomiting. The usual recommended dose is 100 to 150 µg/kg every 6 hours. One clinical trial found efficacy in children as young as 1 month of age; however, the PK were different in the infants younger than 4 months of age, suggesting the need for a greater interval between dosing.[1938] This is not surprising, given that clearance is by hydroxylation, followed by glucuronide or sulfate conjugation in the liver. A mature clearance of 541 mL/minute per kilogram is reported, but ondansetron clearance was reduced by 31%, 53%, and 76% for the typical 6-, 3-, and 1-month-old infant, respectively. Clearance matured with a TM_{50} of 4 months.

Simulations showed that an ondansetron dose of 0.1 mg/kg in children younger than 6 months produced exposure similar to a 0.15-mg/kg dose in older children.[1939] One further concern with this class of drugs is the potential for ventricular tachyarrhthmias (e.g., Torsades de pointes) in patients with long QT syndrome, particularly when they are anesthetized with potent inhalation agents such as sevoflurane.[1940,1941] However, concentrations reached after routine dosing are well below the inhibitory concentration of 50% (IC_{50}) reported for inhibition of Na channels in healthy individuals.[1907]

A number of studies in children demonstrated that the antiemetic effect of drugs from this class can be improved if they are combined with dexamethasone or other anesthetic techniques known to reduce vomiting.[1922,1923,1925,1942,1943] An oral disintegrating tablet of ondansetron is also available.[1944]

Other agents in this class (e.g., granisetron, dolasetron, tropisetron) have all been shown to be effective in ameliorating PONV, which is further improved when combined with other antiemetic modalities.[1918,1936,1945–1952] Granisteron and tropisteron have more prolonged half-lives (7.8 hours) and coincident duration of effect than ondanstron (4 hours); these may be better suited to chemotherapy-induced nausea and vomiting. Tropisteron is metabolized by CYP2D6, which renders its termination susceptible to polymorphisms and an extended elimination half-life of 40 hours is reported in poor metabolizers (PM). CYP3A4 is the predominant enzyme pathway for ondandestron and granisteron metabolism.[1907]

Palonosetron is a new 5-HT_3 receptor antagonist that differs from the 5-HT_3 receptor antagonists described previously in that it allosterically inhibits the receptor rather than physically binding to the receptor.[1953] Because it takes 30 to 40 hours for the receptor to restore its normal conformation, the agent may be metabolized (and is susceptible to polymorphisms of CYP2D6), but that does not affect its antiemetic effect as the receptor remains deformed for the duration. Palonosetron effectively reduces PONV in adults.[1954] In a dose-finding study in children, 0.5 μg/kg palonosetron was as effective as 1 and 1.5 μg/kg for PONV for 48 hours after strabismus surgery.[1955] A double-blind, double dummy study of 502 pediatric patients undergoing emetogenic chemotherapy found non-inferiority for 20 μg/kg 6 hourly compared with ondansetron 150 μg/kg 8 hourly; it is now approved by the FDA and European Medicines Agency for this indication in children as young as 1 month of age.[1956]

NEUROKININ 1 AND OTHER ANTIEMETICS

Despite the introduction of 5-HT_3 receptor antagonists along with dexamethasone to treat PONV, PONV has continued. It has been known that the receptor for substance P, the neurokinin 1 (NK1) receptor, in the brainstem (area postrema and nucleus tractus solitarius) may hold the key to the persistence of PONV.[1957,1958] The first NK1 receptor antagonist is aprepitant (Emend), which has proven effective in reducing nausea and vomiting in adults after chemotherapy and surgery and in children after chemotherapy.[1959,1960] Aprepitant is an oral drug, fosaprepitant is the parenteral formulation of aprepitant, and several others are under development for use (and dosing) in PONV in combination with 5-HT_3 receptor antagonists and dexamethasone.[1961]

Anticholinergics

ATROPINE AND SCOPOLAMINE

Atropine (0.02 mg/kg) and scopolamine (0.01 mg/kg) both have CNS effects, although the sedating effect of scopolamine is 5 to 15 times greater than atropine. Scopolamine possesses two to three times more potent antisialagogue action than atropine. Atropine and scopolamine decrease the ability to sweat, and thus may cause a slight increase in temperature.[1962] Atropine and scopolamine have equipotent cardiovascular accelerator properties. The dose for both anticholinergics in infants to speed the heart rate is greater per kilogram than in adults.[1963] Anticholinergics are appropriate in specific situations, such as to diminish secretions preoperatively, to block laryngeal and vagal reflexes, to treat or prevent the bradycardia associated with succinylcholine, to treat the bradycardia of anesthetic-induced myocardial depression, the muscarinic effects of neostigmine, and the oculocardiac reflex. Atropine is painful when administered intramuscularly. When it is administered as a premedicant, it does not block laryngeal reflexes; it is more effective in blocking laryngeal reflexes when it is given by the IV route. Although some data suggest that children with trisomy 21 are more susceptible to the cardiac effects of atropine,[1964] our clinical experience and that of others do not support this notion.[1965,1966] Because some children with trisomy 21 have narrow-angle glaucoma, atropine must be administered cautiously because it might worsen the glaucoma.[1965,1966] Atropine may be administered orally, rectally, and via the trachea. Oral atropine may blunt the hypotensive response to potent inhalation agents during induction of anesthesia in infants younger than 3 months of age.[1967] When administered via the trachea, atropine is rapidly absorbed, producing physiologic effects.[1968–1971]

Atropine is metabolized in the liver by *N*-demethylation followed by conjugation with glucuronic acid[1972]; both processes are immature in the neonate. Half the drug is also eliminated by the kidneys. An old technique to diagnose atropine poisoning was to place a small aliquot of the victim's urine into the eye of a cat and observe for mydriasis!

It is anticipated that clearance is reduced in the neonatal age range because of an immaturity of renal and hepatic function, but data remain elusive. Children younger than 2 years have an increased Vdss compared with those older than 2 years (3.2 ± 1.5 vs. 1.3 ± 0.5 L/kg).[1973] Clearance was similar in those younger than 2 years (6.8 ± 5.3 mL/minute per kilogram) and those older than 2 years (6.5 ± 1.6 mL/minute per kilogram). The elimination half-life in healthy adults is 3 ± 0.9 hours, whereas that in term neonates is 4 times this.[1973,1974]

PD characterization is similarly lacking in neonates. Some have held that the minimum dose of atropine in neonates and infants is 0.1 mg; recent evidence has demonstrated that 5-μg/kg IV atropine in young infants 1 to 12 months does not increase heart rate or cause bradycardia.[1975] Infants younger than 6 months require a larger dose to increase heart rate than older children.[420] A dose of 5 μg/kg had no impact on heart rate and does not cause bradycardia in young infants 4 to 6 months age.[1975] Systolic BP did not change for any dose of atropine (5–40 μg/kg) in this neonatal cohort.[420]

In clinical practice, scopolamine is usually limited to those situations in which its sedative effect, combined with that of morphine, will be most advantageous, such as during cardiac surgery. It is also very useful as an adjuvant to ketamine anesthesia because of its antisialagogue and central sedative effects. The central sedative effects of both atropine and scopolamine may be antagonized with physostigmine. Most centers no longer routinely administer anticholinergic medications as part of the premedication because they are painful, the optimal effect may not coincide with induction of anesthesia, and current potent inhalation agents produce fewer secretions and infrequent bradycardia.

Scopolamine is a tertiary amine with greater CNS effects than atropine, causing sedation and amnesia. It has moderate antiemetic activity.[1976] To minimize the relatively large incidence of side effects, the transdermal dosage form has been developed for nausea and vomiting; however its use is generally limited to teenagers to avoid potential toxicity.[1977–1979] Scopolamine patch–induced delirium has been reported and is more likely in younger patients.[1980] Unequal pupils have also been reported.[1981]

Scopolamine has a distribution volume of 1.4 L/kg in adults.[1969] Glucuronide conjugation, sulfate conjugation, and hydrolysis by the CYP3A family are involved in its clearance.[1977] Both glucuronidation and the CYP3A enzyme systems are immature at birth and clearance is anticipated to be reduced.[1969]

GLYCOPYRROLATE

Glycopyrrolate (0.005–0.01 mg/kg) is a synthetic quaternary ammonium compound with potent anticholinergic properties. It offers some advantage over atropine and scopolamine because it minimally penetrates the BBB and thus causes few CNS effects. Several studies have demonstrated that glycopyrrolate is superior to atropine because its anticholinergic effects are more prolonged, lasting several hours.[1982,1983] The heart rate changes minimally after IV administration, causing fewer arrhythmias and offering an advantage when tachycardia might be detrimental.[1984,1985] It should be noted that prolonged and severe hypertension has been reported when glycopyrrolate was used to treat dexmedetomidine-induced bradycardia[1808]; the mechanism for the hypertension is unknown. Further pretreatment of children before administration of dexmedetomidine demonstrated no value in blunting bradycardia and resulted in greater increases in systolic BP compared with no pretreatment (~20% vs. ~10%).[1986] In some children, gastric fluid volume and acidity are reduced after glycopyrrolate administration.[1987,1988] The drug remains popular for antagonizing the parasympathomimetic effects of neostigmine and is as effective as atropine for preventing the oculocardiac reflex.[1989]

There is poor absorption from the gastrointestinal tract (10%–25%).[1990] Clearance in infants younger than 1 year (n = 8) was 1.01 (range 0.32–1.85) L/kg per hour and Vdss of 1.83 (range 0.70–3.87) L/kg,[1990] but there are no neonatal data available. However, the renal system accounts for 85% of elimination,[1982] and clearance is anticipated to be reduced in neonates because renal function is immature.[171]

Antagonists

NALOXONE

Naloxone (Narcan) is a pure opioid antagonist with a greater affinity for the μ-receptor compared with the κ- and δ-receptors. When given intravenously, naloxone has a very rapid onset of antagonism of the opioid receptors (within 30 seconds to 1 minute). Naloxone undergoes glucuronidation in the liver, with minimal bioavailability after oral administration. In adults, the elimination half-life is 1 to 1.5 hours, whereas in neonates it is 3 hours. When administered intramuscularly, the apparent elimination half-life is prolonged from 80 minutes to 6 hours in adults because of the depot effect.[1991]

Naloxone is effective for reversing opioid-induced adverse effects, including respiratory depression, chest-wall and glottic rigidity, nausea and vomiting, pruritus,[1992] urinary retention, and constipation. It may be administered via any route, including parenteral, neuraxial, tracheal, and oral. For children who are ventilating and not in extremis, but in whom opioid-induced respiratory depression needs antagonism in the perioperative period, it is reasonable to initiate antagonism with a very small dose of IV naloxone (0.25–0.5 μg/kg). This is similar to the dose recommended in one large review of 10 to 20 μg of naloxone in children in the perioperative period.[1993] If the response is inadequate, the same dose may be repeated until ventilation improves. The same cumulative total IV dose of naloxone can then be administered as an IM injection to ensure that recrudescence of the respiratory depression does not occur. *For children in extremis or in whom a potential opioid overdose has occurred (including neonatal resuscitation), a larger dose of 10 to 100 μg/kg IV of naloxone may be indicated.* The American Academy of Pediatrics simplified the naloxone dosing for infants and children up to 5 years of age, recommending 100 μg/kg, and for children older than 5 years (20 kg), 2 mg naloxone.[1994] This is based, in part, on concerns that smaller doses of naloxone may not be uniformly effective. However, it is equally important to recognize that overzealous dosing of naloxone will not only reverse the opioid analgesic effect but could also lead to profound systemic hypertension, cardiac arrhythmias (including ventricular fibrillation), and pulmonary edema (noncardiogenic).[1995] Evidence suggests that pulmonary edema may not be a dose-dependent response to naloxone, because it has been reported after as little as a single dose of 100 μg. A retrospective review of the management of 195 children and adolescents who received naloxone postoperatively, in the emergency department, or in the pediatric ICU revealed an IV dosing range of 1 to 500 μg/kg; this resulted in resolution of the respiratory depression, systolic hypertension in 17% of children, and one case (incidence of 0.5%) of pulmonary edema.[1993] A continuous infusion of naloxone may be required to treat severe opioid-induced respiratory depression.[1996] *Any child who receives naloxone for antagonism of opioid-induced respiratory depression must be observed in a monitored environment for a minimum of 2 hours to ensure that there is no recrudescence of the respiratory depression.*

The recommended dose of naloxone during neonatal resuscitation far exceeds that in older children. Doses as great as 400 μg/kg have been used without ill effects.[1997] In a systematic review of naloxone use in neonates, evidence demonstrated that naloxone increased alveolar ventilation, although there was no evidence that outcome, in terms of assisted ventilation or admission to a neonatal ICU, was affected by the use of naloxone.[1998] Caution is recommended when administering naloxone to an infant of a mother who has chronically abused opioids because seizures have been reported.[1999]

Naloxone has also been administered via infusion at low doses (≥ 1 μg/kg per hour)[2000] concomitantly to ameliorate adverse effects from opioids, including nausea and vomiting, pruritus, urinary retention, and constipation.[2001] Evidence is mixed regarding the beneficial effect of such a practice,[2002,2003] although double-blind, randomized controlled trials have provided a significant reduction in morphine-associated nausea and pruritus during patient-controlled analgesia when administered as a separate infusion.[2004] When administered for this indication, there is a need to balance antagonism of the opioid-induced side effects with the antagonism of the pain relief.

NALTREXONE

Naltrexone (Depade, ReVia) is an oral opioid antagonist that also has a greater affinity for the μ- rather than κ- and δ-receptors. The activity of naltrexone is thought to be a result of both the parent and its 6β-naltrexol metabolite (via hepatic dihydrodiol dehydrogenase). The mean elimination half-lives for naltrexone

and 6β-naltrexol in adults are 4 hours and 13 hours, respectively. Naltrexone has a good oral bioavailability, with an elimination half-life of up to 8 hours in children, which is similar to adults.[2005] This opioid antagonist has also been used in the management of autism.[2006,2007] Children displaying self-injurious behavior or hyperactivity have been noted to have high CSF endorphin concentrations and decreased pain sensitivity. Some opioid-induced behavior in animals and opioid addicts resembles that seen in autistic children. Naltrexone reduces self-injurious behavior.[2006]

Although naltrexone reverses opioid-associated adverse effects, its use for this purpose has not become popular.[1998] Naltrexone and its primary metabolite, 6β-naltrexol, are excreted, albeit in low concentrations, in breast milk from a lactating female.[2008] Care should be taken when managing infants of opioid-addicted mothers.

METHYLNALTREXONE

Methylnaltrexone (Relistor) is the first quaternary ammonium opioid antagonist that has very limited ability to penetrate the BBB.[2009] It is prepared in an oral as well as in a parenteral formulation for subcutaneous and IV administration. Doses of 0.45 mg/kg have been administered intravenously to adults. Because methylnaltrexone does not cross the BBB, it is suited to reverse the peripheral adverse side effects of opioids without attenuating the central analgesic effect. Opioid-induced side effects, including gastric emptying, urinary retention, postoperative ileus, and chronic constipation,[2010] improve after administration of methylnaltrexone.[2011–2015] There are few pediatric data available. If the preliminary adult safety and efficacy data are also demonstrated in children, this drug may offer the benefit of improving our ability to provide opioid-induced analgesia, while eliminating many of the peripheral adverse effects, thus improving the comfort of children. The drug is used currently for opioid-induced constipation in children with cancer and those in palliative care.[2016]

FLUMAZENIL

Flumazenil (Romazicon) is a specific $GABA_A$ receptor–competitive antagonist that reverses the effects of benzodiazepines. Flumazenil has been administered by rectal, nasal, IM, and IV routes.[2017–2020] After a single IV dose, flumazenil shows limited protein binding (40%) with an elimination half-life of approximately 1 hour in adults, owing primarily to rapid and extensive metabolism by hepatic carboxylesterases.[2021–2023] In adults with severe liver disease, elimination of flumazenil is reduced.[2024] In children, the elimination half-life after a single IV dose of 10 μg/kg flumazenil followed by an infusion of 5 μg/kg per minute is 35 minutes.[2025] The rectal dose required is greater (e.g., 50 μg/kg). The PK of intranasal flumazenil (40 μg/kg) were determined in healthy children with a median age of 4 years. The elimination half-life was 2 hours.[2017] Oral flumazenil is also available, but its bioavailability is only 16% owing to the first-pass effect in the liver.[2023]

In adults, a dose of 17 μg/kg of flumazenil has antagonized benzodiazepine-induced sedation; studies in children have found doses of 24 μg/kg to be clinically effective without evidence of re-sedation.[2025] There is a limited role for flumazenil in clinical pediatric anesthesia, although specific indications are warranted, including benzodiazepine overdose, wake-up test during scoliosis surgery, treatment of a comatose child, and paradoxical response to benzodiazepines.[2026,2027] *With its brief elimination half-life, re-sedation after the initial response has been reported in children 1 to 5 years of age, thus necessitating close observation for at least 2 hours after antagonism of benzodiazepine-induced sedation.*[2028,2029] Caution should be taken in administering larger doses of flumazenil because seizures have been reported.[2030]

PHYSOSTIGMINE

This tertiary ammonium is a reversible cholinesterase inhibitor used to treat central cholinergic syndrome and delirium, and to antagonize the actions of atropine and scopolamine in the peripheral nervous system and CNS.[2031–2033] It is not generally used to antagonize neuromuscular blockade because its nonionized ammonium group facilitates transfer across the BBB, causing CNS effects. After an IV dose, its elimination half-life is 20 to 30 minutes with a duration of action that may exceed 1 hour, depending on the cholinesterase activity. Physostigmine is hydrolyzed at the ester linkage by cholinesterase. The usual single IV dose of physostigmine in children is 10 to 30 μg/kg.[2034] To treat intoxication by long-acting drugs, an infusion of physostigmine may be required at an infusion rate of 30 μg/kg per hour. Side effects of physostigmine include cardiac arrhythmias (bradycardia), cholinergic crisis, and seizures.[2034] Accordingly, physostigmine should be administered with electrocardiographic monitoring.

Upton RN, Foster DJ, Abuhelwa AY. An introduction to physiologically-based pharmacokinetic models. *Paediatr Anaesth*. 2016;26(11):1036-1046.

Physiological based pharmacokinetic (PBPK) models can be used to predict pediatric PK. PBPK models require detailed physiological data. Data on the ontogeny of individual clearance pathways, derived from measurements of enzyme expression and activity in post-mortem livers, and from in vivo data from drugs that are cleared by similar pathways are useful. Information concerning genetic, physiological, organ and tissue size and composition, protein binding, demographic and clinical data has progressively improved their prediction ability.

THE MOST COMMON INDICATIONS for total intravenous anesthesia (TIVA) techniques in children are as follows: those at risk for malignant hyperthermia (in whom inhalational agents are contraindicated); children with a high risk of postoperative nausea and vomiting, brief radiologic or painful procedures when rapid recovery is needed (e.g., magnetic resonance imaging, bone marrow aspiration, gastrointestinal endoscopy); frequent repeated anesthesia (e.g., radiation therapy); major surgery to control the stress response; neurosurgical procedures to assist with control of intracranial pressure and for cerebral metabolic protection; spinal instrumentation requiring evoked motor and auditory brain potentials; and children in need of airway procedures (e.g., bronchoscopy).[1–3] Total intravenous (IV) sedation and anesthesia are used in pediatric intensive care, but propofol is contraindicated for prolonged use in very sick or young children because of the risk of developing propofol infusion syndrome (PRIS).[4–13]

Pharmacokinetic and Pharmacodynamic Principles

The goal of pharmacologic treatment is a desired response, known as the target effect. An understanding of the concentration-response relationship (i.e., pharmacodynamics [PD]) can be used to predict the target concentration required to achieve this target effect in a typical child.[14] Pharmacokinetic (PK) knowledge (e.g., clearance [CL], volume [V]) then determines the dose that will achieve the target concentration. Calculation of the dose for a drug where the PK disposition can be described using a one-compartment model with first-order elimination can be readily calculated:

$$Loading\ dose = V \times Target\ Concentration$$

$$Maintenance\ Dose = CL \times Target\ Concentration$$

However, most drugs used in anesthesia require two or more compartments to describe their disposition and although the principles for drug dosing calculation are the same, calculations are complicated by two or more clearances and volumes (see below).

Although the parameters used in PK and PD equations (known as models) for many drugs are published, the values may vary substantively from child to child. Several covariates have been identified to more accurately predict the dose for a particular child, including weight, age, sex, pathology, drug interactions, and pharmacogenomics. Current pumps used for TIVA incorporate weight and age to predict the typical drug dose and infusion rate for a specific patient.[15]

The use of TIVA for propofol is a good example of "pharmacology in action." The target effect (level of general anesthesia) for propofol has been defined (e.g., bispectral index [BIS] 50–55), the target (plasma) concentration to achieve this level of anesthesia is known (e.g., propofol 4 mg/L) and its PK in children is well described. Advanced concepts in PK modeling and computer technology have led to sophisticated delivery systems that facilitate anesthesia given by the IV route. Further advances involving feedback from receptor organs have also been developed for children.[16,17] Target-controlled infusion (TCI) devices or "smart pumps" are an example of a sophisticated delivery system that may be directed at either plasma (Cp) or effect-site (Ce) drug concentration. These computerized pumps are a considerable advance over earlier manual techniques for children[18,19] that targeted only the Cp of the drug. However, they require input of both PK and PD parameters and a lack of robust PK-PD estimates and variability in the parameter estimates limit the current accuracy of TCI in children under 3 years of age.[20]

PEDIATRIC PHARMACOKINETIC PARAMETER SETS

TCI techniques use propofol and remifentanil as the principal drugs for induction and maintenance of anesthesia. Popular pediatric programs used for propofol infusion targeting a plasma concentration are based on data from Marsh[21] and Gepts,[22] Kataria,[19] Short,[23] Rigby-Jones,[24] Schuttler,[25] Murat,[26] Saint-Maurice,[27] Coppens[28] or Absalom (Paedfusor).[29] These parameter sets are commonly termed "models" and named after the author who

TABLE 8.1 Propofol Parameter Estimates for a 20-kg Child

Parameter	Kataria et al.[19]	Marsh[21] & Gepts[22]	Paedfusor[29]	Short et al.[23]	Schuttler & Ihmsen[25]	Rigby-Jones et al.[24]	Murat et al.[26]	Saint Maurice et al.[27]	Coppens et al.[28]
V1 (L)	10.4	4.56	9.16	8.64	7.68	11.68	20.6	14.44	3.48
V2 (L)	20.2	9.28	18.98	10.8	20.74	26.68	19.4	35.6	4.68
V3 (L)	164	58.04	116.58	69.4	264.82	223.86	121.74	168	19.02
CL (L/minute)	0.68	0.542	0.568	0.836	0.56	0.444	0.98	0.62	0.78
Q2 (L/minute)	1.16	0.51	1.044	1.22	1.036	0.32	1.34	1.24	2.04
Q3 (L/minute)	0.52	0.192	0.384	0.34	0.46	0.268	0.4	0.22	0.66

Performance of these models differed markedly during the different stages of propofol administration. Most models underestimated propofol concentration 1 minute after the bolus dose, suggesting an overestimation of the initial volume of distribution. Not all models tested were within the accepted limits of performance (median performance error, bias <20% and median absolute performance error, precision <30%). The model derived by Short and colleagues performed best[32] in children 3 to 26 months.

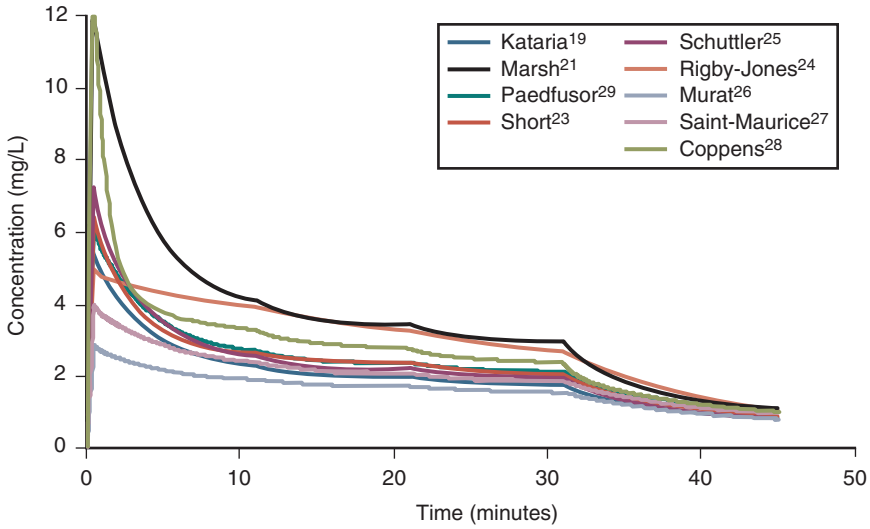

FIGURE 8.1 Simulated time-concentration profiles for propofol using differing parameter sets are shown. A 3-mg/kg bolus was administered and the infusions were administered as for an adult (10-8-6 regimen, see text). (From Anderson BJ. Pharmacology of pediatric TIVA. *Rev Colomb Anestesiol.* 2013;41:205-214. Used with permission.)

reported them (e.g., the Kataria model). Parameter estimates (e.g., CL; intercompartment clearance, Q; central volume of distribution, V1; peripheral volume of distribution, V2) are different for each parameter set (Table 8.1). Although parameter estimates are different for each author, most predict similar concentrations for the same infusion regimen (Fig. 8.1).

Covariate influences that contribute variability to the parameters, such as the severity of illness are often unaccounted for–for example, the volume of the central compartment is increased in children after cardiac surgery.[24] Even weight or age, the most common sources of variability,[30] may be omitted from parameter estimates. Both the administration method (IV bolus or infusion)[31] and the collection of venous blood for assay rather than arterial blood will influence the PK parameter estimates in the early phase when the drug is moving into the effect-site compartment. Time-concentration profiles and context-sensitive half-lives will differ depending on which parameter set is used.[32]

There is a paucity of validation studies for these differing parameter sets.[28] The Paedfusor model[29] is reported to have a median performance error, bias (MDPE) of 4.1% and a median absolute performance error, precision (MDAPE) of 9.7% in children between 1 and 15 years of age.[29] A more recent study concluded that all parameter sets except that based on the Marsh model performed acceptably in children between 3 and 26 months.[32] Others have described a poor fit for the Kataria model, despite the fact that it is the most widely used model.[33] However, clearance (expressed as liters per hour per kilogram) decreases with age and MDPE is minimized at low CL and exaggerated at greater values. Evaluating models outside the age range in which their parameter sets were determined will increase the bias and worsen the precision of the model.

Adult remifentanil PK parameters[34] continue to be used in TCI devices for patients of all ages, despite an increasing knowledge regarding the pharmacology of this drug in children.[35] There is an element of safety with this approach because both volume of distribution[36] and clearance (expressed as milliliters per minute per kilogram)[37] decrease with increasing age and the elimination half-life is small with a constant context-sensitive half-life. The greater volume of distribution in children reduces the peak concentrations of remifentanil after bolus dosing; the increased clearance in children results in a smaller plasma concentration when infused at adult rates expressed as mg/minute per kilograms. Remifentanil PK can be described in all age groups by simple application of an allometric size model (see Chapter 7).[37] This

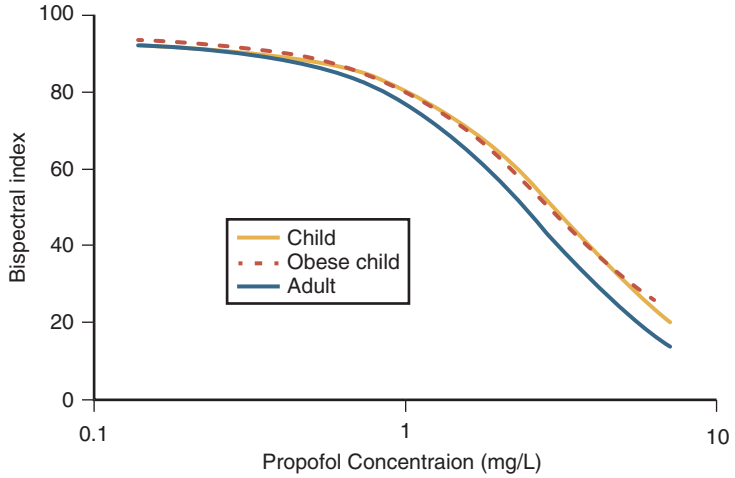

FIGURE 8.2 The propofol concentration and its relationship with bispectral index in children and adults. (Data from Coppens MJ, Eleveld DJ, Proost JH, et al. An evaluation of using population pharmacokinetic models to estimate pharmacodynamic parameters for propofol and bispectral index in children. *Anesthesiology* 2011;115:83-93; and Chidambaram V, Venkatasubramanian R, Sadhasivam S, et al. Population pharmacokinetic-pharmacodynamic modeling and dosing simulation of propofol maintenance anesthesia in severely obese adolescents. *Pediatr Anesth.* 2015;25:911-923.)

standardized clearance of 2970 mL/minute per 70 kg is similar to that reported by others in children[36,38] and adults.[34,39] The smaller the child, the greater the clearance when expressed as milliliters per minute per kilogram. Owing to these enhanced clearance rates, smaller (younger) children will require larger infusion rates of remifentanil than larger (older) children and adults to achieve equivalent blood concentrations.

