albeit incompletely, but it does not seem to affect RyR1 channel activity or its ability to transport Ca^{2+}.[193] Curiously, dantrolene proved to be ineffective in attenuating Ca^{2+} release through single RyRs inserted into lipid bilayers in most in vitro studies.[194] This inconsistency between the in vitro and in vivo studies has been attributed to dantrolene's codependency on adequate concentrations of both calmodulin,[195] which binds to RyR and to Mg^{2+}, which accumulates from the hydrolysis of magnesium adenosine triphosphate (MgATP) during an MH reaction.[196]

A second physiologic process, called store-operated Ca^{2+} entry (SOCE), contributes to the increase in intracellular Ca^{2+} as a result of the RyR1 channel opening in skeletal muscle.[197–199] SOCE is a process by which the SR store of Ca^{2+} is replenished from the extracellular milieu after significant loss of Ca^{2+} from the SR.[200] Experiments with azumolene, a more water-soluble congener of dantrolene, have demonstrated inhibition of skeletal muscle RyR1-dependent SOCE, not SR Ca^{2+} release.[201] These results raise profound questions. Do the induced Ca^{2+} fluxes during excitation-contraction coupling, experimental manipulation, and MH that result in an increase in intracellular Ca^{2+} all result from RyR1-dependent Ca^{2+} release or RyR1-dependent Ca^{2+} entry, or both?

Evidence of a dantrolene-sensitive, excitation-coupled Ca^{2+} entry mechanism of skeletal muscle (ECCE) that is more easily activated in MH skeletal muscle has been described, as well.[202–205] ECCE is different from SOCE in that it does not require depletion of the SR Ca^{2+} store and is activated by high-frequency electrical stimulation of the skeletal muscle membrane. ECCE and SOCE present new physiologic targets of investigation into the pathophysiology of MH that involve Ca^{2+} entry rather than Ca^{2+} release (see Fig. 41.6).

Elucidation of the pathophysiology of MH and the mechanism of action of dantrolene has radically transformed our understanding of muscle physiology and pathophysiology. As our understanding continues to evolve, the future for advances in therapy and testing capabilities hold great promise.

Laboratory Diagnosis

CONTRACTURE TESTING

The standard for testing susceptibility to MH in the human population is an in vitro contracture test that assesses live human muscle fibers from the vastus lateralis in a physiologic bath. With one end of the muscle tissue attached to a strain gauge, the degree of tension developed at baseline and on electrical stimulation is measured as a function of the concentrations of halothane or caffeine. The test is based on the observation that fresh muscle isolated from MHS patients behaved abnormally when exposed to halothane or caffeine in vitro (Fig. 41.9).[206–209] Two variations of this test have been developed and adopted: the CHCT by the North American Malignant Hyperthermia Group (NAMHG) and

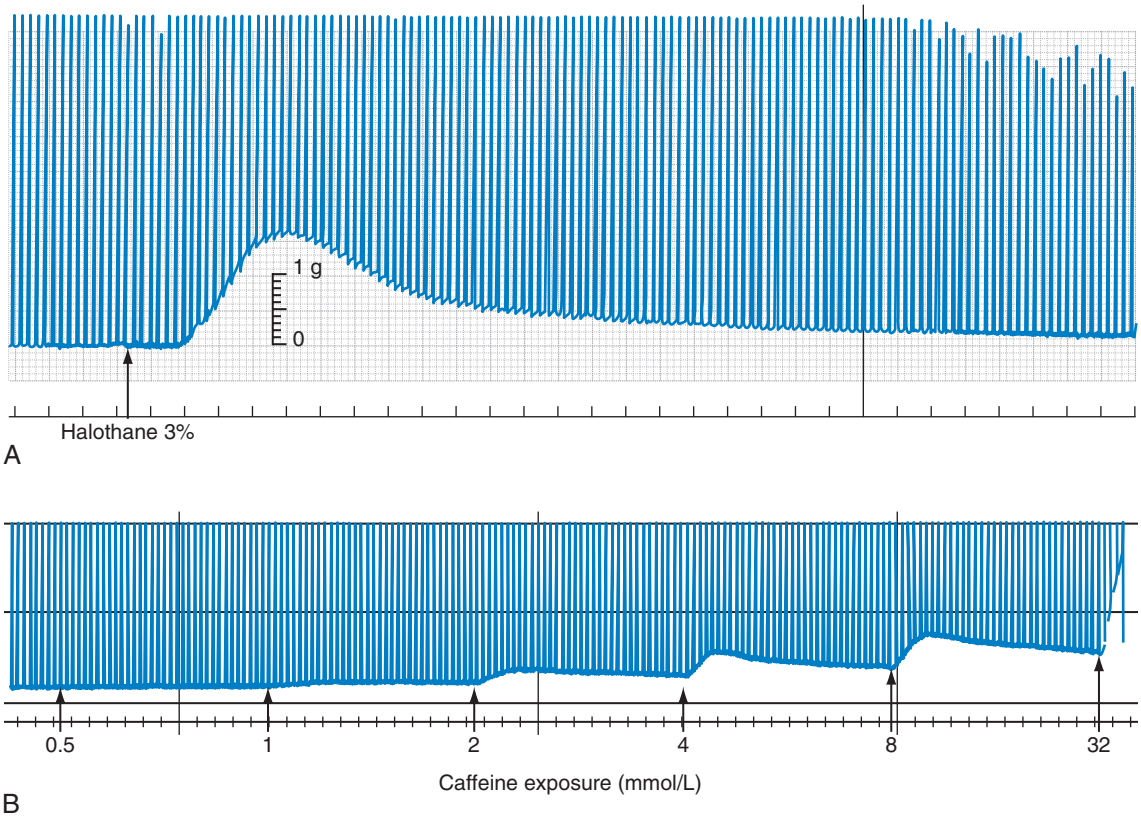

FIGURE 41.9 Caffeine-halothane contracture test. **A,** Abnormal (positive) response to 3% halothane. Each small box represents 0.1 g of tension. The contracture response in this case is 1.6 g. A normal response to 3% halothane is a contracture up to 0.7 g. After exposure to halothane, 32 mmol/L of caffeine is added to the bath to determine maximal response. **B,** Abnormal (positive) response to caffeine. Caffeine exposure is increased to 0.5, 1.0, 2.0, 4.0, 8.0, and 32 mmol/L for 4 minutes. A contracture of greater than 0.3 g to 2 mmol/L of caffeine or less indicates susceptibility. (Modified from Rosenberg H, Antognini JF, Muldoon S. Testing for malignant hyperthermia. *Anesthesiology* 2002;96[1]:232–237.)

the IVCT by the European Malignant Hyperthermia Group (EMHG). The NAMHG test measures the response in separate muscle fascicles to a bolus of 3% halothane or incremental increases in the caffeine concentration,[24,210,211] and it requires a positive response to one of the challenges for a diagnosis of MH susceptibility. Those not responding are considered normal. The EMHG test measures the response to graded increases in the halothane concentration up to 2% and incremental increases in the caffeine concentration in different fascicles. The diagnosis of MH susceptibility by the IVCT requires a positive response to both challenges, whereas a positive response to one of the challenging agents results in equivocal diagnostic categorization (i.e., malignant hyperthermia equivocal).[212–214]

Even though the EMHG protocol may prevent excess false-positive and false-negative results compared with the NAMHG protocol, overall results are comparable.[215] The EMHG reports that the sensitivity and specificity of its protocol are 99% and 94%, respectively,[213] whereas the NAMHG reports that its sensitivity and specificity are 97% and 78%, respectively.[216] Because the North American protocol is less specific and tends to overdiagnose MH susceptibility, it has a very small likelihood of failing to diagnose an MHS individual. The fact that there are some false-positive findings in the contracture testing demonstrates that other myopathic conditions that are not necessarily concordant with MH have muscle tissue that is also capable of giving an abnormal response to halothane and caffeine exposures. Discordance between the results of an IVCT and the presence of MH mutations in *RYR1* can occur in MH families such that 3.1% to 19.4% of family members who do not carry an MH mutation respond positively to an IVCT challenge.[97,213] This presumably indicates that there are other factors (e.g., a second MH susceptibility mutation in *RYR1,* another MH sensitivity locus, a sensitivity to caffeine and halothane that does not reflect MH susceptibility) in these individuals that give a positive IVCT result, but it does not necessarily mean that they are MHS.

GENETIC TESTING

Limited examination of the *RYR1* gene is available for the purpose of diagnosing MH susceptibility at two Clinical Laboratory Improvement Amendments–approved laboratories in North America, as discussed earlier. Any physician can write a prescription for the ryanodine receptor gene test for MH susceptibility or fill out the requisition form and send blood for genetic testing. However, the probability of a positive outcome with genetic testing depends in part on the results of the in vitro CHCT because the clinical signs of MH are nonspecific. Current genetic testing indicates that about 60% of those who have positive CHCT results also have positive genetic results, whereas only 20% of those without a positive CHCT result yield positive genetic results.[97] Thus a negative gene screening test does not eliminate MH susceptibility, but a positive gene screen can be used to trace a family pedigree.

Other Disorders and Malignant Hyperthermia

MYOPATHIC SYNDROMES

An incriminatory association between various myopathies and malignant hyperthermia susceptibility, now known to be far more restricted than originally thought, was described in the 1970s and 1980s with much debate over the biochemical and pathophysiologic character of the clinical episodes that resulted from exposure to MH-triggering agents.[217,218] Did the clinical episodes represent true MH, did the episodes relate to the instability of myopathic muscle membrane with attendant destruction of muscle cells and release of intracellular proteins, and was there sometimes an associated hyperthermic reaction with these exposures? Although both types of episodes may result in increased CK levels, hyperkalemia, myoglobinemia, and myoglobinuria, one results from exaggerated ramping of cellular energy and heat production, and the other results from cellular destruction that does not involve abnormal cellular metabolism as a primary cause. Of the congenital myopathies, central core disease, the related multi-minicore disease, and the myopathy of King-Denborough syndrome are the only myopathies known to have a definite relationship with true MH (see Chapter 24).[219,220]

MALIGNANT HYPERTHERMIA MIMICS

Malignant Hyperthermia–Like Syndrome in Pediatric Diabetes Mellitus

Diabetes mellitus has two well-characterized, life-threatening childhood presentations: diabetic ketoacidosis (DKA) and hyperglycemic hyperosmotic nonketotic syndrome (HHNS).[221–224] DKA, which is associated with type 1 diabetes, usually manifests as nausea, vomiting, dehydration, and weakness, but shock and coma are uncommon (1%-2%) in the absence of cerebral edema. Fever is rarely a symptom and usually spurs a search for an underlying infection. HHNS is usually associated with type 2 diabetes and classically manifests with symptoms of increasing polyuria, polydipsia, and lethargy that develop over a few days. The estimated mortality rate is between 12% and 46%, somewhat more dramatic than that seen for DKA (2%-10%), presumably because most cases of HHNS occur in adults with many other medical problems. The greatest rates of mortality with HHNS occur in adults older than 75 years of age or those with osmolarity values greater than 350 mOsm/L. The incidence of HHNS among U.S. children has been rapidly increasing and appears to be associated with the increase in childhood obesity. Despite this increase, pediatric HHNS is rare, and the presence of fever, as in DKA, usually prompts the search for an underlying infection.

A novel malignant hyperthermia–like syndrome (MHLS) against the background of pediatric diabetes mellitus was described in six adolescent boys between 14 and 18 years of age; the cases were culled from three tertiary care facilities in the United States.[225] The features of the syndrome included HHNS with coma, fever, rhabdomyolysis, and severe cardiovascular instability. Among the six adolescents with MHLS, five were obese, five had acanthosis nigricans, four were African American, and four died. Two more cases were later described; one patient died 14 hours after admission as a result of too rapid a correction of serum osmolarity and resultant cerebral edema and cardiovascular collapse, and a second patient was treated with dantrolene and completely recovered despite developing compartment syndrome in her left upper extremity as the result of rhabdomyolysis.[226] The survivor was tested for metabolic abnormalities, and a deficiency in short-chain acyl-coenzyme A (acyl-CoA) dehydrogenase was found.

Investigators recommend that anyone presenting with symptoms of HHNS and MHLS should be treated with dantrolene as soon as the syndrome is recognized and that fluid and insulin therapy be used for an appropriate rate of correction of serum osmolarity. A search of the literature reveals a similar case described 10 years earlier as fulminant MH associated with DKA in a patient who survived with the addition of dantrolene to his treatment regimen.[227]

Although it is difficult to ascertain the efficacy of dantrolene in abrogating the deleterious effects on skeletal muscle and in saving critically ill patients with MHLS during HHNS with such a small number of successfully treated patients, it seems prudent to initiate immediate treatment with dantrolene in these cases until the data can inform us about the true efficacy of this drug in MHLS.

Disorders of Fatty Acid Metabolism

Growing numbers of reports have documented cases of rhabdomyolysis in patients with disorders of fatty acid metabolism that in some ways mimic awake MH. These disorders arise from mutations in the enzymes responsible for the metabolism of various fatty acids and for ensuring adequate energy substrate for the mitochondria during periods of reduced glucose availability, such as during stress. Although these disorders have profound effects on energy metabolism, they should not be confused with mitochondrial myopathies, which result from completely different molecular defects and have mutations in the proteins of the mitochondrial respiratory chain (see Chapter 24). In neither case has a real association with MH been established, but there have been case reports of rhabdomyolysis and cardiac arrest in patients with carnitine palmitoyltransferase II deficiency.[228–230]

Various forms of acyl-CoA dehydrogenase deficiencies (i.e., very-long-chain, long-chain, medium-chain, and short-chain forms) lead to different types of myopathy that can have severe clinical consequences, including hypoglycemia and rhabdomyolysis with attendant multiple-organ dysfunction, which in some deficiencies are brought about by stress, particularly heat and severe exercise.[231,232] These diseases can manifest early in childhood or late in adolescence or young adulthood, and they can be a particular problem for individuals in the military or those who participate in intense sports.[232] Patients with the very-long-chain acyl-CoA dehydrogenase deficiency can present with acute hypercapnic respiratory failure.[233] Dantrolene has been used successfully to treat one case of recurrent rhabdomyolysis in a patient with very-long-chain acyl-CoA dehydrogenase deficiency,[234] and it may be useful to treat acute intraoperative rhabdomyolysis in these patients, although there is a dearth of evidence in this regard.

Children may present for surgery without a diagnosis of an inborn error of fatty acid metabolism and develop intraoperative rhabdomyolysis, mimicking aspects of a fulminant MH reaction. This may be the first manifestation of the child's fatty acid metabolism disorder. Preoperative increases in serum CK and uric acid levels, presumably owing to subclinical rhabdomyolysis, suggest an inborn error of metabolism or myopathy,[235] but these tests are not part of the usual preoperative panel of blood tests in normal pediatric anesthesia practice. Perioperative stress that may result from fasting, fear, disease states, and other causes can induce metabolic decompensation and hypoglycemia. As a consequence, an IV glucose-electrolyte solution is recommended for affected children.[236] Because of a few reports of rhabdomyolysis when these children are anesthetized with inhalational anesthetics, there has been some reluctance to use inhalational anesthetics.[236,237] It is, however, likely that the number of patients with inborn errors of fatty acid metabolism who undergo surgery is far greater than the paucity of reports of adverse outcomes with inhalational anesthetics. Because these patients vary considerably in their responses to stress, it is not surprising that most do well with any well-managed anesthetic. The available evidence suggests that the perioperative risk is no greater with any particular anesthetic in these children.

If the clinician elects to avoid inhalational anesthetics, two alternatives remain: regional anesthesia and TIVA. In children, peripheral limb surgery often allows for the use of IV sedation and regional anesthesia that may be suitable depending on the age of the child,[213] but most children do not tolerate this technique. However, a propofol based TIVA (see Chapter 8) is often used in children.[238]

Propofol infusion syndrome, a rare, usually lethal complication of prolonged infusions of propofol, is diagnosed by cardiovascular collapse associated with lipemic plasma, enlarged fatty liver, severe metabolic acidosis, and rhabdomyolysis or myoglobinuria.[239–241] In this syndrome, a large increase in particular fatty acids (i.e., malonylcarnitine and C5-acylcarnitine) that points to impaired entry of long-chain fatty acids into mitochondria and to resultant failure of mitochondrial respiration at complex II has been identified.[242] Others suggest that propofol infusion syndrome may uncover medium-chain acyl-CoA dehydrogenase deficiencies, although this remains unproved.[239] The notion that propofol can impair fatty acid uptake and subsequent oxidation raises the possibility that the acute administration of propofol to a patient with a defect in fatty acid metabolism can precipitate a metabolic crisis, although this has never been reported. It has also been suggested that the lipid load from a propofol infusion in the absence of adequate carbohydrate intake can expose a carnitine deficiency as a model for propofol infusion syndrome.[243] Moreover, propofol itself has been shown to inhibit mitochondrial respiration, possibly compounding the effects of fatty acid oxidation deficiencies.[239] In these children, the use of propofol may be associated with an unclear risk of inducing a metabolic crisis. If their metabolic abnormalities are subclinical, there is no easy, inexpensive preoperative screening tool to establish a diagnosis for a rare abnormality. Even if the child is diagnosed with one of the subsets of fatty acid oxidation deficiencies, it is impossible to predict preoperatively which children will be sensitive to propofol and, if they are, how sensitive they are.

Other TIVA regimens that may be considered include ketamine, dexmedetomidine, benzodiazepines, and opioids. In these instances, the preoperative discussion with the parents, children, and surgeons must address the perioperative risks, including the lack of evidence that any particular anesthetic is more likely to precipitate rhabdomyolysis and an MH-like reaction than another.

NEUROLEPTIC MALIGNANT SYNDROME

Neuroleptic malignant syndrome (NMS) is a rare, potentially lethal reaction to neuroleptics (0.1%-2.5% of patients), which is characterized clinically by the slow onset of fever, muscle rigidity, altered consciousness, and autonomic instability over a protracted period of time.[244] Laboratory findings include increased CK levels, leukocytosis, increased liver enzyme values, and reduced serum iron or potassium concentrations.[244] NMS is similar to MH, and the distinction between the two is often difficult to make, except by medication history; neuroleptics are associated with NMS, and inhalational anesthetics and succinylcholine are associated with MH.

NMS has developed in children taking neuroleptics that block all dopamine D_2 receptors (i.e., high-potency neuroleptics, such as haloperidol; atypical neuroleptics, such as thiothixene; low-potency D_2-receptor antagonists, such as metoclopramide; and tricyclic antidepressants) and in those with the withdrawal of antiparkinsonian medications. Although this syndrome has been attributed to a deficiency of central dopamine, other pathophysiologic mechanisms have also been proposed to explain the many clinical findings that cannot be explained by the lack of dopamine.

Successful therapy for NMS depends on early recognition, cessation of the offending medications, and intensive medical and nursing care geared toward hydration and restoration of electrolyte balance.[244] Specific pharmacologic therapy with dopamine agonists such as bromocriptine or with dantrolene has been advocated, although the use of dantrolene is controversial. Despite the fact that dantrolene is listed in psychiatric textbooks as a first-line pharmacologic treatment for NMS, there is no evidence that it is effective in treating NMS, except for the occasional case report declaring dantrolene to be effective.[244–246]

Children with psychiatric diagnoses who require treatment with neuroleptics make up a significant percentage of these pediatric patients. NMS in this pediatric population continues to be a problem, even with the newest drugs. The perioperative period for the pediatric patient taking neuroleptics is one fraught with potential diagnostic dilemmas. For example, one report described postoperative NMS in a child with severe cerebral palsy and seizure disorder who was not taking any neuroleptics and who was successfully treated three times with dantrolene.[247] Was this NMS or a mild form of MH? The answer remains unclear.

Summary

Many clinical scenarios in pediatric anesthesia can mimic MH and challenge our diagnostic acumen and our ability to deliver anesthesia safely. Not all metabolic syndromes that reveal themselves under inhalational anesthesia are MH, and not all metabolic syndromes that respond to dantrolene are MH. The examples given here underscore the need for expert advice during a case of suspected MH. Providers are urged to make use of the Malignant Hyperthermia Hotline when the need arises.

Lower Extremity Blocks
Summary

THE USE OF REGIONAL anesthesia techniques in children has increased dramatically in the past two decades.[1–9] Regional anesthesia is most commonly used in conjunction with general anesthesia in children, although in certain circumstances regional anesthesia may be the sole technique. In addition to central neuraxial blocks, peripheral nerve blocks are used with increasing frequency; the introduction of high-resolution portable ultrasound imaging has opened up new vistas to ensure that these blocks are safe and effective. Ultrasound-guided visualization of anatomic structures permits both greater precision of needle or catheter placement, confirmation that the drug has been deposited at the site of choice, and may reduce the volume of drug needed to achieve successful blockade while reducing the potential for local anesthetic toxicity (see Chapter 43).[10] Ultrasound guidance has also facilitated the performance of numerous blocks, including truncal blocks, approaches to the brachial plexus (supraclavicular and infraclavicular blocks), and several lower extremity blocks (mid-thigh saphenous and adductor canal blocks) that could not be otherwise performed accurately or safely in children using landmark or nerve stimulation techniques. Evidence from several recent large-scale collaborative studies of regional blockade in children supports the contention that peripheral nerve blockade is assuming greater prominence in pediatric anesthesia, and data from the Pediatric Regional Anesthesia Network (PRAN) suggests that the increased use of ultrasound guidance may, at least in part, be driving this trend.[11,12] Supplementing a general anesthetic with a nerve block can result in a pain-free awakening and postoperative analgesia without the potentially deleterious adverse side effects associated with parenteral opioids (see Chapter 43).[13] This benefit may be of particular importance to neonates, former preterm infants, children with cystic fibrosis and children with other conditions that render them vulnerable to opioid adverse effects.[4] There is also evidence that suggests that regional anesthesia may improve pulmonary function in children who have undergone thoracic or upper abdominal surgery.[14–17] Lastly, the greatly increased number of "same day surgery" cases in recent years has made the advantages of regional anesthesia, such as the rapid awakening, enhanced postoperative analgesia with no sedation or altered sensorium, and lack of opioid-induced nausea or vomiting, even more apparent. The safe and effective use of these techniques in children, however, requires an understanding of both the developmental anatomy of the region in which the block is placed and the developmental pharmacology of local anesthetics. Although there is increasing evidence and consensus that ultrasound guidance affords numerous advantages in safety and precision over landmark techniques for many peripheral nerve blocks,[18,19] this chapter will focus on landmark-guided techniques for those who do not have the advantage of an ultrasound imaging machine. Ultrasound techniques are described in Chapter 43. This chapter will also focus on the general issues of regional anesthetics in children that are applicable to any block technique, and on neuraxial anesthesia.

Pharmacology and Pharmacokinetics of Local Anesthetics

There are two classes of clinically useful local anesthetics, the amino amides (amides) and the amino esters (esters) (Table 42.1). The amides are degraded in the liver by cytochrome P450 enzymes,

TABLE 42.1 Commonly Used Local Anesthetics

Esters	Amides
Procaine	Lidocaine
Tetracaine	Mepivacaine
2-Chloroprocaine	Bupivacaine
	Levobupivacaine
	Ropivacaine
	Etidocaine

whereas the esters are hydrolyzed primarily by plasma cholinesterases.[20–24] These degradation pathways account for some of the differences in distribution and metabolism of local anesthetics, particularly in neonates when compared with adults.

AMIDES

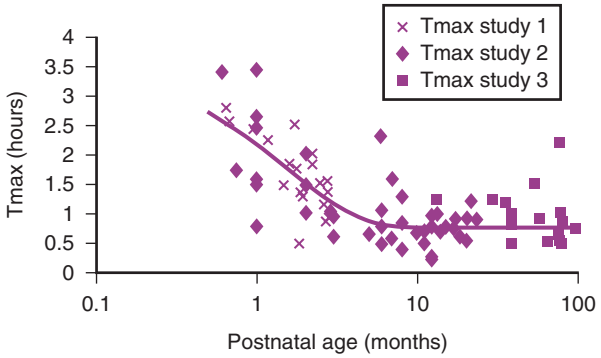
Amide local anesthetics commonly used in children include lidocaine, bupivacaine (and its isomer levobupivacaine), and ropivacaine. The choice of agent most often depends on the desired speed of onset and duration of action of the block, but in small infants and children issues related to potential toxicity are also important. Compared with the liver of an adult, the liver of the neonate has limited enzymatic activity to metabolize and biotransform drugs (see also Chapter 7 and Fig. 7.11). The ability to oxidize and to reduce drugs, in particular, is immature.[23–30] Neonates do not metabolize mepivacaine, with most of it excreted unchanged in the urine.[31–37] Conjugation reactions are limited at birth and do not reach adult rates until approximately 6 to 12 months of age.[25–28,33]

The nature of the epidural space in infants differs from that in the adult with increased vascularity, less fat, and a smaller absorptive surface for local anesthetics. Anatomic studies have shown that the epidural fat is spongy and gelatinous in appearance, with distinct spaces between individual fat globules.[38] With increasing age, fat becomes more tightly packed and fibrous. The absorption half-time of epidural levobupivacaine decreases from 0.36 hours at 1 month postnatal age (PNA) to 0.14 hours at 6 months PNA (E-Fig. 42.1). This, combined with reduced clearance (by the cytochrome P450, CYP3A4), decreases the time to maximum plasma concentration (T_{max}) from 2.2 hours at 1 month PNA to 0.75 hours (80% of the mature value) by 6 months PNA.[39]

Older children also differ from adults with respect to the pharmacokinetics of local anesthetics. The steady-state volume of distribution (Vdss) of amides in children is greater than that in adults, whereas their clearances (Cl) are similar.[40–42] Because the elimination half-life ($T_{1/2}$) is related to the volume of distribution and clearance,

$$T_{1/2} = (0.693 \times \text{Vdss})/\text{Cl},$$

a larger Vdss directly prolongs the elimination half-life. However, it is clearance that determines steady-state concentrations with continuous amide infusion; reduced clearance in neonates implies that repeated doses and continuous infusions will lead to an accumulation of local anesthetic (see E-Fig. 42.1).[43–45] Thus infusion rates and local anesthetic concentrations must be reduced in this vulnerable age group when prolonged administration of amides is used for postoperative analgesia.



Further differentiating the pharmacokinetics in adults from children is that pharmacokinetic differences may be amplified by the location and type of block. Children achieve peak plasma concentrations of amide local anesthetics more rapidly than adults after intercostal nerve blocks, but at similar times (~30 minutes with lidocaine and bupivacaine) after caudal epidural administration.[40,46,47] Ilioinguinal nerve blocks in children weighing less than 15 kg may yield plasma concentrations of bupivacaine in the toxic range if more than 1.25 mg/kg is administered.[48]

Bupivacaine

Bupivacaine may still be the most commonly used amide local anesthetic agent for regional blockade in infants and children at some institutions, although ropivacaine (and in Canada and Europe, levobupivacaine) is increasingly used. After a single administration of bupivacaine, analgesia may be expected for up to 4 hours, although its duration of action is somewhat less in small infants. The concentration used depends on the site of injection, the desired density of blockade, consideration of the toxic threshold of the drug, and dose limitations imposed by the concomitant administration of other local anesthetics, such as local infiltration by the surgeon or intravenous (IV) or topical laryngotracheal administration of lidocaine. The most commonly used concentration for peripheral nerve blocks is 0.25%, with reduced concentrations of 0.0625% to 0.1% used for continuous epidural administration. The 0.5% concentration is infrequently used in children, although it may be used for peripheral nerve blocks where subsequent doses and drug accumulation are not of concern and where the volume of administered drug is sufficiently small to permit that concentration to be used without toxicity. Greater concentrations also increase the density of the motor block, an effect that may be desirable depending on the clinical situation.

Bupivacaine is highly bound to plasma proteins, particularly to α_1-acid glycoprotein. It is a racemic mixture of the levorotary and dextrorotary enantiomers; the *l*-isoform is bioactive with regard to clinical effect, and the *d*-isoform contributes more to toxicity. Levobupivacaine, the *l*-enantiomer of bupivacaine, retains the efficacy and duration of blockade as the racemic formulation (demonstrated in both an ovine model and in adult volunteers), yet carries up to a 30% reduced risk of cardiac and central nervous system (CNS) toxicities.[49,50] Although the beneficial toxicity profile of levobupivacaine has resulted in its widespread use, it is currently unavailable in the United States.[51]

Several experimental preparations of local anesthetics have the prospect to prolong analgesia with a reduced potential for toxicity.[52–54] Bioerodible encapsulated microspheres of bupivacaine administered for peripheral neural blockade[55] release local anesthetic over many hours to several days, depending on the formulation of the microsphere, thus producing very prolonged analgesia.[56] The addition of dexamethasone to the microspheres prolongs the block up to 13-fold, and plasma bupivacaine concentrations in animal studies were far below the toxic threshhold.[57] No adverse local reactions were noted. Several different preparations have been developed and studied, including synthetic bioerodible microspheres, protein-lipid-sugar spheres, and lipospheres.[58–60] The first such preparation (Exparel, Pacira Pharmaceuticals, Inc., Parsippany, NJ) has been approved for use in patients 18 years of age or older by the U.S. Food and Drug Administration for local site infiltration (i.e., not approved for peripheral nerve blocks); toxicology studies suggest a low risk because of the slow rate of drug release.[52,61–63] In several adult studies (there are no pediatric data), however, the actual duration of analgesia was found to be only marginally prolonged over that produced by bupivacaine with epinephrine.[64] While prolonged action of local anesthetics could be particularly useful for those who require prolonged neural

E-FIGURE 42.1 A semi-logarithmic plot of individual predicted levobupivacaine time to peak concentration (T_{max}), after a 2-mg/kg dose, against postnatal age. The *solid line* represents the nonlinear relation between T_{max} and postnatal age. (Adapted from Chalkiadis GA, Anderson BJ. Age and size are the major covariates for prediction of levobupivacaine clearance in children. *Paediatr Anaesth*. 2006;16[3]:275–282, with permission.)

blockade for analgesia but cannot have an indwelling regional anesthetic, it appears that we still await agents with significant clinical efficacy. New drugs with novel mechanisms of action may offer more promise and appear to be on the horizon. Site 1 sodium channel blockers such as neosaxitoxin have low toxicity and high efficacy and are currently undergoing early clinical trials (see Chapter 44).[65–67] Potential applications include intercostal blockade for rib fractures, postoperative analgesia for ambulatory surgery, and children in whom an indwelling epidural catheter poses an excessive risk of infection.

Ropivacaine

Ropivacaine is an amide local anesthetic. Like levobupivacaine, it is an *l*-enantiomer that has reduced risks of cardiac and neurologic toxicities compared with bupivacaine.[68] The lethal dose in 50% of animals (LD_{50}) is greater than that of bupivacaine. Rats of different maturity exhibit a threefold greater tolerance to equipotent doses of ropivacaine than of bupivacaine when administered for a femoral nerve block.[69] Ropivacaine is also reputed to produce a less dense motor block at equianalgesic potency to other local anesthetics, although the data are conflicting in this regard.[70] Some studies report a greater sparing of motor function compared with bupivacaine, whereas others report no difference in motor and sensory block. Ropivacaine produces a denser blockade of the Aδ and C fibers than bupivacaine when low concentrations are used, lending mechanistic credence to the idea of differential blockade.[71] Much of the infant animal data, however, do not support the existence of a greater sensorimotor differential block than that after bupivacaine. The few clinical studies in infants and children currently available do not report a detectable motor-sensory differential, in contrast to the data in adults.[69,72] Several clinical studies in infants and children report a prolonged duration of analgesia with ropivacaine, despite using a solution of reduced potency.[72–74] Although there are still only limited data available in children, the decreased potential for toxicity makes ropivacaine an attractive agent in this age group. Ropivacaine possesses intrinsic vasoconstrictive properties; thus it is not available as an epinephrine-containing solution. Most clinical studies have used a 0.2% solution (2 mg/mL); the volume of drug injected was similar to that of bupivacaine but depended on the type of block and size of the child. We commonly use concentrations of 0.1% for infusions with opioid for continuous neuraxial postoperative analgesia, whereas concentrations up to 0.2% may be used for thoracic epidural infusions and peripheral and plexus blocks.

Lidocaine

Lidocaine has a relatively short duration of action compared with bupivacaine and ropivacaine; it is rarely used for single-injection blocks in pediatric regional anesthesia, where a prolonged effect for postoperative analgesia is usually a priority. However, it can be used effectively in continuous blocks where the drug is continuously infused via a catheter, although here too, ropivacaine, levobupivacaine, and bupivacaine are far more commonly used. In vitro laboratory experiments have suggested that lidocaine might have greater potential for neurotoxicity in the developing nervous system than other local anesthetics, although the clinical implications of these findings remain unclear and unproved.[75]

ESTERS

The pharmacokinetics of the ester local anesthetics are also affected by the quantitative and qualitative difference in plasma proteins. Plasma pseudocholinesterase activity in neonatal umbilical blood is decreased compared with adults;[76] thus the plasma half-life of the ester anesthetics may be prolonged. Despite a prolonged elimination half-life in infants, 2,3-chloroprocaine has been recommended for neonatal regional techniques, particularly for continuous epidural and plexus blockade.[77,78] Limited data suggest that 2,3-chloroprocaine may be safe in this setting and that toxic accumulation does not occur after several hours of use with a 1.5% concentration.

Another enzymatic system with decreased activity in neonates is methemoglobin reductase, which is responsible for maintaining hemoglobin in a reduced valence state where it is capable of binding and transporting oxygen. Hepatic metabolism of prilocaine yields *o*-toluidine, which can produce methemoglobinemia, thereby rendering red blood cells less capable of carrying oxygen.[79] The decreased activity of methemoglobin reductase and the increased susceptibility of fetal hemoglobin to oxidization make prilocaine an unsuitable local anesthetic for use in neonates. Although prilocaine is no longer available for use in the United States as an injected local anesthetic, it is one of the components of EMLA cream (eutectic mixture of local anesthetics, AstraZeneca, Wilmington, DE), a commonly used transdermal local anesthetic. The total dose and surface area for EMLA application must therefore be limited in neonates because methemoglobinemia has been reported (see Chapter 7). Even infants and toddlers are not without increased risk of toxicity, so the dose must be meticulously calculated.[80] Other local anesthetics, particularly topical agents, such as benzocaine, are potentially dangerous in infants because of the risk of methemoglobinemia by this same mechanism.[81] EMLA should only be applied to normal intact skin in appropriate doses[82] (0–3 months or weight <5 kg, 1 g applied to a maximum of approximately 10 cm^2 surface area; 3–12 months and >5 kg, 2 g to a maximum of 20 cm^2; 1–6 years and >10 kg, 10 g applied to a maximum of approximately 100 cm^2 surface area; 7–12 years and >20 kg, 20 g applied to a maximum of approximately 200 cm^2 surface area). The dose must be reduced if EMLA is applied to mucosal surfaces (such as the glans of the penis). The duration of action persists for 1 to 2 hours after the cream is removed. Adverse reactions include skin blanching, erythema, itching, rash, and methemoglobinemia. EMLA should be used with caution and with strict attention to the amount of cream and surface area of application in children younger than 1 month of age. Infants receiving drugs that may induce methemoglobinemia, such as phenytoin, phenobarbital, and sulfonamides, may be at increased risk, and caution is warranted. It is contraindicated in children with congenital or idiopathic methemoglobinemia. Topical amethocaine (Ametop, Smith & Nephew Healthcare, Mississauga, Ontario, Canada) has a more rapid onset of analgesia and increased depth of penetration through the skin and produces minimal vasoconstriction of the skin compared with EMLA.[83] Iontophoresis of lidocaine can also produce excellent transdermal skin analgesia with much faster onset of action (10 minutes) and greater depth of skin penetration than EMLA.[83]

TOXICITY OF LOCAL ANESTHETICS

With the exception of uncommon effects, such as producing methemoglobinemia, the major toxic effects of local anesthetics are on the cardiovascular system and the CNS. Local anesthetics readily cross the blood-brain barrier to cause alterations in CNS function. A consistent sequence of symptoms can be observed as plasma local-anesthetic concentrations progressively increase, although this may not be readily apparent in infants and small children. Because of the smaller threshold for cardiac toxicity

with bupivacaine, cardiac and CNS toxicity may occur virtually simultaneously in infants and children, or cardiac toxicity may even precede CNS toxicity. During the intraoperative use of bupivacaine, early recognition of toxicity may be masked by the concomitant use of general anesthetics, which will obscure the signs of CNS toxicity until devastating cardiovascular effects are apparent.[84]