THE TARGET CONCENTRATION

The target concentration is the concentration desired at the effect site. The plasma and effect-site concentrations are the same at steady state. The target concentration depends on the desired effect. This effect is determined by an understanding of the concentration-response relationship of the drug. This will differ with age, pathology, drug interactions, and stimulus. The target concentration may vary depending on the magnitude of the desired effect. A remifentanil target of 2 to 3 µg/L is adequate for laryngoscopy, 6 to 8 µg/L for laparotomy and 10 to 12 µg/L might be sought to ablate the stress response associated with cardiac surgery.[40]

A propofol concentration of 2 to 3 mg/L is an appropriate target for sedation and 4 to 6 mg/L is adequate for anesthesia. The target effect-site propofol concentrations for both the loss and return of consciousness in children, 2.0 ± 0.9 mg/L and 1.8 ± 0.7 mg/L, respectively, (mean ± standard deviation) are similar to those reported in adults.[41,42] The relation between drug concentration and effect is commonly described by the Hill equation (see Eq. 7.19)[43]:

$$Effect = E0 - \frac{Emax \cdot \mathrm{Ce}^N}{(EC_{50}^N + Ce^N)} \qquad \text{Eq. 8.1,}$$

where $E0$ is the baseline level of consciousness (e.g., BIS = 100), $Emax$ is the maximum response, EC_{50} the concentration at half this maximum response, Ce the concentration in the effect compartment, and N defines the steepness of the slope.

Jeleazcov et al.[44] have described propofol PD in children 1 to 16 years using BIS where $E0$ was estimated as 93.2, Emax 83.4, EC_{50} 5.2 mg/L, and N 1.4. This relationship is very similar to that described in obese children.[45] The equilibration rate constant (*keo*) between the plasma and effect compartment was 0.6/minute ($T_{1/2}keo$ 1.15 minutes). Children may have a slightly lower sensitivity to propofol than adults (Fig. 8.2),[33] although this difference may be due to PK rather than PD factors.[46] The Kataria parameter set is known to underpredict concentration as age increases, consistent with allometric scaling. When this parameter set is used to estimate PD parameters, older children appear to require a smaller concentration to maintain anesthesia[47]; this is a PK effect and not a PD effect.[48]

Maintenance infusion requirements for propofol in neonates differ substantively from those in older infants and children. These may be attributed to differences in PK and/or PD. In terms of the kinetics, the clearance of propofol in neonates is reduced compared with older infants; clearance decreases with decreasing postmenstrual age owing to immature enzyme clearance systems.[49] To develop a dosage scheme for propofol infusion rates in infants and children, the adult dosage scheme was adapted to the requirements in the younger population by observing the total number and time of administration of boluses and time to awakening from propofol in infants younger than 3 years (n = 2271) (Table 8.2).[50] The predicted infusion rates for the first 10 minutes in neonates are large (24 mg/kg per hour; 400 µg/kg per minute), values that should be used cautiously because of the danger of an overdose if the infusion continues beyond 10 minutes. Delayed awakening, hypotension, and an increased incidence of bradycardia have been reported in neonates and infants.[50] Propofol can cause profound hypotension in neonates and PK-PD relationships in this age group remain elusive.[51]

LINKING PHARMACOKINETICS WITH PHARMACODYNAMICS

A simple situation in which drug effect is directly related to concentration does not mean that drug effects parallel the time

TABLE 8.2 Propofol Dose Requirements in Children Younger Than 3 Years of Age

Time (minutes)	0-3 months	3-6 months	6-9 months	9-12 months	1-3 years
0–10	24.3	19.7	15.3	14.8	12.1
10–20	20.4	15.2	12.3	11.9	9
20–30	15.1	12	9	9	6
30–40	12	9	6	6	6
40–50	9	6	6	6	6
50–60	6	6	6	6	6

Infusion rates are expressed as milligrams per kilogram per hour.
(Adapted from Steur RJ, Perez RS, De Lange JJ.. Dosage scheme for propofol in children under 3 years of age. *Paediatr Anaesth*. 2004;14:462-467.)

course of concentration. This occurs only when the concentration is low in relation to EC_{50}. In this situation, the half-life of the drug may correlate closely with the half-life of drug effect.

A plasma concentration-effect plot can form a hysteresis loop because of a delay in effect. Hull et al.[52] and Sheiner et al.[53] introduced the effect compartment concept for muscle relaxants. A single first-order parameter ($T_{1/2}$keo) describes the equilibration half-time:

$$T_{1/2}\text{keo} = {Ln(2)}/{\text{keo}} \qquad \text{Eq. 8.2}$$

This mathematical trick assumes the concentration in the central compartment is the same as that in the effect compartment at equilibration, but that a time delay exists before drug reaches the effect compartment. The concentration in the effect compartment is used to describe the concentration-effect relationship.[54]

Adult $T_{1/2}$keo values are well described–for example, morphine 16 minutes; fentanyl 5 minutes; alfentanil 1 minute; propofol 3 minutes. This $T_{1/2}$keo parameter is commonly incorporated into TCI pumps to achieve a rapid effect-site concentration.

There are few estimates of the $T_{1/2}$keo for propofol in children using simultaneous PK-PD modeling. An estimate of 1.86 min (95% confidence interval [CI] 1.16–2.31) was reported in healthy children 2 to 12 years,[55] and 1.2 minutes (95% CI 0.85–2.1) in obese children.[45] We might expect a smaller $T_{1/2}$keo with decreasing age based on size models.[56] Faster half-times in children can be accounted for by considering the physiologic time that scales to a power of ¼[57]:

$$T_{1/2}\text{keo}_{\text{Child}} = T_{1/2}\text{keo}_{\text{ADULT}} \times \left({\text{WT}}/{70}\right)^{1/4} \qquad \text{Eq. 8.3}$$

An increasing $T_{1/2}$keo with age (linked to weight) has been described for propofol in children (Fig. 8.3).[44] Similar results have been demonstrated for sevoflurane and BIS in patients 3 to 71 years.[58] If unrecognixed, this will result in excessive dose in a young child if the effect site is targeted and peak effect (Tpeak) is anticipated to be later than it actually is because it was determined in a teenager or adult (Fig. 8.4).

When both PK and PD data are collected simultaneously and parameters for both models are estimated together, then the model is described as "integrated." PK estimates should not be used in conjunction with PD estimates from a different data set without a few "fudge factors." Tpeak methodology (see Chapter 7) is commonly used to estimate $T_{1/2}$keo that then links separate PK and PD data sets. Tpeak will increase with age (see Fig. 8.3). Model

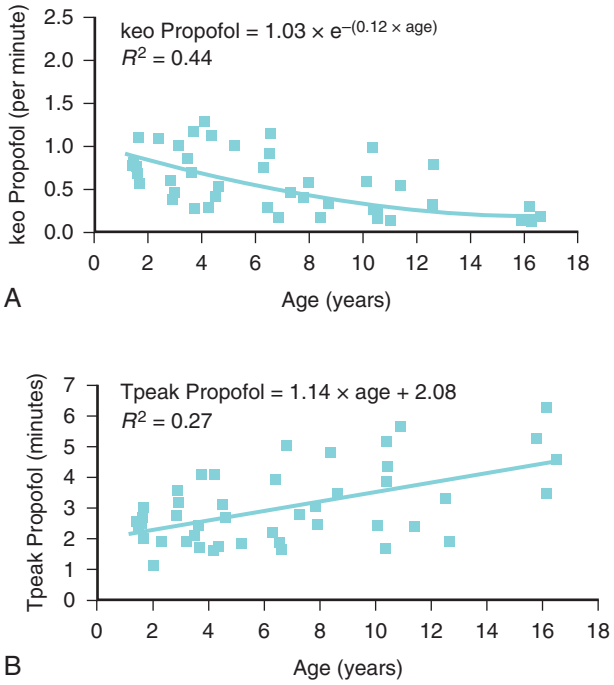

FIGURE 8.3 This figure shows the equilibration rate constant of propofol and time to peak propofol concentration as a function of age. The keo decreases with age; that is. the $T_{1/2}$keo increases with age. This results in a later time to peak concentration (Tpeak) as age (and weight) increases. (Data from Jeleazcov C, Ihmsen H, Schmidt J, et al. Pharmacodynamic modelling of the bispectral index response to propofol-based anesthesia during general surgery in children. *Br J Anaesth*. 2008;100:509-516.)

dependence of the $T_{1/2}$keo was demonstrated by an estimate of 1.7 min with the Kataria[19] parameter set and 0.8 minute with the Paedfusor model (Graseby Medical Ltd., Hertfordshire, UK) parameter set.[29]

Pharmacodynamic Interaction Models

Drugs may interact with each other at multiple levels. These are discussed in Chapters 6 and 7. Drug interactions for those drugs used in TIVA are commonly described using PD interaction models.

TRADITIONAL METHODS

Traditional methods of evaluating PD interactions include using isoboles (graphs illustrating equi-effective combinations of drugs), shifts in dose (or concentration) response curves (see Chapter 7), or interaction indexes based on parameters of potency derived from separate monotherapy and combination therapy analyses. Such methods provide an estimation of the magnitude of effect for dose or concentration combinations, but they do not inform us on the time course of that effect or its associated variability.

Competitive antagonists reduce receptor availability by competing for occupancy at the same receptor site. Drugs that elicit an effect are called agonists, whereas those that do not are called antagonists, so the occupancy of some receptors by the antagonists results in less effect. In general, competitive antagonists shift the effect-concentration curve to the right by altering the EC_{50}. Noncompetitive antagonists shift the observed maximum effect (Emax) rather than the EC_{50}.

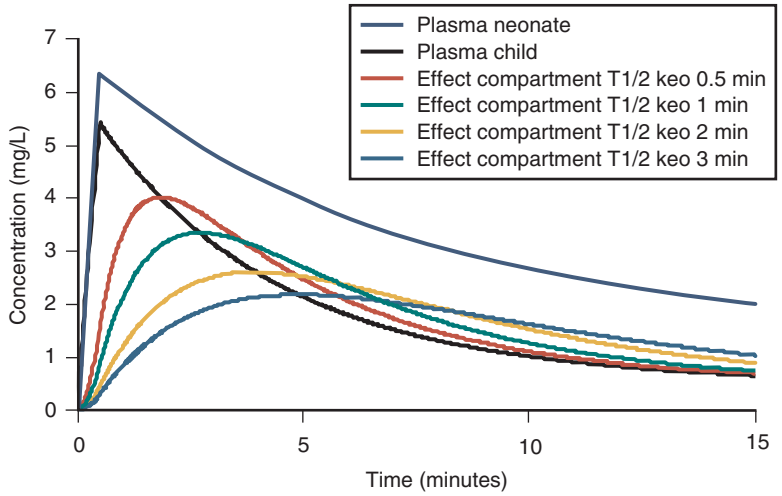

FIGURE 8.4 This figure shows simulated plasma time-concentration profiles for a typical 20-kg child given propofol 3 mg/kg using the Kataria parameter set. The $T_{1/2}$keo used will affect predicted effect-site concentrations—that is, the greater the $T_{1/2}$keo, the longer it takes to achieve the target concentration.

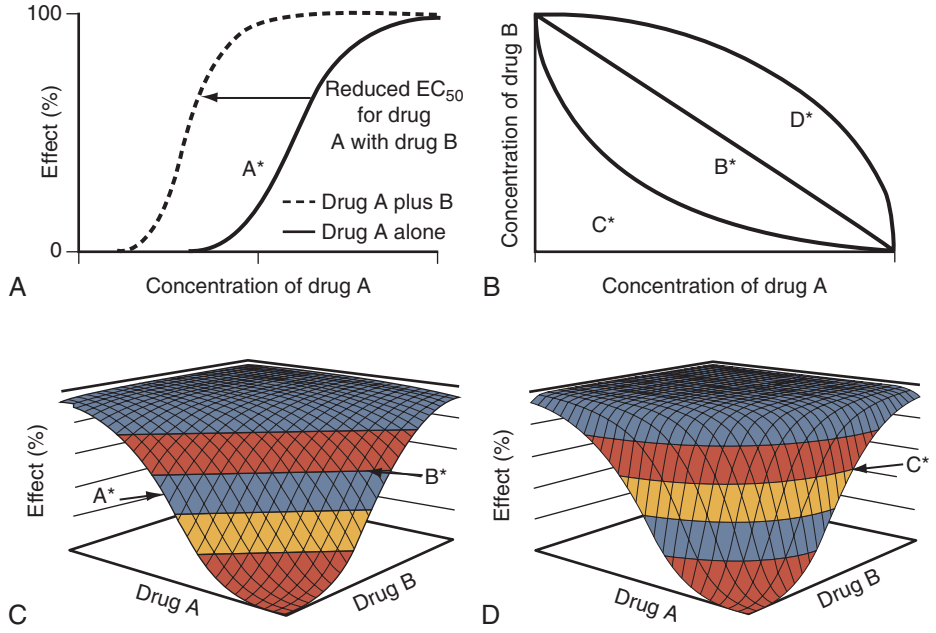

FIGURE 8.5 Methods of investigating interactions. **A,** Shift in response curve analyses involve plotting the concentration (or dose)-effect relationship for one drug alone and in the presence of steady-state concentrations of a second drug. **B,** Isoboles are constructed using iso-effect lines with curves derived from observations assessed against the expected (or "additive") response line (B*). Supra-additivity is depicted by curves bowing toward the plot origin (C*), while infra-additivity is shown with outward curves (D*). Information from both methods is represented within response surfaces with isoboles displayed as horizontal planes and individual concentration-response curves as vertical slices (indicated by *arrows* on surfaces for A* single concentration-response curve drug A, B* additive isobole, and C* supra-additive isobole). **C** shows the additive response surface for two drugs. **D** shows the synergistic response surface for two drugs, with synergy depicted through outward bowing of the surface. (Data from Hannam JA, Anderson BJ. Pharmacodynamic interaction models in pediatric anesthesia. *Pediatr Anesth.* 2015;25:970–980.)

RESPONSE SURFACE MODELS

Emax models for individual drugs can be combined and extended to incorporate PD interactions between two or more drugs. The "response surface" models are an extension of empirical, single-drug models that can be used to describe and predict the combined effects between two or more drugs (Fig. 8.5). Horizontal lines within the response surface hold equivalent information to that given by isoboles. Surface parameters are estimated using data points pertaining to all areas of the concentration and effect range for both drugs simultaneously (as opposed to considering individual concentration pairs or effect levels in isolation, as is done with isobolographic analyses). Resulting

PD models can be used to characterize the type of interaction across the entire range of concentrations and responses and make predictions about response (effect) for any ratio of the studied drugs.[59]

Two equations are commonly used: those of Greco et al.[60] and Minto and Vuyk[61] (see Chapter 7). The Greco equations have been used to describe additive effects for propofol, remifentanil, and fentanyl on BIS response in children aged 1 to 16 years undergoing general surgery.[44] These authors reported EC_{50} estimates of propofol 5.20 µg/mL, remifentanil 24.1 ng/mL, and fentanyl 8.6 ng/mL, and suggested a propofol and remifentanil pair of 2.3 µg/mL and 4.3 ng/mL, respectively, to maintain hemodynamic parameters and sedation scores within ranges suitable for surgery. The Greco model has also been used to describe loss of response to various noxious stimuli under propofol-remifentanil anesthesia.[62] Synergistic surfaces for sedation and response to laryngoscopy were reported.

The Minto equations have been used to assess synergy for hypnosis among three commonly combined drugs for anesthesia: propofol, midazolam, and alfentanil.[63] Computer simulations based on interactions at the effect site predicted that a synergistic three-drug combination (midazolam, propofol, and alfentanil) tripled the duration of effect compared with propofol alone. Response surfaces can describe anesthetic interactions, even those among agonists, partial agonists, competitive antagonists, and inverse agonists.[63]

Synergism between propofol and alfentanil has been demonstrated using response-surface methodology. Remifentanil alone had no appreciable effect on response to shaking and shouting or response to laryngoscopy, whereas propofol could ablate both responses. Modest remifentanil plasma concentrations dramatically reduced the concentrations of propofol required to ablate both responses.[64] When comparing the different combinations of midazolam, propofol, and alfentanil, the responses varied markedly at each endpoint assessed and could not be predicted from the responses of the individual agents.[65] Similar response-surface methodology has been used to investigate the combined administration of sevoflurane and alfentanil[66] and remifentanil and propofol[67] on control of ventilation. These combinations have a strikingly synergistic effect on respiration, resulting in severe respiratory depression in adults.

The ability of propofol to ablate responses to noxious stimuli has been studied in children between 3 and 10 years undergoing esophagogastroduodenoscopy.[68] The EC_{50} for 50% probability of no response was reduced from a propofol concentration of 3.7 µg/mL to 2.8 µg/mL when it was combined with a remifentanil infusion at 0.025 µg/kg per minute. Remifentanil infusions at greater infusion rates did not further reduce the propofol requirements, but they did increase the risk of remifentanil-related adverse respiratory events. The concurrent administration of opioids during TIVA techniques in children has a significant "propofol-sparing" effect while providing analgesia and stress control.[68,69] It is sensible to take advantage of this synergism to avoid excessive propofol dosing and long-chain triglyceride loads, particularly with concerns about PRIS during prolonged surgeries or sedations. *Remifentanil provides the most effective propofol-sparing effect, but fast recovery means alternative techniques of analgesia must be well established before the remifentanil is discontinued.* Other analgesics and anesthetics are also effective in reducing the propofol dose required. Fentanyl, alfentanil, and sufentanil are effective, as are local and regional analgesia techniques, once the block becomes established. Nitrous oxide as well as low concentrations of inhalational anesthetics also act synergistically with propofol and opioids to attenuate the dose required.

Depth of Anesthesia Monitoring

A common effect measure used to assess depth of anesthesia is the electroencephalogram (EEG) or a modification of detected EEG signals (spectral edge frequency, BIS, entropy). Physiologic studies in adults and children indicate that EEG-derived anesthesia depth monitors can provide an imprecise and drug-dependent measure of arousal. Although the outputs from these monitors do not closely represent any true physiologic entity, they can be used as guides for anesthesia and in so doing have improved outcomes in adults. In older children the physiology, anatomy, and clinical observations indicate the performance of the monitors may be similar to that in adults. The BIS showed a close relationship with the modeled effect-site propofol concentration and serves as a measure of anesthetic drug effect in children older than 1 year.[44] Their use in infants anesthetized with propofol cannot yet be supported in theory or in practice.[70,71] During anesthesia, the EEG in infants is fundamentally different from the EEG in older children; there remains a need for specific neonate-derived algorithms if EEG-derived anesthesia depth monitors are to be used in neonates.[72,73]

Depth of anesthesia monitors were used in 1% of all general anesthetics in the United Kingdom in 2015. However, these monitors were used in 33% of children undergoing general anesthesia using a TIVA technique with a neuromuscular blocking drug, but not at all in infants.[74] Despite limitations in infants, BIS is useful in older children, particularly when neuromuscular blocking drugs are used in conjunction with TIVA; modified EEG has also been successfully used for closed-loop anesthesia.[16,20] These systems may prove superior to open-loop systems that rely on a calculated effect Ce that are associated with large variability.

Awareness has been more commonly reported after TIVA than after gaseous anesthesia. However, many reports of awareness occur after the switch from gaseous anesthesia to TIVA where a loading dose was not given.[75] Clearance of the gaseous anesthesia agent occurs before attainment of effective steady-state propofol concentrations. The future ability for point-of-care propofol assay using either breath[76,77] or plasma[78–80] may be useful to reduce this complication.

COMMON TIVA DRUGS

The commonly used medications include propofol, remifentanil, alfentanil, and sufentanil; ketamine is occasionally used but has a long context-sensitive half-time with consequent delayed awakening.[81] Delivery can be achieved using either a manual infusion scheme (Table 8.3) or PK model–driven infusion devices with software developed specifically for use in children. Unfortunately, the commercially available software packages usually limit the applicable age to 1 to 3 years or older or weight to 10 to 15 kg or greater, and the PK parameters are derived from studies of a relatively few healthy children. Propofol programs that allow for age-, weight- and gender-related changes in central compartment volume, clearance, and distribution have been developed and perform well in healthy children.[82,83] However, there are considerable gaps in knowledge for some drugs, for ill children, and for young children, infants, and neonates. Consequently, caution is needed when applying such programs to these populations. The anesthesiologist can use these preprogrammed devices as a basis for initiating a TIVA technique but must also use skill, knowledge,

TABLE 8.3 Manual Infusion Schemes

Drug	Loading Dose	Maintenance Infusion	Notes
Propofol[84]	1 mg/kg	10 mg/kg per hour for 10 minutes, then 8 mg/kg per hour for 10 minutes, then 6 mg/kg per hour thereafter	Adult regimen to achieve blood concentration of 3 µg/mL
			Underdelivers to children and achieves lower blood concentration of 2 µg/mL
Propofol[69]	1 mg/kg	13 mg/kg per hour for 10 minutes, then 11 mg/kg per hour for 10 minutes, then 9 mg/kg per hour thereafter	Concurrently with alfentanil infusion
Alfentanil[85]	10–50 µg/kg	1–5 µg/kg per minute	Results in blood concentration of 50–200 ng/mL
Remifentanil[86]	0.5 µg/kg per minute for 3 minutes	0.25 µg/kg per minute	Produces blood concentrations of 6–9 ng/mL
Remifentanil[86]	0.5–1.0 µg/kg over 1 minute	0.1–0.5 µg/kg per minute	Produces blood concentrations of 5–10 ng/mL
Sufentanil[86,87]	0.1–0.5 µg/kg	0.005–0.01 µg/kg per minute	Results in blood concentration of 0.2 ng/mL for sedation and analgesia
Sufentanil[86,87]	1–5 µg/kg	0.01–0.05 µg/kg per minute	Results in blood concentrations of 0.6–3.0 ng/mL for anesthesia
Fentanyl[85]	1–10 µg/kg	0.1–0.2 µg/kg per minute	
Ketamine[85]	1–2 mg/kg	0.1–2.5 mg/kg per hour	Smaller dose and infusion rate for analgesia and sedation. Larger dose and infusion rate for anesthesia titrated to effect
Midazolam[85]	0.05–0.1 mg/kg	0.1–0.3 mg/kg per hour	

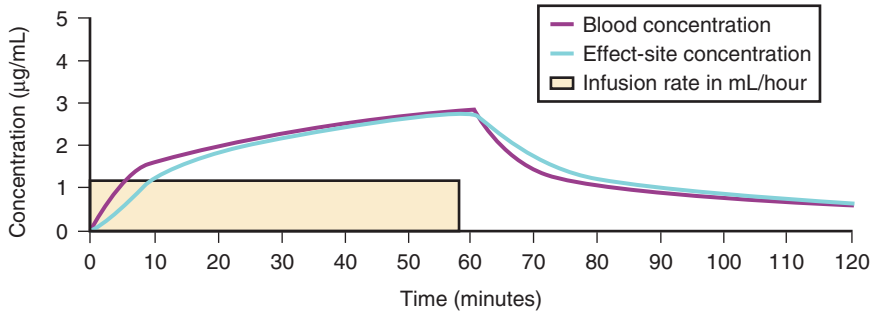

FIGURE 8.6 A fixed-rate infusion of propofol at 10 mg/kg per hour with no bolus dose in a healthy 10-kg, 1-year-old infant. Note that a steady state is not reached even after 1 hour. There is a lag of effect-site concentration behind blood concentration both during infusion and after stopping infusion. Effect-site concentration reaches blood concentration at about 1 hour. The context-sensitive half-time is 9 minutes (simulated using Tivatrainer; available at http://www.eurosiva.org/TivaTrainer/tivatrainer_main.htm).

and experience to titrate the IV agents to effect to avoid awareness, pain, and adverse effects.

ACHIEVING THE TARGET CONCENTRATION IN A MULTICOMPARTMENT MODEL

For a fixed infusion rate in a single-compartment model, it takes five half-lives to reach a steady-state concentration (>96% of the target) in the blood (Fig. 8.6). A loading dose is required to more rapidly achieve the target concentration. This dose rapidly fills the volume of distribution, after which the calculated infusion maintains the blood concentration (Fig. 8.7). Calculation of the loading dose is relatively easy for a simple one-compartment model. Unfortunately, drugs such as propofol require two- or three-compartment models to describe their disposition. A loading dose may be too large if calculated using the volume of distribution at steady state (Vss, where Vss = V1 + V2 + V3 for a three-compartment model) for a drug that is described by multiple compartments because it is initially administered into the smaller central compartment (V1) to effect the desired response: loss of consciousness. A loading dose based on the Vss will cause adverse effects, hemodynamic instability, and/or toxicity. Even a remifentanil bolus should be administered over several minutes to reduce the risk of bradycardia, hypotension, and/or difficult mask ventilation. An anticholinergic drug may prove useful if remifentanil 3 µg/kg is used for rapid-sequence intubation.

To more clearly understand the disposition of drugs after an IV dose, it is useful to consider a three-compartment model (Fig. 8.8, Table 8.4). The drug is delivered and eliminated from a central compartment V1 (which includes the blood) but also distributes to and redistributes from two peripheral compartments, one representing well-perfused organs and tissues (fast compartment, V2) and the other representing more poorly perfused tissues such as fat (slow compartment, V3). The transfer of the drug between V1 and the two peripheral compartments (V2, V3), in addition to the elimination of the drug from V1, is described by a series of clearances (CL, Q2, Q3) indicating the distribution back and forth between paired compartments, such as V1 to V2 and then V2 back to V1. The primary target organ that intravenous anesthetic agents affect is the brain. Therefore, an additional rate constant is added to describe the equilibration between the central

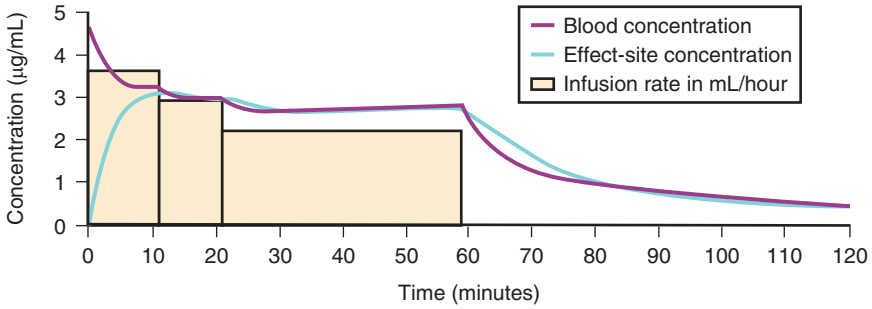

FIGURE 8.7 This figure illustrates the manual infusion technique in a healthy 70-kg 40-year-old. Note the importance of the early higher initial infusion rates to ensure that the target concentration is more constant. (Data from the Diprifusor pharmacokinetic data set.) Bolus dose (propofol 1%) was 1 mg/kg, then 10 mg/kg per hour for 10 minutes, 8 mg/kg per hour for 10 minutes, then 6 mg/kg per hour thereafter until 60 minutes when the infusion is discontinued. The maximum blood concentration is 4.5 µg/mL. Effect-site concentration reaches 3 µg/mL after around 10 minutes but drifts down to around 2.6 µg/mL and then very gradually rises. The context-sensitive half-time after 1-hour infusion is 7 minutes.

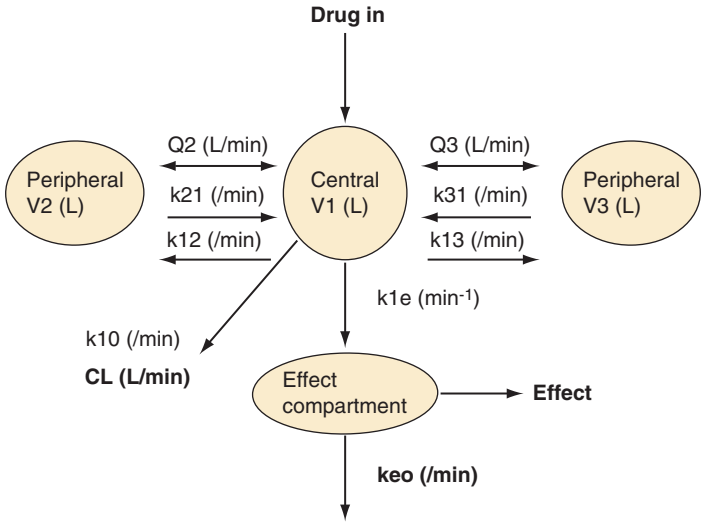

FIGURE 8.8 A three-compartment model with an additional compartment used to describe concentration in the effect compartment. A single first-order parameter (k1e = keo at steady state) describes the equilibration rate between the central (V1) and effect compartment. This compartment model is conceptualized in Fig. 8.9, where hydraulics are used to illustrate compartment interactions. The *arrows* in this figure could be considered "pipes" that deliver drug into the central compartment, out rapidly to V2 (and back to V1) and out more slowly to V3 (and back to V1) and are then eliminated through simultaneous clearance. k1e is the rate constant describing drug movement from compartment 1 to the effect compartment.

compartment and the effect site in the brain (keo = k1e at equilibrium). This compartment is not represented by a volume but rather by the time required to equilibrate. Consequently, there is a time lag before changes in the blood concentration are reflected in the effect site (shown on Figs. 8.6 and 8.7).