In awake patients, the earliest sign of local-anesthetic toxicity is circumoral paresthesia, which is the result of the high tissue concentrations of local anesthetic rather than CNS effects. The development of circumoral paresthesia is followed by the prodromal CNS symptoms of lightheadedness and dizziness, which progress to both visual and auditory disturbances, such as difficulty in focusing and tinnitus. Objective signs of CNS toxicity during this time are shivering, slurred speech, and muscle twitching. As the plasma concentration of local anesthetic continues to increase, CNS excitation occurs, resulting in generalized seizures. Further increases in the local anesthetic concentration depress the CNS, with respiratory depression leading to a respiratory arrest. In adults, cardiovascular toxicity usually follows CNS toxicity. In this case, the systemic blood pressure decreases (1) because the peripheral vasculature dilates and (2) because of direct myocardial depression, leading to a progressive bradycardia. These effects culminate in a cardiac arrest. In large doses, bupivacaine produces ventricular dysrhythmias, including ventricular tachycardia, peaked T waves, and ST-segment elevation that suggest myocardial ischemia, especially when epinephrine-containing solutions are used. Bupivacaine has a particularly strong affinity for the fast sodium channels, as well as the calcium and slow potassium channels in the myocardium. These effects explain why it is so difficult to resuscitate children from a toxic dose of bupivacaine.[85–87] Stereoselectivity of the sodium channel in the open state, however, has not been demonstrated. There is also evidence that the slow or "flicker" potassium channels may play a significant role in bupivacaine toxicity.[88]

With an intravascular injection of bupivacaine with epinephrine, characteristic changes on the electrocardiogram (ECG) may be observed in the absence of symptoms of CNS toxicity. Fig. 42.1 shows an ECG tracing obtained during an unintended intravenous injection of bupivacaine with and without epinephrine (positive test dose). Even a small IV dose of 1 to 2 μg/kg of epinephrine in a 1 : 200,000 solution with 0.25% bupivacaine produces peaked T waves with elevated ST segments, particularly in the lateral chest leads.[89–91] When the ECG effects of bupivacaine, with and without epinephrine, and epinephrine alone were compared in children, the most reliable ECG changes (peaked T waves at 1 minute) and an increase in arterial pressure and heart rate, required the presence of epinephrine.[92] It should be noted, however, that these changes in the T waves depended on age, diminishing in responsiveness beyond 8 years of age. These data suggest that careful observation of the ECG during test dose administration may be a sensitive indicator of unintended intravascular injection of bupivacaine in the child anesthetized with an inhalational anesthetic (see Technique of Administration later).[93]

Plasma protein binding is the most important pharmacologic factor that determines the toxicity of local anesthetics, particularly for amides, because it is the free (unbound) fraction of the drug that produces toxicity. Reduced plasma protein concentrations cause more drug to remain in the unbound active form with greater potential for toxicity (see Chapter 7). Concentrations of α_1-acid glycoprotein in neonates are less than in older infants and children, producing a clinically crucial greater free fraction of amide local anesthetics in neonates. The significantly greater concentrations of free lidocaine and bupivacaine in infants and neonates are attributed to the decreased levels of α_1-acid glycoprotein, the primary binding protein of these drugs, compared with adults.[43,94–98] Current data suggest that the plasma concentration of free drug may be 30% greater in infants younger than 6 months of age and even greater in preterm infants than in adolescents.[99] α_1-Acid glycoprotein is an acute-phase reactant whose concentration increases after surgery. Concentrations of α_1-acid glycoprotein in infants are less in those undergoing elective rather than emergency surgery.[100] It is not known whether these increased α_1-acid glycoprotein concentrations are sufficient to afford any protective effect on the risk of toxicity from bupivacaine accumulation in the perioperative period. Decreased protein binding appears to be especially important in neonates in whom continuous infusions of local anesthetics are used, as reduced clearance contributes to drug accumulation and consequent high concentrations of unbound drug.[101,102]

Plasma concentrations of lidocaine that depress the cardiovascular and respiratory systems in human neonates are about half

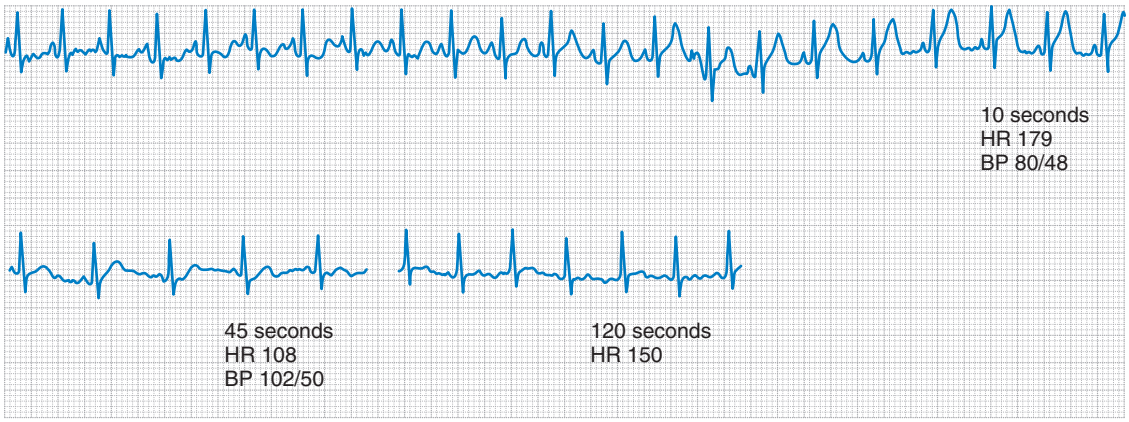


FIGURE 42.1 Electrocardiographic changes associated with the intravenous injection of bupivacaine and epinephrine 1 : 200,000. Note the marked increase in the height of the T waves at 10 seconds. *BP*, blood pressure; *HR*, heart rate. (From Freid EB, Bailey AG, Valley RD. Electrocardiographic and hemodynamic changes associated with unintentional intravascular injection of bupivacaine with epinephrine in children. *Anesthesiology* 1993;79[2]:394–398.)

those that cause similar toxicity in adults.[103] In contrast, 2-day-old guinea pigs were less susceptible to the toxic effects of bupivacaine than 2-week or 2-month-old guinea pigs, even though the blood concentrations in the 2-day-olds were greater.[84] Data regarding toxicity in infant versus adolescent versus adult rats for both bupivacaine and ropivacaine are similar.[69] Young dogs, however, have a decreased threshold to both seizure and cardiac toxicity caused by excessive doses of bupivacaine.[104] Because species differences are important in toxicity studies, it is difficult to predict which study represents the human neonate.[105] No data exist in humans regarding age-dependent differences in the toxic threshold of bupivacaine at a given blood concentration. Seizures and cardiovascular collapse have been reported in human infants at the same blood concentrations of bupivacaine as in adults. Whereas data from some animal studies suggest that the greater volume of distribution of amides in younger children may protect against bupivacaine toxicity, retrospective analyses of large databases of infants who have received epidural infusions indicate that these findings may not be applicable to the human infant, particularly during continuous infusions or with repeated dosing. Current data on the pharmacokinetic and pharmacodynamic differences associated with early infancy suggest that caution should be exercised when using local anesthetics in infants. Several reports document that infants and children may develop systemic toxicity, including dysrhythmias, seizures, and cardiovascular depression from the accumulation of epidural infusions of bupivacaine.[43,101,106–108] Meticulous attention must be paid to the total dose of local anesthetic administered, the rate of administration, the site of injection, and the use of vasoconstrictors to diminish the rate of uptake of the local anesthetic. This is particularly important when a continuous regional anesthetic technique is used postoperatively or during prolonged surgery when repeated doses of local anesthetic are administered.

We recommend that both the bolus and infusion doses of bupivacaine and lidocaine be reduced by approximately 30% for infants younger than 6 months of age to decrease the risk for toxicity. This would result in a maximal bupivacaine rate of no more than 0.3 mg/kg per hour.[44] Whereas these recommendations are particularly applicable to continuous infusions of bupivacaine for postoperative analgesia, the same caveats apply to large single injections, repeated injections, and continuous infusions of local anesthetics during long surgical procedures.

The *d*-stereoisomer (or enantiomer) of racemic mixtures of local anesthetics may also be a primary factor in the risk for both cardiac and CNS toxicity.[87] As described earlier, both ropivacaine and levobupivacaine, which are *l*-enantiomers, have decreased toxicity compared with bupivacaine, a racemic mixture, as demonstrated in adults and experimental animals.[88] This may be due in part to the reduced affinity of cardiac and CNS tissues for the *l*-enantiomer.[68] The inclusion of levobupivacaine and ropivacaine into the clinical armamentarium may prove beneficial in decreasing local anesthetic toxicity.

PREVENTION OF TOXICITY

Few data have correlated the anesthetic block, blood concentration of local anesthetic, and dose in infants and children. Most dosing guidelines have been extrapolated from studies in adults. Table 42.2 lists the maximum recommended doses of local anesthetics, as well as their approximate durations of action. To avoid overdose and the possibility of toxic effects, it is prudent to remain within these guidelines until studies in children clarify the pharmacokinetics and pharmacodynamics of local anesthetics for specific nerve blocks. As discussed earlier, all of these doses should be reduced by ~30% in infants younger than 6 months of age.

TABLE 42.2 Maximum Recommended Doses and Duration of Action of Commonly Used Local Anesthetics

Local Anesthetic	Maximum Dose (mg/kg)[a]	Duration of Action (minutes)[b]
Procaine	10	60–90
2-Chloroprocaine	20	30–60
Tetracaine	1.5	180–600
Lidocaine	7	90–200
Mepivacaine	7	120–240
Bupivacaine	2.5	180–600
Ropivacaine	3	120–240

[a]These are maximum doses of local anesthetics. Doses of amides should be decreased by 30% in infants younger than 6 months of age. When lidocaine is being administered intravascularly (e.g., during intravenous regional anesthesia), the dose should be decreased to 3 to 5 mg/kg; there is no need to administer long-acting local anesthetic agents for intravenous regional anesthesia, and such a practice is potentially dangerous.
[b]Duration of action depends on the concentration, total dose, site of administration, and the child's age.

Toxic reactions from local anesthetics are a function of (1) the total dose administered; (2) the site of administration; (3) the rate of uptake; (4) pharmacologic alterations in toxic threshold; (5) the technique of administration; (6) the rate of degradation, metabolism, and excretion of local anesthetic; and (7) the acid-base status of the child.[109–114] Thus recommendations (including those of the authors) of a specific dose limit for a given drug are both overly simplistic and potentially misleading.[115] Because of the multiplicity of factors that drive the final concentration of unbound local anesthetic, and in the absence of definitive and comprehensive data, conservative dosing remains the most prudent course.

Total Drug Dose

The dose of local anesthetic should be determined by a child's age, physical status, the area to be anesthetized, and *weight according to lean body mass*. A severely ill child who is in congestive heart failure, for example, has a reduced capacity to metabolize amide local anesthetics because of a reduced cardiac output and hepatic blood flow. Similarly, a markedly obese child must not be given a larger dose simply on the basis of increased weight. If a large volume of local anesthetic is required for a particular procedure, a dilute concentration should be used to avoid exceeding the maximum recommended safe dose. Doses are calculated based on the lean body weight of the child (e.g., a 20-kg child could receive up to 50 mg of bupivacaine). An easy approximation for bupivacaine is 1 mL/kg of 0.25% bupivacaine, reduced by approximately one-third for infants younger than 6 months of age.

Site of Injection

Injection of local anesthetics into very vascular areas leads to greater blood concentrations than the same dose injected into less vascular areas. The order of uptake (i.e., maximum blood concentration) of local anesthetics (in order from greatest to least) from regional blocks in adults is (1) intercostal nerve blocks, (2) caudal blocks, (3) epidural blocks, and (4) brachial plexus and

femoral-sciatic nerve blocks.[116] An easy way to remember this is by the mnemonic **ICE Block**:
I = intercostal
C = caudal
E = epidural
Block = peripheral nerve blocks

Studies are required to determine whether this order holds true for children. Blood concentrations of bupivacaine twice those measured in older children have been reported in children weighing less than 15 kg after ilioinguinal nerve block for herniorrhaphy using only 1.25 mg/kg of 0.5% bupivacaine without epinephrine, which is half the usual recommended maximal dose.[48] However, the fascia iliaca block in older children produced blood concentrations of bupivacaine that were within the acceptable safe range.[117] Neonates who received a transversus abdominis plane block of 0.125% bupivacaine for a total volume of 1 mL/kg had greatest plasma concentration of 0.38 μg/mL at 30 minutes after the block; one-quarter to one-fifth the toxic threshold, 1.5 to 2.0 μg/L.[118] Local infiltration of the wound in herniorrhaphy has not been associated with increased blood concentrations of local anesthetics,[119] but scalp infiltration during neurosurgery may produce relatively greater blood concentrations.[120] As would be expected, spinal anesthesia results in very small blood concentrations, even in neonates.[98]

Rate of Uptake

The rate of uptake of a local anesthetic depends on the vascularity of the site of injection. Increased perfusion increases uptake, whereas decreased perfusion decreases uptake.[121] The rate of uptake in children is usually more rapid than in adults. In general, the addition of a vasoconstrictor to the local anesthetic reduces the rate of uptake and prolongs the duration of the block. In adults, the dose of epinephrine is usually limited when used in conjunction with potent anesthetic agents because of the risk of inducing cardiac arrhythmias. If epinephrine is combined with the ester anesthetics, there is no increased risk of arrhythmias. For example, in adults anesthetized with halothane, the maximum recommended dose of epinephrine is 1.0 to 1.5 μg/kg. In children, however, larger doses of epinephrine may be safe.[122–124] We have used as much as 10 μg/kg of epinephrine in children, with a maximum dose of 250 μg, during halothane anesthesia without evidence of ventricular irritability, and these doses are likely to be even safer with currently used inhalational anesthetics, which do not sensitize the myocardium to the arrhythmogenic effects of epinephrine. An epinephrine concentration of 1:100,000 should not be exceeded, and 1:200,000 or less is generally used. A quick reference for converting local anesthetic concentrations and the amount of epinephrine in various dilutions is presented in Tables 42.3 and 42.4. *Epinephrine is contraindicated in blocks in which vasoconstriction of an end-artery could lead to tissue necrosis, such as for digital and penile blocks, although this historical practice has recently been challenged, setting the stage for prospective studies.*[125–127]

TABLE 42.3 Epinephrine Dilution and Conversion to μg/mL

Epinephrine Dilution	μg/mL

1:200,000	5
1:400,000	2.5
1:800,000	1.25

Alteration in Toxic Threshold

Medications, such as diazepam or midazolam, that increase the seizure threshold (i.e., the threshold for CNS toxicity) can be valuable adjuncts to regional anesthesia. Premedication with diazepam (0.15–0.3 mg/kg) decreases a child's anxiety but also offers some protection from the toxic CNS effects of a local anesthetic overdose.[128] Although diazepam is no longer in common clinical use in children in the perioperative period, evidence in animal models and considerable clinical experience in humans suggests that midazolam is also effective in terminating seizure activity.[129] Animal data, however, suggest that the concomitant use of diazepam and bupivacaine decreases the elimination of bupivacaine from serum and cardiac tissue in mice.[130] This effect is not a result of changes in protein binding.[131] It is not known if this is true for all benzodiazepines or if this is also the case in humans. Although premedication with a benzodiazepine prevents manifestations of CNS toxicity, the threshold for cardiovascular toxicity is unchanged.[132] Thus after premedication with a benzodiazepine, cardiovascular collapse can occur without warning because the symptoms of CNS toxicity may be blunted. Because most regional anesthesia administrations performed in children are placed after induction of general anesthesia (with the exception of some blocks in former preterm infants), this may be a moot point in most circumstances.

Technique of Administration

Whenever regional anesthesia is performed, the operator must be prepared for an adverse reaction and resuscitation supplies, including drugs, suction, and airway equipment, must be immediately available. The needle or catheter must always be inspected for blood as soon as it is positioned, but before injecting the local anesthetic, to determine if the tip is within an artery or a vein. It is preferable to observe the needle or catheter for passive blood flow rather than to actively aspirate for blood because the blood vessels, such as the epidural venous plexus, are thin walled and collapse readily when negative pressure is applied. As a result, the inability to aspirate blood is not absolute proof that the needle or catheter is not in a blood vessel. For this reason, a small volume of local anesthetic with a marker for intravascular injection, such as epinephrine in a concentration of 1:200,000, is administered first, while the ECG is observed for 30 to 60 seconds. Data from awake adults indicate that the heart rate will increase within 1 minute of intravascular administration.[133] When the drugs are administered during general anesthesia, however, the efficacy of the test dose to detect an intravascular injection may be greatly reduced. Heart rate increases in only 73% of children after an IV injection of 0.5 μg/kg of epinephrine during halothane anesthesia, suggesting that this marker of an intravascular injection is not

TABLE 42.4 Local Anesthetic Concentration and Its Conversion to mg/mL

completely reliable.[134] Administration of atropine several minutes before the test dose increased the rate of positive responders to 92%, suggesting that vagal tone and the anesthetic's blunting of the sympathetic reflexes are responsible for the reduced sensitivity to the test dose. Test doses during isoflurane anesthesia appear to have the same limitations.[135] With sevoflurane, positive results were obtained in 100% of children if the threshold for a positive response was an increase in heart rate of 10 beats/minute and a dose in excess of 0.5 μg/kg of epinephrine was used; positive results were obtained in 85% if 0.25 μg/kg of epinephrine was used.[136] In all children, a change in the T-wave amplitude was a reliable indicator of intravascular injection with both doses of epinephrine (see Fig. 42.1). All children in that study were pretreated with atropine (10 μg/kg). It is not known if increasing the dose of epinephrine to 1.0 μg/kg or increasing the concentration of epinephrine in the test dose solution to 1 : 100,000 during general anesthesia would increase the sensitivity of the heart rate response test without atropine. Systolic blood pressure increased by more than 10% within 60 seconds of the test dose injection, suggesting that an increase in blood pressure may be a more sensitive indicator of intravascular injection than heart rate during inhalation anesthesia. ST-segment and T-wave changes also appear to be sensitive indicators of intravascular injection of local anesthetic. Observation of the ECG yields a very sensitive indicator of an intravascular injection of bupivacaine with epinephrine. These ECG changes were present in 97% of infants and children who received an IV dose of bupivacaine and epinephrine.[90] These investigators did not confirm the efficacy of pretreatment with atropine on the heart rate. During total IV anesthesia (TIVA) with propofol and remifentanil, however, quite different results have been reported. A prospective study of children who received an IV injection of bupivacaine with epinephrine as a simulated positive test dose during TIVA found that T-wave alterations were inconsistent and could not be relied on as an indicator of intravascular injection.[115] Only blood pressure (particularly diastolic) was a consistent and reliable marker of intravascular injection, increasing more than 10% in all subjects during TIVA.