A hydraulic model is useful for understanding these concepts. The central compartment is connected to the peripheral compartments and effect site by a series of pipes of different diameters and also a drainage pipe to represent elimination (Fig. 8.9A-F). The height of the columns of fluid, which represents the concentration of drug, illustrates the gradient down which the drug travels between the central and peripheral compartments; this can be animated over time to show filling and emptying of compartments relative to each other. The diameter of the interconnecting pipes between the central and peripheral compartments represents the intercompartment clearances (Q2, Q3), and the size of the drainage channel represents elimination (CL). This hydraulic analogy is used in the TIVA Trainer simulation program.[88]

Fixed Infusion Rate and a Three-Compartment Model

When a fixed infusion rate is started (see Fig. 8.6), the blood concentration will increase but, almost simultaneously, distribution of the drug to the fast compartment and elimination both begin. Distribution of drugs throughout the body contributes more to the removal of drug from blood than elimination for most medications. Remifentanil is an exception; it has extremely rapid esterase clearance and elimination of this drug is far greater than redistribution from the central compartment. As the concentrations within each compartment equilibrate, the concentration gradient between compartments lessens (slowing drug transfer between compartments) but distribution to the slow compartment continues along with elimination. The net effect is that the blood

concentration continues to increase, albeit at a slower rate. As the blood concentration increases toward equilibrium, elimination becomes relatively more important; Fig. 8.6 illustrates how far behind the effect-site concentration lags. Eventually, after several hours (or in some cases, days), a steady state is reached where the infusion rate is directly proportional to clearance.

Bolus and Variable Rate Infusion in a Three-Compartment Model

A loading dose can start to fill the central compartment and ideally should attempt to create an effect-site concentration at a specific target concentration without overshoot. Then the rate of infusion should decrease in a stepwise manner to maintain a constant effect-site concentration until a steady state is reached. As drug is delivered into the central compartment, it continuously distributes to the peripheral compartments while it is also continuously eliminated. The infusion rate must vary because it has to match the concurrent changes in the contribution of distribution and elimination with time (Figs. 8.10 and 8.11). When the infusion is stopped, then elimination will continue to drain the central compartment, and drug will continue to distribute to V2 and V3 along concentration gradients from V1 for some time. Equilibrium may be reached, but the drug now begins to move back from the peripheral compartments into the central compartment, maintaining the central compartment drug concentration. This can continue for a protracted interval, particularly for highly lipid-soluble drugs that have a very large slow compartment V3 contributing a reservoir or depot effect (e.g., fentanyl; see Fig. 8.9F). Eventually the central compartment concentration will decrease. For most anesthetics, the longer the duration of an infusion, the more the drug has distributed into the peripheral compartments and the larger the reservoir of drug to be redistributed back into the central compartment and eliminated once the infusion ceases. The half-time of the decrease in drug concentration in blood is related to the duration of the infusion for most drugs (except remifentanil). This is termed the *context-sensitive half-time (CSHT)*, where the context is the duration of the infusion and relates to a pseudo-steady state maintained by a TCI. For an individual drug in an individual patient, CSHTs can be plotted against the duration of the infusion (Fig. 8.12A and B). The CSHT will eventually asymptote and this is when the pseudo-steady state becomes a true steady state. At that time, the infusion has become context *in*sensitive. This pattern is observed for nearly all IV anesthetics. In the case of propofol, the slope of the context-sensitive half-life with time increases from adults to children to infants to full-term and then preterm neonates, with preterm neonates having the greatest half-life of all age groups. The exception is remifentanil, whose half-time becomes context insensitive almost immediately after initiation of the infusion because its elimination is rapid and complete; the capacity of the red cell, plasma, and tissue esterase enzyme systems are enormous.

PK parameters for remifentanil, alfentanil, and sufentanil are summarized in Table 8.5.[86] The differences in context-sensitive

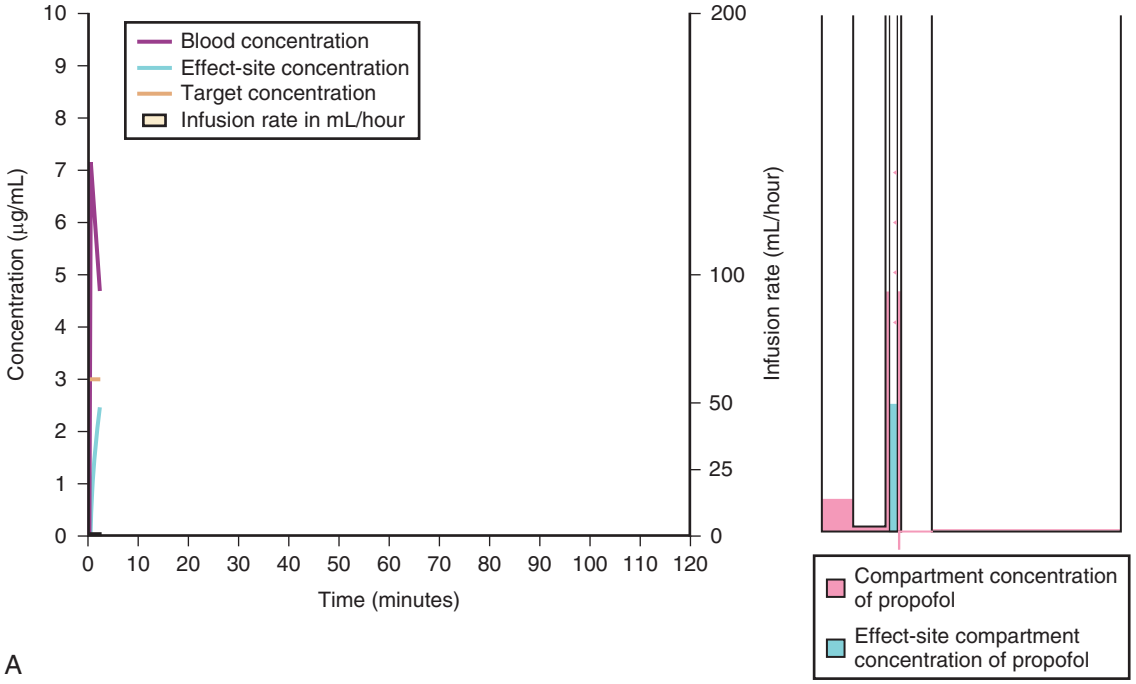

TABLE 8.4 Nomenclature for TCI Systems

Term	Meaning	Units
TCI	Target-controlled infusion	
Vc or V1	Central compartment volume	L
V2	Fast compartment volume (vessel-rich group) = V1 × k_{12}/k_{21}	L
V3	Slow compartment volume (vessel-poor group) = V3 × k_{13}/k_{31}	L
Cl 1 or CL	Elimination clearance = V1 × k_{10}	L/hour
Cl 2 or Q2	Clearance between V1 and V2 = V2 × k_{21}	L/hour
Cl 3 or Q3	Clearance between V1 and V3 = V3 × k_{31}	L/hour
Cp	Blood concentration	
Ce	Effect-site concentration	
T	Target concentration	
CALC	Concentration calculated by TCI software	
MEAS	Concentration measured	
k_{10}	Elimination rate constant	/minute
keo	Rate constant for equilibration between blood and effect-site	/minute
$T_{1/2}keo$	Half-time for equilibration between blood and effect site $T_{1/2}keo = {}^{L_N(2)}/_{keo}$	minutes
k_{12}, k_{21}	Rate constants for movement between V1 and V2	/minute
k_{13}, k_{31}	Rate constants for movement between V1 and V3	/minute

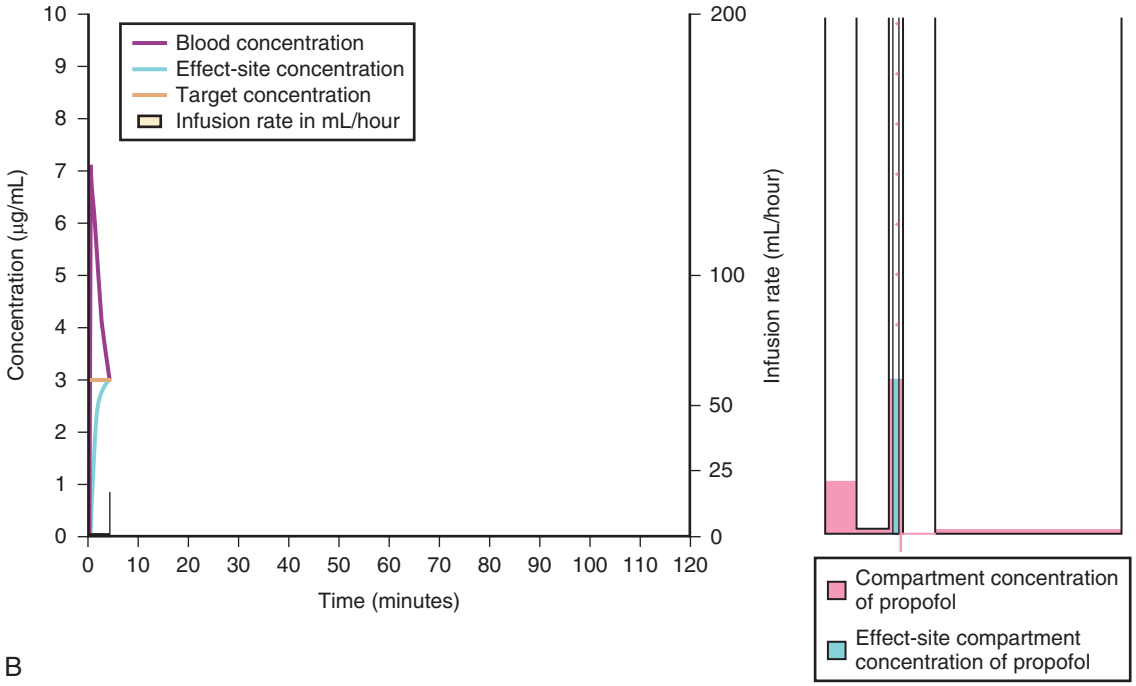

TABLE 8.5 Pharmacokinetic Parameters for Short-Acting Opioids

	Remifentanil[34,89,90]	Alfentanil[91]	Sufentanil[92]
V1	5.1–0.0201 × (age – 40) + 0.072 × (LBM – 55)	Male: 0.111 × weight Female: 1.15 × 0.111 × weight	0.164 × weight
V2	9.82–0.0811 × (age – 40) + 0.108 × (LBM – 55)	12.0	0.359 × weight
V3	5.42	10.5	1.263 × weight
k_{10}	2.6–0.0162 × (age – 40) + 0.0191 × (LBM – 55)/V1	0.356/V1	0.089
k_{12}	2.05–0.0301 × (age – 40)/V1	0.104	0.35
k_{21}	2.05–0.0301 × (age – 40)/V2	0.067	0.16
k_{13}	0.076–0.00113 × (age – 40)/V1	0.017	0.077
k_{31}	0.076–0.00113 × (age – 40)/5.42	0.0126	0.01
keo	0.595–0.007 × (age – 40)	0.77	0.12

Age in years; weight in kilograms.
LBM, lean body mass.

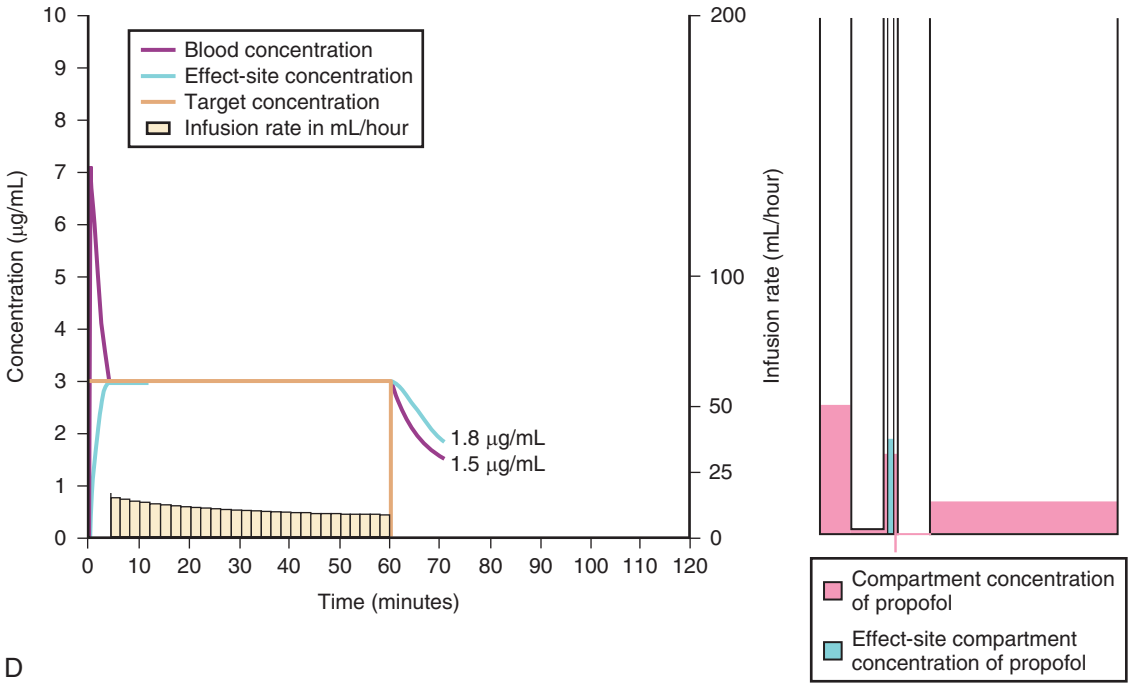
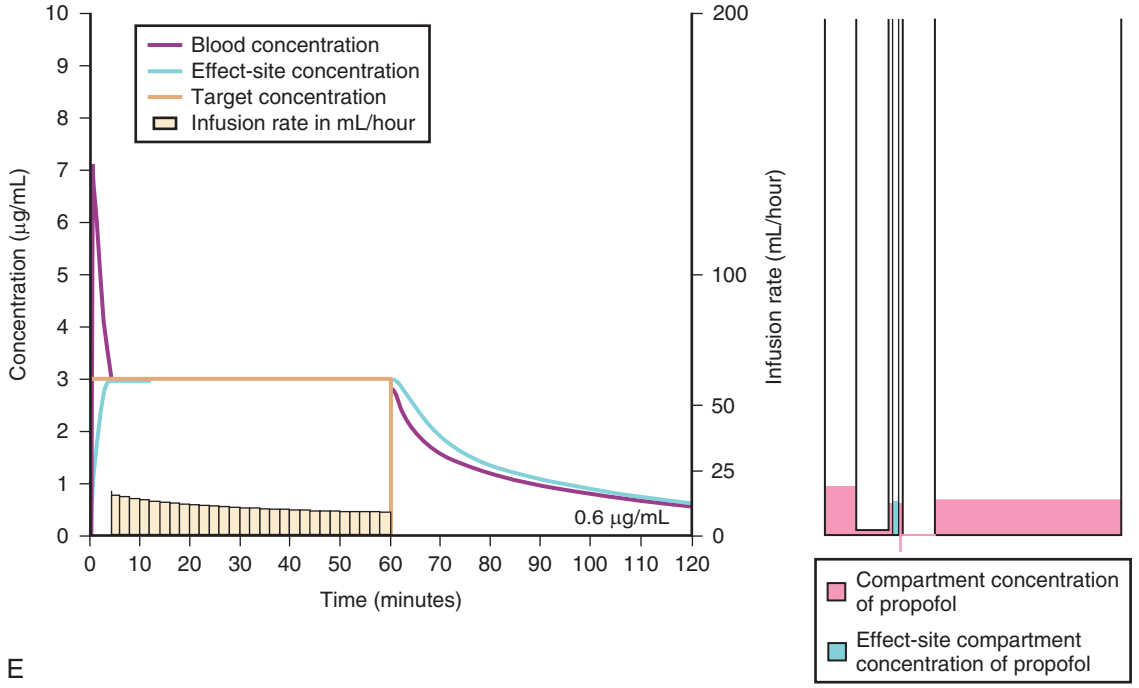
A

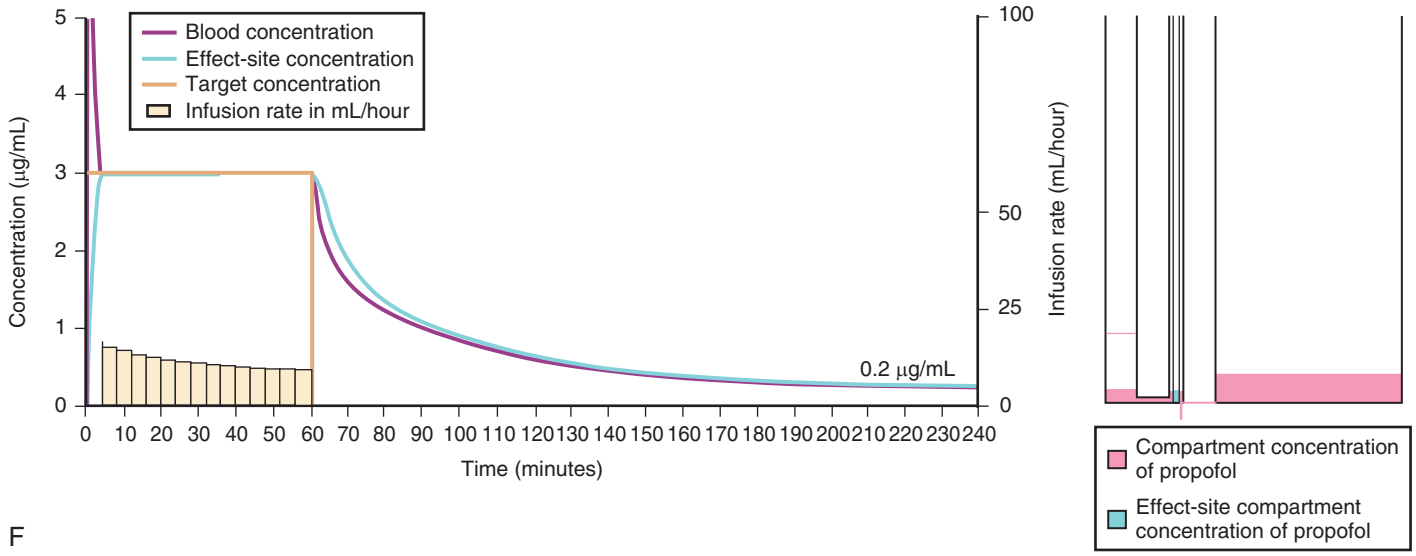


B

FIGURE 8.9 **A,** Hydraulic model representation of effect-site TCI. Compartment volumes and intercompartmental clearance values for the Paedfusor model in a healthy 10-kg, 1-year-old infant. In the first few minutes the central compartment to effect-site concentration gradient is marked to "overpressure" the transfer of propofol to the effect site. The peak blood concentration is 7.1 μg/mL. Distribution from the central compartment (C1) to the first peripheral compartment (C2) occurs rapidly also, which slows the rise in effect-site concentration and blood concentration. Elimination from C1 and distribution from C1 to the second peripheral compartment (C3) is also occurring. **B,** At 4.5 minutes, the effect-site concentration has reached the target of 3 μg/mL and has equilibrated with the concentration in C1. The infusion device, which has been off after the initial loading infusion, now switches back on to maintain the effect-site target concentration at 3 μg/mL.



C



D

FIGURE 8.9, cont'd C, After 1 hour of maintenance at an effect-site concentration of 3 μg/mL, the target is set to 0 μg/mL and the pump switches off. A total of 14 mL of propofol (1%) has been administered, or 14 mg/kg. There is now a considerable accumulation of propofol in C2 and C3, while C1 and the effect site are still in equilibrium. **D,** Approximately 10 minutes after the effect-site target concentration is set to 0, the blood concentration has halved; thus the context-sensitive half-time is 10 minutes. The lag in the decline in effect-site concentration is clearly seen, and there is now a gradient between effect site and C1. There is now also a concentration gradient from C2 to C1 and to C3 and this slows the decline in the concentration in C1.

Continued

E

F

FIGURE 8.9, cont'd E, One hour after the infusion is stopped, the blood and effect-site concentrations have fallen to 1/5 of the maintenance effect-site concentration. There are still considerable quantities of propofol in compartments C2 and C3 that slow the decline of the concentration of C1 and effect-site concentrations. **F,** Even after 4 hours, the depot of propofol in C2 and C3 is considerable, although blood and effect-site concentrations are extremely low. However, these low concentrations may still be exerting significant antiemetic and anxiolytic effects (data from the Paedfusor pharmacokinetic data set).

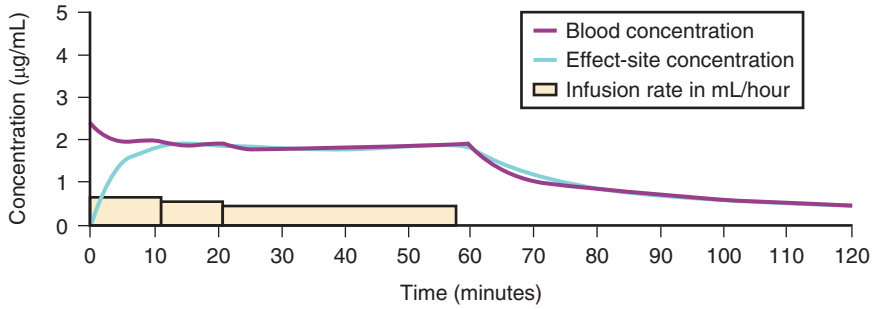


FIGURE 8.10 This figure illustrates the manual infusion technique of propofol in a healthy 1-year-old, 10-kg child. Note the importance of the early higher initial infusion rates to ensure that the target concentration is more constant. The adult dose regimen is illustrated. The figure shows a bolus dose of 1 mg/kg, then 10 mg/kg per hour for 10 minutes, then 8 mg/kg per hour for 10 minutes, then 6 mg/kg per hour thereafter. The infusion was stopped at 60 minutes. The effect-site concentration dose does not equilibrate until 11 minutes. The blood and effect-site concentrations stabilize around 1.8 µg/mL. However, this is unlikely to represent a sufficient depth of anesthesia for surgery. The context-sensitive half-time after 1 hour infusion is 9 minutes (data from the Paedfusor pharmacokinetic data set).

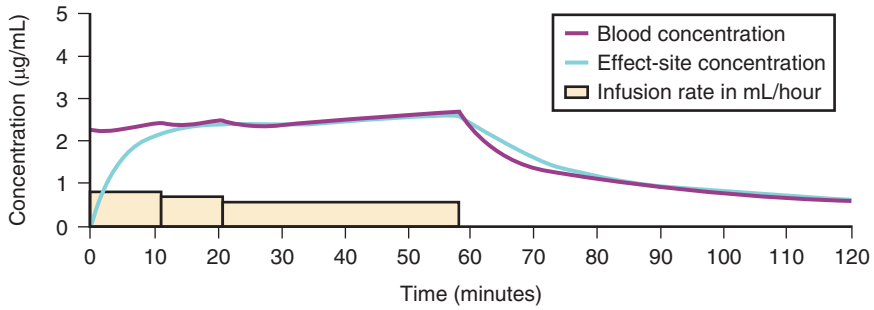

FIGURE 8.11 Manual infusion of propofol in 1-year-old, 10-kg child. The figure shows a bolus dose of 1 mg/kg, then 13 mg/kg per hour for 10 minutes, then 11 mg/kg per hour for 10 minutes, then 9 mg/kg per hour thereafter. The infusion was stopped at 60 minutes. The effect-site concentration does not equilibrate until 20 minutes. The blood and effect-site concentrations stabilize around 2.4 µg/mL but gradually rise over the next hour to 2.6 µg/mL. This concentration is larger than that achieved using the adult 10-8-6 regimen but may still be inadequate. Larger infusion doses are required in a 1-year-old child. (Data from the Paedfusor pharmacokinetic data set.)

half-times are illustrated in Table 8.6 and Fig. 8.12A and B. Fentanyl has a small CSHF when given by infusion for a short time, but this dramatically increases as the duration of the infusion increases. Alfentanil's CSHF reaches a plateau after approximately 90 minutes.

TABLE 8.6 Context-Sensitive Half-Times (minutes) of Opioids in Children

	Infusion Duration (minutes)				
Opioid	***10***	***100***	***200***	***300***	***600***
Remifentanil	3–6	3–6	3–6	3–6	3–6
Alfentanil	10	45	55	58	60
Sufentanil		20	25	35	60
Fentanyl	12	30	100	200	

THE TARGET-CONTROLLED INFUSION

A TCI is accomplished by a computer that performs rapid sequential calculations every 8 to 10 seconds to estimate the infusion rate required to produce a user-defined drug concentration in the blood or at the effect site of action of the drug in the brain in an open-loop system.[86] *Thus TCI may be blood targeted or effect-site targeted.* The standard nomenclature for TCI systems is listed in Table 8.4. Modern TCI systems are computer-controlled syringe drivers capable of infusion rates up to 1200 mL/hour with a precision of 0.1 mL/hour. They incorporate a user interface and display a range of safety alarms, monitoring functions, and warning systems. For most programs, the user has to choose a drug and its concentration from a menu and also select a PK parameter set (referred to as a model). The models suitable for use in children are quite limited, and some models are not suitable for all age groups. Others may be suitable but have not been validated in younger children; neonatal and infant models are quite rare. Experience with the various models may be gained by running the simulation programs such as Tivatrainer (http://eurosiva.org/; European Society for Intravenous Anaesthesia [EuroSIVA; Amsterdam, The Netherlands) or Rugloop (http://www.demed.be/rugloop.htm; Demed, Temse, Belgium) on a personal computer. Tivatrainer now allows uploading of new models via a central website and server and contains details and simulations of pediatric models for propofol and neonatal and pediatric models for sufentanil, in

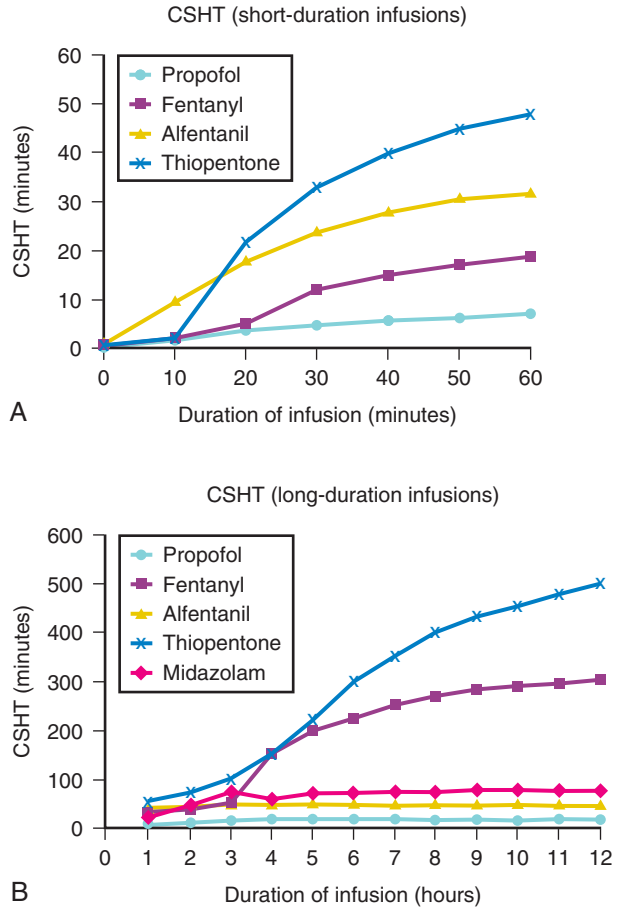

FIGURE 8.12 A, Context-sensitive half-times *(CSHTs)* after short-duration infusions. **B,** CSHTs after longer-duration infusions. For very lipid soluble drugs such as fentanyl and propofol, V3 is very large compared with V1. Intercompartmental clearance between V1 and V3 is given by the equation V1 χ k_{13} = V3 χ k_{31}, which implies that if V1 is much smaller than V3, rapid distribution from V1 to V3 is associated with very slow redistribution from V3 to V1. This is indeed seen with propofol and fentanyl, which have a slow offset of effects after prolonged infusions. Propofol has a CSHT that varies between approximately 3 minutes for a short-duration infusion to approximately 18 minutes after a 12-hour infusion. This is because elimination is quite rapid compared with the rate of redistribution from V3. For alfentanil, the concentration of the un-ionized form is 100 times greater than that of fentanyl (pKa alfentanil 6.4, fentanyl 8.5). Alfentanil therefore has a more rapid onset time and shorter half-life *keo,* a smaller V1, lower volume of distribution at steady state, and lower clearance than fentanyl. Fentanyl does, however, have a shorter CSHT than alfentanil after a short-duration infusion lasting less than 2 hours **(A)**; but for longer-duration infusions, alfentanil reaches a maximum CSHT after about 90 minutes, whereas for fentanyl the CSHT continues to increase after 12 hours **(B)**. This is because fentanyl has a huge V3, and redistribution back to V1 maintains the blood concentration when the infusion stops. (Simulated using Tivatrainer; available at www.eurosiva.org/TivaTrainer_main.htm.)

keo	0.26[a]	N/A[a]

[a]This is the value for adults, but Munoz et al.[101] have studied these two models to define a more accurate keo for children age 3–11 years, and the values are 0.91 for the Paedfusor model and 0.41 for the Kataria model. Jeleazcov et al.[102] have derived age-related keo values by the formula *keo* = 1.03 × e$^{-0.12 \times age}$.

addition to a wide range of adult models for propofol, alfentanil, remifentanil, fentanyl, ketamine, and midazolam. The simulation shows animated graphs of blood and effect-site concentrations against time, infusion rates, volumes, compartment sizes, and many other features.

The models within TCI systems are derived from studies of small numbers of healthy patients and are only a guide to drug administration for an individual patient.[83] The accuracy of TCI propofol has been assessed in children.[83,93] TCI propofol has been incorporated into a modified version of the commercial Diprifusor device and is known as the Paedfusor,[94] which has been evaluated clinically and performs well (Table 8.7).[93,95,96] In children undergoing cardiac surgery, the model performed significantly better than the adult model in adults.[94,97,98] Parameter estimates for the Kataria model are similar (Table 8.8) and it also performs reasonably well,[83,99] but all models have shortcomings.[100] Experience shows that clinicians need to learn how to use each model to optimize levels of anesthesia, ensure stability during

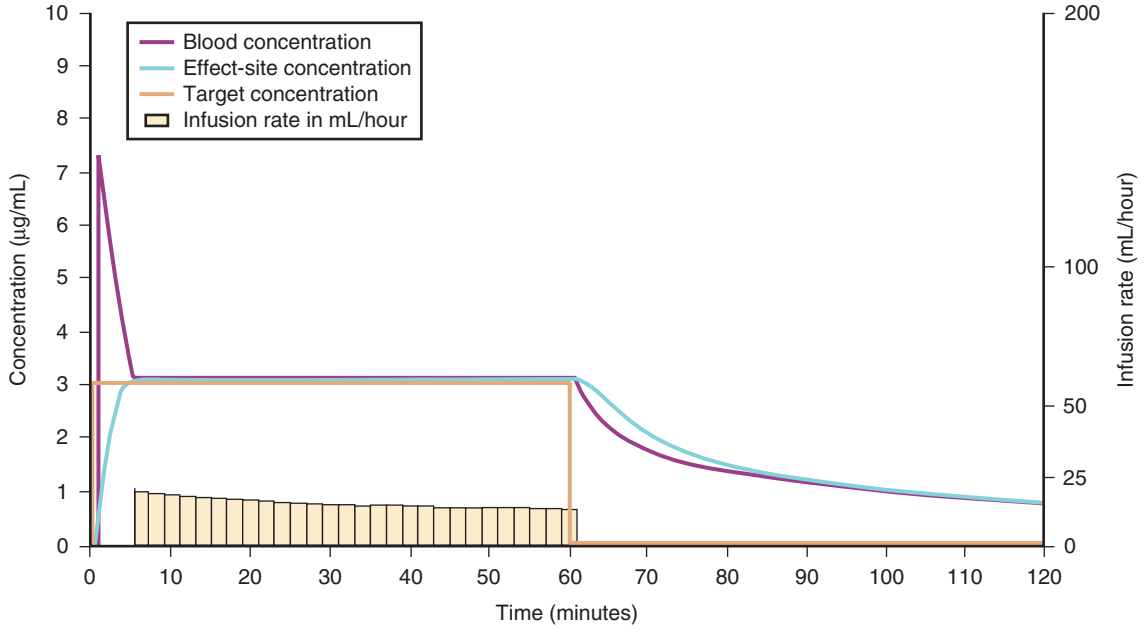

FIGURE 8.13 Target-controlled infusion modeled using the Paedfusor pharmacokinetic data set. Effect-site–targeted infusion of propofol in a healthy 1-year-old, 10-kg child. The effect-site target is 3 µg/mL. The figure shows a bolus dose of 3.4 mg/kg delivered at 45.5 mL/hour to accentuate the gradient from blood to effect site, then the infusion switches off for 4 minutes. Peak blood concentration after bolus dose is 7.1 µg/mL. Stepwise-reducing the infusion from 15.7 mg/kg per hour to 9.5 mg/kg per hour for 1 hour was done. The infusion was stopped at 60 minutes (i.e., effect-site target is set for 0 µg/mL). The effect-site concentration reaches 3 µg/mL at 3 minutes 39 seconds. The total dose of propofol is 14 mg/kg. The context-sensitive half-time is 10 minutes 37 seconds.

induction and maintenance phases, and enhance recovery speed and quality. Most pediatric models overestimate the initial volume of distribution, which risks too large an initial bolus dose.[83] The Paedfusor model makes an allowance for the increased clearance with age (per kilogram) in younger children; particularly those below 30 kg in weight (see Tables 8.7 and 8.8, Fig. 8.13). The minimum age and weight limits for each model also differ with age 1 year and 5 kg for the Paedfusor system and 3 years and 15 kg for the Kataria system. Below a weight 12.5 kg and age 2 years, the second compartment becomes negative with the Kataria model, which means that model cannot be used clinically in such young patients. For simulation using the Paedfusor data set, the adult value for keo of 0.26/minute ($T_{1/2}$keo 2.7 minutes) can be used (see Table 8.8). This means effect-site targeting may be simulated with the Paedfusor model (Table 8.9), and it may be possible to display an effect-site predicted concentration while using a pump in blood-targeted TCI mode, as with Diprifusor. Attempts have been made to define a more accurate keo for children in an ingenious study using auditory evoked responses with both the Paedfusor and Kataria models.[101] For children age 3 to 11 years, the median extrapolated keo values for the Paedfusor models was 0.91/minute ($T_{1/2}$keo 0.8 minutes) and for the Kataria model 0.41/minute ($T_{1/2}$keo 1.7 minutes). The BIS was used to derive a value for the time to peak effect, and hence, keo.[87,102,103] It was concluded that the time to peak effect after a bolus dose was shorter in children than adults as the extrapolated $T_{1/2}$keo values were considerably smaller.[100] Similar findings were reported by Hahn et al. using state entropy monitoring.[104] This approach has enabled calculation of an age-specific range of values for the keo (see Fig. 8.3), which should allow more accurate effect-site targeting using propofol in the future. It must be stressed that compartmental values are highly specific to a single model and are not interchangeable.[83,100] It can be argued that these calculations and extrapolations are a trick to sidestep imperfect PK values.[83,100] Integrating pharmacokinetic and pharmacodynamics into models appropriate for use in children is challenging, not the least because of doubts about the sensitivity and specificity of the depth of anesthesia monitoring in children.[33,104–106]

Some pumps display predicted plasma or effect site concentrations from the programmed PK model and are invaluable as an educational tool for demonstrating the intricacies of TIVA. TCI pumps do not have current FDA approval within North America,

TABLE 8.9 Example of Target-Controlled Infusion (Propofol 5 µg/mL) Based on Calculated Blood-Concentration Targeting Compared With Calculated Effect-Site Concentration Targeting for a Healthy 1-Year-Old (10 kg), Using the Paedfusor Pharmacokinetic Data Set

	Blood Concentration Targeting	Effect-Site Concentration Targeting
Loading dose	1.7 mg/kg	5.7 mg/kg[a]
Maximum blood target reached	5 µg/kg	12 µg/kg[a]
Total propofol infused after 60 minutes	23.2 mg/kg	23.3 mg/kg
Time to achieve effect site target of 5 µg/mL	17.5 minutes	4.5 minutes[b]

[a]Potential for hemodynamic changes due to high peak blood concentration from larger bolus dose.
[b]Very much shorter time to achieve effect-site target.

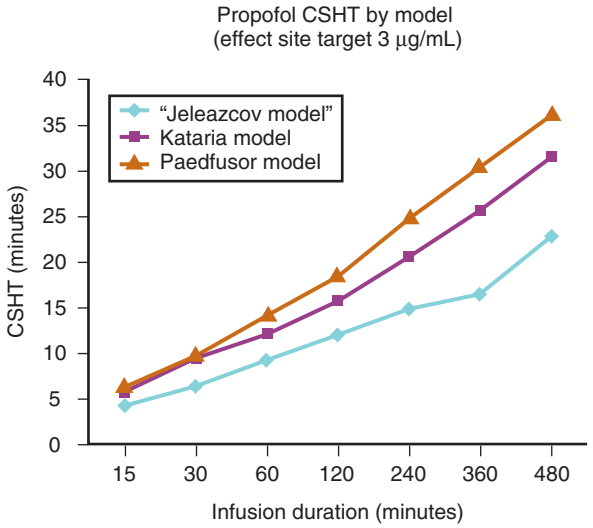

FIGURE 8.14 The predicted context-sensitive half-time (CSHT) of propofol depends on the pharmacokinetic model. Effect-site targeting can result in higher propofol doses if the keo is incorrect. The Jeleazcov model uses age-appropriate keo values and this results in the shortest predicted CSHTs for all infusion durations. This has clinical importance as it predicts a shorter recovery time for a given target concentration. (Data from Limb J, Morton NS. Age specific effect-site TCI in children; modelling using Tivatrainer. *Anaesthesia* 2010;65:542; and Absalom A, Vereecke HE, Eleveld DJ. A hitch-hiker's guide to the intravenous PK/PD galaxy. *Paediatr Anaesth.* 2011;21:915-918.)

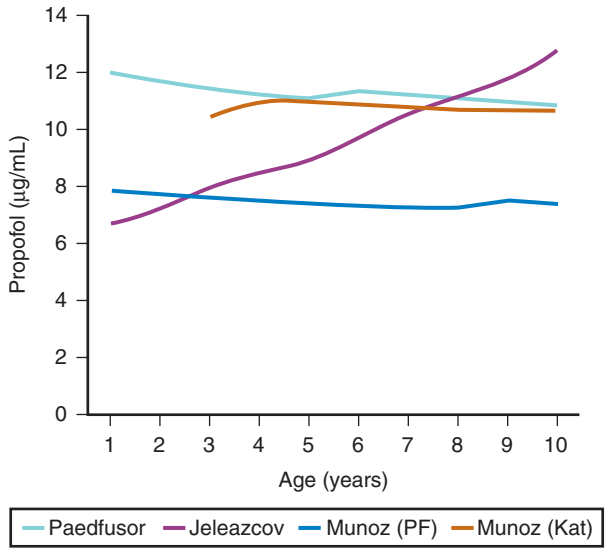

FIGURE 8.15 The peak plasma concentrations attained in simulations in Fig. 8.14 for an effect-site target of 5 µg/mL are shown. A large bolus dose does not necessarily equate to high peak plasma concentrations because of the variable volumes of distribution in the pediatric models at different ages. Even though more drug may be administered when using effect-site targeting if the keo is inappropriate, this may not mean an increase in peak plasma concentration because the peripheral volumes of distribution may be increased in any one model. More drug is redistributed. (Data from Limb J, Morton NS. Age specific effect-site TCI in children; modelling using Tivatrainer. *Anaesthesia* 2010;65:542; and Absalom A, Vereecke HE, Eleveld DJ. A hitch-hiker's guide to the intravenous PK/PD galaxy. *Paediatr Anaesth.* 2011;21:915-918.)

but it is anticipated that approval will be granted in the near future.

Effect-site targeting offers the advantages of more rapid achievement of desired depth of anesthesia and less titration of the target depth in practice, but while it has been used in research in children, it has yet to become a clinical tool.[107] Table 8.9 shows how the behavior of the TCI infusion differs between blood and effect-site targeted infusion using the adult keo of 0.26/minute ($T_{1/2}$keo 2.7 minutes). It can be expected that effect-site targeting may have more profound cardiovascular and respiratory effects than blood targeting owing to the larger initial bolus doses with resultant higher peak blood propofol concentrations attained.[107] It is known that slower administration of propofol preserves spontaneous respiration in children,[108] and the use of an age-appropriate $T_{1/2}$keo value and careful titration from a low initial target value may ameliorate some adverse effects. Without such titration, adverse effects may be more marked in infants (Fig. 8.14).[102,107] Although the use of BIS remains uncertain in children,[109] particularly those younger than age 1 year, the use of age- or weight-appropriate $T_{1/2}$keo values in TCI systems provides the prospect of more accurate and efficient propofol delivery to children.[107] This has safety implications in terms of reducing lipid load and clinical utility by increasing speed of recovery (Fig. 8.15).

A Practical Approach in Children

Mastery of TIVA requires familiarity with the technique. Such familiarity can be gained by practice with older children before progressing to those younger and beginning with children who present for elective, nonurgent surgery where a known stimulus will be applied. Cooperation from surgical colleagues is always advantageous when mastering the use of TIVA.

DRUG DELIVERY

Secure IV access is essential to safely administer TIVA. A dedicated line is not necessarily required as long as there is access to the IV cannula being used. Syringes that screw into infusion sets reduce the risk of poor or leaky connections. Infusion lines should be placed as close as possible to the venous cannula.[110] The setup should prevent retrograde infusion of propofol up the IV infusion set if resistance to flow into the cannula is greater than that in the fluid line. This is optimally achieved using one-way, nonreturn valves to prevent backflow up the IV fluid line. Percutaneous intravenous central catheters (PICC) may be unsatisfactory because high infusion rates are not possible. Combined infusions into a single vein run the risk of an inadvertent bolus of a companion drug. Anesthesia for major surgery may be best served using central venous access, diminishing the risk of unintended subcutaneous infusion. The infusion site is not always readily accessible in small children whose limbs may be covered in surgical drapes, and inadvertent dislodgment, obstruction, or subcutaneous tissue infiltration may occur. Common drug delivery problems are listed in Table 8.10.

Although closed-loop anesthesia is currently impractical because effect measures are poor in infants and neonates, changes in cerebral effect measures with changes of dose may at least confirm that the infusion is not disconnected or subcutaneous. Pump performance characteristics (e.g., lag time), IV tubing dead space, and syringe size and type all contribute to the observed response (see also Chapter 52). The more dilute the solution, the faster the syringe plunger travels with a better matched delivery to change the drug delivery prescription.[110] Dilution is especially important

TABLE 8.10 Potential Problems With Drug Delivery From Intravenous Anesthesia Pumps[a]

Problem	Prevention/Detection/Solution
IV cannula disconnect/out of vein	Venous access should be visible and accessible during procedure
Disconnection of infusion tubing from pump or cannula	Pump and tubing connections should be visible
	Use Luer-lock syringes
Pump power supply failure or pump paused	Ensure pump has an audible alarm
Occlusion of IV cannula or tubing	Pump high-pressure alarm
Occlusion alarm because of small cannula or long infusion tubing (e.g., PICC)	Ability to alter alarm threshold
"Backtracking" of propofol into intravenous fluid infusion tubing	Use of one-way valves
Drug disparity between settings and drug used (e.g., different concentration)	Keep only one concentration of propofol in hospital. Double-check drug dilution concentrations (or dispense from pharmacy premixed)
	A dedicated IV with a constant carrier solution for TIVA is the ideal
Wrong drug programmed into pump (remifentanil rather than propofol)	Prominent pump displays with the drug name.
	Color coding of the pump LCD displays and syringe labels
	Bar coding

Royal College of Anaesthetists and the Association of Anaesthetists of Great Britain and Ireland, 2014:151-158. *PICC,* percutaneous intravenous central catheters.

in improving the accuracy of delivery in infants and neonates. Modified EEG monitoring (e.g., BIS) is not necessary in the spontaneously breathing patient but should be considered in the patient who is receiving TIVA and neuromuscular blockade. The BIS is reasonably valid for children as young as approximately 3 years of age with propofol, but there are very limited data for other medications. It is essential to appreciate that in younger children the BIS number may not be reliable, but some interpretation can be made from BIS number changes rather than the absolute BIS number displayed.

TCI parameter sets (models) available for use in children generate different plasma propofol concentrations. It is important to be aware of these differences; this is especially so with regard to the initial loading dose. Consequently, it is important to be aware of the performance of the infusion pump being used, the particular parameter set installed, and its appropriateness for a given clinical scenario. The immature neonate, the critically ill child, or the child with major organ failure needs a smaller dose of IV anesthetic agent; care is particularly needed in children receiving vasoactive medication and those with congenital heart disease.[111] Titration is advisable to allow for between-subject variability of PK and PD parameters.

Pumps should be serviced regularly. Unrecognized pump failures can occur with subsequent patient awareness or overdose so vigilance is required. If problems with anesthesia occur, then the prudent thing to do may be to convert to an inhalational anesthetic technique if clinically appropriate.

TABLE 8.11 Possible Weight-Based Propofol Regimes in Children

Weight	Infusion Scheme
>35 kg	Schneider effect-site concentration model
15–35 kg	Kataria plasma concentration model *or*
	McFarlan manual plasma concentration regimen
<15 kg	Steur manual infusion regimen

INFUSION REGIMES

In general, the TCI pumps deliver propofol more accurately than manual regimes, result in better hemodynamic stability, use a lower induction dose, and result in improved recovery time. If a dedicated TCI pump is available, then it should be preferred over a manual regime. Surgical anesthesia is generally obtained with a propofol effect site concentration of 4 to 6 μg/mL. This will be achieved more rapidly with an effect-site target model than with plasma-targeted models because of equilibration between the plasma concentration and effect-site concentration.

Most TCI programs (models) are inaccurate for some ages within their specified age ranges[28–30] or when parameter estimates have not been tested (e.g., intensive care patients or children with neuromuscular disease undergoing scoliosis surgery).[80] Clearance (per kilogram) is increased as age decreases in children (allometric theory). The Kataria parameter set is known to underpredict concentration as age increases, consistent with allometric scaling. When this parameter set is used to estimate PD parameters, it appears that the older children require lower concentrations to maintain anesthesia[47]; this is a PK effect and not a PD effect.[48]

The adult Schnider[112] model may be more accurate than either the pediatric Kataria,[19] pediatric Marsh[21] or Schuttler[25] models in children weighing more than 35 kg.[33] The Schnider effect-site–targeted model has also been shown to have better accuracy in adults.[113] The Kataria TCI model is plasma targeted and is valid for children from 3 to 15 years weighing 15 to 65 kg. For children younger than 3 years, Steur et al.[50] have produced a manual regime (see Table 8.2). Neonates are susceptible to hypotension with propofol[51] and it is advisable to gradually increase infusion rate until anesthesia is achieved rather than starting at a high infusion rate.[114] Manual regimes have also been produced to mimic Kataria plasma targeted infusion for 3 to 6 μg/mL.[18,115] One approach to the use of propofol regimes in children for TIVA is shown in Table 8.11.

The Obese Child

Problems with drug dosing in obese adults are also common in children. The size metric varies with both drug and infusion type. The initial bolus may depend on the lean body mass, whereas the infusion rate may depend on another size metric. For example, propofol infusion rates relate best to total body weight scaled using allometry,[45,116] whereas lean body weight is a better metric for remifentanil infusions. A further complication is that the calculator program[117] of the pump used to estimate lean body mass fails in short obese people.[118] Solutions to this problem include setting limits on maximum weight,[119] inventing a fictitious height,[120] or creating a new metric[121]; use of a better metric such as fat-free mass might be the best solution.[118] Investigations using normal fat mass[122] as a size metric suggest that the appropriate

"size" may differ for each drug. These dose calculation problems can be circumvented by reducing the target concentration (e.g., propofol 4 µg/mL rather than 6 µg/mL) and then titrating to effect. The use of a cerebral function monitor such as BIS can be helpful.

Remifentanil as an Adjunct

Remifentanil is very useful as an adjunct.[123,124] It adds a degree of "smoothing" even in those children who require sedation only (e.g., radiologic imaging). Propofol is not an analgesic and the addition of remifentanil reduces movement in response to surgical stimulation[125]; there is approximately 30% more movement with propofol compared with an inhalational anesthetic. Remifentanil also reduces the propofol target concentration.[67,126] The consequent propofol dose reduction can be useful when anesthesia duration is prolonged because the concomitant context-sensitive half-life of propofol increases over time and concomitant remifentanil adjunct allows earlier awakening. Remifentanil is also useful to reduce pain during limb procedures where a tourniquet is used.

Most children will maintain spontaneous respirations with a remifentanil-propofol combination. Fig. 7.26 demonstrates the remifentanil infusion rates that will maintain a spontaneous respiration rate of 10 breaths/minute. Use of the adult Minto parameter set for remifentanil infusion in children confers a degree of safety because concentrations measured will be lower than those predicted because of the higher clearance (expressed as per kilogram) in children. Occasionally some respiratory support may be required; that is easily done using the pressure support ventilation mode. Controlled ventilation is required when high target concentrations of remifentanil are used. High effect-site remifentanil concentrations (>10 ng/mL) are associated with hypotension (Fig. 8.16) and this property can be used advantageously during some neurosurgical procedures or spinal instrumentation.[127]

Fixed propofol-remifentanil combinations (mixed together in the same syringe) are frowned upon by some because (1) they do not allow separate titration of analgesia and sedation and (2) targeting a propofol concentration can result in a relatively large bolus of remifentanil. However, they remain widely used–for example, propofol 10 mg/mL with remifentanil 5 µg/mL. If a combination is used with a TCI pump then a propofol target concentration of 3 µg/L usually allows spontaneous breathing, whereas a propofol target of 6 µg/mL requires ventilatory support. Although such mixtures are widely used, remifentanil in such mixtures may become unstable and has a limited life span in the syringe. The weaker the mixture, the less stable it is. This is due to a pH effect on the rate of ester hydrolysis of the remifentanil.[128]

Injection Pain With Propofol

The pain associated with IV injection of propofol is problematic. This is especially common when given through the small veins in the hands or feet. Perhaps the best approach to reduce injection pain is to place a larger-bore cannula in a large vein. Lignocaine 1 mg/kg placed in the IV with a proximal tourniquet (or just manual compression of the arm to stop the IV from flowing) applied for 30 to 60 seconds effectively attenuates this pain. Opioid or ketamine administered IV before propofol injection is also helpful. This can be best done by beginning the remifentanil infusion first and running it at a Cp of approximately 2 to 3 ng/mL for 2 minutes (using the Minto model) before starting the propofol infusion; most children and adults will continue to maintain spontaneous respirations through this short period. Alternatively, a bolus of fentanyl 1 µg/kg or remifentanil 1 µg/kg through the IV cannula is effective.

ESTABLISHING TIVA AFTER AN INHALATIONAL INDUCTION

Inhalational induction is standard in many pediatric centers. Propofol TIVA can start once gaseous induction has been performed and IV access obtained. The use of a fixed infusion rate only is frowned upon because steady-state concentrations will not be established before 3 to 4 elimination half-lives (see Fig. 8.6). While end-tidal inhalational agent partial pressure decreases, it is reasonable to target a reduced propofol concentration of 3 µg/mL as an initial target and then titrate against clinical response. If using a manual regimen, then reduce the initial bolus, especially if spontaneous respirations is required; a bolus of propofol 1 mg/kg is usually satisfactory.

PRACTICAL APPROACHES FOR SOME CLINICAL SCENARIOS

Spontaneously Breathing Diagnostic Procedures (Radiology Investigations)

Anesthesia and spontaneous respiration will generally be maintained at a target of 4 to 6 µg/mL in the absence of opioids or other

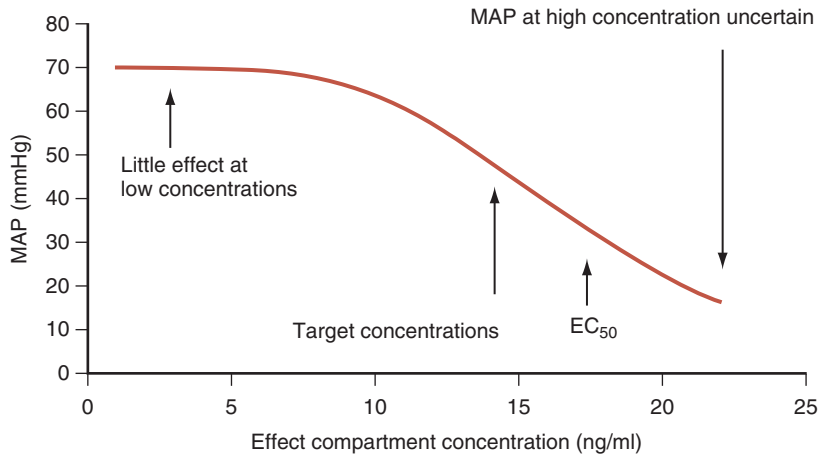

FIGURE 8.16 The relationship between remifentanil concentration and mean arterial blood pressure (MAP) in infants (4 months to 1 year) undergoing cranioplasty surgery. A steady-state remifentanil concentration of 14 µg/L would typically achieve a 30% decrease in mean arterial blood pressure. *EC50,* concentration is that at half maximum response. (From Anderson BJ, Holford NH. Leaving no stone unturned, or extracting blood from stone? *Paediatr Anaesth.* 2010;20:1-6. Used with permission.)

adjuncts. Pressure-supported respirations using either an endotracheal tube (ETT) or a laryngeal mask airway (LMA) will generally maintain normal or near normal $PaCO_2$. In the absence of pressure support ventilation, $PaCO_2$ will increase.

Spontaneously Breathing Airway Procedures Without an Endotracheal Tube (Flexible Respiratory Bronchoscopy, Rigid Laryngobronchoscopy)

Anesthesia may be induced by either inhalational or IV means. If induction is inhalational, then an initial propofol target of 3 μg/mL is reasonable to maintain desired spontaneous respirations and this target can then be titrated against response. If IV induction is used, then a plasma target of 4 to 6 μg/mL is reasonable but induction should be slow, especially if using an effect target model, because the relatively larger propofol bolus used to rapidly obtain the target Ce may cause apnea.

Remifentanil helps dampen airway reactivity and is a useful adjuvant. A remifentanil bolus of 1 μg/kg followed by an infusion at a low dose of 0.02 to 0.03 μg/kg per minute is effective. The remifentanil infusion can then be titrated to maintain a normal respiratory rate. If using the Minto Ce TCI model, then starting at an initial target of 1 μg/mL can be titrated to effect.

Laryngoscopy and topicalization with lidocaine can be carried out following induction. Generally laryngoscopy is tolerated more quickly if inhalational induction has been performed first. If using an IV induction, it pays to bide your time before performing laryngoscopy and topicalization; this allows effect-site equilibration.

Once the procedure has commenced, reactivity can be addressed by slow increments of propofol (1 μg/mL Cp or Ce if using TCI or 1 mg/kg bolus if using a manual regimen) and by increasing the remifentanil infusion. Further topicalization may be useful. It is generally best to avoid large boluses of propofol as this may induce apnea.

Spontaneously Breathing Procedures With an Endotracheal Tube (Adenotonsillectomy)

Induction may be either inhalational or IV. Intubation can be performed once the desired Cp or Ce has been achieved or after a bolus dose has been administered. The most stimulating part of the procedure is often mouth gag (e.g., Boyle-Davis) placement. Propofol can be increased in anticipation of this response to gag stimulation. This may cause apnea but once surgery has commenced, propofol can be slowly reduced until spontaneous respirations return.

Spontaneously Breathing Surgical Procedures With an LMA (Orthopedic and Peripheral Surgical Procedures)

Induction can be inhalational or an IV technique can be used. Commence propofol with an appropriate bolus if using a manual regimen. Remifentanil is a very useful adjunct, especially with peripheral orthopedic procedures where regional local anesthesia blockade has not been placed, to prevent movement in response to surgical stimulation.

BIS monitoring is a useful adjunct to titrate the propofol dose. Generally children will maintain spontaneous respirations with a BIS score in the 40 to 60 range and a remifentanil infusion of 0.1 to 0.2 μg/kg per minute or an effect concentration of 3 μg/mL Ce using the Minto model. Spontaneous respirations may not be adequate to provide CO_2 clearance and respiratory support may be required. Remifentanil remains a useful agent even if regional blockade has been used. It facilitates rapid induction and ready performance of the block without response to needle placement. Furthermore, it provides analgesia while the block takes effect and reduces any response to tourniquet pain. With the absence of surgical stimulation owing to a functional block, the propofol dose can generally be reduced. The remifentanil infusion or target concentration can also be reduced to assess block function.

Remifentanil is not necessarily useful if central blockade is used. However, it is still helpful for induction and during airway management and block placement. Infusion rate or target concentration can then be reduced or stopped once the block is established.

Major Invasive Procedures With Intubation (General, Thoracic, Neurosurgical, or Major Orthopedic Surgery (e.g., Posterior Spinal Fusion)

Commencement of TCI or a manual regimen can be followed by neuromuscular blockade and airway management. Remifentanil blunts the intubation response. Modified EEG monitoring in such patients undergoing major surgery is prudent. This may be achieved using the actual BIS score or the processed EEG waveform if the patient is younger than 3 years of age. Remifentanil is useful to reduce the total propofol dose and avoid delayed awakening at the end of the procedure. Analgesia can be managed with multimodal analgesia schemes and/or regional or neuraxial blockade.