Even though no test dose regimen is completely infallible and the difficulty of interpreting a negative test dose has resulted in a European Society of Regional Anaesthesia and Pain Therapy (ESRA)/American Society of Regional Anesthesia and Pain Medicine (ASRA) practice advisory deeming its use as discretionary,[137] it appears most prudent to use an epinephrine-containing test dose before administering the therapeutic dose of local anesthetic, particularly if the block is administered in an anatomic location near a blood vessel.[136] The test dose should be repeated before subsequent bolus injections through a catheter. If the drug injection is visualized in real time using ultrasound, test dosing may be less critical, as the actual drug deposition can be visualized during the injection, although this, too, may not be infallible. If the child is receiving a general inhalation anesthetic, blood pressure and the ST-segment configuration, in addition to the heart rate, should be carefully and frequently observed after injection of the test dose.[93] Pretreatment with atropine (10 μg/kg) may increase the rate of detecting an unintended intravascular injection. In addition, the rate of injection may also be a factor in the development of toxicity. If injection is partially or completely intravascular, a slow injection may not exceed the toxic threshold, whereas a rapid injection could. Thus slow, incremental injection of the therapeutic dose of local anesthetic (over several minutes) may further increase the safety of regional blockade, even though repeated injections within a brief period might also result in toxic reactions.

TREATMENT OF LOCAL ANESTHETIC SYSTEMIC TOXICITY

Treatment of toxic reactions to local anesthetic overdose requires knowledge of the signs and symptoms previously described. The signs of local-anesthetic systemic toxicity (LAST), with the exception of the catastrophic cardiovascular events, are all masked by general anesthesia. Indeed, inhaled anesthetics may actually raise the threshold for seizures and thereby delay the detection of toxicity until cardiovascular collapse occurs. Even in the unanesthetized child, the progression from prodromal signs to cardiovascular collapse may be very rapid and the initial resuscitative therapy in some cases may need to be directed at reestablishing circulation and normal cardiac rhythm, including the timely institution of chest compressions, while definitive treatments are being readied. As always, initial management should consist of establishing and maintaining a patent airway and providing supplemental oxygen. The timely administration of a CNS depressant that alters the seizure threshold may prevent seizures. Administration of midazolam (0.05–0.2 mg/kg IV), thiopental (2–3 mg/kg IV), or propofol (1–3 mg/kg IV) effectively prevents or terminates seizure activity; however, the latter two agents are also potent myocardial depressants and should be used with great caution. If seizure activity is present and the airway is not secured, the use of succinylcholine or other relaxant may facilitate tracheal intubation but does not prevent seizure activity. It should be remembered, however, that the acute morbidity from seizures is the result of airway complications (hypoxia and aspiration) and that securing the airway takes precedence over the actual control of the electrical activity of the seizure. CNS excitability is exacerbated in the presence of hypercarbia; it is, therefore, important to mildly hyperventilate children who have seizures. None of these interventions should in any way supplant or delay the administration of lipid emulsion to directly treat the toxic levels of local anesthetic, and help should be sought to carry out these treatments simultaneously. Indeed, two case reports suggest that lipid emulsion may reverse the CNS symptoms of LAST in the absence of cardiovascular collapse and might be a preferable first-line therapy.[138,139]

Advances in the treatment of LAST have dramatically altered the therapeutic interventions that should be initiated in the event of cardiovascular collapse after a large intravascular injection of an amide local anesthetic. IV lipid emulsion has been shown to be effective for resuscitation of cardiac arrest caused by both bupivacaine and ropivacaine toxicity. In dogs, successful resuscitation after cardiac arrest and 10 minutes of external cardiac massage was demonstrated after lipid administration.[140] Although 100% of the dogs that received an infusion of 20% lipid emulsion were successfully resuscitated, none of the controls that received a saline solution infusion survived. A clear relationship between the tissue concentration and the response has also been established.[141] Lipid emulsion was superior to epinephrine, which fared no better than control in restoring metabolic and hemodynamic indexes in a rat model of bupivacaine toxicity.[142] These animal studies have been corroborated by several anecdotal reports of rescue from cardiac arrest in humans that followed intravascular injections of all of the amide local anesthetics in common use.[143–146] The mechanism of action of lipid emulsions to treat bupivacaine toxicity is not entirely understood, but studies in isolated rat heart preparations suggested that the lipid treatment elutes bupivacaine from the myocardium and accelerates the recovery from bupivacaine-induced asystole.[147] This "lipid sink" hypothesis suggests a novel mechanism of action compared

with more conventional antidysrhythmic drugs, and the treatment appears to be more effective as well. An inverse relationship between the concentration of lipid emulsion and the myocardial bupivacaine concentration (greater lipid concentrations were more effective at decreasing the bupivacaine concentration in the myocardium) suggests that this lipid sink hypothesis is correct.[141] Furthermore, a study in infant pigs suggested that administering epinephrine in the initial arrest phase may actually impair resuscitation with lipid emulsion, preventing a sustained response to treatment, and that treatment with lipid alone was superior to both treatment with epinephrine and treatment with lipid plus epinephrine.[148]

The adult and experimental literature suggests that 1 mL/kg of 20% lipid emulsion should be administered over 1 minute and repeated every 3 to 5 minutes, up to a maximum of 3 mL/kg, followed by a maintenance infusion rate of 0.25 mL/kg per minute until the circulation is restored.[149,150] Several pediatric events report success with this intervention, with a range of doses similar to those reported in adults.[144,151,152] However, excess intralipid emulsion has been reported in a child; this reminds us to follow the infusion rate of intralipid carefully in children.[153] Although the dose of lipids in children remains speculative and has not been subject to controlled investigation, the adult guidelines are effective in children as well. There is a consensus that 20% lipid emulsions should be immediately available in any location where regional anesthesia is performed to permit rapid treatment of cardiac toxicity. Although propofol is compounded in a lipid emulsion, it is ***not*** recommended as a substitute for lipid emulsion to resuscitate patients with LAST because the intralipid in propofol formulation includes propofol, which is a myocardial depressant that may impair recovery.

Because the initial stage of cardiovascular toxicity consists of peripheral vasodilation, supportive treatment should include IV fluid loading (10–20 mL/kg of isotonic crystalloid) and, if necessary, titration of a peripheral vasoconstrictor, such as phenylephrine (initial rate of 0.1 μg/kg per minute), to maintain vascular tone and systemic blood pressure at acceptable limits. As toxicity progresses to cardiovascular collapse, profound decreases in myocardial contractility occur, followed by dysrhythmias. In dogs, echocardiography showed that decreased systolic function always preceded the development of dysrhythmias. Many toxic reactions are self-limited because the local anesthetic redistributes throughout the body and plasma concentrations rapidly decrease. All current data, however, strongly suggest that, in addition to the standard cardiopulmonary resuscitation algorithm, lipid infusion should be immediately administered as the next first line of therapy; see the end pages for a suggested treatment algorithm. To date, there are no reports of treatment failure when lipid emulsion was administered in a timely manner.

HYPERSENSITIVITY TO LOCAL ANESTHETICS

Hypersensitivity reactions to local anesthetics are rare.[154–156] Ester local anesthetics are metabolized to *p*-aminobenzoic acid, which is usually responsible for allergic reactions in this group. However, these agents may cause allergic phenomena in children who are sensitive to sulfonamides, sulfites, or thiazide diuretics.[157,158] Among the amide local anesthetics, only one case of a true allergic reaction has been documented. These drugs may contain the preservative, methylparaben, which can produce allergic reactions in those sensitive to *p*-aminobenzoic acid.[158,159] When in doubt, local anesthetic allergy must be ruled out. Detailed protocols are described elsewhere.[160]

Placement of Blocks in Patients Under General Anesthesia

Although concerns about the risks of neural injury in the unconscious patient have been raised in the adult literature, this is based entirely on individual case reports, and the standard of care in pediatric anesthesia has long been to administer most regional blocks to children who are anesthetized. The safety of this practice has now been confirmed by a large prospective study from the PRAN in an unselected cohort of more than 50,000 regional blocks in children.[161] This is the only prospective investigation of regional anesthesia complications in children under general anesthesia, and researchers detected no serious sequelae in any subject. Block placement in children under general anesthesia was deemed as safe as placement in the awake or sedated child, with postoperative neurologic symptoms occurring at a rate of 0.93/1000 (95% confidence interval [CI] 0.7–1.2) compared with 6.82/1000 (95% CI 4.2–10.5) in sedated and awake patients. The authors concluded that administering regional blocks to children under general anesthesia should be considered safe, remain the standard of care, and that prohibitive recommendations based on anecdotal or case reports were unsupported. These conclusions are further supported in a joint consensus statement by the ASRA and ESRA with level B2 evidence.[137]

Equipment

USE OF ULTRASOUND

Recently there has been great interest in the use of ultrasound-guided peripheral nerve blocks in children.[162] The availability of high-resolution portable ultrasound machines has become increasingly commonplace and has revolutionized the practice of regional anesthesia in children. Many argue that it is already the new standard of care for most peripheral nerve blocks.[19] Emerging evidence suggests ultrasound guidance increased success rates, reduced pain scores, prolonged block duration, and reduced time of block performance and the number of needle passes, particularly in younger children.[19] Although this practice requires sophisticated expensive equipment and the acquisition of new skills, it is likely to have an essential role in pediatric regional blockade because most blocks are performed while the child is anesthetized. The cost-effectiveness of acquiring these devices is justified because they serve a dual purpose for placing invasive central lines, peripheral and arterial catheters. Direct visualization of the nerve may facilitate correct placement of the local anesthetic and may also help reduce the total dose of local anesthetic needed for successful blockade. It is imperative to use an ultrasound machine that is capable of scanning superficially because most of the nerves in children are usually less than a few millimeters from the skin. A more in-depth discussion of ultrasound guidance for peripheral nerve blocks can be found in Chapter 43. Because ultrasound might still not be available to every practitioner, a complete discussion of landmark and nerve stimulator–guided peripheral blockade is included in this chapter.

USE OF A NERVE STIMULATOR

The use of a peripheral nerve stimulator is an alternative safe and effective method to locate the nerve to be blocked. Despite the increasing use of ultrasound to guide the placement of peripheral nerve blocks, some anesthesiologists still use nerve stimulation to verify the position of the tip of the needle when ultrasound is not available, or in combination with ultrasound, particularly when imaging is not available or suboptimal. A nerve stimulator is not a substitute for anatomic knowledge, but it is a useful adjunct that allows the performance of the block in an unconscious

or uncooperative heavily sedated child. It avoids the need to seek sensory paresthesias or to rely purely on anatomic landmarks. The tiny amount of current flowing from the uninsulated needle tip stimulates the nerve and produces a motor response when the needle is in close proximity to the nerve. The nerve stimulator is attached to the child as shown in E-Fig. 42.2. The cathode (negative pole) cable is attached to the low-output terminal of the nerve stimulator at one end and to the proximal (uninsulated) shaft of a Teflon-insulated needle via a sterile alligator clip, or to the plug-in lead of a specially designed block needle at the other end (the child). The anode (positive lead) cable is attached to the high-output terminal of the stimulator at the one end and to the child, distant to the block site, via an ECG electrode at the other end.[163,164] The needle is advanced in the appropriate anatomic direction, and when it appears to be in the correct position, the nerve stimulator is adjusted to approximately 0.5 mA with repetitive single-pulse output at 1-second intervals. Local muscle contraction should be minimal at this setting, although direct muscle stimulation can occur and must be distinguished from neural stimulation. The area innervated by the nerves to be blocked is observed for the appropriate muscle contractions. As the uninsulated needle tip approaches the nerve, the muscle contractions will increase in intensity and become weaker as the needle tip moves away from the nerve. One should be able to decrease the current to approximately 0.2 mA with continued elicitation of easily perceptible muscle contraction to ensure that the needle tip is correctly positioned. It should be noted that the injection of even a very small volume of local anesthetic will ablate or dramatically attenuate responses produced by the low current of the nerve stimulator, so the needle position should be optimized before injection (Video 42.1). The responses to stimulation of the radial, median, ulnar, and musculocutaneous nerves are shown in Fig. 42.2.

An insulated epidural catheter may also be advanced cephalad to the abdominal and thorax levels while motor parathesias are stimulated using a low current to determine the dermatomal level of the tip of the catheter.[165,166]

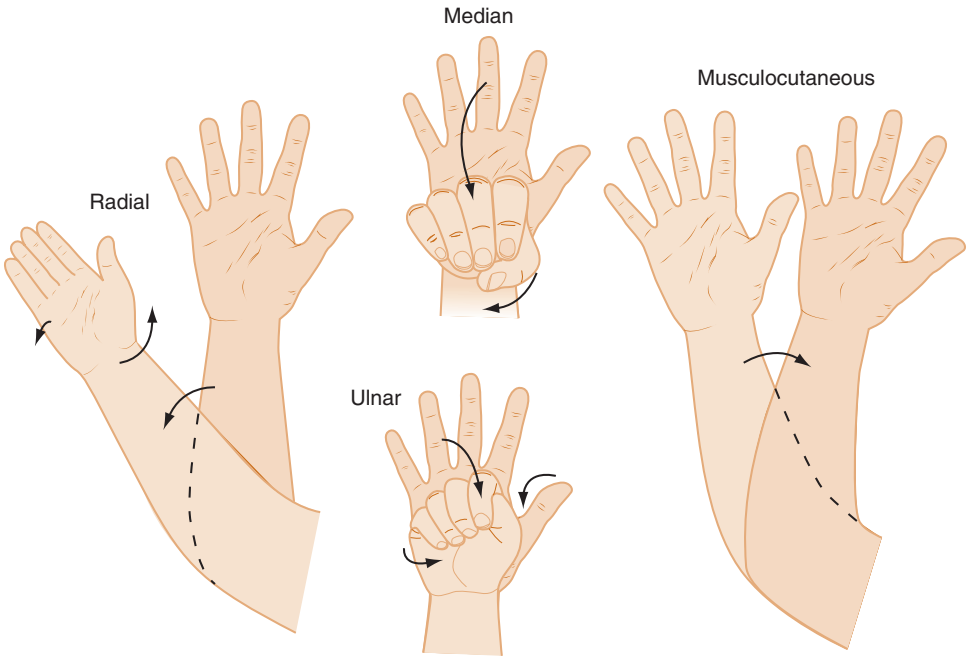
Specific Procedures

CENTRAL NEURAXIAL BLOCKADE

Anatomic and Physiologic Considerations

Several anatomic and physiologic differences between adults and children affect the performance of regional anesthetic techniques. The conus medullaris (the terminus of the spinal cord) in neonates and infants is located at the L3 vertebral level, which is more caudal than in adults.[166a] It does not reach the adult level at L1 until approximately 1 year of age (Fig. 42.3) owing to the difference in the rates of growth between the spinal cord and the bony vertebral column. Thus lumbar puncture for subarachnoid block in neonates and infants should be performed at the L4-5 or L5-S1 interspace to avoid needle injury to the spinal cord. The vertebral laminae are poorly calcified at this age, so a midline approach is preferable to a paramedian one in which the needle is "walked off" the laminae. Another anatomic difference is noted in the sacrum. In neonates, the sacrum is narrower and flatter than in adults (see Fig. 42.3). The approach to the subarachnoid space from the caudal canal is much more direct in neonates than in adults, making dural puncture more likely, so the needle for a caudal block must not be advanced deeply in neonates.[167] The presence of a deep sacral dimple may be associated with spina bifida occulta, greatly increasing the probability of dural puncture. Thus a caudal block may be contraindicated in these children.

The distance from the skin to the subarachnoid space is quite small in neonates (~1.4 cm) and increases progressively with age (Fig. 42.4).[168] The ligamenta flava are much thinner and less dense in infants and children than in adults, which makes the engagement of the epidural needle more difficult to detect and unintended dural puncture during epidural catheter placement



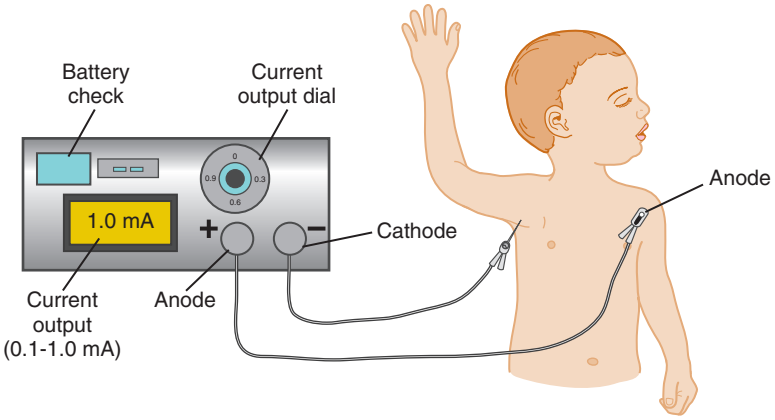


FIGURE 42.2 Characteristic movements of the fingers, wrist, and elbow in response to nerve stimulation of four specific nerves (Modified from Cousins MJ, Bridenbaugh PO, editors. *Neural Blockade in Clinical Anesthesia and Management of Pain*. 2nd ed. Philadelphia: JB Lippincott; 1988:406.)

E-FIGURE 42.2 A nerve stimulator should be used to locate a nerve in a child who is anesthetized, and in the awake, sedated child, to avoid the need to seek a sensory paresthesia. In this example, the brachial plexus is sought in the axilla. Note that the appropriate muscle response to nerve stimulation is elicited at 0.5 mA of current and should continue to respond with 0.2 mA of current.

a greater risk for the infrequent operator. Cerebrospinal fluid (CSF) volume as a percentage of body weight is greater in infants and young children than in adults (E-Fig. 42.3), although these studies are limited.[169–173] This finding may account in part for the comparatively larger doses of local anesthetics required for surgical anesthesia with subarachnoid block in neonates and young infants. The rate of turnover of CSF in infants and children is also greater than that in adults, accounting in part for the much briefer duration of subarachnoid block with any given agent in the former. These anatomic differences necessitate meticulous attention to detail to achieve successful and uncomplicated spinal or epidural anesthesia.