Toward the later stages of the procedure, the propofol infusion may be reduced by titration against the EEG. This allows for a more rapid return of consciousness. One approach at the end of the procedure is to reverse residual neuromuscular blockade and stop both propofol and remifentanil infusions. Generally by the time the remifentanil effect has worn off, spontaneous respirations will have returned and anesthesia is still deep, attributable to propofol's prolonged CSHT; extubation can then proceed safely.

A Neonate Having Combined Anesthesia and Regional Blockade

There are concerns that some anesthetic drugs may cause neuronal apoptosis in the developing brain of a human neonate (see also Chapter 25) because drugs that bind to γ-aminobutyric acid-A ($GABA_A$) receptors cause neuronal apoptosis and other neurodegenerative changes in animal models ranging from rodents to primates.[129] Dexmedetomidine[130,131] and remifentanil[130,131] may be alternative options because their action is not mediated through $GABA_A$ receptors and they do not cause neuronal apoptosis or other neurodegenerative effects in rodents and primates. Dexmedetomidine also attenuates isoflurane-induced neurocognitive impairment in neonatal rats.[132] One regimen consists of IV premedication of glycopyrrolate 5 μg/kg followed by a dexmedetomidine 1-μg/kg loading dose over 10 minutes and remifentanil 1 μg/kg over 1 to 2 minutes. The dexmedetomidine infusion 1 μg/kg per hour can be started and titrated up or down within 50% of starting doses as needed, although it is crucial to appreciate that dexmedetomidine is not a complete general anesthetic. Similarly, a remifentanil infusion 0.1 μg/kg per minute can be titrated up or down (maximum infusion 0.5 μg/kg per minute). Airway management may require an ETT or LMA and ventilation assisted to maintain normocapnia.

COMMON MANUAL PROPOFOL INFUSION SCHEMES

Adults

A simple scheme was devised to maintain a blood concentration of propofol in healthy adults of 3 μg/mL.[133] A bolus IV dose of 1 mg/kg is followed by a continuous infusion of 10 mg/kg per hour for 10 minutes, then 8 mg/kg per hour for 10 minutes, then 6 mg/kg per hour (Fig. 8.17).[133] When this "10-8-6" regimen is modeled and verified using the Marsh model for an adult patient, the

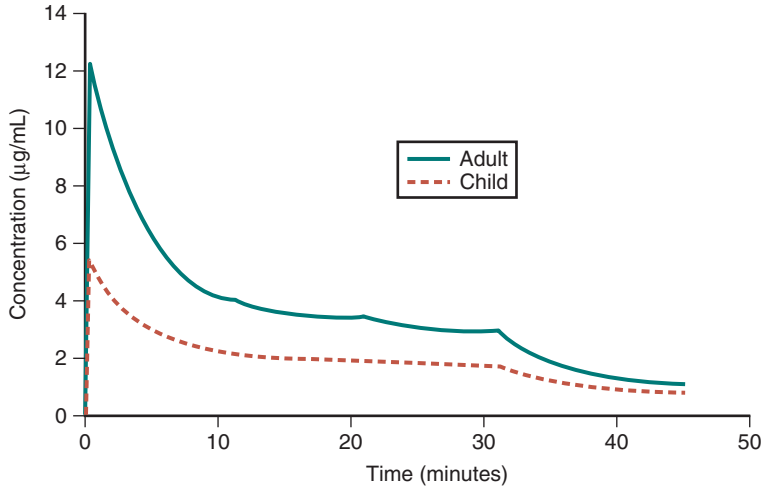

FIGURE 8.17 Simulated time-concentration profiles for propofol using a pediatric parameters set and an adult set. A 3 mg/kg bolus was administered and the infusions were administered as for an adult (10-8-6 regimen). Peak concentrations in the child are lower because of an increased volume of distribution. Increased clearance (expressed per kilogram) in children means subsequent concentrations also remain lower.

estimated blood concentration slightly exceeds 3 µg/mL but remains reasonably stable.[93]

Adolescents

Adolescents can generally be grouped as small adults and the 10-8-6 regimen can be used (see Table 8.3).[133]

Children

Children require larger infusion rates of propofol than adults to maintain clinical anesthesia (Fig. 8.17) because clearance (expressed per kilogram) is greater in children than in adults (Table 8.12). Parameter estimates reported by Kataria[19] were used to determine infusion regimens that maintain a steady-state blood concentration of 3 µg/mL in children aged 3 to 11 years. A loading dose of 2.5 mg/kg followed by an infusion rate of 15 mg/kg per hour for the first 15 minutes, 13 mg/kg per hour from 15 to 30 minutes, 11 mg/kg per hour from 30 to 60 minutes, 10 mg/kg per hour from 1 to 2 hours, and 9 mg/kg per hour from 2 to 4 hours was proposed. The CSHT in children was greater than in adults, increasing from 10.4 minutes at 1 hour to 19.6 minutes at 4 hours compared with adult estimates of 6.7 minutes and 9.5 minutes, respectively.[18] Subsequent clinical assessment of the infusion regimen's performance proved acceptable.[115]

This increased dose requirement for propofol in children can cause problems because it is formulated as a lipid emulsion and the lipid load can be considerable, particularly in young infants (Fig. 8.18). Propofol formulations are now available in some countries in concentrations varying from 5 mg/mL to 20 mg/mL (0.5%–2%); the most effective "lipid-sparing" strategy for infusions is to use 20 mg/mL propofol (2%) as this immediately halves the lipid load.

Infants

With the clearance of propofol reduced in infants, one might anticipate infusion rates at steady state reduced to similar extents. However, infusion rates for children younger than 3 years of age based on clinical experience from a pilot study of 50 patients were actually increased. This experience was used to develop dose regimens that were then evaluated in 2271 children undergoing

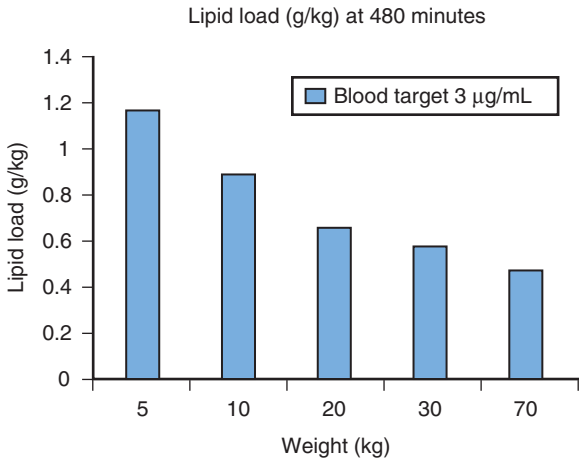

FIGURE 8.18 Lipid load after 480 minutes of a blood targeted propofol 1% infusion (formulated in vehicle containing 0.1 g/mL lipid) with target concentration of 3 µg/mL. Note the smaller infants have almost twice the lipid load and so 2% propofol is recommended to halve the relative lipid exposure and other propofol-sparing and lipid-sparing measures should be used. (Simulated using Tivatrainer; available at http://www.eurosiva.org/TivaTrainer/tivatrainer_main.htm.)

TABLE 8.12 Differences Between Adult and Pediatric Propofol Pharmacokinetic Parameters

Age	Vd (mL/kg)	Elimination Half-Life (minutes)	Clearance (mL/minute per kg)
1–3 years	9500	188	53
3–11 years	9700	398	34
Adult	4700	312	28

Notes: The apparent volume of distribution (Vd) of propofol in the child is twice that of adults. The clearance of propofol in young children is twice that of adults and elimination is much more rapid.
Data from Absalom A, Struys MMRF. *An Overview of TCI and TIVA*. Gent, Belgium: Academia Press; 2005.

anesthesia with mechanical ventilation. Infusion changes were every 10 minutes, similar to that proposed by Roberts et al. in adults.[133] These are shown in Table 8.2. Few adverse effects were recorded–(bradycardia (12%), blood pressure decrease (8%), oxygen saturation decrease (1%)–all of which were easily countered by routine measures.[50]

COMMON MANUAL OPIOID INFUSION SCHEMES

Simple manual infusion regimens can be used for the opioids fentanyl, alfentanil, remifentanil, and sufentanil. The manual infusion regimens for these opioids in children are summarized in Table 8.3. Maintenance analgesia after infusions of these opioids should be planned, and it is important that adequate doses of systemic analgesics are given well before the infusion is discontinued. Transitioning is somewhat smoother after sufentanil than after alfentanil or remifentanil in children. The problem of acute tolerance to ultra-short-acting opioids (see Chapter 7) has been noted after use of remifentanil in surgery for pediatric scoliosis.[134]

READY MIXES

Individual anesthesia practitioners, like good chefs, often have their own recipes using fixed drug mixes for some clinical scenarios. These have the advantage of simplicity but lack the versatility of separate infusions. Sterile infusions are prepared by the pharmacy in some centers, although there can be reluctance to prepare such infusions because of concerns about stability and the lack of clinical studies documenting the safety and efficacy of these mixtures. A common example used for endoscopy is shown in Table 8.13.

Ketofol is a mixture of ketamine and propofol (1:1) that is finding a niche for procedural sedation in the emergency room.[135] Stable hemodynamics, analgesia, and good recovery are reported.[136] The additive interaction for anesthesia induction in adults has been reported.[137] These data have been used to simulate effect in children[138]; an optimal ratio of racemic ketamine to propofol of 1:5 for 30 minutes of anesthesia and 1:6.7 for 90 minutes of anesthesia was suggested (Fig. 8.19).[138] The "ideal mix" for sedation will depend on the duration of sedation and the degree of analgesia required. The CSHT of ketamine increases with the duration of the infusion, resulting in delayed recovery.[139]

ACKNOWLEDGEMENT

We wish to thank Neil Morton, Frank Ebers, Grace Lai-Sze Wong, and James Limb for prior contributions to this chapter.

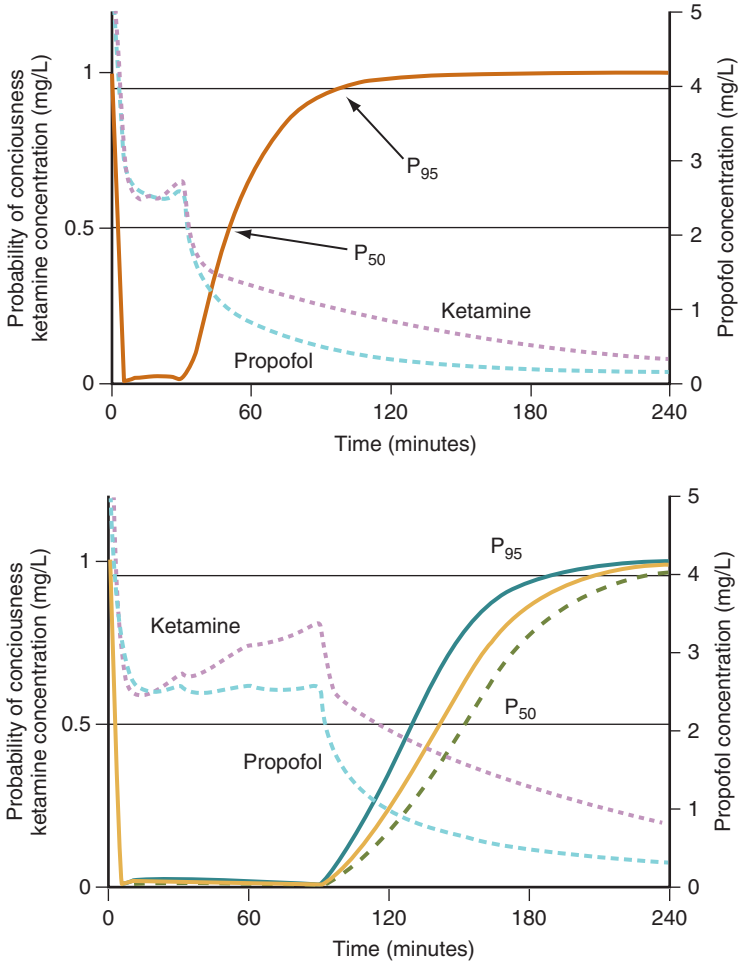

FIGURE 8.19 The upper panel shows the probability of consciousness during anesthesia using a propofol/ketamine ratio of 5:1. The loading dose for induction of anesthesia was 2.5 mg/kg propofol and 0.5 mg/kg of ketamine.The infusion rate was 67% of that suggested by McFarlan, Anderson, and Short[18] for propofol alone. Ketamine time-concentration profile is shown as a purple dotted line. Propofol time-concentration profile is shown as a blue dotted line. The lower panel shows simulation results for a 90-minute infusion. This panel also shows the probability of consciousness as age increases from a 2-year-old *(solid blue line),* to a 5-year-old *(solid orange line),* and a 10-year-old *(green dashed line)* child. The younger children have greater clearance and regain consciousness earlier than older children. P_{50} is the probability of consciousness in 50% of children; P_{95} is the probability of consciousness in 95% of children. (From Coulter FL Hannam JA, Anderson BJ. Ketofol simulations for dosing in pediatric anesthesia. *Pediatr Anesth.* 2014;24:806-12. Used with permission.)

TABLE 8.13 A Recipe for Gastrointestinal Endoscopy Using a Propofol-Remifentanil Mixture

Age >10 Years
50 µg remifentanil in 19 mL propofol (2.5 µg/mL remifentanil)
Start propofol mix at 175 µg/kg per minute
Age <10 Years
100 µg remifentanil in 18 mL propofol (5 µg/kg remifentanil)
Start propofol mix at 150 µg/kg per minute
If a higher remifentanil concentration is used in teenagers, then they breathe at 2–4 breaths/minute and have systolic blood pressure of approximately 75 mm Hg. If a lower remifentanil concentration is used, they breathe at 8–10 breaths/minute and have a systolic blood pressure of 76–84 mm Hg. Those aged <10 years generally do not usually require any up or down change in the rate of infusion and breathe at normal rates.

ANNOTATED REFERENCES

The other widely used parameter set (children 1-15 years) programed into target-controlled infusion pumps is the Paedfusor model. This parameter set is one of the few whose performance has been validated.

Holford NHG, Sheiner LB. Understanding the dose-effect relationship: clinical application of pharmacokinetic-pharmacodynamic models. *Clin Pharmacokinet*. 1981;6:429-453.

This classic study explains use of the Hill equation to explain the concentration-response relationship. The equation and its variants are used to relate both vapors and drugs to anesthesia depth using such monitors as BIS.

Kataria BK, Ved SA, Nicodemus HF, et al. The pharmacokinetics of propofol in children using three different data analysis approaches. *Anesthesiology*. 1994;80:104-122.

Population modeling was used to determine a propofol parameter set in children 3 to 11 years. This parameter set is known as the Kataria model and is programmed into many target-controlled infusion pumps.

Minto CF, Schnider TW, Egan TD, et al. Influence of age and gender on the pharmacokinetics and pharmacodynamics of remifentanil. I. Model development. *Anesthesiology*. 1997;86:10-23.

This is an important study that characterized remifentanil pharmacokinetics in adults. The parameter set is also used in children. There is an element of safety with this approach because both volume of distribution and clearance decrease with increasing age. The greater volume of distribution in children reduces the peak concentrations of remifentanil after bolus dosing; the increased clearance in children results in a smaller plasma concentration when infused at adult rates expressed as milligrams per minute per kilogram.

Roberts FL, Dixon J, Lewis GT, et al. Induction and maintenance of propofol anaesthesia. A manual infusion scheme. *Anaesthesia*. 1988;43(suppl):14-17.

The authors describe a manual infusion regimen for propofol that uses a decreasing infusion rate change every 10 minutes to account for compartment kinetics. This 10-8-6 rule is still widely used and the principle has been adopted by others for use in children administered drugs such as propofol, ketamine, and methadone.

Steur RJ, Perez RS, De Lange JJ. Dosage scheme for propofol in children under 3 years of age. *Paediatr Anaesth*. 2004;14:462-467.

This analysis yielded one of the few infusion regimens available for neonates. Data are limited in this age group, who are prone to an increased incidence of adverse effects, and practitioners are advised to use caution with this technique. Dose-response relationships for hypotension are lacking and the impact of postmenstrual age on clearance and infusion regimens or combination therapy that retains spontaneous respiration are awaited.

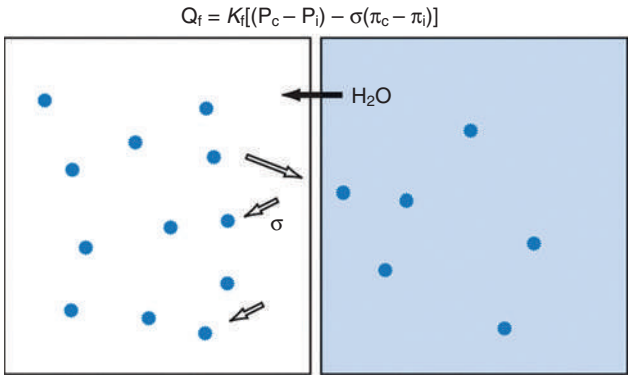
ELECTROLYTE DISTURBANCES ARE COMMON in children because of their small size, large ratio of surface area to volume, and immature homeostatic mechanisms. As a result, fluid management can be challenging. On the ward, in the operating room, or in the intensive care unit (ICU), additional difficulties may result when fluid management is not tailored to the individual or when therapeutic decisions are based on extrapolations from adult data. To better understand the former and to limit the latter, this chapter reviews the basic mechanisms underlying fluid and electrolyte regulation, the developmental anatomy and physiology of fluid compartments, and the management of selected pediatric disease states relevant to anesthesia and critical care.

Regulatory Mechanisms: Fluid Volume, Osmolality, and Arterial Pressure



Water is in thermodynamic equilibrium across cell membranes, and it moves only in response to the movement of solutes (E-Fig. 9.1). Movement of water is described by the Starling equation:

$$Q_f = K_f [(P_c - P_i) - \sigma(\pi_c - \pi_i)],$$

where Q_f is fluid flow; K_f is the membrane fluid filtration coefficient (a proportionality constant); subscripts c and i refer to capillary and interstitial; P_c and P_i are hydrostatic pressures and π_c and π_i are osmotic pressures on either side of the membrane; and σ is the reflection coefficient for the solute and membrane of interest. The reflection coefficient gives a measure of a solute's permeability and, consequently, its contribution to osmotic force after equilibration. Across the blood-brain barrier, for example, the σ for sodium approaches 1.0,[1] whereas in muscle and other cell membranes, σ is on the order of 0.15 to 0.3.[2] Therefore, when isotonic sodium-containing solutions are given intravenously, usually only 15% to 30% of administered salt and water remains in the intravascular space, whereas the remainder migrates to the interstitium.[3,4] In contrast, hypertonic solutions permit greater expansion of circulating blood volume with smaller fluid loads and less fluid in the interstitium (e.g., as edema).[5–7]

Both the amount and the concentration of solute are tightly regulated to maintain the volumes of intravascular and intracellular compartments. Because sodium is the primary extracellular solute, this ion is the focus of homeostatic mechanisms concerned with maintenance of intravascular volume. When osmolality is held constant, water movement follows sodium movement. As a result, total body sodium (although not necessarily serum Na^+) and total body water (TBW) generally parallel one another. Because sodium "leak" across membranes limits its contribution to the support of intravascular volume, this compartment also critically depends on large, impermeable molecules such as proteins. In contrast to sodium, albumin molecules, for example, follow the Starling equilibrium with a reflection coefficient in excess of 0.8.[8] Soluble proteins create the so-called *colloid oncotic pressure,* approximately 80% of which is composed of albumin.

Although the presence of albumin supports intravascular volume, protein leak into the interstitium (and consequent water movement) may limit its effectiveness. It has been observed, for example, that the reflection coefficient for albumin decreases by

E-FIGURE 9.1 Movement of water from the intracellular to extracellular compartments is described by the Starling equation. See text for details.

as much as one-third after mechanical trauma.[9] Furthermore, because of ongoing leakage, a slow continuous infusion of albumin is superior to bolus administration for increasing the serum albumin concentration in critically ill individuals.[10]

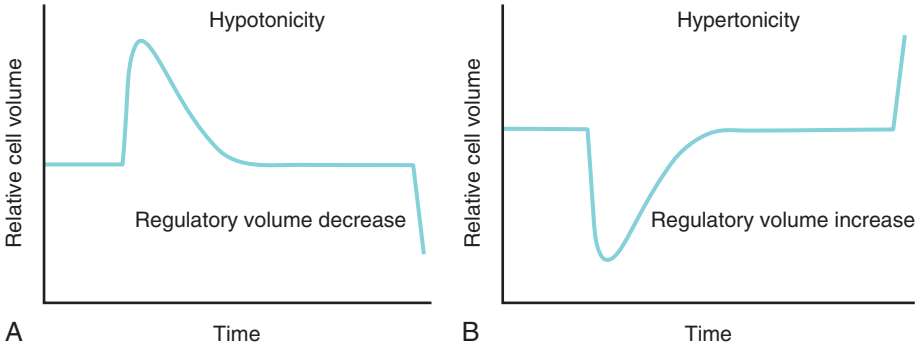
Potassium is the primary intracellular solute, with approximately one-third of cellular energy metabolism devoted to Na^+/K^+ exchange. Sodium continuously leaks into cells along its concentration gradient, yet it is rapidly extruded in exchange for potassium. As the cell is exposed to varying osmolarity, water movement occurs, causing cell swelling or shrinkage. Because stable cell volume is critical for survival, complex regulatory mechanisms have evolved to ensure that stability is maintained.[11,12] The processes by which swollen cells return to normal size are collectively termed *regulatory volume decrease* processes, and those returning a shrunken cell to normal are termed *regulatory volume increase* processes (Fig. 9.1). With sudden, brief changes in osmolality, regulatory volume increase or decrease processes are activated after small (1%–2%) changes in cell volume, returning cell volume to normal primarily through transport of electrolytes. If anisosmotic conditions persist, chronic compensation occurs through the accumulation or loss of small organic molecules termed *osmolytes* or idiogenic osmoles. These osmogenic agents can also be cytoprotective under stress and include polyols, sorbitol, myoinositol, amino acids and their derivatives (e.g., taurine, alanine, proline), and methylamines (e.g., betaine, glycerylphosphorylcholine).

Like intracellular volume, circulating blood (intravascular) volume is also tightly controlled. Increases in intravascular volume result from increases in sodium and water retention, whereas decreases in intravascular volume result from increases in excretion of sodium and water. As noted earlier, serum osmolality must be maintained within a very narrow range if serum sodium is to be an effective focus of intravascular volume control. Serum osmolality is usually maintained between 280 and 300 mOsm/L; changes in osmolality as small as 1% trigger compensatory mechanisms.

Serum osmolality is primarily regulated by arginine vasopressin (AVP), thirst, and renal concentrating ability. Because the indirect aim of osmolar control is actually volume control, these same osmoregulatory mechanisms are also influenced by factors such as blood pressure (BP), cardiac output, and vascular capacitance.[13,14] In pathologic conditions such as ascites or hemorrhage, intravascular volume preservation takes precedence over osmolality and osmoregulatory mechanisms operate to restore intravascular volume, even at the expense of disrupting solute balance.

AVP is released from neurons within the supraoptic and paraventricular nuclei of the hypothalamus.[15] Microelectrode recordings suggest that different subpopulations of neurons are responsive to osmotic input, baroreceptor-mediated input, or both. Osmoresponsive cells react to osmolar fluctuations in cell size, so solutes that readily permeate cell membranes (such as urea) increase the serum osmolality without triggering the release of antidiuretic hormone (ADH). Infusion of solutes with large actual or effective cell membrane reflection coefficients (σ) (e.g., sodium, mannitol) elicit a robust AVP release. Typically, AVP release begins when the serum osmolality reaches a threshold of approximately 280 mOsm/L. In keeping with our understanding of cell volume regulation, rapid increases in osmolality lead to greater release of AVP rather than slow increases. Meanwhile, baroreceptors on the arterial side of the circulation (left ventricle, carotid sinus, aortic arch, and juxtaglomerular apparatus) provide tonic inhibition of nonosmotic AVP release. Hypovolemia and hypotension diminish this inhibition, release AVP stores, and increase the overall "gain" of the system (E-Fig. 9.2). Thus, in a volume-depleted or hypotensive child, brisk AVP release occurs even in the presence of plasma osmolalities as low as 260 to 270 mOsm/L. On balance, baroreceptor signals always override osmotic signals so that water is retained as needed to maintain circulatory homeostasis.

Intravascular fluid volume, salt and water intake, electrolyte balance, and cardiovascular status are interrelated at several levels.[16] For example, as the veins and arteries distend with fluid and the systemic BP increases, AVP release decreases, and both *pressure diuresis* and *natriuresis* begin.[17] The resulting relationship between urine output and arterial pressure is termed the *renal function curve* and its intersection with salt and water intake determines the *equilibrium point* at which arterial BP ultimately stabilizes (Fig. 9.2). Equilibrium (chronic) BP is influenced only by shifts of the



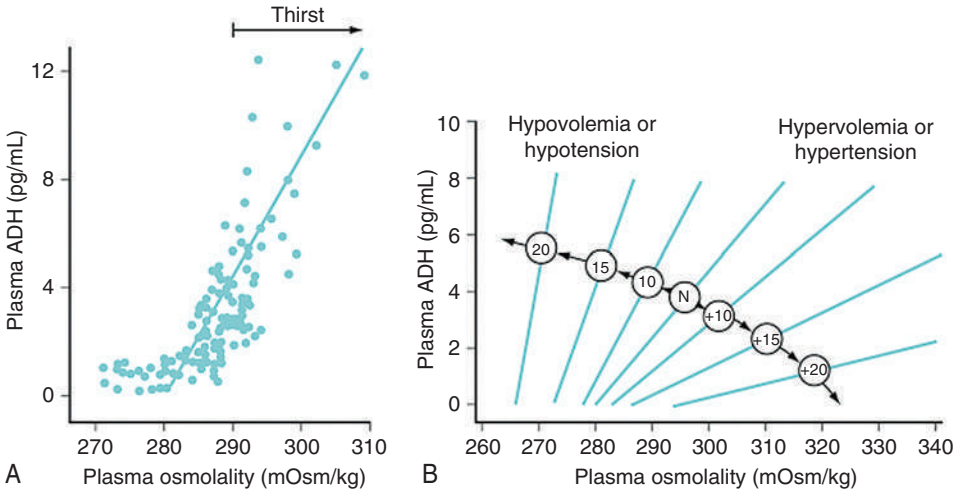


FIGURE 9.1 Activation of mechanisms regulating cell volume in response to volume perturbations. Volume-regulatory losses and gains of solutes are termed *regulatory volume decrease* **(A)** and *regulatory volume increase* **(B),** respectively. The course of these decreases and increases varies with the type of cell and experimental conditions. Typically, however, a regulatory volume increase mediated by the uptake of electrolytes or a regulatory volume decrease mediated by the loss of electrolytes and organic osmolytes occurs over a period of minutes. When cells that have undergone a regulatory volume decrease **(A)** or increase **(B)** are returned to normotonic conditions, they swell above or shrink below their resting volume. This is caused by volume-regulatory accumulation or loss of solutes, which effectively makes the cytoplasm hypertonic or hypotonic, respectively, as compared with normotonic extracellular fluid. (From McManus ML, Churchwell KB, Strange K. Regulation of cell volume in health and disease. *N Engl J Med*. 1995;333:1260–1266. ®Massachusetts Medical Society.)

E-FIGURE 9.2 A, Relationship between plasma antidiuretic hormone (ADH) concentration and plasma osmolality in healthy humans in whom the plasma osmolality was changed by varying the state of hydration. Notice that the osmotic threshold for thirst is a few milliosmols per kilogram higher than that for ADH. **B,** The influence of hemodynamic status on the osmoregulation of ADH in otherwise healthy humans. The numbers in the *center circles* refer to the percentage change in volume or pressure; *N* (*in the center circles*) refers to the normovolemic normotensive subject. Notice that the hemodynamic status affects both the slope of the relationship between the plasma ADH and osmolality and the osmotic threshold for ADH release. (**A** Adapted from Robertson GL, Aycinena P, Zerbe RL. Neurogenic disorders of osmoregulation. *Am J Med*. 1982;72:339–353; B from Rose DB. *Clinical Physiology of Acid-Base and Electrolyte Disorders*. 4th ed. New York: McGraw-Hill; 1994;159–163.)

renal function or fluid intake curves. Transient changes in arterial pressure secondary to peripheral vascular resistance changes are always resolved by opposing shifts in total body salt and water.

In response to a decreasing arterial pressure, the renin-angiotensin system is also activated. With decreased renal perfusion, juxtaglomerular cells release renin, which in turn converts renin substrate (angiotensinogen) to angiotensin I. Angiotensin I is then rapidly converted to angiotensin II by angiotensin-converting enzyme present in lung endothelium. Angiotensin II supports arterial pressure in three ways: (1) direct vasoconstriction, (2) increased salt and water retention (via renal vasoconstriction and decreased glomerular filtration), and (3) stimulation of aldosterone secretion (Fig. 9.3).