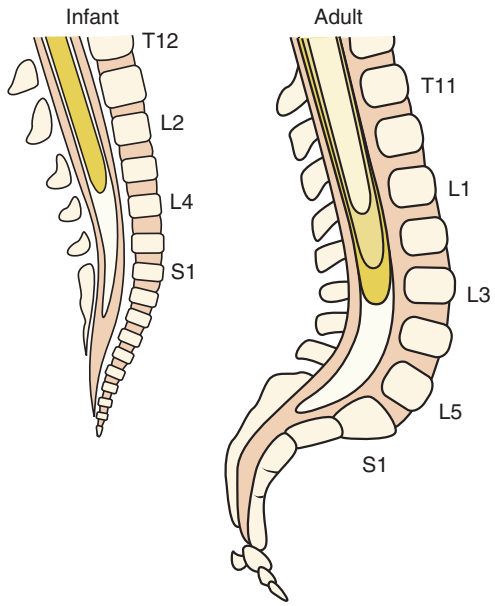

FIGURE 42.3 Anatomic differences between adults and children that affect the performance of spinal and epidural anesthesia; an infant's sacrum (*left*) is flatter and narrower than an adult's (*right*). Note that the tip of the spinal cord in a neonate ends at L3 and does not achieve the normal adult position (L1-2) until approximately 1 year of age. The relative location of the spinal cord with growth to adulthood is illustrated on the *right* as different shades of yellow, the darkest being neonates and the lightest being the final adult configuration.

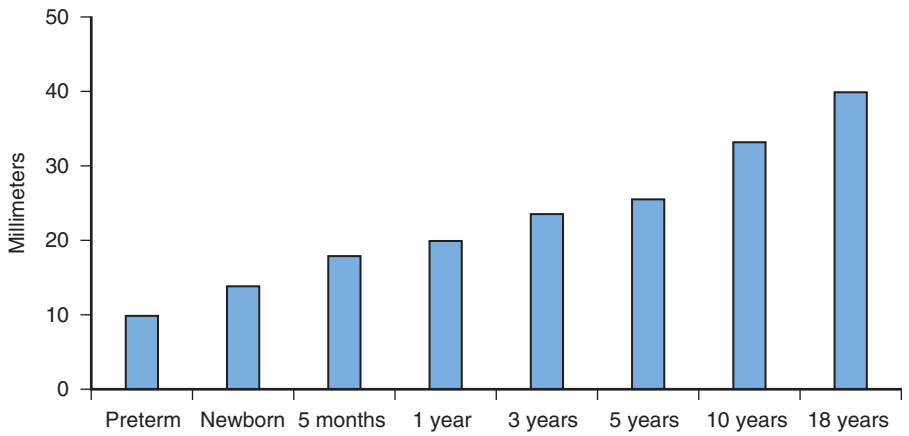
In contrast to older children and adults, subarachnoid and epidural blockade in infants and small children is characterized by hemodynamic stability, even when the level of the block reaches the upper thoracic dermatomes.[174,175] Although heart rate variability, as determined by spectral analysis, is less, the heart rate is preserved, because the parasympathetic activity modulating the heart rate appears to be attenuated in infants who receive spinal anesthesia.[176] This attenuated vagal tone allows the heart rate to compensate for any changes in peripheral vascular tone, an effect that may be the most important factor in preserving hemodynamic stability compared with any other factor, such as the relatively small venous capacitance in the lower extremities in infants, and the relative lack of resting sympathetic peripheral vascular tone.[177] Very high levels of spinal anesthesia can cause significant bradycardia that may require treatment with vagolytics.[178] Nonetheless, data suggest that alterations in vascular resistance and blood flow to some vascular beds may occur, at least under certain conditions, in infants. In former preterm infants who received isobaric bupivacaine for subarachnoid block, cerebral blood flow decreased concomitant with changes in systemic blood pressure, although the conditions under which the baseline pressures were measured were not clear.[179] In a study in which changes in regional temperature were used as a surrogate sign of sympathetic activity, extremity but not truncal temperature increased during subarachnoid block, together with small insignificant changes in blood pressure.[180] In our clinical experience, and that of others including the University of Vermont neonatal spinal anesthesia database, clinically significant systemic blood pressure changes do not occur in young infants after a subarachnoid block.[178]

Central neuraxial blockade can affect the respiratory mechanics of the chest wall and diaphragm by diminution in intercostal muscle activity. This may be particularly relevant in infants and young children, whose chest walls are very compliant because the ribs are minimally ossified.[181] Infants rely more on excursions of the diaphragm to maintain tidal volume to a greater extent than



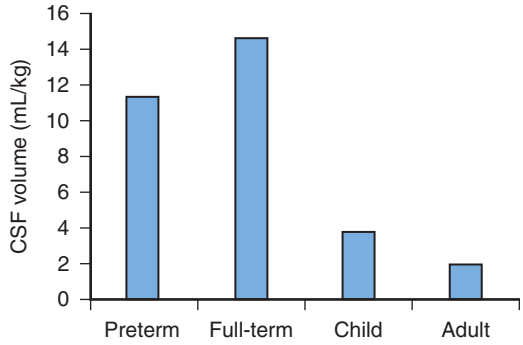


FIGURE 42.4 Distance from the skin to the subarachnoid space as a function of age. (Data from Bonadio WA, Smith DS, Metrou M, et al. Estimating lumbar puncture depth in children. *N Engl J Med*. 1988;319[14]:952–953; Kosaka Y, Sato K, Kawaguchi R. E-FIGURE 42.3 Approximate volume of cerebrospinal fluid (*CSF*) relative to weight and age. Note that preterm and full-term infants have a much greater CSF volume relative to weight than a child or adult; this may account in part for the increased dose (milligram per kilogram) of local anesthetic required in infants to produce a successful subarachnoid block. (Data from Lups S, Haan AMFH, Bailey P. *The Cerebrospinal Fluid*. Amsterdam: Elsevier; 1954; Cutler RWP, Spertell RB. Formation and absorption of cerebrospinal fluid in man. Brain 1968;91[4]:707–720; Otila E. Studies on the cerebrospinal fluid in premature infants. *Acta Paediatr*. 1948;35[Suppl 7]:9–100; Kruse F. Der normale Liquor cerebrospinalis im ersten Lebenstrimenon. *Gesamte Neurol Psychiat*. 1930;128:494–503.)

older children and adults. Paradoxical movement of the chest wall—that is, inward displacement of the rostral edge of the rib cage even in the absence of airway obstruction—occurs during inspiration in healthy infants during deep sleep. This paradoxical chest wall motion increases as the force of diaphragmatic excursion increases during rapid eye movement (REM) and deep sleep.[182] In a similar fashion, suppression of intercostal muscle activity leads to decreased rib cage contribution to ventilation in infants during spontaneous respiration under halothane anesthesia.[183] When respiratory inductance plethysmography was used to study rib cage and diaphragmatic contributions to breathing in seven former preterm infants who underwent spinal anesthesia for herniorrhaphy,[181] high thoracic (T2-4) levels of motor blockade were achieved, outward motion of the lower rib cage decreased, and paradoxical motion of the lower rib cage was noted in more than half of the infants. The diaphragmatic contribution to respiration, as estimated by abdominal displacement, was increased in all infants. This suggests a shift of respiratory workload from rib cage to diaphragm in compensation for the loss of the intercostal muscle contribution to breathing. Other factors, such as altered conformation of the diaphragm relative to the chest wall, with concomitant changes in the size of the zone of apposition (the portion of the anterior diaphragm that lies against the lower rib cage), may also contribute. These measurements were compared with each infant's measurements before administration of the spinal anesthetic, but it is not known if these findings would be different if measured in unanesthetized infants during deep sleep. It is likely that these effects are well tolerated and that the ability of the diaphragm to compensate for loss of the contribution of the rib cage to breathing is adequate in the vast majority of infants.

Upper abdominal and thoracic surgery causes changes in respiration in the postoperative period by neurally inhibiting diaphragmatic function.[184–186] The afferent pathways that induce this inhibition are presumed to arise from the chest and abdominal walls and perhaps the diaphragm itself, although they have not been conclusively identified.[187] Contrary to popular belief, pain itself is not a major contributor to postoperative respiratory dysfunction. Numerous studies have demonstrated that opioids administered either parenterally or in the central neuraxis exert limited impact on postoperative respiratory function.[188–190] Regional blockade, on the other hand, has been shown to improve several indexes of postoperative respiratory function.[17,185,191] These data suggest that regional anesthesia has an important role in attenuating diaphragmatic dysfunction postoperatively. Although the mechanism for this improvement has been attributed to blockade of the putative inhibitory neural pathways, other data suggest that alterations in respiratory mechanics, in particular an increase in the resting length of the diaphragm to its control value and a shift in the workload from the rib cage to the diaphragm, may have a greater role in this regard.[16] These data also suggest that the beneficial effects of regional anesthesia on postoperative respiratory function may, in part, be related to the degree of motor blockade. It is not known if the preoperative administration of regional blockade enhances respiratory function compared with postoperative application of the blockade, as has been postulated in "preemptive analgesia."

Spinal Anesthesia

Spinal anesthesia has been successfully performed in children since the first published reports from 1900 to 1910.[192–195] The observation of postanesthetic apnea in former preterm infants led to a resurgence in the use of spinal anesthesia in infants, particularly for herniorrhaphy in the latter 20th century.[196,197] Spinal anesthesia has even been administered for myelomeningocele repair[198] by direct injection of tetracaine into the sac and supplemented as needed by direct application of tetracaine by the surgeon. It has also been used with success for a variety of other surgical procedures performed on infants.[198–201]

It has been recognized since the early 1980s that preterm and former preterm infants are at significant risk for developing perioperative apnea after undergoing general anesthesia.[202–204] The reason for these postanesthetic apneas is not well understood. Spinal anesthesia has been proposed as an alternative to general anesthesia to reduce the incidence of perioperative apnea. However, when the spinal anesthetic was supplemented with ketamine, the incidence of postoperative apnea was even greater than with general anesthesia.[205] In addition to several retrospective reports, some prospective analyses of infants undergoing spinal anesthesia demonstrated fewer or no episodes of postanesthetic apnea compared with those undergoing general anesthesia.[197,205] Although most of these studies were confounded by the absence of preoperative and postoperative pneumograms to control for baseline apnea and bradycardia, a prospective investigation confirmed that neonates who received a subarachnoid block exhibited no changes in heart rate and oxygen saturation when preoperative and postoperative pneumograms were compared.[206] The infants in the general anesthesia group, however, experienced both reduced oxygen saturations and slower heart rates in the postoperative period than those in the spinal anesthesia group, changes that were more severe than those observed preoperatively. These events were not consistently associated with central apnea, defined as a cessation of respirations lasting more than 10 seconds with no demonstrable chest wall movement. These data suggest that the several case reports of apnea after subarachnoid block may have occurred even in the absence of the anesthesia and surgery, but one cannot entirely discount that they may have indeed been caused by the anesthetic or, perhaps, by the stress of surgery itself. Although the data from this study are persuasive, we remain cautious and have not modified the use of routine postoperative monitoring in these infants. The most recent prospective study of spinal versus general anesthesia included apnea as a secondary outcome variable and found that the frequency of early apnea (first 30 minutes after the end of anesthesia) was reduced, but not eliminated, after spinal anesthesia, although the frequency of late apneas (up to 12 hours) was similar in both groups.[207] However, these data should be interpreted with caution as they included infants who were not premature, the data were based on intermittently observed apneas rather than recorded monitored apneas (i.e., without postoperative pneumograms), and reported an overall frequency of apnea that was less than that reported in previous studies. Until studies with greater numbers of infants can distinguish which criteria would define a group with a reduced risk of apnea, all former preterm infants less than approximately 60 weeks postconceptional age should be managed similarly, regardless of the anesthetic technique.[208–211] We believe, however, that the best data available at this time suggest that regional anesthesia is preferred in former preterm infants for whom it would provide adequate operating conditions.

Epidural anesthesia has also been reported for lower extremity and abdominal surgery in former preterm infants. Continuous epidural anesthesia, and even continuous spinal anesthesia, for surgical procedures that outlast the duration of a "single-shot" subarachnoid block have also been reported and are alternative strategies that can achieve the same goals as single-injection

subarachnoid block. The risk of LAST with a continuous caudal epidural blockade must be recognized; some have suggested that 2,3-chloroprocaine may be the most prudent agent in this situation.[212] For cardiac surgery, high spinal anesthesia with tetracaine (2.4 mg/kg) has been used for ligation of the patent ductus arteriosus. Because spinal anesthesia in infants is associated with hemodynamic stability, it has been advocated as an ideal anesthetic for cardiac catheterization in infants with congenital heart defects and has been used, in conjunction with a light general anesthetic, for cardiac surgery.[199,213–216] Those infants whose tracheas were not intubated before surgery were successfully extubated immediately after the operation. Hemodynamic stability was maintained without the use of inotropic agents in most children. A series of infants with gastroschisis closures, as well as open pyloromyotomies, have been reported using subarachnoid block.[201,213]

Concerns regarding the potential for adverse neurodevelopmental sequelae of general anesthetics administered to infants has led to additional interest in spinal anesthesia even in term infants. The most recent studies, including one large prospective, randomized controlled trial, show that for procedures lasting an hour or less there is no difference in neurodevelopmental outcome between spinal and general anesthesia (see Chapter 25).[217,218]

When an effective block[38,210,219–222] is achieved, most neonates will fall asleep as a result of *deafferentation*, a reduced level of consciousness because of diminished sensory input to the reticular activating system from the periphery, a mechanism confirmed in an animal model using spectral edge frequency analysis.[223] Sedation levels have been measured using bispectral index and spectral edge frequency analysis in infants undergoing spinal anesthesia without the use of adjunctive agents.[224] The investigators found a decrease in bispectral index, from 97 to 66.5 after 30 minutes, and in spectral edge frequency, from 26.1 to 9.9. These data indicate that sedation with dense regional blockade is a real physiologic phenomenon and can be used to the anesthesiologist's advantage during spinal anesthesia in infants. They also suggest that if sedation is administered to these infants, smaller doses than usual should be considered to avoid oversedation.

Technique

After routine monitors (ECG, blood pressure cuff, pulse oximeter, and precordial stethoscope) are affixed, the child is placed in a sitting or lateral decubitus position. For neonates and infants, care must be taken to avoid excessive flexion of the neck because this position may obstruct the airway (Fig. 42.5A).[225,226] The sitting position may aid in recognizing successful dural puncture increasing CSF hydrostatic pressure, which increases flow through the spinal needle. The skin is infiltrated with a minute quantity of 1% lidocaine (<0.2 mL is sufficient; the authors use a 30-gauge needle on an insulin syringe); alternatively, a small amount of EMLA or other transcutaneous local anesthetic cream is applied to the infant's lumbar area at least 1 hour before spinal placement. The lumbar puncture is performed using a midline approach with a 22-gauge or smaller, 1.5-inch styletted spinal needle (see Fig. 42.5B and C). We do not routinely use a 25-gauge spinal needle because of the time delay between entering the subarachnoid space and the appearance of CSF in the needle hub. This delay may make it difficult to recognize that the subarachnoid space has been entered. Whitacre, Sprotte, Marx, and other "pencil point" needles are available in pediatric sizes.[227,228] Lumbar puncture is performed only at the L4-5 or L5-S1 interspaces, for reasons previously described. The

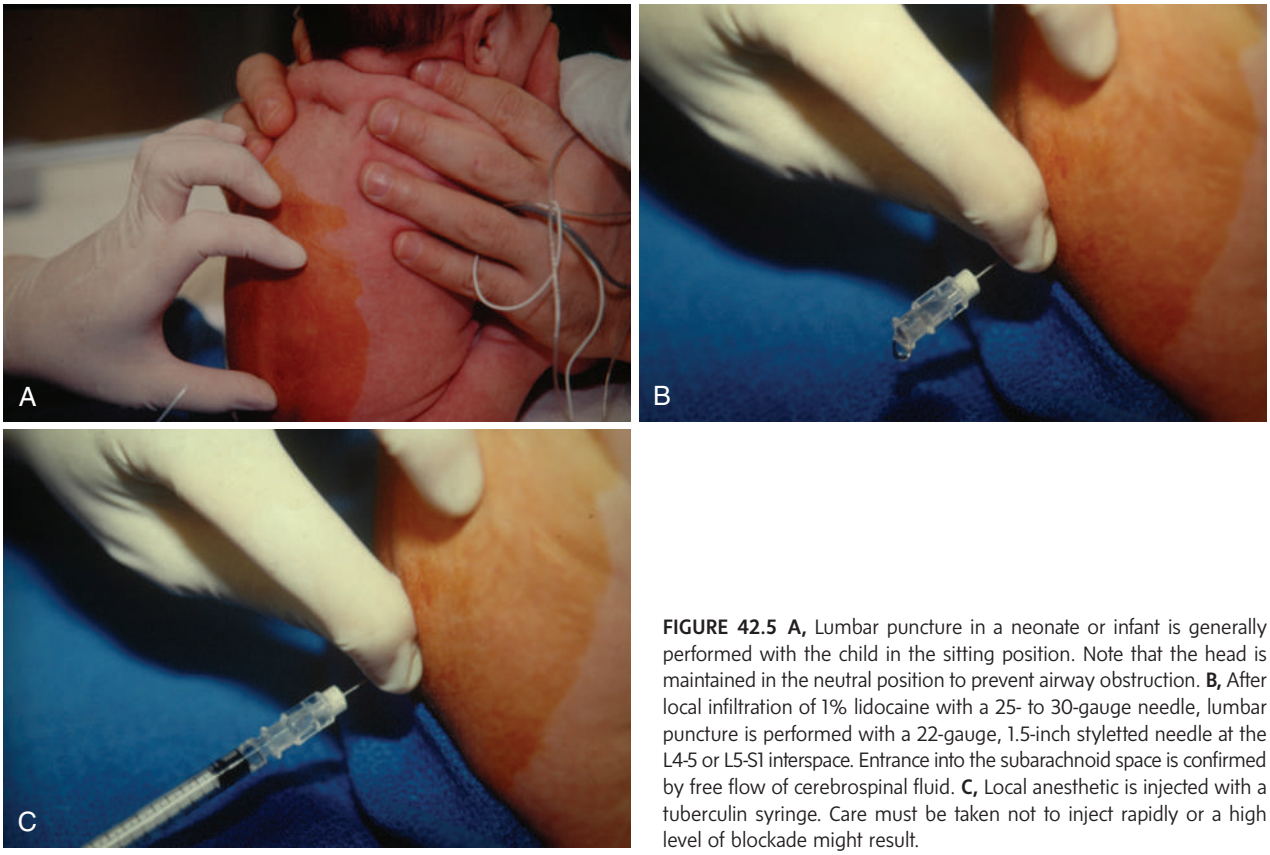

FIGURE 42.5 A, Lumbar puncture in a neonate or infant is generally performed with the child in the sitting position. Note that the head is maintained in the neutral position to prevent airway obstruction. **B,** After local infiltration of 1% lidocaine with a 25- to 30-gauge needle, lumbar puncture is performed with a 22-gauge, 1.5-inch styletted needle at the L4-5 or L5-S1 interspace. Entrance into the subarachnoid space is confirmed by free flow of cerebrospinal fluid. **C,** Local anesthetic is injected with a tuberculin syringe. Care must be taken not to inject rapidly or a high level of blockade might result.