AVP, pressure diuresis, and the renin-angiotensin system permit wide ranges in salt and water intake while maintaining the BP and volume status within narrow ranges; all serve to support the systemic circulation when threatened and to complement the more immediate activity of the sympathetic nervous system. In addition to high-pressure sensors such as aortic arch and carotid sinus baroreceptors, intravascular volume information is provided by low-pressure thoracic sensors. For this reason, effective increases or decreases in intrathoracic blood volume may mimic changes in whole-body volume status and produce natriuresis, diuresis, or fluid retention. Intravascular volume may also be sensed by atrial muscle fibers; as the fibers stretch, atrial natriuretic peptide (ANP) is released.[18] Although its complete physiologic role is uncertain, ANP may serve to "fine-tune" the volume status by vasodilating modestly, gently increasing the glomerular filtration rate (GFR), and decreasing reabsorption of sodium. The combination of complex autoregulatory mechanisms with complementary actions operating on varying time scales, all responding to different, yet interrelated, effector stimuli, yields an elegant system by which the mature individual may maintain circulation amid a variety of challenges. In this context, it is interesting to observe that successful heart transplant recipients, despite general cardiovascular stability, typically manifest fundamental derangements in body fluid homeostasis.[19]

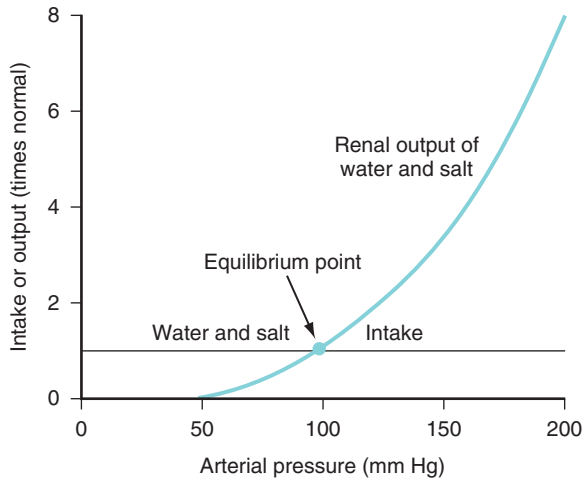

FIGURE 9.2 Analysis of arterial pressure regulation by equating the renal output curve with the salt and water intake curve. The equilibrium point describes the level to which the arterial pressure will be regulated. (That portion of the salt and water intake that is lost from the body through nonrenal routes is ignored in this figure.) (From Guyton AC, Hall JC, eds. *Textbook of Medical Physiology*. Philadelphia: WB Saunders; 1996;221–237.)

Maturation of Fluid Compartments and Homeostatic Mechanisms

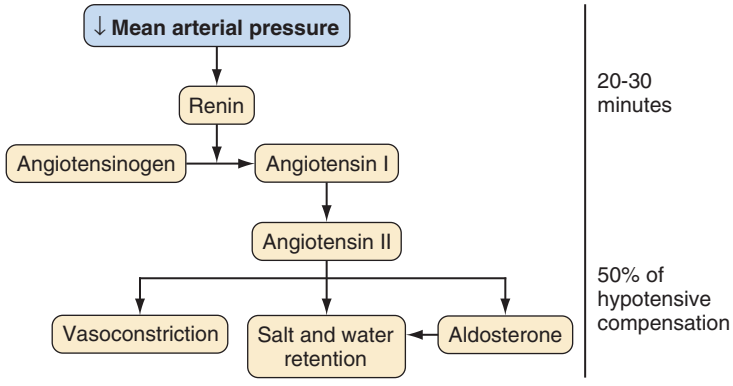
BODY WATER AND ELECTROLYTE DISTRIBUTION

Much of our understanding of the development of body water compartments is derived from deuterium oxide dilution studies performed in the 1950s.[20] In a series of 21 neonates, TBW was found to be approximately 78 ± 5% of body weight. Subsequent measurements in fewer subjects showed that TBW decreased to approximately 60% in the second 6 months of life with most of the loss being extracellular. A smaller decrease (to about 57%) is observed late in childhood (Fig. 9.4).

The importance of the extracellular compartment, its relationship to the intracellular space, and much of the chemical anatomy of both were first described by Gamble in educational monographs issued during the first part of the 20th century (E-Fig. 9.3).[21,22] The chemical compositions of mature body fluid compartments are provided in Table 9.1.

CIRCULATING BLOOD VOLUME

The blood volume in neonates was determined to be 82 ± 9 mL/kg using an iodine 121–labeled human serum albumin technique, although substantial variability may result from the degree of placental-fetal transfusion.[23] In low–birth-weight (LBW), preterm, or critically ill infants, values as high as 100 mL/kg have been measured.[24] Blood volume increases slightly during the first few months of life, reaching its zenith at 2 months of age (approximately 86 mL/kg), then returns to near 80 mL/kg and finally stabilizes at 70 mL/kg by the end of the first year of life. In general, the



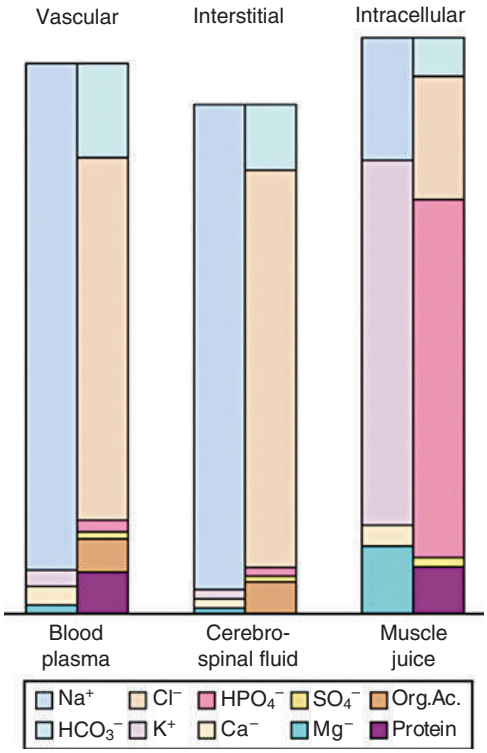


FIGURE 9.3 Physiologic responses to hypotension.

E-FIGURE 9.3 Acid-base composition of body fluids. These diagrams are constructed from average values for the individual factors expressed in terms of acid-base equivalence—that is, as cubic centimeters of one-tenth normal solutions per hundred cubic centimeters of fluid. The base factors are superimposed in the left column and the acid factors are superimposed in the right column for each fluid. The diagrams represent, as is actually the case, a structure composed not of salt but of individually sustained concentrations of ions. The exact acid-base equivalence indicated by the equal height of the two columns is obtained by adjustability of the bicarbonate ion concentration (HCO_3^-) to any change elsewhere in the structure. (From McIver MA, Gamble JL. Body fluid changes due to upper intestinal obstruction. JAMA. 1928;92:1589–1592. Copyright 1928, American Medical Association.)

Preterm infant	100
Full-term neonate	90
Infant	80
School age (5 years)	70
Adults	70

ratio of blood volume to weight decreases with growth. The most accurate basis for prediction of blood volume is lean body mass, the consideration of which removes any male/female variation even into adulthood.[25] An estimate of the circulating blood volume is presented in Table 9.2.

MATURATION OF HOMEOSTATIC MECHANISMS

Renal development begins at approximately 5 weeks of gestation and continues in a centrifugal pattern until the full complement of nephrons is in place by about the 38th week. In the outermost regions of the renal cortex, postnatal nephron differentiation may continue for several weeks to months. In the early stages of gestation, renal blood flow is approximately one-fifth of normal. Initially this is related to structural immaturity, and later it is caused by increased renovascular resistance. By 38 weeks of gestation, renal blood flow is approximately one-third of normal. High renovascular resistance protects the developing nephron from both pressure and volume overload. The resulting renal contribution to metabolic homeostasis in utero is limited.

As with the pulmonary bed, vascular resistance in the kidney decreases after birth, leading to abrupt increases in renal blood flow and GFR. In utero, despite a low GFR, urine output is brisk, owing to poor reabsorption of salt and water. Plasma renin activity is increased in utero, decreases immediately after birth, and then increases again as excess extracellular water is mobilized and excreted. Aldosterone levels are increased in cord blood and are maintained at this level for the first 3 days of life. The increased aldosterone may be necessary for sodium retention during periods of increased anabolism early in life.

Intrarenal gradients of NaCl and urea are less steep in the immature kidney, and full nephron length has yet to be achieved. Consequently, urine-concentrating ability is limited in neonates, with maximum urine osmolality being about half that of the adult (700–800 mEq/L vs. 1300–1400 mEq/L). In part, this also relates to low circulating ADH levels and decreased renal responsiveness to ADH. Although overall ADH production is not impaired, excessive secretion may occur in some disease states. Limited urine-concentrating ability necessitates large urine volumes for elimination of large solute loads.

Renal plasma flow and GFR (based on body surface area or allometry) are 30% of adult values in neonates. Both increase during the first year, reaching 50% of adult values by 6 months age (350 and 70 mL/minute per meter squared, respectively, and 90% by approximately 1 year[26] see Figs. 7.11 and 7.12).[27] At birth, the serum creatinine reflects the maternal concentration, which may be increased in term and preterm infants, but normalizes in the second month after birth, reflecting creatinine production. Fractional excretion of sodium (FE_{Na}) is markedly increased in preterm infants, decreases somewhat by term, and stabilizes at adult rates by the second month of life. Although the adult kidney may easily achieve FE_{Na} values as small as 0.5%, the 34-week-gestation infant is limited to no less than 2%.

These maturational features limit the ability of the preterm or young infant to handle large fluctuations in fluid and solute loads. Both sodium conservation and regulation of extracellular fluid volume are impaired in comparison with the older child and adult. Limited GFR makes excretion of a fluid challenge difficult. Excessive urinary sodium loss leads to increased maintenance requirements; hyponatremia is common. Conversely, diminished concentrating ability increases free water losses during excretion of a solute load, whereas the high ratio of surface area to volume increases evaporative water loss. Consequently, fluid requirements are relatively high, and dehydration is common. Any errors in fluid management are poorly tolerated. As a rule, the most severe impairment exists in preterm infants, and the majority of homeostatic mechanisms are fully developed after the first year of life.

Fluid and Electrolyte Requirements

Holliday summarized the evolution of contemporary hydration therapy.[21] In 1831, Latta first reported the use of intravenous (IV) fluids in the resuscitation of patients dehydrated by cholera.[28] In 1918, growing information on the subject permitted Blackfan and Maxcy to successfully treat nine infants by intraperitoneal injection.[29] In 1923, Gamble and associates detailed the anatomy of fluid and electrolyte compartments, introducing the use of milliequivalents to clinical practice.[22] This paved the way for the development of the "deficit therapy" regimen of Darrow.[30]

In subsequent decades, various recipes to replace the extracellular and intracellular fluid losses were suggested. For the most part, these failed because of excessive potassium and insufficient sodium content. Hyponatremia was common. When the focus of the treatment shifted to replacing the extracellular fluid deficit, rapid restoration of extracellular fluid volume using solutions with sodium concentrations similar to those in blood became commonplace. This, along with oral rehydration, is the preferred method of treatment today.

The concept of "maintenance fluids" is a complex subject. Although water and salt are required to sustain life, it is fair to say that for an individual child at any particular time, the precise amounts necessary are unknown (and perhaps unknowable). Instead, fluids and electrolytes, like anesthetics, are titrated to effect with general guidelines provided by clinical assessment, basic physiologic principles, and limited published data. The term *maintenance fluids* is often more limiting than helpful, and in all cases it is less precise than other terms familiar to anesthesiologists, such as *minimum alveolar concentration* (MAC) or *median effective dose* (ED_{50}).

Holliday and Segar provided calculations for a first approximation of *"the maintenance need for water in parenteral fluid therapy"* in 1957.[31] Integrating the relevant known physiology at that time, these authors observed that "*insensible loss of water and urinary water loss roughly parallel energy metabolism and do not parallel weight*." However, because water utilization parallels energy metabolism, energy metabolism follows surface area, and surface area follows weight, it should be possible to estimate water requirement from weight alone. The authors then proceeded under a series of assumptions to extrapolate from limited data to a *"relationship between weight and energy expenditure that might easily be remembered."*

Assuming energy requirements of "*hospitalized patients*" to be "*roughly midway between basal and normal levels*," they constructed a curve of caloric requirement versus weight.[31] This curve could be seen as consisting of three linear sections: 0 to 10 kg, 10 to 20 kg, and 20 to 70 kg (Fig. 9.5). Viewing the curve in this manner, the authors reasoned that *"fortuitously, the average need for water, expressed in milliliters, equals energy expenditure in calories":* 100 mL/kg per day for weights to 10 kg, an additional 50 mL/kg per day for each kilogram from 11 to 20 kg, and 20 mL/kg per day more for each kilogram beyond 20 kg. In anesthetic practice, this formula has been further simplified, with the hourly requirement referred to as the "4-2-1 rule" (4 mL/kg per hour for the first 10 kg of weight, 2 mL/kg per hour for the next 10 kg, and 1 mL/kg per hour for each kilogram thereafter; Table 9.3).

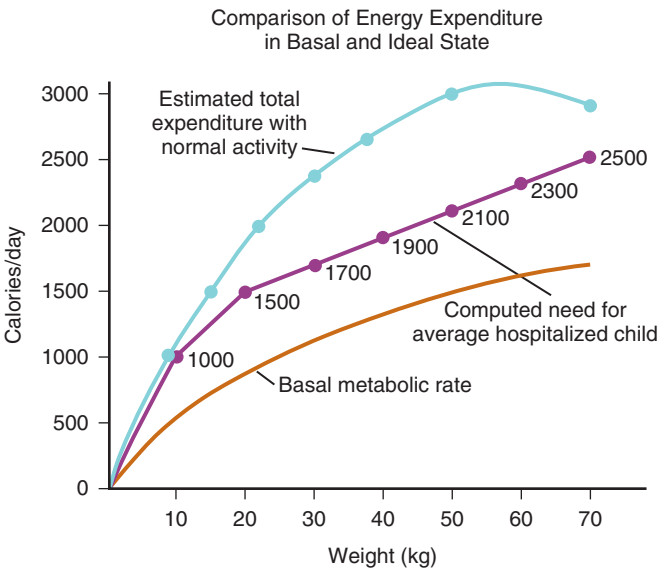

FIGURE 9.5 The upper and lower curves were plotted from data from the study by Talbot.[32] Weights at the 50th percentile level were selected for converting calories at various ages to calories related to weight. The computed line for the average hospitalized child was derived from the following equations:

- 0–10 kg: 100 kcal/kg.
- 10–20 kg: 1000 kcal + 50 kcal/kg for each kg over 10 kg
- ≥20 kg: 1500 kcal + 20 kcal/kg for each kg over 20 kg

(From Holliday MA, Segar WE. The maintenance need for water in parenteral fluid therapy. *Pediatrics* 1957;19:823–832.)

TABLE 9.3 Relationship Between Weight and Hourly or Daily Maintenance Fluid Requirements of Children as per the 4-2-1 Rule

	MAINTENANCE FLUID REQUIREMENTS	
Weight (kg)	**Hour**	**Day**
<10	4 mL/kg	100 mL/kg
10–20	40 mL + 2 mL/kg for every kg >10 kg	1000 mL + 50 mL/kg for every kg >10 kg
>20	60 mL + 1 mL/kg for every kg >20 kg	1500 mL + 20 mL/kg for every kg >20 kg

Renal insufficiency
Hepatic insufficiency

For decades, the simplicity and elegance of the Holliday and Segar formula has made it the starting point for fluid management in healthy children. Until recently, the majority of consultant anesthetists in the United Kingdom administered hyponatremic glucose-containing solutions intraoperatively and postoperatively to children undergoing elective surgery.[33] However, the uncritical use of these solutions was never intended, and their blind application in the operating room, or in any clinical situation, resulted in instances of hyponatremia, aspiration, and death.[34–36] Further, as Holliday has since pointed out, their original approach involved hyponatremic glucose-containing solutions rather than near-isotonic solutions such as 0.9% saline or lactated Ringer's solution (LR).[37] In addition, these requirements were assessed at a basal metabolic state and not when the child was acutely ill or under physiologic stress during which increased levels of ADH were present. As the authors cautioned, *"understanding of the limitations and of exceptions to the system [is] required. Even more essential is the clinical judgment to modify the system as circumstances dictate."* General water losses for infants and children are summarized in Table 9.4.

More recently, Holliday and colleagues revised the approach to fluid therapy in children that he and Segar enshrined with several caveats.[38] In a related commentary, he pointed out several problems with applying the original 4-2-1 rule to acutely ill children.[39] Namely, dysregulation of ADH is a hallmark of critical illness because ADH secretion is affected by a variety of nonosmotic factors such as pain, stress, mechanical ventilation, and medications (Table 9.5).[40] As a result, the choice of IV fluid and the rapidity of deficit replacement must be approached with care. The authors recommended a relatively simple strategy for healthy children undergoing elective surgery (including outpatients) to turn off ADH secretion and prevent perioperative water retention and subsequent hyponatremia. When a child (who is without significant heart or kidney disease) presents with marginal to moderate hypovolemia (e.g., after fasting for surgery), 20 to 40 mL/kg of isotonic fluids should be given during the surgery and postanesthesia care unit stay (as rapidly as 10–20 mL/kg per hour). Clinical judgment must always allow for modification of these recommendations if indicated for an individual child.[37,41] If hypovolemia is more severe (e.g., after an extensive bowel preparation), 40 to 80 mL/kg may be necessary during the perioperative period. Some have expressed concern that such volumes of fluid could cause volume overload even in healthy children. However, evidence suggests that children handle crystalloid volumes much more efficiently than adults.[42]

Postoperative IV fluid therapy should consist of an isotonic solution infused to replace ongoing fluid losses plus about half the rate described in the original 4-2-1 fluid regimen (i.e., 2 mL/kg for the first 10 kg, 1 mL/kg for the next 10 kg, and 0.5 mL/kg for each additional kilogram thereafter). Historically, when a child is unable to tolerate oral intake postoperatively, routine maintenance fluid therapy has been resumed with hypotonic saline solution (e.g., 0.45% saline). Although this regimen was believed to limit the ADH response and reduce the risk of postoperative hyponatremia and hypernatremia,[37,38,41] pain and surgical stress can maintain increased ADH levels and risk the development of hyponatremia with seizures and encephalopathy.[35,36,43,44] In the postoperative setting therefore, an isotonic salt solution is a better choice for maintenance[45] at a rate of 2 : 1 : 0.5 rule for the first 12 hours then returning to the 4 : 2 : 1 rule thereafter, until the child tolerates oral fluids.[36,46,47] Regardless of the fluids administered, it remains prudent to serially monitor plasma electrolyte concentrations until the child is drinking normally and homeostasis is restored.[45,48,49]

NEONATAL FLUID MANAGEMENT

In the first few postnatal days, isotonic losses of salt and water cause the healthy neonate to lose 5% to 15% of body weight. Although GFR increases rapidly, urine output is initially minimal, and renal losses are modest. Day 1 fluid requirements of the wrapped neonate, therefore, are relatively small. Over the next few postnatal days, losses and fluid requirements increase. In the poorly feeding infant, progression to hypernatremia and dehydration are common. When intake is appropriate, the term infant will regain body weight during the first week.

Three distinct phases of fluid and electrolyte homeostasis have been described in LBW[50] and very low–birth-weight (VLBW)[51] infants. In the first postnatal day, there is minimal urine output, and body weight is stable despite limited fluid intake. In the second phase, days 2 and 3 of life, diuresis occurs irrespective of the amount of fluid administered. By the fourth and fifth days, urine output begins to vary with changes in fluid intake and state of health.

Prematurity increases neonatal fluid requirements substantively. Fluid requirements are therefore estimated and then titrated to the infant's changing weight, urine output, and serum sodium concentration.

No less important is glucose homeostasis. In the ninth month of gestation, the fetus begins to form glycogen stores at a rate of more than 100 kcal/day. In the unstressed, term infant, hepatic glycogen stores are 5% of body weight. Immediately after birth, glycogenolysis depletes most of these stores within the first 24 to 48 hours. Gluconeogenesis must then proceed to yield glucose at a rate of approximately 4 mg/kg per minute.

At birth, the serum glucose concentration in the fetus is 60% to 70% of the maternal value. This may decrease within the first postnatal hours before recovering but should exceed 45 mg/dL to avoid neurologic injury. Symptoms of hypoglycemia may include jitteriness, lethargy, temperature instability, and convulsions. Ten percent dextrose in water ($D_{10}W$) may be given as a bolus of 2 to 4 mL/kg followed by a continuous infusion (using a pump) at 4 to 6 mg/kg per minute. The serum glucose concentration is then analyzed frequently and the infusion adjusted as necessary to prevent hypoglycemia and hyperglycemia. Alternately, neonatologists are switching to a 40% dextrose gel that is applied to the buccal mucosa for rapid absorption and resolution of hyponatremia.[52,53] This obviates the need for IV access if one has not been established by this time. It is important that the amount of glucose being provided be calculated in milligrams per kilogram per minute to avoid errors during fluid changes and to facilitate the diagnosis of persistent hypoglycemia.

Typical *day 1* infant fluid orders recommend 70 to 80 mL/kg of $D_{10}W$. Because $D_{10}W$ contains 10 g of glucose per deciliter, this regimen provides

$$\begin{aligned} 10\ \text{g/dL} \times 70 - 80\ \text{mL/kg per day} &= 7 - 8\ \text{g/kg per day} \\ &= 0.333\ \text{g/kg per hour} \\ &\cong 5\ \text{mg/kg per minute} \end{aligned}$$

On *day 2*, fluids are routinely increased to at least 100 mL/kg per day, and sodium is added at 2 to 3 mEq/dL. After urine output is established, potassium is added at 1 to 2 mEq/dL. The final solution, containing 30 mEq Na^+ and 10 to 20 mEq K^+ per liter, approximates the 0.2% saline "maintenance" solution commonly used previously in older children.

In the neonatal ICU, fluid management focuses on provision of adequate nutrition, maintenance of electrolyte balance, and limitation of fluid overload. The last factor is of particular concern because plasma oncotic pressure is reduced in preterm infants and the whole-body protein reflection coefficient is less than that in adults.[54] VLBW infants are at particular risk for fluid and electrolyte imbalances.[55] Even modest fluid overload may exacerbate pulmonary edema, prolong ductal patency, and more readily produce congestive heart failure. This perspective typically accompanies the infant to the operating room, where the primary considerations are routinely quite the opposite: restoration of circulating blood volume after third-space accumulation, maintenance of intravascular volume amid ongoing blood loss, replacement of potentially massive evaporative losses, and maintenance of BP despite anesthetic-induced vasodilatation and increased venous capacitance. During surgery, these concerns must take precedence, yet unnecessary administration of fluid is best avoided.

Intraoperative Fluid Management

INTRAVENOUS ACCESS AND FLUID ADMINISTRATION DEVICES

In infants and children, the first step toward intraoperative fluid management is often the most challenging: that is, establishing IV access. In general, simple procedures in healthy children are successfully approached using a single peripheral IV line. Although preferences vary among anesthesiologists, establishing IV access is most easily accomplished after induction of anesthesia. In young children, anesthesia is often induced by inhalation, and a catheter is inserted by an assistant into a hand or foot vein. In older children, or when IV access is desirable before anesthesia is induced, IV access may be facilitated by the use of topical anesthesia (e.g., EMLA [eutectic mixture of local anesthetics] cream, amethocaine, lidocaine infiltration) or sedation or both.

Complex surgeries in sicker children usually require at least two large-bore catheters. In pediatrics, however, "large-bore" is a relative term, with 22-gauge catheters typically providing sufficient access in infants. Preferred sites for larger catheters include the antecubital and saphenous veins (see Fig. 49.1). In cases in which access to the central circulation is required (as for pressure monitoring, infusion of vasoactive medications, or prolonged access), longer catheters may be placed via the femoral, subclavian, or internal jugular vein (the latter usually via a high, anterior approach; see Figs. 49.2–49.5).[56] Although secure access may also be obtained via the external jugular vein, it is often difficult to negotiate the J-wire or catheter tip into the central circulation.[57] Peripherally inserted central catheter (PICC) lines have become common among hospitalized children. Although they represent a long-term means of delivering IV fluids and medications to those who need them, their intraoperative utility is very limited for several reasons. First, modern patient safety practices prohibit repeated access to central lines and practitioners must maintain strict sterile technique whenever entering them. Second, flow resistance is great within long, small-diameter catheters, precluding their use for large-volume resuscitation. Finally, PICCs are often placed for delivery of hyperalimentation or other solutions, which may be incompatible with anesthetic needs. For these reasons and others, separate IV access is often required and secure larger-bore shorter IV catheters with much lower resistance must always be placed if large fluid shifts or significant blood loss is anticipated.

In selecting the appropriate IV catheter, it is useful to consider the relative effects of catheter length and diameter on solution flow rates. Longer catheters offer more resistance to flow than shorter ones and are therefore less desirable when rapid infusion of a large volume of fluids is necessary (see E-Figs. 52.1, 52.2, and Fig. 51.1). In vitro, catheters designed for peripheral venous access had 18% to 164% greater flow rates compared with the same-gauge catheters designed for central venous use. Under pressure, as might be used during emergent volume resuscitation, rates differed up to 17-fold.[58] Although this seems to suggest that short peripheral catheters should be preferred, in vivo data are more complex. In animal models, overall catheter flow rates are less than in vitro rates, and central access presents somewhat less resistance to flow than

peripheral access.[59] Finally, when the risks and benefits of central versus peripheral access are compared, central administration of resuscitation medications may provide little practical advantage compared with peripheral administration.[60]

Intraosseous devices are now commonly used in the initial resuscitation of critically ill or injured children (see E-Figs. 49.1 and 49.6 and 49.7).[61,62] Flow rates via these devices depend less on needle diameter than on resistance in the marrow compartment.[63] In the operating room, the intraosseous route has been used for both induction and maintenance of anesthesia.[64–66] However, onset of drug effect is less predictable, and the device is more easily dislodged than an IV catheter. Potential complications include compartment syndrome[67–69] and, very rarely, damage to the growth plate.[62,70] Such devices are probably best considered an emergency or last-resort option.[65]

To prevent accidental volume overload, the amount of IV fluid available to administer to a child at any one time should not exceed the child's calculated hourly requirement. Particularly in infants, a volumetric chamber should be used to limit the amount of fluid available for infusion. Similarly, a microdrip infusion set limits the rate of fluid administration and permits much greater control. Although a fluid infusion pump provides the most precise mode of regulating the rate of fluid administration (and is therefore very useful in providing supplemental fluids or medications), such devices are impractical on primary access lines because they hinder the ability to administer drugs and fluids rapidly. In addition, the clinician should be mindful that pumps may continue to infuse through dislodged catheters, giving misleading reassurance that adequate IV access is present and fluids are being administered. Administering large volumes of fluid and drugs interstitially will not deliver the anticipated results. Moreover, if an identification or allergy bracelet is on a limb proximal to the IV insertion site, it may act as a tourniquet if the IV is interstitial, possibly causing ischemia to digits. Therefore access to the IV site is important in children, as well as removing all bracelets proximal to ipsilateral IV insertion sites.

In neonates and small infants, when rapid infusion of resuscitation solutions or blood products is anticipated, many practitioners insert a stopcock manifold into the IV infusion. Additional fluids may be prepared in syringes and warmed separately; during periods of sudden blood loss, stored syringes may then be inserted into the manifold and a fluid volume rapidly infused.

Finally, in prolonged surgeries or when volume replacement is great, all IV infusions may be warmed to maintain thermal homeostasis. Also, in younger infants and children in whom communication exists between the right and left sides of the circulation (e.g., patency of the foramen ovale), an in-line "bubble" filter is desirable.

CHOICE AND COMPOSITION OF INTRAVENOUS FLUIDS

In the early 1960s,[71] simultaneous measurements of plasma and extracellular fluid volumes demonstrated that, during surgery, plasma volume is supported at the expense of the extravascular space. At the same time, it was classically observed that isotonic resuscitation fluids temporarily redistribute from the intravascular spaces to what was originally believed to be a third, nonfunctional space. However, when the endothelial glycocalyx is perturbed, as can occur with surgical trauma, fluid may shift from the intravascular to interstitial space. Therefore the historical "third space" may simply represent the reversible expansion of the interstitium. Because of the differences in fluid distribution and renal function in infants compared with older children, it was at first unclear that these findings could be extended to infancy. Thus fluid restriction remained the standard of care until careful studies specifically demonstrated that fluid and electrolyte requirements are often extremely large in neonates who are undergoing major surgical procedures.[72–74]

Historically, hypotonic fluids were used as the maintenance solutions throughout the hospital, but this is no longer the practice. Isotonic solutions are preferred intraoperatively for several reasons. First, most ongoing volume losses are isotonic, consisting of shed blood and interstitial fluids. Second, large volumes of hypotonic solutions may rapidly diminish serum osmolality, producing very low concentrations of electrolytes (in particular, sodium) and undesirable fluid shifts. Indeed, even large volumes of "isotonic" fluids significantly decrease the serum osmolality in adult volunteers.[75] Third, as discussed earlier, the plasma volume expansion that is necessary in response to diminished vascular tone under anesthesia is difficult to achieve even with isotonic fluids. Finally, increases in ADH levels and other elements of intraoperative physiology retain free water in excess of sodium if inadequate amounts of the latter are provided.