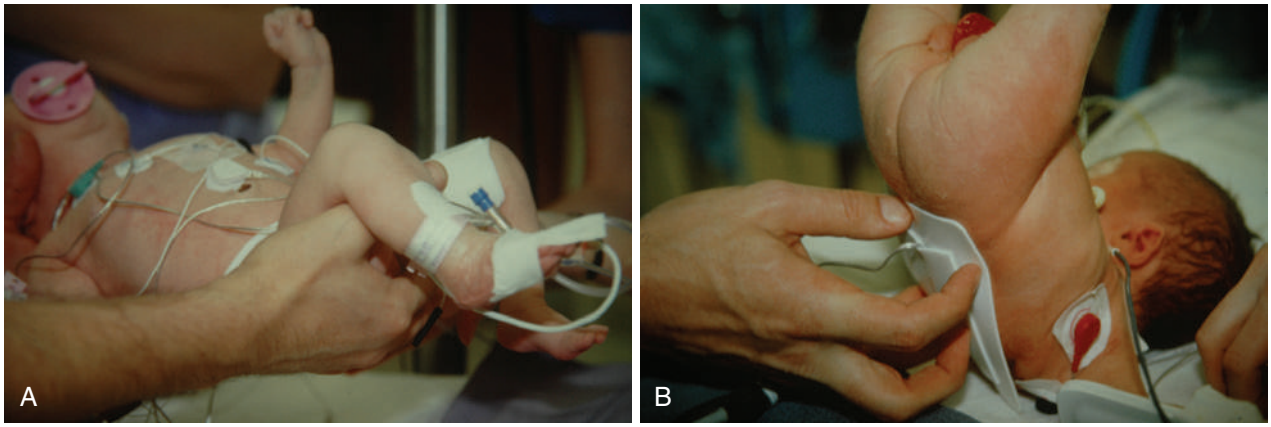

FIGURE 42.6 A, The proper method of applying an electrocautery pad; the infant's entire body is elevated while maintaining the horizontal position or the infant is log-rolled along its long axis to avoid excessively high spread of subarachnoid blockade. **B,** Improper method of applying an electrocautery pad in a neonate after subarachnoid administration of local anesthetic; the legs should never be elevated as this may lead to a high or total spinal block.

subarachnoid space in infants less than 60 weeks postconceptional age is approximately 1.5 cm from the skin (see Fig. 42.4); care must be taken not to pass the needle too deeply, passing beyond the subarachnoid space.[168] When the subarachnoid space is located, the local anesthetic is slowly administered. Immediately thereafter, the child is placed in the supine position. Once the block is in place, the child should remain completely horizontal to preclude cephalad spread of the local anesthetic. If the legs are raised soon after the block is placed, a "total" spinal anesthetic may occur (Fig. 42.6A and B).[229] The grounding pad is best applied by lifting the entire infant while maintaining the body in the horizontal plane or simply log-rolling the infant, or the pad can be affixed to the anterior thigh if sufficient space and muscle mass are available. *The legs should never be raised above the torso once the spinal block is in place as this may produce a high spinal block.*

Because spinal anesthesia maintains remarkable hemodynamic stability in infants, some pediatric anesthesiologists have advocated starting the IV line after the onset of lower extremity analgesia. Although this may be relatively safe in this setting, if a "total spinal" occurred and the airway had to be instrumented or resuscitation drugs had to be administered, having IV access before the spinal block would be important. In addition, should IV access prove difficult, valuable operating time and spinal block time would be lost while searching for a suitable vein. We have found that applying the pulse oximeter to a toe of one leg and the blood pressure cuff to the thigh of the other allows the neonate to remain undisturbed during the surgical procedure (e.g., inguinal herniorrhaphy) (E-Fig. 42.4).

Because the addition of sedatives has been associated with postanesthetic apnea with an incidence at least as great as that of general anesthesia, we try to avoid all sedatives, especially ketamine.[205] Most neonates will fall asleep once the block has set. A pacifier dipped in 50% dextrose will also help the infant to remain quiet and still. Gentle restraint is necessary in many cases, particularly during the most stimulating phase of the operation, when traction is applied to the hernia sac, and the peritoneum. It is particularly important for the infant to be still and not bear down when the hernia sac is dissected to avoid both tearing of the sac and extrusion of abdominal contents through the open hernia. Should the infant become agitated or unsettled at this point, one should administer inhalational anesthesia by mask until the stimulation abates, allowing the operation to proceed without difficulty.

Selection of Drug

NEONATES AND INFANTS. The proportional dose of local anesthetic required for subarachnoid block in neonates is much greater than that required for adults. When calculated on a per-kilogram basis, the drug requirement in neonates is 5- to 10-fold greater than that in adults to achieve a similar dermatomal distribution. In addition, the duration of the relatively larger dose lasts only about one-third to one-half as long as in the adult. This appears to be due in part to the greater volume of CSF per kilogram and to the more rapid turnover of CSF in neonates. The drugs that have commonly been used for spinal anesthesia in neonates and infants include tetracaine, bupivacaine, and lidocaine.[169,230–234] Hyperbaric bupivacaine (0.75 mg/kg of 0.75% bupivacaine in 8.25% dextrose), isobaric bupivacaine (0.5–1.0 mg/kg of a 0.5% solution), or hyperbaric tetracaine (0.75–1.0 mg/kg [equal volumes of tetracaine 1.0% and 10% dextrose]) with 0.01 mL/kg of epinephrine (1 : 100,000) is commonly used to achieve an adequate height and duration of blockade. Isobaric levobupivacaine (1 mg/kg of 0.5% levobupivacaine) has also been reported.[235] Isobaric and hyperbaric bupivacaine have a reported duration similar to that of tetracaine, although the duration of action of the isobaric solution is slightly greater than for the hyperbaric solution.[233,234,236] Epinephrine prolongs the duration of tetracaine blockade by more than 30%[237] but does not prolong bupivacaine blockade.[237] This can be best compounded by drawing a 1 : 1,000 epinephrine solution into a tuberculin or glass syringe and expelling the contents, leaving only a residual amount of epinephrine "wash" in the hub of the needle. These doses usually provide adequate analgesia for inguinal hernia repair with a duration of motor block of 70 to 90 minutes and a dermatome height in the mid to upper thoracic region. For surgeries of limited duration that involve a lower extremity, smaller doses (0.5–0.6 mg/kg) may be used. A dose-ranging study reported that the addition of clonidine (1 μg/kg) prolonged the duration of blockade from a mean of 67 minutes (plain bupivacaine) to 111 minutes.[238] The use of larger doses of clonidine (2 μg/kg), however, caused transient hypotension and apnea, which required treatment with caffeine. Although lidocaine (2 mg/kg) is useful for a block of brief duration,

E-FIGURE 42.4 During spinal anesthesia, the intravenous catheter and oximeter probe are placed on one leg and the blood pressure cuff is applied to the other. The infant is thus allowed to remain undisturbed.

TABLE 42.5 Local Anesthetics for Spinal Anesthesia in Neonates and Infants

Anesthetic Drug	Usual Dose (mg/kg)	Range (mg/kg)
1% Tetracaine in 10% dextrose	0.75	0.75–1
0.5% Bupivacaine (isobaric)	0.8	0.5–1
0.75% Bupivacaine in 8.25% dextrose	0.75	0.5–1

such as for a muscle biopsy of the lower extremity, the duration of useful block is only approximately 30 minutes. In light of concerns regarding lidocaine in the subarachnoid space, we no longer recommend its use in infants.[239–241] A summary of doses for commonly used local anesthetics for subarachnoid block in neonates and infants is provided in Table 42.5.

CHILDREN. There is little information regarding the dose of local anesthetics for spinal anesthesia in children, as subarachnoid block is much less commonly used beyond infancy. When a regional technique is desirable in children, an epidural or caudal block together with a "light" general anesthetic is often preferred. For spinal anesthesia, 0.3 to 0.5 mg/kg of bupivacaine (5 mg/mL concentration) may be used in children 2 months to 12 years of age.[228] Doses of 0.3 to 0.4 mg/kg hyperbaric tetracaine have been used for subarachnoid block in children between 12 weeks and 2 years of age, and 0.2 to 0.3 mg/kg in children older than 2 years of age.[242–244] These limited data suggest that the dose requirement for spinal anesthesia decreases with increasing age. Because there are few data available on drug doses and the height of anesthetic block produced in this age group, it is prudent to use these values as an appropriate reference point and to revise the dose as determined by clinical experience.

Complications

Complications of spinal anesthesia include block failure, total spinal anesthesia, post–dural puncture headache, backache, neurologic sequelae, and the risk of lumbar epidermoid tumors if nonstyletted needles are used for subarachnoid puncture.[227–229,245–250,251]

Block failure is a risk with any regional anesthetic technique, although this is uncommon with spinal anesthesia in infants. The General Anesthesia Compared to Spinal Anesthesia Study (GAS) consortium reported that fewer than 10% of patients in that trial required conversion from spinal to general anesthesia, and just 6.8% required a brief period of sedation. The overall failure rate for spinal anesthesia, however, was approximately 19%.[207,211,235]

Total spinal anesthesia has been reported in neonates. It is most commonly manifested by apnea with no change in systemic blood pressure or heart rate, although should pronounced bradycardia occur, a reduction in cardiac output is likely and should be treated aggressively.[178,229,252] It can occur after a dose of as little as 0.6 mg/kg of tetracaine.[229] Alteration in position, particularly by raising the lower body above the level of the head or thorax, may be the most common cause of a high spinal block. Although the rate of administration of the local anesthetic does not appear to affect the level of spinal anesthesia in adults, similar studies have not been conducted in neonates or infants.[253] It is possible that factors, such as the use of a relatively large-bore needle (22-gauge) and a tuberculin syringe providing the means for injecting with high pressure, along with the small distance between vertebrae, combine to make the rate of injection an important consideration in neonates and infants by producing unintended barbotage. We have observed this complication with rapid drug administration. Management consists of assisted or controlled ventilation until the return of spontaneous respiratory function.

The incidence of post–dural puncture headache appears to be infrequent in infants and children, although the incidence in preverbal children is unknown. An early study reported an incidence of spinal headache of approximately 2% using 20- to 22-gauge needles in children 2 to 17 years of age.[244] However, no details were provided about the distribution of headache with respect to age. Other studies reported a 5% incidence of headaches in children ranging from 2 months to nearly 10 years of age, but again, no age distribution was cited.[227,228] A prospective study of pediatric oncology patients undergoing diagnostic or therapeutic lumbar puncture with a 20-gauge needle reported that post–dural puncture headache was relatively rare in children younger than 13 years of age.[246] In most instances, the headaches were mild and resolved spontaneously. It is not entirely clear why young children should have a very low incidence of post–dural puncture headache. Several possible reasons include reduced CSF pressure,[247] the increased rate of CSF production, and hormonal changes with age.[246] As more pediatric regional anesthesia equipment becomes readily available, we expect that the use of pencil point (e.g., Whitacre, Marx, or Sprotte) needles will become more commonplace and will further reduce this already low incidence of headache.

Backache is a frequent postoperative complaint after both general and regional anesthesia in adults. It is thought to occur because of flattening of the normal lordotic lumbar curve secondary to muscle and ligament relaxation that occurs with spinal anesthesia. The incidence in children is unknown. Neurologic sequelae after spinal anesthesia are exceedingly rare. There are no reports in the literature of permanent neurologic injury caused by subarachnoid block, but good data in children are lacking. There have been no cases detected in more than 1700 consecutive spinal anesthetics at the University of Vermont Medical Center, in another large series from Schneider Children's Medical Center (Petah Tikva, Israel), or in the PRAN database.[11,126,252]

Epidural Anesthesia

Epidural anesthesia administered by the caudal, lumbar, or thoracic route can be used for the same types of surgical procedures and indications as spinal anesthesia. The most common indication, however, is for augmentation of general anesthesia and for postoperative pain management. The details of postoperative epidural infusions are discussed in Chapter 44.

Caudal Epidural Anesthesia

Caudal epidural anesthesia is the regional technique used with the greatest frequency in children, although this may decline as familiarity with lumbar and thoracic epidural techniques and peripheral nerve blocks increases. Although epidural use was first described in 1933,[254] it was not until the early 1960s that caudal anesthesia gained any degree of popularity.[254–269] Improvements in catheter material, the availability of pediatric-sized needles and catheters, and the growing recognition of the benefits of regional analgesia in general have increased the interest in this technique for children. Caudal anesthesia has a well-deserved reputation for safety in children. In a prospectively collected cohort of more than 18,000 children, the PRAN investigators detected no sequelae after caudal blockade.[270]

TECHNIQUE. The child is placed either in the lateral decubitus or prone position with a small roll beneath the anterior iliac crests.

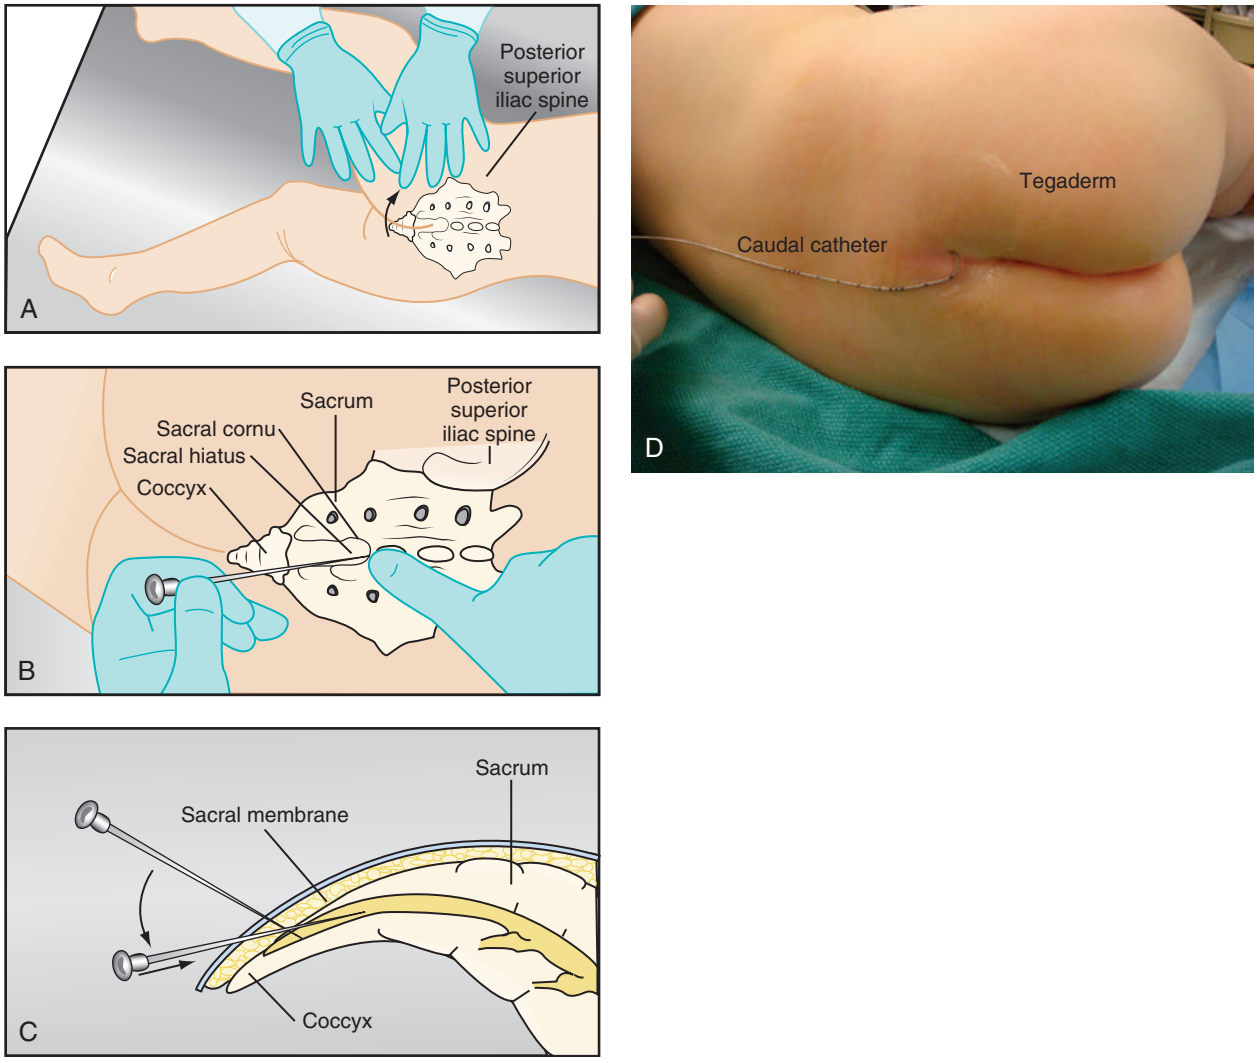

FIGURE 42.7 Performing a caudal block. **A,** The child is placed in a lateral decubitus position. **B,** The posterior superior iliac spines are located and the sacral cornu is palpated; an intravenous needle, an intravenous catheter, or a Crawford needle of appropriate size is advanced at an angle of approximately 45 degrees until a distinct "pop" is felt as the needle pierces the sacrococcygeal ligament. **C,** The angle of the needle with the skin is reduced parallel to the sacrum, and the needle or intravenous catheter is advanced into the caudal canal. **D,** If a continuous technique is used, the caudal catheter is advanced to the mid level of the surgical incision (it usually readily passes in children younger than 5 years of age) and the introducing needle or catheter is withdrawn. The catheter is secured with benzoin and an occlusive dressing.