The compositions of commonly used IV solutions are presented in Table 9.6. Assuming normal plasma osmolality is 275 to 290 mOsm/L, 0.9% NaCl (normal saline, NS) is theoretically hypertonic to plasma but is effectively isotonic when the in vivo activities of its constituents are considered.[76] For dextrose-containing solutions, the osmolality decreases rapidly as sugar is metabolized, resulting in increased volumes of free water. Therefore, administration of 5% dextrose in water is ultimately equivalent to administering free water.

Controversy regarding the perioperative use of colloid versus crystalloid fluid replacement remains unresolved. Colloid solutions carry the theoretical benefit of more effective expansion and retention of intravascular volume. Crystalloid solutions are much less expensive, easier to store, and carry few side effects. Although an initial meta-analysis of adult studies suggested worse outcomes

TABLE 9.6 Composition of Extracellular Fluid and Common Intravenous Solutions

		CATIONS (mEq/L)			ANIONS (mEq/L)				
	mOsm/L	Na^+	K^+	Ca^{2+}	Mg^{2+}	NH_4^+	Cl^-	HCO_3^-	HPO_4^-
Extracellular fluid	280–300	142	4	5	3	0.3	103	27	3
Lactated Ringer's (LR) solution	273	130	4	3			109	28	
0.45% NaCl	154	77					77		
0.9% NaCl (normal saline)	308	154					154		
PlasmaLyte A[a]	294	140	5		3	1.6	98	98	
3% NaCl	1024	513					513

after albumin resuscitation,[77] this was not confirmed in a subsequent randomized controlled trial.[78] However, subgroup analyses from the latter trial suggested that some patients, such as those with head injury,[79] may be harmed by albumin, whereas others, such as those with septic shock,[80] may realize some benefit. Thus the choice of solution may depend on the underlying medical conditions and remains a matter of clinical judgment.

It is worth noting that aside from 5% albumin, synthetic colloids are gaining popularity among pediatric practitioners. One reason for this is the development of newer synthetic colloids with a more favorable side effect profile. Hydroxyethyl starches (HES) are synthetic colloids that are simply modified polysaccharides. Circulating amylases quickly degrade natural polysaccharides, but HES solutions are not quickly degraded because the solutes contain hydroxyethyl groups in place of hydroxyl groups at carbon positions C-2, C-3, and C-6, rendering the molecules resistant to hydrolysis. These compounds are characterized by three attributes: average mean molecular weight (MW), molar substitution (MS), and the C-2/C-6 ratio, which relates to the relative positions of hydroxyethyl groups on the polysaccharide molecule.

HES solutions with a greater MW/MS ratio remain in the intravascular space for longer periods than those with smaller ratios. However, they also are prone to more adverse effects including hypocoagulability. Newer, low MW/low MS solutions have much less effect on hemostatic mechanisms than older, higher MW/higher MS solutions. The precise mechanism by which HES compounds affect coagulation remains unclear, although it has been attributed to interference with von Willebrand factor, factor VIII, and platelet function. A greater C-2/C-6 ratio is responsible for a slower degradation of the starch by amylase with fewer adverse effects.[81] When renal function is normal, newer HES solutions (e.g., HES 130/0.42/6 : 1) are safe for children undergoing elective surgery, since they maintain hemodynamic stability and produce only mild to moderate changes in acid-base status.[82] Synthetic colloids such as these can therefore be considered in surgical patients who demonstrate the need for aggressive intraoperative fluid resuscitation (see also Chapter 12). Use of these solutions in cardiac surgery remains controversial given the effects on coagulation factors and platelet function induced by the cardiopulmonary bypass circuit.

The routine intraoperative use of glucose-containing solutions has also been a subject of debate. As a rule, operative stress evokes physiologic responses that increase serum glucose. In practice, therefore, hypoglycemia is seldom a problem in healthy, fasted children when glucose is omitted from perioperative IV fluids.[83,84] Indeed, the risk should be particularly small if the period of fasting is limited to less than 10 hours.[84] At the same time, rapid administration of dextrose solutions may certainly produce acute hyperglycemia and hyperosmolality.[83,84] Therefore, glucose-containing electrolyte solutions should not be used to replace fluid deficits, third-space losses, or blood losses, but they may be used as a background electrolyte maintenance solution.[85] Some populations, such as debilitated infants,[86] children who are malnourished, neonates and infants younger than 6 months of age,[83,87,88] and those undergoing cardiac surgery, are at risk for intraoperative hypoglycemia.[89,90] The use of glucose-containing solutions (1%–2.5% dextrose),[83,85,87,91] along with intraoperative glucose monitoring, may be beneficial in these children.

HYPERALIMENTATION

It is now common practice that critically ill children arrive in the operating room with hyperalimentation solutions infusing.

TABLE 9.7 Common Contents of Parenteral Nutrition Solutions[a]

Carbohydrates
10%, 12.5%, 20%, 25%, 30% Dextrose
Limited to D_{10} or $D_{12.5}$ if through a peripheral catheter
Protein
In the form of amino acids
0.5, 1.0, 1.5, 2.0, 2.5, or 3.0 g/kg per day
Lipids
10%, 20% Lipids
Standard Additives
Sodium: 30 mEq/L
Potassium: 20 mEq/L
Calcium: 15 mEq/L
Magnesium: 10 mEq/L
Phosphorus: 10 mmol/L
Heparin

[a]Common contents of parenteral nutrition solutions containing dextrose, protein, lipids, and standard additives such as electrolytes. These values represent standard starting points that may be modified based on individual patient needs.

Common contents of hyperalimentation solutions are shown in Table 9.7. In general, children require 0.5 to 3.0 mg/kg per day of protein, 6 to 9 mg/kg per minute of glucose, and 0.5 to 3 g/kg per day of fat. Children receiving parenteral nutrition preoperatively should continue to receive those infusions separately, and a corresponding volume should be deducted from isotonic operative fluids. Hyperalimentation typically consists of two infusions: fat (e.g., Intralipid, Fresenius Kabi AB, Uppsala, Sweden) and a concentrated glucose/protein solution. It is prudent to discontinue the Intralipid solution during surgery, but if that is not possible, then every effort should be made to avoid accessing any ports in the line to reduce the risk of contaminating the Intralipid. Conversely, the concentrated glucose/protein solution should be continued at the same rate (because circulating insulin concentrations have acclimated accordingly). Because of hyperglycemic responses to the stress of surgery and reduced metabolism related to anesthesia and hypothermia, some practitioners routinely decrease hyperalimentation infusion rates by one-third to one-half. If the latter practice is followed, clinicians should consider checking serum glucose concentrations at regular intervals to monitor for hypoglycemia. Under no circumstances should concentrated glucose solutions (such as D_{10} or D_{20}) be abruptly discontinued, because high concentrations of circulating insulin may cause a precipitous and profound decrease in the serum glucose concentration.

Concerns regarding the routine intraoperative use of dextrose-containing solutions increased with recognition that hyperglycemia may exacerbate neurologic injury after an ischemic or hypoxic event. As a result, many clinicians now elect to avoid dextrose-containing solutions during routine surgery. When dextrose-containing solutions are used, appropriate monitoring is advised to avoid serum glucose extremes. Many practitioners administer glucose-containing solutions as a separate piggyback infusion using an infusion pump or other rate- or volume-limiting device to avoid accidental bolus administration. Alternatively, evidence indicates that isotonic solutions that contain reduced glucose concentrations (e.g., 1% or 2.5% vs. 5%) are safe alternative solutions for

intraoperative use.[92] In the United States, several Food and Drug Administration (FDA)-approved solutions containing 2.5% dextrose are available but none with concentrations lower than 2.5%. In Europe, 1% dextrose electrolyte solutions are available.[87,92] Because intraoperative administration of solutions containing 5% dextrose (D_5LR) frequently causes hyperglycemia, prudent anesthesiologists should selectively administer dextrose-containing solutions to those who are at particular risk for intraoperative hypoglycemia (i.e., neonates, chronic malnourished children, and cachectic children). In these instances, it may be sensible to administer solutions with a reduced dextrose concentration.[81,87]

FASTING RECOMMENDATIONS

The goal of fasting is to minimize the volume of gastric contents and thereby lessen the risk of vomiting and aspiration during induction of anesthesia. In children, as opposed to adults, this is of particular concern because in many institutions induction in children is more often accomplished by inhalation than by IV anesthesia and the period of vulnerability to regurgitation is potentially protracted compared with an IV induction.

At issue is the effectiveness of fasting in reducing a child's gastric volume and the benefits of this effect when weighed against the added discomfort and risk of dehydration. Numerous studies of gastric volume and pH have convincingly demonstrated that clear liquids are rapidly emptied from the stomach and the stimulated peristalsis actually serves to decrease gastric volume and acidity. Taking this together with the benefits of improved hydration and mental status, it is clear that prolonged *nil per os* (NPO) status is unwarranted. Clear fluids are emptied from the stomach with a half-life of ~20 minutes,[93] depending, in part, on the volume of sugar fluid ingested.[94] Recent evidence indicates that an NPO time of 1 hour for clear fluids does not increase the risk of pneumonitis if aspiration occurred in healthy children presenting for elective anaesthesia.[95,96] NPO guidelines currently in use in many institutions are included in Table 4.1.[97] As described earlier, for the vast majority of children, 20 to 40 mL/kg of LR given intraoperatively will provide adequate fluid deficit replacement.

ASSESSMENT OF INTRAVASCULAR VOLUME

Once the child is anesthetized, many clinical clues to volume status are lost or confounded by operative events. For example, although tachycardia is a fairly reliable indicator of volume status in the quietly resting preoperative child, a number of factors besides the intravascular volume status may increase the heart rate. Systolic BP (SBP) also reflects the volume status intraoperatively; fluid resuscitation should take priority over administering vasopressors and other inotropes and chronotropes. It is the challenge of the anesthesiologist to view the entire clinical picture, consider the possibilities, integrate them into a hypothesis, and then test the hypothesis.

Assessment of intravascular volume begins with knowledge of age-related norms for heart rate and BP (see Tables 2.7 and 2.8). Is the heart rate persistently increased or does it vary only with surgical stimulation? Is the pulse pressure (PP) narrow or, more ominously, is the BP reduced for age? Does it vary with positive-pressure breaths? Are the extremities warm? Is capillary refill brisk? What is the urine output? Are these variables changing? What is the rate of the change?

Measurement and continuous monitoring of central venous pressure (CVP) is commonly taken as both a direct measure of cardiac preload and an indirect measure of circulating volume (see Figs. 49.2 to 49.5). In addition to traditional central lines introduced into the superior vena cava or left atrium, animal[98] and limited clinical[99] data suggest that femoral lines that terminate in the abdominal vena cava may also be useful. In one study of infants and children, mean end-expiratory pressure measurements of venous pressure in the right atrial and inferior vena cava differed by less than 1 mm Hg.[99] Unfortunately, CVP as a static measure of volume status is confounded by many factors, including right ventricular compliance, positive end-expiratory pressure, abdominal pressure, and so on. In sum, these confounders render the CVP a relatively poor predictor of preload and volume status.[100]

Dynamic assessments best reflect the volume status and "volume responsiveness" (>10%–15% increase in stroke volume after a bolus) best indicates the volume for administration.[101] The respiratory cycle produces cyclic changes in stroke volume that are augmented when the ventricle is underfilled. This is particularly true under positive-pressure ventilation (PPV). As a result, SBP, diastolic BP (DBP), and pulse pressure (SBP-DBP, PP) variation is readily apparent on the arterial waveform of a hypovolemic child (see Fig. 12.10). PP variation may be quantified as $(PP_{max} - PP_{min})/[PP_{max} + PP_{min}/2] \times 100$, and volume responsiveness inferred from decreasing PPV. With this guidance, volume has been administered by some in 5- to 10-mL/kg test challenges until SBP and PPV no longer respond.[100] However, the usefulness of variability to determine volume status in children continues to be debated and should be performed carefully.[102–104]

ONGOING LOSSES AND THIRD-SPACING

During all surgical procedures, fluid loss from the vascular space is primarily the result of three simultaneous physiologic processes. First, whole blood is shed at various rates and must be replaced. Second, capillary leak and surgical trauma result in extravasation of isotonic, protein-containing fluid into interstitial compartments (the so-called third space). Third, anesthetic-induced relaxation of sympathetic tone produces vasodilatation (increased capacitance) and relative hypovolemia (a virtual loss). In very small infants, a fourth source of losses, direct evaporation, must also be considered. These ongoing losses are often difficult to quantitate (or even estimate). Although these losses occur in children of all sizes, the small circulating blood volume of an infant (e.g., for a 5-kg infant, 80 mL/kg × 5 kg = 400 mL) leaves little room for error. Faced with uncertainty, the prudent response is constant vigilance and reliance on general principles.

As a rule, 1 mL of shed blood is replaced with 1 mL of colloid (5% albumin or blood) or about 1.5 mL of isotonic crystalloid such as LR.[78,91] Isotonic crystalloid is also used to replenish third-space losses. Surgical procedures that involve only mild tissue trauma may entail third-space losses of 3 to 4 mL/kg per hour. More extensive surgical procedures involving moderate trauma may require replacement equivalent to 5 to 7 mL/kg per hour to adequately support intravascular volume. In small infants undergoing very large abdominal procedures, the losses may approach 10 mL/kg per hour or more.[72,74] In neonates, fluid requirements for emergent abdominal surgery for necrotizing enterocolitis have been estimated at up to 50 mL/kg per hour.[91] These "losses" include both evaporation and redistribution of fluid to the interstitium. The latter must be considered most carefully because it is exacerbated by the hemodilution and increased capillary pressures that results from excessive fluid administration.

Although necessary intraoperatively, third-space accumulation represents whole-body salt and water overload that will need to be mobilized postoperatively. The price of unchecked fluid administration is generalized anasarca, pulmonary edema, bowel swelling,

and laryngotracheal edema. In the healthy child, this relative fluid overload is well tolerated, with most excess fluid excreted over the first 2 postoperative days. In children with impaired pulmonary, cardiac, or renal function, however, such fluid excess may result in clinically important postoperative morbidity.

Postoperative Fluid Management

GENERAL APPROACH

Well-planned postoperative fluid management complements the intraoperative plan and accounts for evolving physiology as the child recovers from anesthesia. Both fluid deficits and ongoing losses are replaced. The child is repeatedly reassessed, adjusting the intake until normal fluid and electrolyte homeostasis are present. To aid in decision making, trends in vital signs are identified, all sources of fluid intake and output are quantitated, urine specific gravity is monitored, daily weights are obtained, and serum electrolytes are measured.

In simple outpatient surgeries, discharge from the hospital is possible after fluid deficits have been replaced. In complex cases, replacement fluids may require hourly readjustment based on the prior hour's intake and output. Rather than reacting to isolated variables, such as low urine output, one must discern overall patterns. High urine output and low urine specific gravity may indicate overhydration or diabetes insipidus. Oliguria may suggest hypovolemia when it is accompanied by high urine specific gravity and clinical signs of dehydration or low cardiac output when it is accompanied by signs of poor perfusion. In the well-hydrated child, oliguria may represent renal failure if the urine specific gravity is normal (or dilute) but increased concentrations of ADH if the urine is concentrated. A careful physical examination is necessary; in many cases, certainty in diagnosis requires simultaneous measurement of serum and urine electrolytes.

Frequently, losses via surgical or gastric drains are large in both real and relative terms. For example, a neonate with a nasogastric tube may lose more than 100 mL/kg per day (normally 20–40 mL/kg per day) in gastric fluid. Therefore, in determining the volume and composition of replacement fluids, it is sometimes helpful to consider the electrolyte content of various losses (Table 9.8).

POSTOPERATIVE PHYSIOLOGY AND HYPONATREMIA

Children retain salt and water postoperatively, in part as a result of neuroendocrine activation by stress, continued capillary leak with third-space accumulation, nonosmotic stimulation of ADH (see Table 9.5) and hypovolemia-induced renin secretion. As outlined earlier, depleting the intravascular volume is a potent nonosmotic signal to retain fluid that may override osmotic signals under a variety of clinical circumstances.

At the same time, ongoing fluid and electrolyte losses after surgery via chest tubes, nasogastric suction, weeping incisions, and even continued slow bleeding may be substantial. Postoperatively, children often depend entirely on IV fluids to replace these and other losses.

Therefore, unless isotonic, sodium-containing fluids are provided, postoperative children are universally at risk for developing hyponatremia.[105,106] In a retrospective review of 24,412 surgical admissions to a large children's hospital, the incidence of significant postoperative hyponatremia was 0.34%, with a substantial mortality rate (8.4%) in these previously healthy children.[34] If this measured incidence were extended to the entire U.S. population, 7448 children would present annually with postoperative hyponatremia and 626 would die from an entirely avoidable cause. Mortality rates as great as 40% to 60% have been reported after hyponatremia, although it may only be a surrogate marker for a disease with a poor prognosis rather than the actual cause of the death.[107,108]

In reviewing the etiology of hyponatremia, two factors stand out: extensive extrarenal loss of electrolyte-containing fluid and IV replacement with hypotonic fluids.[34] In addition, delay in recognition often plays a major role in associated morbidity. The solution seems a simple one: (1) administration of hypotonic fluids without a specific indication should be avoided postoperatively, (2) ongoing losses should be replaced in a timely fashion, and (3) serum electrolytes should be measured routinely in children exhibiting potential symptoms of hyponatremia (see later discussion).

POSTOPERATIVE PULMONARY EDEMA

Children who receive large volumes of fluid intraoperatively are at risk for development of pulmonary edema as operative fluids are mobilized. Usually, fluid begins to be mobilized on the second postoperative day and continues through day 3 or 4. Although this is less common in children than in the elderly, it occurs occasionally in children with burn injuries[109] or in pediatric patients receiving large amounts of fluid during resuscitation from trauma or sepsis. In one review,[110] 13 patients (11 adults and 2 children) developed postoperative pulmonary edema; all began to exhibit symptoms within 36 hours after surgery and had total net fluid retention in excess of 67 mL/kg postoperatively.

TABLE 9.8 Composition of Body Fluids

Source	Na^+ (mEq/L)	K^+ (mEq/L)	Cl^- (mEq/L)	HCO_3^- (mEq/L)	pH	Osmolality (mOsm/L)
Gastric	50	10–15	150	0	1	300
Pancreas	140	5	0–100	100	9	300
Bile	130	5	100	40	8	300
Ileostomy	130	15–20	120	25–30	8	300
Diarrhea	50	35	40	50		
Sweat	50	5	55	0	Alkaline	
Blood	140	4–5	100	25	7.4	285–295
Urine	0–100[a]	20–100[a]	70–100[a]	0	4.5–8.5[a]	50–1400[a]

Pathophysiologic States and Their Management

FLUID OVERLOAD AND EDEMA

Edema is essentially a "sodium disease," representing sodium and water overload with excessive fluid residing in the extracellular space. Although intracellular volume changes can sometimes be substantial, prolonged cell swelling represents failure of essential volume regulatory functions and is likely a preterminal event. In fluid-overload states, plasma volume is generally increased unless the balance of Starling forces is disturbed, as in nephrotic syndrome or lymphatic obstruction. Edema formation is opposed by (1) low compliance of the interstitial compartment, (2) increased lymphatic flow, (3) osmotic washout of interstitial proteins, and (4) impedance and elasticity of the proteoglycan gel. The differential diagnosis of fluid overload and edema formation is presented in Table 9.9. Principles of therapy for fluid overload states include the following:

- Fluid restriction
- Salt restriction
- Diuresis, dialysis
- Salt-poor albumin for diminished plasma volume

DEHYDRATION STATES

Dehydration states are common in children. The extent of dehydration is best assessed by weight, because clinical signs such as tachycardia, capillary refill, and skin elasticity,[111] although often reliable, may be influenced by factors other than hydration status. A capillary refill time of 1.5 to 3.0 seconds, for example, suggests a fluid deficit of between 50 and 100 mL/kg, yet this sign is extremely dependent on ambient temperature.[112] Similarly, poor skin elasticity reflects significant volume loss, yet elasticity may be well preserved in children with hypernatremic dehydration.[111] Clinical signs associated with varying levels of dehydration are presented in Table 9.10.

As a first approximation, correction of most dehydration states in older children is most readily achieved with administration of a simple bolus of NS, LR, or PlasmaLyte 148 (balanced crystalloid solution). In infants or children with unusual, prolonged, or severe dehydration, however, management must be more precise. A 5-point questionnaire to assess the severity of dehydration may help develop an appropriate treatment strategy[113]:

1. *Does a volume deficit exist and, if so, how great is it?*
   As noted previously, assessment of volume deficit is best made by weight, yet rough estimates of 5% (mild), 10% (moderate), and 15% (severe) may be made in infants based on clinical signs (see Table 9.10).
2. *Does an osmolar disturbance exist?*
   Is it acute or chronic? An osmolar imbalance is determined by measuring the serum sodium concentration. The majority of clinically encountered dehydration states (~80%) are isotonic (Na^+ = 130–150 mEq/L). These isotonic losses are easily managed by almost any strategy.
   Approximately 15% of dehydrated children present with hypertonic dehydration (Na^+ >150 mEq/L). These children are at greatest risk and have usually experienced the greatest fluid losses for a given set of clinical signs.[114] If the condition is chronic, they may require extensive, slow rehydration over prolonged periods.[115]
   Five percent of children present with hypotonic dehydration (Na^+ <130 mEq/L). For a given fluid deficit, these individuals are often more symptomatic than others, and their requirement for sodium replacement is greatest. Surprisingly, rapid improvement in clinical condition often results after the first fluid bolus.
   In general, states of acute dehydration (<24 hours) may be corrected rapidly, whereas states of chronic dehydration must be corrected slowly. This difference in treatment plan is attributed to the speed at which the cell volume equilibrates: acutely through gain or loss of electrolytes

TABLE 9.9 Differential Diagnosis of Fluid Overload and Edema Formation

Condition	Differential Diagnosis
Imbalance of intake and output	Salt poisoning
	Formula dilution errors
	Intravenous infusion errors
	Drugs given as sodium salts
Steroid excess with normal sodium intake	Congenital adrenal hyperplasia
	Exogenous steroids
Perceived decreases in effective plasma volume	↓ MAP → baroreceptors → ↑ sympathetic tone, ADH, renin, aldosterone
	Vasodilators
	Congestive heart failure
	Cirrhosis
	Nephrotic syndrome
Impaired sodium excretion	Chronic renal failure
	Acute glomerular disease (↓ GFR with normal tubular function)
	Nonsteroidal antiinflammatory drugs (↓ PGE_2 and RBF)
Water excess	SIADH
	Hypotonic infusion
	Stress (↑ ADH)

ADH, antidiuretic hormone; *GFR,* glomerular filtration rate; *MAP,* mean arterial pressure; *PGE_2,* prostaglandin E_2; *RBF,* renal blood flow; *SIADH,* syndrome of inappropriate antidiuretic hormone secretion.

TABLE 9.10 Clinical Signs and Symptoms for Estimation of Severity of Dehydration in Infants

	DEGREE OF DEHYDRATION		
Clinical Signs	Mild	Moderate	Severe
Weight loss (%)	5	10	15
Behavior	Normal	Irritable	Hyperirritable to lethargic
Thirst	Slight	Moderate	Intense
Mucous membranes	May be normal	Dry	Parched
Tears	Present	Normal to reduced	Absent
Anterior fontanel	Flat	Possibly sunken	Sunken
Skin turgor	Normal	Slightly increased	Increased
Urine output	Normal	Oliguric	Anuric

Modified in part from Herrin J. Fluid and electrolytes. In: Graef J, ed. *Manual of Pediatric Therapeutics.* 6th ed. Philadelphia: Lippincott-Raven; 1997:63–75.

(which are transported rapidly across membranes) or chronically through gain or loss of organic osmolytes (which are transported more slowly).[11] Reequilibration of brain cell volume during correction of hypertonicity can be very slow, mandating patience in correction of chronic fluid deficits. Similarly, rapid correction of hyponatremic disturbances can be hazardous,[34] even when seemingly safe isotonic solutions are infused.[116]

3. *Does an acid-base abnormality exist?*

Quantitation of the child's acid-base status gives useful, although limited, information in terms of the severity of dehydration. When evaluating acid-base status, it is important to recall that bicarbonate reabsorption and urine acidification are limited in preterm and young infants, leaving even the normal infant in a state of mild metabolic acidosis (pH, 7.3; serum bicarbonate 20–21 mEq/L [normal 22–26 mEq/L]). Although slow, spontaneous correction of acid-base status is typically observed on rehydration, rapid fluid boluses in poorly perfused children may result in a transient "reperfusion acidosis" as returning circulation washes the products of anaerobic metabolism out of the tissues. In this setting, or when renal insufficiency exists, blood-buffering capacity is such that children with serum bicarbonate concentrations less than 8 mEq/L or pH less than 7.2 may benefit from administration of supplemental base (sodium bicarbonate) (Fig. 9.6).[113]

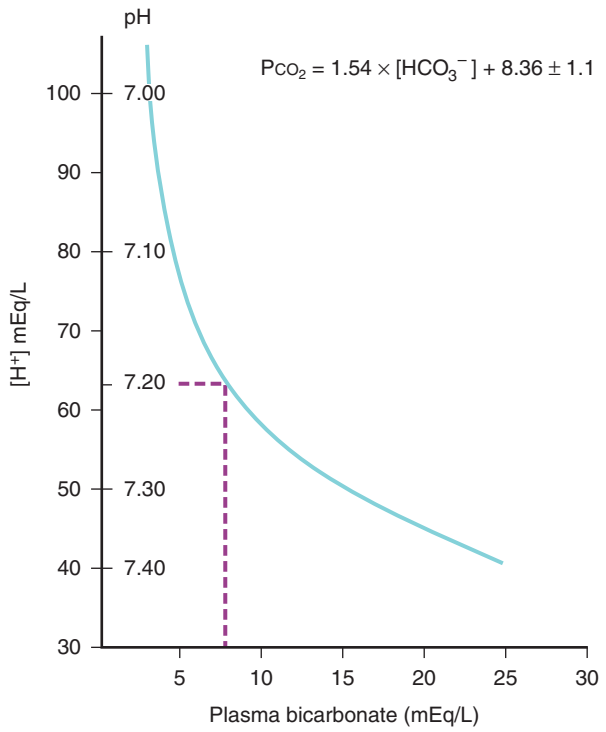

FIGURE 9.6 Data from children with metabolic acidosis[117] were used to depict the displacement of pH as serum bicarbonate declines. The zone of rapid pH displacement (pH <7.20) has a slope that is several times greater than the zone of gradual pH displacement (pH ≥7.20). As the pH moves through the zone of rapid pH displacement, a further decline of serum bicarbonate of as little as 1 or 2 mEq/L produces a highly leveraged further decrease of pH. *[H],*$^+$ hydrogen ion concentration; *[HCO_3^-],* bicarbonate ion concentration; *Pco_2,* carbon dioxide tension. (From Kallen RJ. The management of diarrheal dehydration in infants using parenteral fluids. *Pediatr Clin North Am.* 1990;37:265–286.)

Rapid bedside evaluation of acid-base status uses the following general relationships: a pH decrease of 0.1 unit accompanies a base excess (BE) of approximately 6 mEq/L or an increase in carbon dioxide tension (Pco_2) of 10 to 12 mm Hg. The total replacement base required is then determined by the following equation:

$$\text{Dose (mEq)} = 0.3 \times \text{Weight (kg)} \times \text{BE (mEq/L)}$$

Clinically, a smaller sodium bicarbonate dose (1–2 mEq/kg) is given initially, the response is verified by blood gas analysis, and the remaining doses are titrated to effect.

4. *Is renal function impaired?*

Initial evaluation includes the timing of the last urine void and recent urine output, measurement of urine specific gravity, and serum levels of blood urea nitrogen and creatinine. If uncertainty persists, measurement of serum and urine electrolytes for comparison and calculation of the FE_{Na} are indicated (see Chapter 28).

FE_{Na} values of less than 1% imply prerenal conditions causing renal dysfunction, whereas FE_{Na} values greater than 2% to 3% suggest renal insufficiency. In prematurity, however, values as large as 9% have been recorded in otherwise normal infants.

5. *What is the state of potassium balance?*

Potassium homeostasis is critical to life, and serum potassium concentrations are generally maintained within a very narrow range. Nonetheless, serum potassium concentrations do not reflect whole-body stores and substantial potassium depletion may exist in the presence of modest changes in serum potassium concentration (K^+_{serum}). Gastrointestinal losses or metabolic acidosis is usually accompanied by a potassium deficit, whereas other dehydration states are not. Rapid fluid boluses or pH correction, or both, may acutely reduce K^+_{serum},[118] and refractory hypokalemia may occur in children deficient in magnesium.[119] In all cases, adequate renal function should be present before administration of potassium, and complete repletion should span 48 to 72 hours. Once the nature and severity of dehydration have been determined, the clinician may proceed using any of a variety of correction strategies. In one approach, moderate to severe dehydration deficits may be estimated, as in Table 9.10. Fluid and electrolyte repair may then proceed according to a three-phase approach wherein circulating plasma volume, perfusion, and urine output are restored rapidly using isotonic crystalloid or colloid solution and remaining deficits are corrected over 24 hours as follows[120]:

- Emergency Phase: 20 to 30 mL/kg isotonic crystalloid/colloid bolus
- Repletion Phase 1: 25 to 50 mL/kg over 6 to 8 hours. Anions: Cl^- 75%, acetate 25%
- Repletion Phase 2: remainder of deficit over 24 hours (isotonic) or 48 hours (hypertonic). Include calcium replacement as necessary.