The cornua of the sacral hiatus are most easily palpated as two bony ridges, about 0.5 to 1.0 cm apart, when the examiner moves his or her finger in a medial to lateral direction (Fig. 42.7A). When the sacral cornua are not prominent or easily appreciated, it may prove easier to locate the space by palpating the L4-5 intervertebral space in the midline and then palpate moving caudally until the sacral hiatus is reached. Because the space between the sacrum and coccyx may be mistaken for the sacral hiatus, the latter technique may make identification of the landmarks easier. The proper location is often, but not always, located just at the beginning of the crease of the buttocks. A short-bevel styletted needle, 22-gauge, should be used because a long-bevel needle may increase the risk of intravascular injection.[271] Some practitioners think that a styletted needle avoids the possibility of introducing a dermal plug into the caudal space, whereas others think that if the skin and subcutaneous tissues are punctured with an 18-gauge needle, an IV catheter can be inserted without entraining a dermal plug and transferring it to the subarachnoid space. Still others suggest that if an IV catheter is used, it should be inserted with the bevel facing down because once in place, easy advancement of the IV catheter off the needle suggests that the caudal canal has been entered and may reduce the risk of intravascular placement. Although smooth and easy advancement of the cannula off the stylet is not a completely reliable sign that placement is correct, difficulty in doing so, or buckling of the catheter, is virtually always a sign that the needle has penetrated bone or another extraspinal structure. The needle is initially directed cephalad at a 45- to 75-degree angle to the skin until it "pops" through the sacrococcygeal ligament (see Fig. 42.7B) into the caudal canal, which is contiguous with the epidural space. If bone is encountered before the sacrococcygeal

ligament is reached, the needle should be withdrawn 1 to 2 mm, the angle with the skin decreased to approximately 30 degrees, and the needle again should be advanced in a cephalad direction until the sacrococcygeal ligament is pierced (see Fig. 42.7C). As the needle is advanced slightly farther, bone (the anterior table of the sacrum) may be encountered. Orientation of the needle should be altered slightly before it is advanced, parallel to the plane of the child's back. The needle should then be advanced into the caudal-epidural space with the needle advanced only a few millimeters. Advancing the needle any farther should not be attempted because the dural sac lies relatively caudad in infants and may be entered a very short distance from the ligament (Video 42.2).[167,272]

Once it is confirmed that neither blood nor CSF has been aspirated, a test dose of local anesthetic is administered. If neither ECG changes during inhalational anesthesia nor blood pressure changes during TIVA are evident after the test dose, the remainder of the dose of local anesthetic should be slowly injected in an incremental fashion over 1 to 2 minutes while observing the ECG for peaked T waves and changes in heart rate and/or blood pressure. We strongly recommend the use of a test dose, even with single-shot caudal anesthesia. In addition to the risk of intravascular injection, it is also possible that the needle could be misplaced in the intramedullary cavity of the sacrum. Intraosseous injection of drugs results in very rapid uptake, similar to direct IV injection. The authors are aware of at least one case of circulatory collapse that occurred from this complication when a test dose was not used.

The block may be placed before the onset of surgery without a significant decrement in duration of postoperative analgesia for short surgical procedures.[273] This has the advantage of reducing the amount of general anesthesia needed, resulting in a more rapid recovery. In addition, there is adequate time for the block to "set up," improving the chances of a pain-free awakening.

Inserting a catheter for a continuous caudal block follows a similar procedure (Video 42.3). First, one should determine the length of catheter that should be inserted into the caudal space by measuring the distance from the sacral hiatus to the desired site where the catheter tip will be positioned. Instead of a small-gauge needle or catheter, an 18-gauge IV catheter[274] or an 18-gauge Crawford needle is used to enter the epidural space (see Fig. 42.7D). Because the internal diameters of different IV cannulae vary, it is advisable to test that the epidural catheter easily passes through the IV cannula before puncturing the sacrococcygeal membrane. Once the epidural space has been accessed, the IV catheter and needle are advanced several millimeters. The catheter is then advanced off the needle several millimeters. Localization of the IV catheter tip in the epidural space is confirmed by lack of resistance to the injection of a small volume of saline solution and the absence of CSF or blood. During injection, the area of the back overlying the IV catheter tip should be palpated; swelling or a fullness on injection of local anesthetic indicates a subcutaneous (SC) rather than an epidural catheter placement. It is also possible to use ultrasound to confirm the injection and cannula in the epidural space.[275] The epidural catheter is advanced through the IV catheter and the IV catheter is withdrawn. After confirming the presence of neither blood nor CSF, a test dose of local anesthetic containing 1:200,000 epinephrine may be administered (see earlier). Test doses should be repeated each time a catheter is reinjected with a bolus dose of local anesthetic.

For those younger than 5 years of age, the catheter can often be advanced to any level desired without exiting a dural sleeve or becoming tangled or knotted, although catheter misplacements that were not suspected clinically, have been identified using epidurograms.[38,276] It is thus prudent to use some method of localization when a catheter is threaded cephalad more than several centimeters. Epidurograms are easily performed in the operating room when the catheter is placed. A small (0.5 to 2 mL maximum) volume of iopamidol is injected and imaged using fluoroscopy. A characteristic "bubbly" pattern in the midline is diagnostic of proper placement (Fig. 42.8). In addition to confirming placement in the epidural space and the location of the catheter tip, spread of the contrast may give a sense of how much volume is needed to cover the desired dermatomes. Besides epidurography, there are two other useful localizing techniques. The Tsui stimulating catheter, a catheter with an electrode at its uninsulated proximal end that is connected to a low voltage nerve stimulator, produces motor twitches in the myotome at the catheter's tip. One can mark the catheter's advance by watching the motor paresthesias move up the legs, abdomen, and thorax. Ultrasound has also been used to visualize the catheter in the epidural space, although this technique becomes more difficult with increasing age because the posterior spinal column ossifies and the technique is frequently technically impossible in children older than 6 months of age.[277,278] For infants who weigh less than 5 kg, successful catheter advancement may be less reliable than in older children, and an epidurogram, ultrasound, or use of a stimulating catheter may be needed to confirm proper placement of the catheter tip if the catheter is

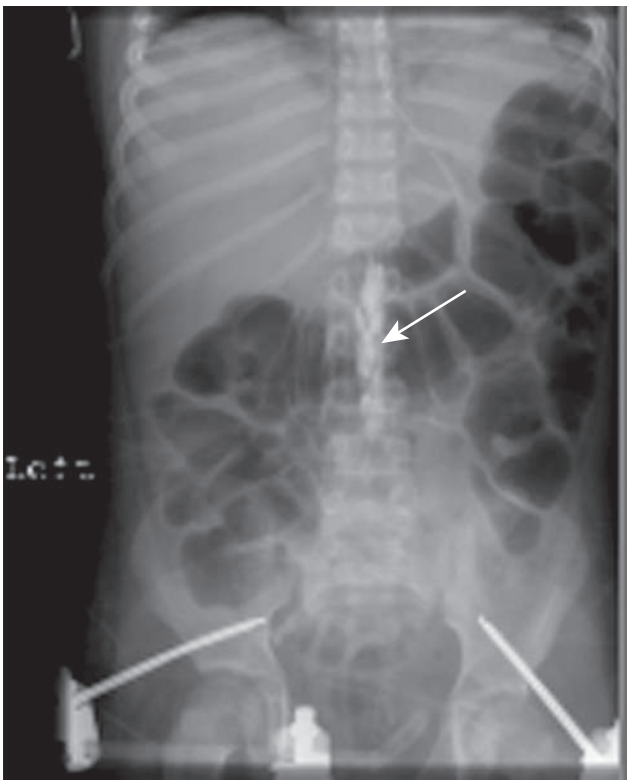

FIGURE 42.8 Epidurogram, performed with 0.5 to 2 mL (maximum) of iopamidol nonionic contrast agent, demonstrating the "bubbly" appearance of contrast in the epidural space (*arrow*). Note the central localization of contrast within the borders bounded by the vertebral bodies. On occasion, contrast may be seen only on one side of the epidural space, with a sharp line of demarcation in the midline. This usually results in unilateral blockade, and is theorized to result from septation or some other impediment to bilateral spread of anesthetic within the epidural space.

not radiopaque.[279] An epidurogram can be useful in any situation in which the catheter is threaded or when there is concern for proper catheter position, although the routine use of an epidurogram is not standard practice. We usually strive to place the catheter tip at a level near or at the midpoint of the dermatomes encompassing the surgical incision. This position allows a more specific site of administration for both intraoperative anesthesia and continuous infusions for postoperative pain management, with the attendant advantage of being able to use reduced doses of medication. If the catheter does not pass easily to the desired level, it should be withdrawn several millimeters and a localizing technique used to ascertain its location. The catheter should never be forced or advanced against resistance. It is thus prudent to use some method of localization when a catheter is threaded cephalad more than several centimeters.

Because caudal catheters are at increased risk of contamination from fecal soiling in children who are not yet continent of stool, meticulous attention to the dressing is necessary. Our practice is to use Mastisol (Ferndale Pharma Group, Ferndale, MI) or tincture of benzoin to secure the catheter with several layers of an adherent clear dressing, such as Tegaderm (3M, St. Paul, MN) or OpSite (Smith & Nephew, Andover, MA), to affix the dressing in the crease of the buttocks (Video 42.4). This transparent dressing permits the observation of the insertion site, which is the most likely source of infection (see later). A piece of single adhesive-edged plastic drape (e.g., Steri-Drape 1010; 3M, St. Paul, MN) can be affixed just caudad to the lower edge of the dressing in a similar manner; this helps prevent direct soiling of the dressing. If there is any question of contamination, the catheter should be promptly removed.

In an observational study of 307 neonates with caudal or epidural catheters, 2.9% of infants had a catheter contamination requiring premature removal, which contributed to an overall complication rate of 13.3% (95% CI 9.8%–17.4%). Catheter malfunction was the primary complication (4.8%).[280]

Lumbar and Thoracic Epidural Anesthesia

It may be preferable to place epidural catheters at a lumbar or thoracic interspace when the area of operation is innervated by higher dermatomes. Advantages include less risk of contamination by stool and urine, closer proximity to the desired tip location, and smaller volume of drug required for a more cephalad dermatomal level (if the caudal catheter is not threaded cephalad). Both lumbar and thoracic epidural catheters may be safely placed in anesthetized infants and children by experienced anesthesiologists.[281]

The technique for both lumbar and thoracic epidural catheter placement is similar to that in adults, with several important differences (see Chapter 43 for ultrasound techniques). The midline approach is most commonly used, for the same reasons cited earlier regarding subarachnoid block. The ligamenta flava are considerably thinner and less dense in infants than in older children and adults. This makes recognition of engagement in a ligament more difficult and requires both extra care and slower, more deliberate passage of the needle to avoid subarachnoid puncture. It takes experience to perceive the more subtle differences in "feel" that are characteristic of the tissue planes in small children. The angle of approach to the epidural space is slightly more perpendicular to the plane of the back than in older children and adults, owing to the orientation of the spinous processes in infants and small children. The loss-of-resistance technique should be used with saline solution, not air. There are several reports of venous air embolism in infants and children when air was used to test for loss-of-resistance.[282–284] Another method used to identify the epidural space is to attach an IV infusion chamber with a minidrip or other free-flowing fluid delivery device to the epidural needle; commencement of dripping identifies entry into the epidural space.[285–287] We use a short (5-cm) 18-gauge Tuohy needle and a 20- or 21-gauge catheter in infants and children. The shorter length offers much better control than an adult-length (9- to 10-cm) needle. These catheters have fewer problems than the 24-gauge catheters, which in our experience are prone to kinking under the skin, resulting in very high resistance to injecting the solution. Epidural kits specifically for infants and children are available, but aside from the substitution of a shorter needle, they are identical to the adult sets.

SELECTION OF DRUG. The drug dose required for epidural blockade to reach a given dermatomal level depends on the volume (not the concentration) of the local anesthetic and the volume and capacitance of the epidural space, which changes with age. The greater the volume of local anesthetic, the higher the level of block achieved. In two studies, the height of the block achieved when local anesthetic was administered caudal epidurally varied inversely with age using ultrasound to detect the spread; for example, the maximum spinal level of local anesthetic in infants younger than 1 year of age was one to two levels more cephalad than in those older than 1 year.[275,288] This effect of age on the spread of local anesthetic however has been disputed.[288,289] Numerous studies investigated the doses of local anesthetic drugs used for caudal anesthesia in children.[a] The volumes of local anesthetic reported to block from a T4 to a T10 dermatome level span a fivefold range. In our experience, the volume of local anesthetic required is 0.05 mL/kg per dermatome to be blocked.[261]

Thus in a 10-kg child in whom we wish to produce a T10 dermatome level, we would use a volume of (0.05 mL/kg per dermatome) × (10 kg) × (12 dermatomes) = 6 mL.

Another simple method is to administer 1 mL/kg (up to 20 mL) of local anesthetic (usually 0.125% bupivacaine with 1:200,000 epinephrine). This generally provides a sensory block with minimal motor block up to the T4-6 level; this volume limits the potential for toxicity for children older than 6 months of age and is on the border for younger infants. If repeated doses are anticipated, or in infants younger than 6 months of age, it is prudent to reduce the concentration or volume to avoid the risk of accumulation.

A third simple regimen for a caudal block used in the United Kingdom and Australasia is that of Armitage[268]: 0.5 mL/kg for lumbosacral, 1 mL/kg thoracolumbar, and 1.25 mL/kg mid thoracic. If the total volume is less than 20 mL, then use bupivacaine 0.25%. If the volume exceeds 20 mL, then use bupivacaine 0.19%.

Because the level of the block depends on the volume of drug administered, the concentration of the local anesthetic should be based on the desired density of the block (less dense for postoperative analgesia, more dense for intraoperative anesthesia) and on the risk of toxicity.

Continuous Epidural Infusions

Although intermittent doses of local anesthetic are often used to maintain epidural anesthesia during a prolonged surgical procedure, it is also common practice to initiate continuous infusions of local anesthetics during surgery. Continuous infusions maintain the block at a constant level, assuming that the infusion rate is appropriate. This obviates the need for repetitive test dosing.

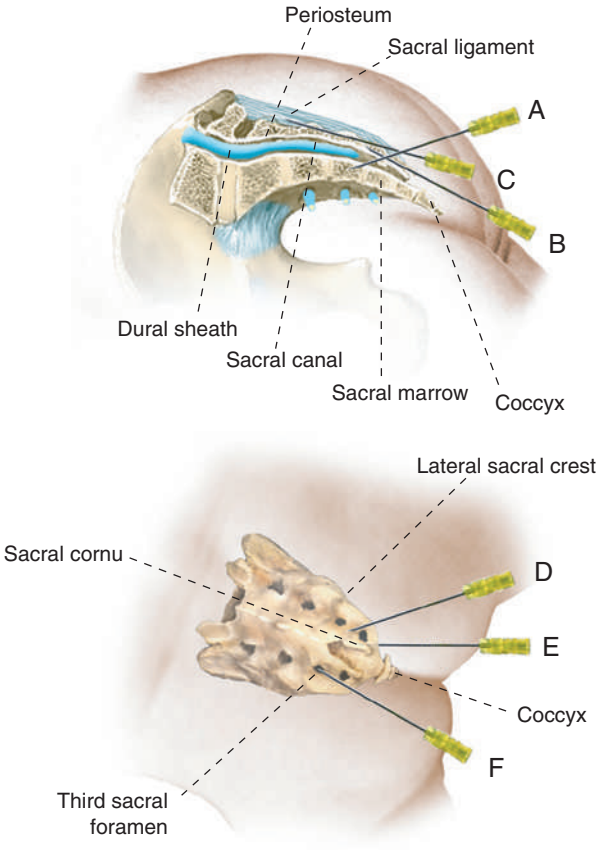
[a]References 254, 256–258, 260, 261, 263–269, 288, and 289.

Theoretically, fewer entries into the epidural catheter may reduce the risk of infection and the risk of accidental administration of the wrong drug. Strict attention to the total drug administered per hour (i.e., the drug concentration and infusion rate) is required to preclude potentially toxic drug doses. We recommend that the same dosing guidelines for postoperative infusion rates be followed intraoperatively: *a maximum of 0.4 mg/kg per hour of bupivacaine after the initial block is established, with this dose reduced by approximately 30% for infants younger than 6 months of age.*[44] The concentration of local anesthetic solution depends on the age of the child, the surgical procedure, and the extent of the area that needs to be blocked. When a denser block is required in a small infant, it may be beneficial to use 2,3-chloroprocaine because its action is terminated by ester hydrolysis and has a minimal risk of accumulation compared with amide local anesthetics. A denser block with a more concentrated solution may then be achieved. The amides ropivacaine and levobupivacaine, because they are levorotary enantiomers and carry reduced risks of toxicity, may also successfully address these issues and allow the administration of more concentrated agents to produce denser blockade with less potential for adverse effects (see Chapters 43 and 44). In a study of children 1 to 9 years of age, infusion rates of up to 0.4 mg/kg per hour of ropivacaine that followed a 2-mg/kg bolus were found to result in stable levels of unbound ropivacaine in plasma, all well below the toxic threshold; clearance did not differ with age.[290]

Epidural Opioids

Epidural opioids can be safely used to augment intraoperative anesthesia in children, as well as to provide postoperative analgesia. Their use is discussed in detail in Chapter 44. If extubation of the trachea is expected at the end of the surgical procedure, one must account for both the systemic and the central neuraxial opioid doses to avoid excessive respiratory depression.

Adjunctive Drugs



Numerous agents have been injected into the epidural space in attempts to prolong analgesia, to improve the quality of analgesia while reducing the dose of opioid and local anesthetic, or to replace the local anesthetic or opioid with a drug that may have fewer adverse effects. It is concerning, however, that several of these agents have neither undergone exhaustive neurotoxicity testing nor are prepared or labeled for neuraxial use.[291] In the United States, the only adjunctive drug accepted for epidural administration is clonidine, an α_2-adrenoceptor agonist. The effect of clonidine to prolong the duration of epidural analgesia remains controversial in the literature. Several studies, including a meta-analysis, reported clonidine prolonged the duration of analgesia by 2 hours, as measured by the time to first supplemental analgesic requirement.[291–295] Other investigators found no significant increase in the duration of analgesia, including one double-blind, randomized trial.[296,297] In neonates, neuraxial clonidine at doses of 2 μg/kg or greater has been associated with apnea. Increased sedation has been reported after epidural clonidine in older infants and children at the same doses. We recommend a dose of 1 μg/kg, especially in ambulatory patients.