SEPTIC SHOCK

Both the Pediatric Advanced Life Support (PALS) recommendations from the American Heart Association and the "Surviving Sepsis" campaign from the Society of Critical Care Medicine have long emphasized fluid administration as the cornerstone of successful resuscitation. As a Ib recommendation, the original "Surviving Sepsis" campaign called for "a minimum

of 30 mL/kg of crystalloid," whereas PALS guidelines directed "20 mL/kg of isotonic crystalloid over 5 to 20 minutes" repeated as needed with expectations for "at least 60 mL/kg" during the first hour.[121,122] Since these guidelines have been widely adopted, fluid overload has been associated with poor outcome in a variety of settings including certain populations of children with sepsis.[123–127] Alternative views now hold that administration of large crystalloid volumes (20–30 mL/kg) is unphysiologic and, ultimately, counterproductive in sepsis and cardiac arrest since little stays in the circulation, saltatory effects dissipate rapidly, and resulting edema can exacerbate circulatory and respiratory derangements.[128] Recent PALS recommendations acknowledge this controversy and call for a less aggressive approach; an initial fluid bolus of 20 mL/kg is "reasonable" but "should be undertaken with extreme caution" with "individualized patient evaluation."[129] Meanwhile, "Surviving Sepsis" consensus bundles now call for 30 mL/kg of crystalloid "for hypotension or lactate ≥4 mmol/L" and redefine "septic shock" as a severe subset of "sepsis."[130] Anesthesiologists are accustomed to continually reassessing circulatory homeostasis, and so in the setting of septic shock, should feel comfortable pursuing standard physiologic endpoints with judicious fluid administration complemented with inotropes and vasopressors.

HYPERNATREMIA AND HYPONATREMIA

As previously detailed, disorders of sodium equilibrium are primarily marked by disturbances of fluid balance and are corrected according to the principles outlined earlier. Serious hypernatremia or hyponatremia is accompanied by neurologic symptoms whose severity is determined by the degree and rate of change of Na^+_{serum}.

Hypernatremia

In contrast to its rareness in adults, acute hypernatremia is common in children. A mortality rate greater than 40% for the acute disorder and 10% for the chronic disorder has been quoted (serum sodium >160 mEq/L).[107,131] Mortality and permanent neurologic injury are even more common in infants. Depending on the degree and duration, neurologic findings include irritability and coma; seizures may be a presenting symptom, but are more commonly encountered after the start of therapy. Children with acute conditions are usually symptomatic, whereas those with chronic conditions (acclimated individuals) are typically asymptomatic. General principles for treatment of hypernatremia are as follows:

- In the setting of circulatory collapse, colloid or NS bolus should be administered. Although the assertion is debatable, a colloid bolus provides the theoretical benefit of sustained hemodynamic support with a smaller fluid load. Saline, in contrast, rapidly reequilibrates, necessitating repeated boluses while adding to the total salt burden.
- Once a stable circulation has been restored, fluid deficit should be assessed as accurately as possible and corrected over 48 to 72 hours. Cautious correction of the serum sodium concentration is required. The serum sodium concentration and osmolality should be continuously reassessed during fluid administration, aiming for a correction of no more than 1 to 2 mOsm/L per hour. After as little as 4 hours of hypernatremia, idiogenic osmoles (e.g., trimethylamines) appear in the brain to prevent cerebral volume depletion. Rapid administration of free water could induce cerebral edema, seizures, and death. Therefore free water should be administered slowly. Because of possible associated hypoglycemia, some solutions should be glucose-containing, and serum glucose levels should be monitored.
- Vigilance for seizures, apnea, and cardiovascular compromise is essential because appropriate and timely treatment of such complicating factors can be the primary determinants of successful outcome.

Hyponatremia

Hyponatremia is also common in infants and children; increasing prevalence owing to erroneous formula dilution has intermittently been reported.[132,133] In the practice of anesthesiology, mild hyponatremia is a common postoperative condition after surgery of any severity[134–136]; in neurosurgical patients, hyponatremia may represent cerebral salt wasting or syndrome of inappropriate antidiuretic hormone secretion (SIADH).[137] In general, symptomatic patients are acutely hyponatremic and asymptomatic individuals are chronically hyponatremic.[138] After surgery, acutely hyponatremic children may present with nonspecific symptoms that are often erroneously attributed to other causes. Early central nervous system symptoms include headache, nausea, weakness, and anorexia. Advancing symptoms include mental status changes, confusion, irritability, progressive obtundation, and seizures. Respiratory arrest (or irregularity) is a common manifestation of advanced hyponatremia.

When planning to correct hyponatremia, the presence of symptoms must be considered a medical emergency, whereas asymptomatic children do not require rapid intervention. Chronic hyponatremia must be corrected slowly and by no more than 0.5 mEq/L per hour to avoid neurologic complications that include central pontine myelinolysis.[139] The best treatment for acute hyponatremia is early recognition and intervention. Because hypoxia exacerbates the neurologic injury, the simple ABCs of resuscitation are attended to first, and the airway is secured in the child who has seizures or respiratory irregularity. Hyponatremic seizures may be quieted by relatively modest (3–6 mEq/L) increases of serum sodium.[140] In several series,[133,141,142] such limited, rapid correction of symptomatic hyponatremia with hypertonic saline (514 mEq/L NaCl) was well tolerated. It should be emphasized, however, that complete correction is unnecessary and unwise.[143] Initial therapy is aimed at increasing the Na^+_{serum} no more than is necessary to stop seizure activity (usually 3–5 mEq/L). Further, the correction takes place over several days. Hypertonic saline may be used for the correction until the Na^+_{serum} increases to greater than 120 mEq/L. Remembering that TBW may range from 75% in infancy to 60% or less in older children, total sodium deficit is estimated as follows:

$$\text{Sodium change (mEq/L)} \times \text{fraction TBW (L/kg)} \times \text{weight (kg)} = \text{mEq sodium}$$

$$(\text{Desired } [Na^+]_{serum} - \text{observed } [Na^+]_{serum}) \times 0.6 \times \text{weight (kg)} = \text{mEq sodium required}$$

For example, in a 25-kg child, to correct a serum sodium concentration of 110 mEq/L to 125 mEq/L using hypertonic saline (514 mEq/L), infuse

$$(125 \text{ mEq/L} - 110 \text{ mEq/L}) \times 0.6 \times 25 = 225 \text{ mEq total}$$

or

$$225 \text{ mEq}/514 \text{ mEq/L} = 0.44 \text{ L over 48 hours} = 9 \text{ mL/hour}$$

Because such calculations involve estimates, frequent measurement of the Na^+_{serum} is necessary during correction. As with hypernatremia, much of the morbidity and mortality associated with hyponatremia relates to complicating factors such as seizures and hypoxia that may occur during therapy. Therefore, children undergoing therapy should be cared for in a monitored setting. When overzealous correction has occurred, there may be value in acutely relowering Na^+_{serum} using hypotonic fluids,[138] although such therapy is not without its own hazards.

General principles for treatment of hyponatremia are as follows:

- Asymptomatic hyponatremia in and of itself need not be rapidly corrected. Associated cardiovascular compromise caused by volume depletion may be addressed by colloid bolus or administration of isotonic saline (1 L/m^2 per day). Provision of sodium is accompanied by free water restriction.
- Symptomatic hyponatremia is a medical emergency and may sometimes reflect irreversible neurologic injury. Correction should be rapid, yet limited, as discussed previously. A dose of 2 to 3 mL/kg of 3% saline (514 mEq/L) may be administered over 20 to 30 minutes to halt seizures.
- Subsequent correction is accomplished through calculation of the sodium deficit and provision of sodium so as to slowly correct at a rate not to exceed 0.5 mEq/L per hour or 12 to 25 mEq/L (total) in 24 to 48 hours.
- If the attendant fluid load is excessive or if oliguria is present, diuretics may be useful.

DISORDERS OF POTASSIUM HOMEOSTASIS

Hyperkalemia

Hyperkalemia is occasionally the presenting finding in conditions such as congenital adrenal hyperplasia. More commonly, it results from acute renal insufficiency, massive tissue injury, acidosis, or iatrogenic mishaps. In the operating room, acute hyperkalemia may follow the use of succinylcholine in children with myopathies, burns, upper and lower motor neuron lesions, chronic sepsis, or disuse atrophy and occasionally during massive, rapid transfusion of red blood cells or whole blood (see Chapter 12).[144] It may occur with rhabdomyolysis or as a late sign in malignant hyperthermia (see Chapter 41).

Although neurologic status is the main concern for children with abnormal Na^+_{serum}, cardiac status (rate and rhythm) determines the care of children with hyperkalemia. In children with hyperkalemia, the appearance of peaked T waves is followed by lengthening of the PR interval and widening of the QRS complex until P waves are lost. Finally, the QRS complex merges with its T wave to produce a sinusoidal pattern (Fig. 9.7). Successful treatment traditionally uses the following approach:

- Emergent therapy is first directed toward antagonism of the cardiac effects of potassium by cautious administration of IV calcium (chloride 20 mg/kg, or 60 mg/kg of calcium gluconate as a 10% solution) over 3 to 5 minutes to avoid bradycardia. Calcium does not decrease the serum potassium concentration but rather reestablishes the gradient between the resting membrane potential, which is increased in the presence of hyperkalemia, and the threshold potential, which is determined by the calcium concentration. It also increases the refractory period of the action potential, the net effect being the prevention of spontaneous depolarization.
- Serum potassium is then reduced by returning potassium to the intracellular space. This is achieved by correcting the acidosis by administering sodium bicarbonate (1–2 mEq/kg) intravenously, a β-agonist, and mild to moderate hyperventilation.

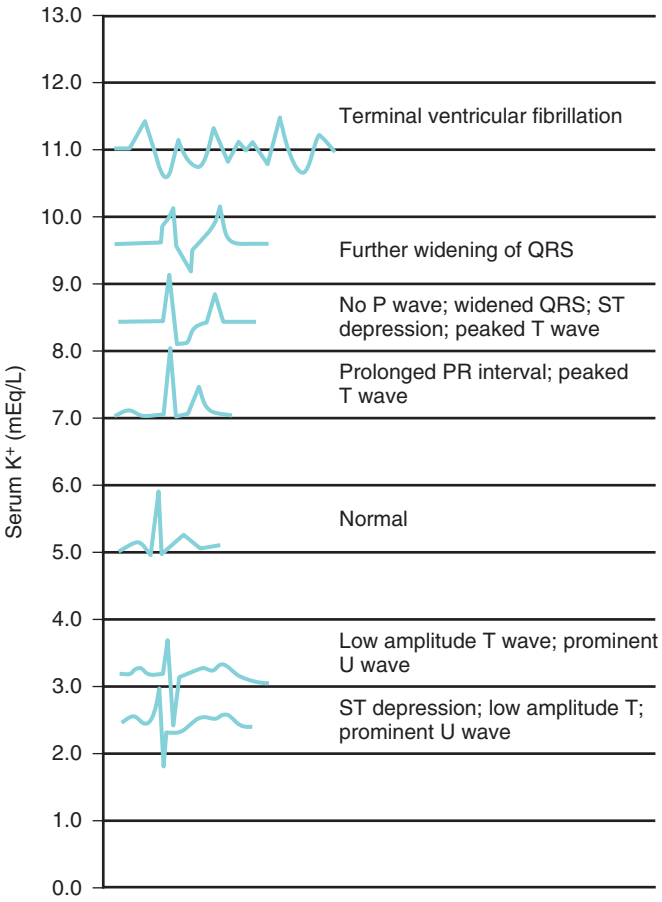

FIGURE 9.7 Electrocardiographic changes associated with hypokalemia and hyperkalemia. (From Williams GS, Klenk EL, Winters RW. Acute renal failure in pediatrics. In: Winters RW, ed. *The Body Fluids in Pediatrics: Medical, Surgical, and Neonatal Disorders of Acid-Base Status, Hydration, and Oxygenation.* Boston: Little, Brown; 1973;523–557.)

- To maintain potassium in the intracellular space, glucose and insulin are administered by infusion (0.5–1 g/kg glucose with 0.1 U/kg insulin over 30 to 60 minutes).
- After stabilizing the K^+_{serum}, attention is directed toward removal of the whole-body potassium burden (sodium polystyrene sulfonate [Kayexalate], furosemide, dialysis) and correction of the underlying cause (Fig. 9.8).

The knowledge that β-adrenergic stimulation modulates the translocation of potassium into the intracellular space[145,146] prompted the consideration of β-agonists in the treatment of acute hyperkalemia.[147–150] In children, a single infusion of an IV β-agonist such as salbutamol (5 μg/kg over 15 minutes) effectively reduces serum potassium concentrations within 30 minutes. Because of the rapidity, efficacy, and safety of salbutamol in children, it has become the first-choice treatment for hyperkalemia.[147] In addition to IV therapy, salbutamol[151] (also known as albuterol[150]) by inhalation effectively reduces the serum potassium concentration. The inhalation route has the significant advantages of being readily available in emergency departments and not requiring IV access. However, the observation that a paradoxical exacerbation of hyperkalemia sometimes occurs on initiation of treatment,[151] together with concerns regarding the possibility of associated arrhythmias,[152] suggests that more experience is required before such therapy can be considered the standard of care. Inhalation of salbutamol during such an event in the operating room may

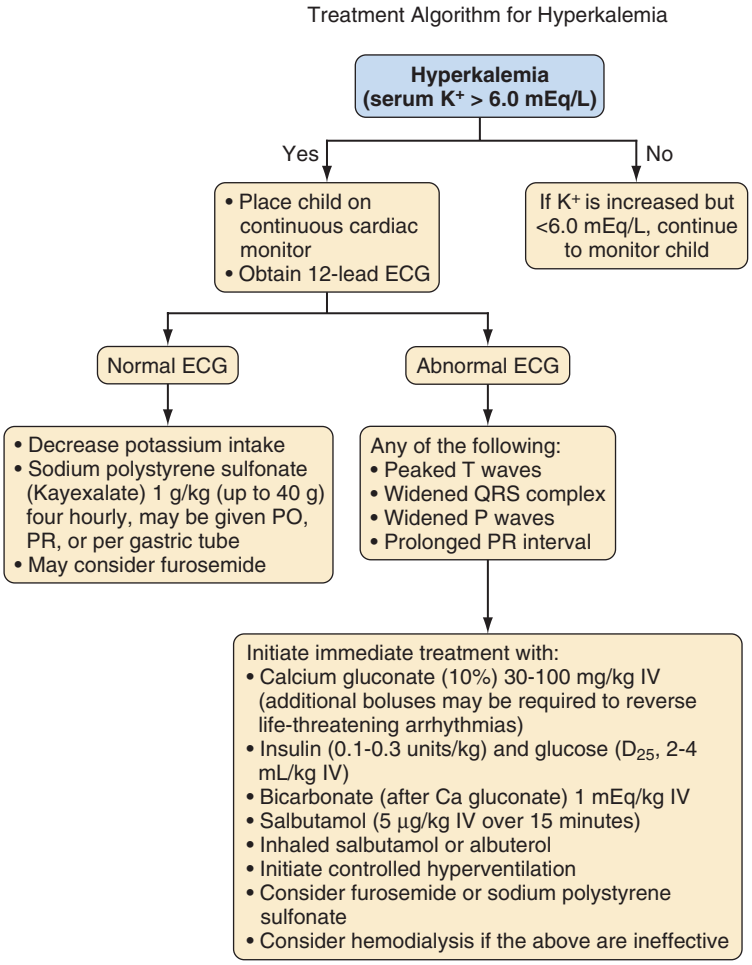

FIGURE 9.8 Algorithm for treatment of hyperkalemia. After stabilization, attention is directed toward removal of the whole-body potassium burden (Kayexalate, dialysis) and correction of the underlying cause. *D_{25},* 25% dextrose; *ECG,* electrocardiogram; *IV,* intravenous; *PO,* orally; *PR,* per rectum.

speed the reduction in serum potassium while other methods of treatment are instituted.

Hypokalemia

Hypokalemia is most common in children as a complication of diarrhea or persistent vomiting associated with gastroenteritis. Muscle weakness is the most common sign in hypokalemia and has been correlated with the serum potassium concentration.[153] In the operating room or ICU, hypokalemia may also accompany a wide variety of other conditions, including diabetes, hyperaldosteronism, pyloric stenosis, starvation, renal tubular disease, chronic steroid or diuretic use, and β-agonist therapy. Severe hypokalemia can also be accompanied by electrocardiographic changes, including QT prolongation, diminution of the T wave, and appearance of U waves (see Fig. 9.7).

As noted previously, the K^+_{serum} does not accurately reflect total potassium homeostasis, and low serum concentrations may or may not be associated with significant depletion of total body potassium. Indeed, the extracellular fraction of potassium is only a tiny proportion (approximately 3%) of the entire body store. For these reasons, the precise point at which to begin replacement therapy is controversial, and total replacement requirements are impossible to calculate. In general practice, serum potassium values (K^+_{serum}) between 2.0 and 2.5 mEq/L are corrected before surgery on the assumption that further decreases may predispose the child to muscular weakness, arrhythmias, and hemodynamic instability.

Potassium replacement is best accomplished orally over an extended period while the underlying cause is evaluated and treated. When IV correction is required, concentrations up to 40 mEq/L should be given slowly *(not to exceed 1 mEq/kg per hour)* in a monitored setting. Because such solutions often cause phlebitis, large-bore or central catheters are preferred. In the setting of hypochloremia and hypokalemia, chloride deficits must first be replaced, usually by administration of normal saline.

SYNDROME OF INAPPROPRIATE ANTIDIURETIC HORMONE SECRETION

Many nonosmotic factors are capable of stimulating ADH release, and these can occasionally override osmotic control priorities. When this occurs, clinicians have historically deemed the increased ADH concentrations "inappropriate" because control of the serum osmolarity is lost (see Chapter 28). As detailed earlier, however, intravascular depletion is the most potent stimulus for vasopressin release, and it is hardly *inappropriate* that defense of circulation takes priority over defense of serum sodium levels. Pain, surgical stress, critical illness, sepsis, pulmonary disease, central nervous

system injury, drugs, and a variety of other factors may all stimulate ADH release above and beyond that necessary to maintain osmolar balance (see Table 9.5).

SIADH is common in children yet it is often overlooked. Minor head trauma, for example, may elicit spikes in ADH levels, although infrequently to the extent that it produces serious hyponatremia and seizures.[154] Urine output after spinal fusion is often reduced because of increased concentrations of ADH, which usually return to normal within 24 hours without therapy.[155] Infants with bronchiolitis and hyperinflated lungs frequently demonstrate markedly increased plasma ADH concentrations and exhibit fluid retention, weight gain, urinary concentration, and plasma hypoosmolality until their illness begins to resolve.[156] Hyponatremia to the point of seizures, however, is only occasionally observed.

The diagnosis of SIADH rests on the identification of impaired urinary dilution in the setting of plasma hypoosmolality. Hyponatremia (Na^+ <135 mEq/L), serum osmolality less than 280 mOsm/L, and urine osmolality greater than 100 mOsm/L in the absence of volume depletion, cardiac failure, nephropathy, adrenal insufficiency, or cirrhosis are generally considered sufficient for diagnosis. Therapeutic principles are similar to those for hyponatremia and depend on the following:

- Restriction of free water
- Repletion of sodium deficits (if present)
- Administration of diuretics to offset the effects of vasopressin

DIABETES INSIPIDUS

In the operating room and the ICU, diabetes insipidus is most commonly associated with the care of neurosurgical patients.[157–159] Diabetes insipidus is also caused by neuroendocrine failure in brain death and management may be necessary if organ donation is planned.[160,161] Diabetes insipidus results from decreased secretion of, or renal insensitivity to, vasopressin (see Chapter 27). Manifestations include massive polyuria, volume contraction, dehydration, and plasma hyperosmolality. Dilute polyuria (<250 mOsm, >2 mL/kg per hour) in the presence of hypernatremia (Na^+ >145 mEq/L) with hyperosmolality (>300 mOsm/L) is the hallmark. In central diabetes insipidus, administration of desmopressin concentrates the urine although water deprivation does not. Postoperative diabetes insipidus may initially be difficult to distinguish from mobilization of operative fluids.

Children with craniopharyngioma or a similarly situated pathologic lesion may not manifest vasopressin deficiency early in the disease but become symptomatic preoperatively after steroid administration or intraoperatively during surgical manipulation. Postoperative diabetes insipidus typically begins on the evening after surgery and may resolve in 3 to 5 days if osmoregulatory structures have not been permanently injured. An often-confusing triphasic response may also occur wherein postoperative diabetes insipidus appears to resolve, fluid status normalizes, or SIADH appears and then vasopressin secretion ceases and diabetes insipidus returns. It is hypothesized that this pattern reflects nonspecific vasopressin release from degenerating neurons in the hypothalamic supraoptic and paraventricular nuclei.

Attempts have been made to develop protocols for perioperative management of diabetes insipidus.[162] Because vasopressin is difficult to titrate to urine output, our practice involves maximal antidiuresis and fluid restriction. In this setting, volume status must be monitored closely, because urine output is no longer a marker of renal perfusion. Children who need close perioperative monitoring for the development of diabetes insipidus include those with preexisting diabetes insipidus as well as those who are undergoing resection of craniopharyngiomas or pituitary lesions or other procedures that involve resection or manipulation of the pituitary stalk.[163]

HYPERCHLOREMIC ACIDOSIS

Administration of large amounts of NS can lead to excess serum chloride.[164] NS-induced acidosis has been attributed to the Stewart physicochemical approach to acid-base balance.[165,166] In this framework, plasma pH is determined by its "strong ion difference" (SID), or the concentration differences between dominant cations and anions ($[SID] = [Na^+] + [K^+] + [Ca^{+2}] + [Mg^{+2}] - [Cl^-]$). Because electroneutrality must be preserved, the SID must always be balanced by additional negative charges arising collectively from weak acids and HCO_3^-. Since the mass of weak acids is relatively fixed and $[HCO_3^-]$ is an immediately responsive buffer, acute changes in SID translate directly to acute changes in [HCO3]. *Increases* in the SID therefore *increase* [HCO3$^-$] to yield plasma *alkalinization,* whereas *decreases* in the SID *decrease* [HCO3$^-$] to yield plasma *acidification*. Since administration of saline in large volumes produces hyperchloremia, this must be accompanied by a decrease in [HCO3$^-$]. Typically, the SID is ~40 to 42 mEq/L (example, $140 + 4 + 4.5^a + 2^b - 110$). Increasing $[Cl^-]$ can be expected to increase the base deficit by an equivalent amount.

A simpler explanation of NS-induced acidosis is that it arises through dilution of $[HCO_3]$. When plasma volume is expanded by saline, its primary buffer system ($CO_2/[HCO_3^-]$) is diluted. Because it is an open system, respiration holds the buffer acid (CO_2) constant while the buffer base ($[HCO_3^-]$) decreases. This physicochemical behavior and the resulting base deficit acidosis can be reproduced in model systems.[167]

Regardless of the source, it is clinically apparent that administration of large NS volumes is accompanied by metabolic acidosis related to both the amount and rate of infusion. In healthy women undergoing gynecologic surgery, 35 mL/kg NS over 2 hours produced acidosis, whereas similar infusions of LR did not.[164] In a study of children undergoing craniofacial surgery, 80% of those who received NS (40% to pH ≤ 7.25) and 37% of those who received Ringer lactate (8% to pH ≤ 7.25) developed an acidosis.[168] The clinical significance of the saline-associated acidosis is still being clarified, although one large study observed less postoperative morbidity in adults receiving balanced solutions, other than saline, for replacement of losses during abdominal surgery.[169]

HYPOCHLOREMIC METABOLIC ALKALOSIS

Infants with pyloric stenosis and other children with chronic vomiting may develop a hypochloremic metabolic alkalosis. In both of these conditions, chronic vomiting results in large losses of hydrogen and chloride ions and water. This leads to an alkalotic, dehydrated state. In the absence of IV fluid therapy, the renal response is to conserve water by retaining sodium through upregulation of aldosterone, in which hydrogen ions (which are already in short supply because of the vomiting) and potassium ions are excreted in the urine in exchange for sodium. Excretion of the remaining hydrogen ions in exchange for sodium exacerbates the existing alkalosis or prevents resolution of the alkalosis. It also leads to the unusual syndrome of paradoxical aciduria in the presence of a metabolic alkalosis.

[a]Normal Ca = 8-10 mg/dL = 4-5 mEq/L (mg/dL × 10 × 2 Eq/mol × 1/40 g/mol, so multiply by 0.5).

[b]Normal Mg = 2 mg/dL = 1.6 mEq/L (mg/dL × 10 × 2 × 1/24 g/mol, so multiply by 0.83).

The potassium loss leads to hypokalemia. Although hypokalemia between 3.4 and 4.4 mEq/L may appear trivial because the concentration is within the normal range, chronic hypokalemia equilibrates throughout all bodily fluids including the intracellular fluid volume. The intracellular potassium concentration, 135 to 145 mEq/L, is 30- to 40-fold greater than the extracellular concentration. Hence, a chronic decrease of 1 mEq/L in extracellular potassium, which is only 1% to 2% of the total body potassium, may reflect an enormous deficiency in total body potassium stores, on the order of 100 to 200 mEq K^+ in an adult. However, potassium loss from the extracellular fluid is not linearly related to the total body potassium (owing to interference from Na^+/K^+ pumps and other electrolyte-stabilizing mechanisms). With an extracellular K^+ concentration less than 3.5 mEq/L, this small loss in extracellular potassium translates into a huge loss of total body potassium, whereas with an extracellular K^+ concentration greater than 4 mEq/L, extracellular potassium losses exert an attenuated effect on the total body potassium.

In infants and children with chronic hypokalemic, hypochloremic, metabolic alkalosis, correction of the electrolyte abnormalities and hypovolemia is optimally achieved using NS with 20 mEq/L K^+ infused at a rate of 10 to 20 mL/kg per hour through a peripheral IV line until the potassium level is greater than 3.0 mEq/L, the chloride concentration is greater than 95 mEq/L, and the clinical signs of hypovolemia are resolved. In the case of pyloric stenosis, this may take 24 to 48 hours depending on the severity of the electrolyte and fluid imbalance.

CEREBRAL SALT WASTING

Cerebral salt wasting (also known as renal salt wasting) is a hyponatremic syndrome of unclear etiology. Most commonly recognized in neurosurgical patients, it is a primary natriuresis probably related to dysregulation of brain or atrial natriuretic peptides. The condition has been increasingly recognized, and an incidence as great as 5% has been reported in children with brain tumors.[170] Cerebral salt wasting can sometimes be difficult to distinguish from SIADH but the former is marked by hyponatremia, natriuresis, and *hypovolemia*, unlike the latter, which features hypervolemia. Initial therapy consists of fluid resuscitation with isotonic solutions and ongoing correction of intravascular volume depletion with sodium-containing solutions. Although spontaneous resolution is the norm, persistent cases may require mineralocorticoid therapy.

ACKNOWLEDGMENT

The authors acknowledge the contributions of Letty M. P. Liu to previous editions of this chapter.

This review is an excellent description of alternative methods of evaluating acid-base status. The focus of this paper is on the physiology behind the acidosis created by large, rapid administration of normal saline.

Holliday MA, Friedman AL, Segar W, et al. Acute hospital-induced hyponatremia in children: a physiologic approach. *J Pediatr*. 2004;145:584-587.

This update to the authors' classic 1957 article addresses the problems associated with applying the original formula (4-2-1 rule) to perioperative fluid management. The authors present an alternative approach to perioperative fluid management with a focus on attenuating the antidiuretic hormone response to perioperative stress.

Oh GJ, Sutherland SM. Perioperative fluid management and postoperative hyponatremia in children. *Pediatr Nephrol*. 2016;31:53-60.

This thorough review traces the history of fluid management in the perioperative period with a focus on the development of postoperative hyponatremia. The review is evidence-based, analyzing how the composition of common perioperative electrolyte solutions may contribute to hyponatremia in the face of perioperative upregulation of ADH.

Sümpelmann R, Becke K, Brenner S, et al. Perioperative intravenous fluid therapy in children: guidelines from the Association of the Scientific Medical Societies in Germany. *Pediatr Anesth*. 2017;27(1):10-18.

The Scientific Working Group for Paediatric Anaesthesia updated its 2006 guidelines for perioperative intravenous fluid therapy in children. The recommendations highlighted as brief a fasting interval as possible preoperatively, balanced isotonic electrolyte solution with 1% to 2.5% glucose as a background maintenance solution and a glucose-free balanced electrolyte solution to maintain circulatory homeostasis. Colloid solutions may be administered in place of balanced electrolyte solution to replace ongoing fluid losses when blood products are not indicated. Monitoring electrolyte concentrations should be undertaken serially when intravenous fluids are continued postoperatively to ensure electrolyte and glucose homeostasis.