Complications

Complications after epidural anesthesia or analgesia include cardiac arrest from an intravascular or intraosseous injection, hematoma, neural injury, and infection. E-Fig. 42.5 illustrates sites of unintended needle placement during the performance of a caudal epidural block. Injection of local anesthetic into an epidural blood vessel or intraosseous injection into the marrow cavity may result in a rapid increase in the blood concentration of the local anesthetic and a toxic reaction as discussed previously. It is also possible to pass the needle through the sacrum and perforate bowel or the pelvic organs, particularly in infants in whom ossification of the sacrum is incomplete.

There are now several large-scale prospective audits that examined both the incidence and the nature of complications in regional anesthetics in children. The prospective audit from the United Kingdom and Ireland is the largest and most carefully described study on complications of epidural anesthesia in pediatrics to date.[298] A total of 10,633 cases were accrued over a period of 5 years, and all complications were reviewed and categorized by severity and type. Only five complications were graded as serious, and of these only one, the result of a drug error, had lasting sequelae. The French-Language Society of Pediatric Anesthesiologists (ADARPEF) published a follow-up prospective study on regional anesthetics in children in which they reported on 10,098 epidural blocks without a single child sustaining permanent sequelae.[75] The PRAN consortium in the United States reported data from their first prospective cohort in which 9073 epidural and caudal blocks were accrued: 6127 single-injection (mostly caudal) and 2946 continuous caudal or epidural anesthesias.[11] In this study there were no complications of any kind that lasted more than 3 months. The most common complication was catheter displacement or malfunction in the postoperative period in continuous blocks. Caudal safety was further supported in a subsequent PRAN analysis of 18,650 single-injection caudal epidurals, which detected an overall incidence of complications of 1.9% (95% CI 1.7%–2.1%) and no instances of temporary or permanent sequelae, calculated as 0.005% (95% CI 0% to 0.03%).[270]

Infection is of grave concern when it occurs in either the subarachnoid or the epidural space.[299] A study of 1620 children over a 6-year period reported a zero frequency of epidural abscess.[300] Catheters remained in situ for a mean of 2 days (maximum 8 days). The adult literature also suggests that infection is an uncommon complication.[301,302] However, both superficial and deep abscesses may rarely occur, particularly in those children with immunodeficiency syndromes or cancer who are receiving long-term infusions.[303] Epidural abscess and meningitis are the most potentially serious complications.[299,304] The development of an epidural abscess is a surgical emergency, because failure to treat it can lead to a permanent neurologic injury. The signs and symptoms (Table 42.6) are the same as those for epidural hematomas, although fever, increased erythrocyte sedimentation rate, and increased leukocyte count with a leftward shift are also often present. Surgical drainage may be necessary. In a British audit, three serious infections (two epidural abscesses and one case of meningitis) were noted. These infections were all related to infections at the insertion site. All cultures grew *Staphylococcus aureus*. Twenty-five local infections were reported, mostly *S. aureus,* and 80% were associated with catheters left in place more than 48 hours. Of note is that some localized infections that developed at the catheter insertion site only became apparent several days after the catheter had been removed (see Fig. 44.9). Similar findings were reported in the PRAN data. In the British study, one case progressed to an epidural abscess. Whether these infections developed while the catheter was in place, leaving bacteria to track through the open site in the skin after the catheter was removed, or by hematologic spread is unknown, although the former etiology is most frequently cited. Infants and toddlers who are in diapers require meticulous

E-FIGURE 42.5 Sites of misplacement of the needle tip and the local anesthetic for caudal block anesthesia. Note that injection may be made into bone marrow **(A),** into subperiosteum **(B),** into posterior sacral ligaments **(C),** into a false "decoy" hiatus **(D),** into the anterior sacral wall and possibly out into the pelvis **(E),** or into a lateral foramen **(F),** producing a limited block. management of these catheters and their insertion site. A mild erythema occasionally occurs at the site of catheter insertion when children have indwelling catheters in place for several days, and this must be distinguished from a cellulitis (see Fig. 44.9). In most cases these superficial infections resolve with removal of the catheter and local care. On occasion, these superficial infections may require treatment with a systemic antibiotic. If there is any question that the site is infected, the catheter should be removed. Although no serious systemic infection occurred in a prospective study of 210 children with 170 caudal catheters (age 3 ± 1 years) and 40 lumbar epidural catheters (age 11 ± 3 years) that were in place for 3 ± 1 days, 35% were colonized with bacteria.[305] This rate of colonization was similar with both caudal (25%) and lumbar epidural (23%) approaches. These results suggest that colonization is not synonymous with infection and that caudal catheters are not necessarily associated with greater infectious risk than lumbar epidural catheters. The factors that transform colonization into infection remain unknown.

It is common to have epidural fluid leak from the insertion site in caudal epidural catheters, especially in the presence of presacral edema. If an indwelling caudal epidural catheter is in place when a child develops a fever of unknown origin, the catheter should be removed because it may be causing the infection or become seeded by the infection (see Chapter 44).

Epidural hematoma is also a rare complication after epidural blockade. Optimal outcome depends on rapid diagnosis and prompt treatment and decompression. Signs and symptoms are presented in Table 42.6. The presence of clinically important coagulopathy or thrombocytopenia is an unacceptable risk for developing an epidural hematoma and is a contraindication to central neuraxial blockade. Guidelines for the conduct of neural blockade in the anticoagulated patient have been published by the ASRA.[306] Of particular note is that there is a difference in the management of the patient who is receiving conventional (unfractionated) heparin and low–molecular-weight heparins, such as enoxaparin. Guidelines for the management of patients who are anticoagulated are shown in Table 42.7.[306]

Postoperatively, *urinary retention* has been associated with the presence of both epidural and spinal anesthesia. In this regard, it is important to distinguish between the effects of local anesthetics and central neuraxial opioids in the blocks. There is no evidence that regional anesthesia with local anesthesia causes urinary retention, and, indeed, there are data to the contrary. In a prospective study of infants and children undergoing inguinal herniorrhaphy or orchiopexy, caudal blockade, ilioinguinal-iliohypogastric nerve block by the surgeon, or a control consisting of caudal injection of 1 : 200,000 epinephrine (no local anesthetic) yielded similar times to voiding postoperatively.[307] In a retrospective study of 326 children undergoing inguinal herniorrhaphy and urologic surgery, 237 received a caudal block and 66 received local anesthesia by the surgeon. The incidence of urinary retention was similar for the two groups, with the type of surgery being the primary determinant of urinary retention.[308]

TABLE 42.6 Signs and Symptoms of Epidural Hematoma and Abscess

Abscess	Hematoma
Fever	Afebrile
± Increased WBC	WBC normal
± Increased sedimentation rate	Sedimentation rate normal or slightly increased
± Left WBC shift	
Localized back pain	Localized back pain
Radicular pain	Radicular pain
Paraplegia	Paraplegia
Sensory loss	Sensory loss
Urinary and fecal retention	Urinary and fecal retention
Incontinence	Incontinence
Local tenderness	Local tenderness
Defect on myelography	Defect on myelography
Localized lesion on magnetic resonance imaging	Localized lesion on magnetic resonance imaging

WBC, white blood cell count.

TABLE 42.7 Guidelines for the Use of Regional Anesthesia in the Anticoagulated Patient

Drug (Generic)	Common Trade Names	Interval for Catheter Placement After Last Dose	Interval for Catheter Removal After Most Recent Dose	Time Interval to Restart Anticoagulant After Catheter Is Removed
Enoxaparin[a] (therapeutic)	Lovenox (>60 mg daily or 1 mg/kg bid or 1.5 mg/kg daily)	24 hours	Catheter should be removed before first dose. If med given, wait >24 hours	2–4 hours after catheter removed
Enoxaparin[a] (prophylactic)	Lovenox (≤60 mg per day)	12 hours	12 hours	2–4 hours
Heparin SC bid	Heparin	No significant risk at dose of 5000 units bid		
Heparin SC tid	Heparin	Unknown risk at 5000 units tid: suggest check PTT. 10,000 units tid: check PTT		
Heparin IV	Heparin	2–4 hours, PTT < 35 seconds	2–4 hours, PTT < 35 seconds	2 hours
NSAID, ASA	Celebrex, Motrin, Naprosyn, and so on	No significant risk		
Streptokinase	Streptase	10 days	10 days	Uncertain; at least 24 hours
Warfarin	Coumadin	3–5 days, INR ≤ 1.5	If >24 hours, check INR ≤ 1.5	Same day

[a]Note for low–molecular-weight heparin: Prophylactic dosing may be started 6 to 8 hours postoperatively. Therapeutic dosing or bid dosing should be started at least 24 hours postoperatively. Epidural catheters should be removed before initiation of therapy.
ASA, acetylsalicylic acid; *INR*, international normalized ratio; *IV*, intravenous; *NSAID*, nonsteroidal antiinflammatory drug; *PTT*, partial thromboplastin time; *SC*, subcutaneous.
Modified from the guidelines of the Massachusetts General Hospital Department of Anesthesia, Critical Care and Pain Medicine, 2011.

The epidural and subarachnoid use of opioids, however, is associated with an increased incidence of urinary retention. Epidural morphine in a dose of 70 µg/kg (a dose that would now be considered excessive) was associated with a 50% incidence of urinary retention[309]; 70% of those with urinary retention required treatment. Another study reported an incidence of urinary retention of 27% after caudally administered morphine, 33 to 100 µg/kg, although most of the children had urinary catheters.[310] Finally, 50 µg/kg diacetylmorphine was associated with an 11% incidence of urinary retention.[311] A dose of 33 µg/kg epidural morphine is the most common recommended in current practice.

Data from the large prospective databases indicate that the incidence of *neural injury* after epidural blockade is very small and that long-term neurologic sequelae of neuraxial blockade is rare. One must slightly temper these conclusions, however, based on the limited follow-up of children in these studies who did not have problems reported within the immediate time frame of the block. A prospective study of more than 2500 infants and children who received epidural blocks demonstrated no evidence of neurologic complications, although a retrospective review of the first ADARPEF data determined that 1 in 5000 infants younger than 3 months of age had neurologic complications with magnetic resonance imaging evidence of spinal cord ischemia.[106,312] In four of the five cases reported in that study, the epidural space was identified using loss-of-resistance to air (in the fifth case, the technique was not specified) and the authors concluded that the etiology of the neurologic injury was an air embolus. Based on these data, the use of air for loss of resistance in infants and children has been strongly discouraged, using saline solution instead. However, this reasoning has been questioned. The use of loss of resistance to saline solution with an air bubble has been advocated by some experts.[137] In the follow-up ADARPEF study there were no cases of neurologic injury.[75] The British epidural audit found 6 cases of neural injury in 10,633 (1 : 1770) children in that prospective study. Of particular note was the delay in recognition of the injury, as no cases were discovered before 2 days had elapsed from the time the block was placed, and some diagnoses were not made for 10 days after the block. All children had complete resolution of their symptoms within 1 year. Two children were referred to a chronic pain service and treated with gabapentin, and one child developed a common peroneal nerve injury that was attributed to malpositioning of the leg during surgery. In our experience, one child who developed symptoms of complex regional pain syndrome after common peroneal nerve injury from positioning in the postoperative period sustained persistent motor block, which emphasizes (1) the importance of early recognition of motor blockade as a potential for injury after surgery and (2) the critical importance of positioning and nursing care in preventing pressure injuries. There were no cases of persistent neurologic injury in the initial PRAN data cohort. In young rabbits, a decrease in blood pressure coincident with epidural anesthesia with lidocaine, decreased spinal cord blood flow was detected using colored microspheres.[313] The addition of epinephrine to the local anesthetic solution did not increase the incidence of ischemia. These studies suggest that it may be particularly important to maintain adequate systemic blood flow during "combined technique" anesthesia in infants and children, and to treat hypotension promptly. Because blood pressure changes caused by neuraxial blockade are uncommon in infants and small children, hypotension in these patients is most likely to be due to other causes and should prompt an assessment of intravascular filling pressures, inotropic state, and the depth of general anesthesia.

PERIPHERAL NERVE BLOCKS

Peripheral nerve blocks are useful adjuvants to general anesthesia. These blocks are also useful as a means for providing postoperative pain relief. Peripheral nerve blocks differ from central neuraxial blocks in several respects:

- A targeted area is anesthetized.
- Side effects, such as weakness of extremities, are minimal.
- The dose of local anesthetic is reduced.
- There is no risk of an unintended spinal anesthetic.
- There is no risk of urinary retention.
- Peripheral blocks can be used in areas where a central neuraxial block is not possible (e.g., face and scalp).

There are many peripheral nerve blocks that can be used in the practice of pediatric anesthesia and each is described in the following text (Table 42.8; see also Chapter 43).

Selection of a Local Anesthetic

Local anesthetics commonly used for peripheral blocks in children include lidocaine, mepivacaine, bupivacaine, and, more recently, levobupivacaine and ropivacaine.[72,74,314] Longer-acting agents have a greater role in peripheral blocks than shorter-acting agents because of the increased duration of postoperative analgesia. Lidocaine can be combined with bupivacaine to provide both a rapid onset and a long duration of action, a practice that we advocate if the child is having the procedure performed with a local block under sedation. If this is done, one must be careful to calculate the doses of the two drugs properly to avoid toxicity. Alternatively, the addition of sodium bicarbonate (1 mEq of bicarbonate/10 mL

of local anesthetic [lidocaine]) can speed the onset and reduce the pain of injection of the block by increasing the pH of the solution.[315–318] This alters the pK_a of the solution, increasing the active cationic form of the local anesthetic in the solution.[319] Bicarbonate should be added to the local anesthetic solution immediately before administration because precipitation of the local anesthetic and therefore loss of bioavailability increases over time (it should be administered within 10 minutes after alkalinization).[320] This is particularly a problem with mepivacaine, bupivacaine, and ropivacaine in which the addition of 0.1 mL of 8.4% bicarbonate precipitates the anesthetic within 10 minutes.[319,320] The total drug dose administered should not exceed the maximum milligram per kilogram dose permitted for the local anesthetic (see Table 42.2). The addition of epinephrine (1 : 200,000) may decrease both the vascular absorption and the potential for toxicity; for some local anesthetics the addition of epinephrine will also extend the duration of the block. The exact dose of local anesthetic in terms of volume or concentration needed for most peripheral blocks in children has not been adequately studied. Most blocks performed in children are based on adult experience. Suggested dosing for common peripheral blocks based on volume per kilogram and our experience is presented in Table 42.9.

HEAD AND NECK BLOCKS

Peripheral nerve blocks for postoperative pain relief for the head and neck can be performed with the child under general anesthesia.[321] These blocks can also be used for the provision of pain relief in children with chronic painful problems, such as headaches. Anatomically, two major nerves, the ophthalmic division (V_1) of the trigeminal nerve and the branches of the cervical root C2, supply the sensory innervations of the face and scalp (Fig. 42.9).

Supraorbital and Supratrochlear Nerve Block

ANATOMY. The supraorbital and supratrochlear are the end branches of the ophthalmic division (V_1) of the trigeminal nerve. The supraorbital nerve, the terminal branch of V_1, exits the supraorbital foramen to supply the scalp anterior to the coronal suture. The supratrochlear nerve leaves the orbit between the trochlea and the supraorbital foramen and innervates the lower part of the forehead (Fig. 42.10A). We use this combined block to provide pain relief in children undergoing frontal craniotomies and in children undergoing frontal ventriculoperitoneal shunt revisions. The technique can be used as the sole anesthetic in very sick neonates,[322] and to control postoperative pain in children undergoing excision of scalp lesions.[323] The major advantage is the avoidance of opioids, thereby facilitating an early hospital discharge.

TECHNIQUE. With the child supine and the head in the neutral position, the supraorbital notch is palpated by running a finger from the midline laterally along the eyebrow (the supraorbital

TABLE 42.9 Suggested Dosing for Local Anesthetic Volumes for Common Peripheral Nerve Blocks

Technique	Dose (mL/kg)
Head and neck blocks	0.05
Brachial plexus blocks	0.2–0.3

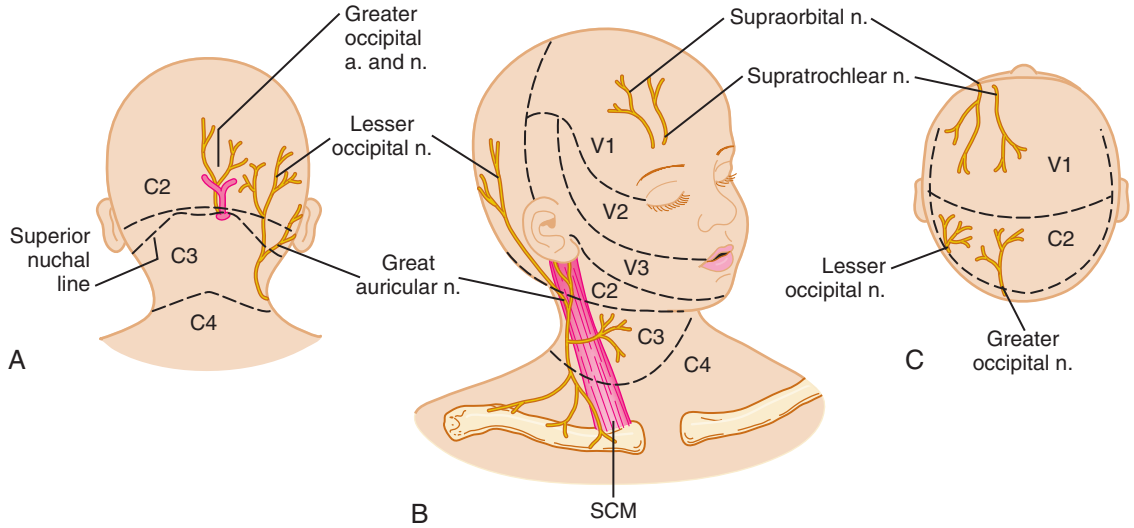

FIGURE 42.9 Dermatomal innervation of head and neck. Sensory and dermatomal innervation of greater and lesser occipital nerves and the innervation of the anterior head by the first division of the trigeminal nerve. Note the sensory innervation anterior to the coronal suture is from the first division of the trigeminal nerve (supraorbital and supratrochlear nerves) and posterior to the coronal suture is from branches of C2 (greater and lesser occipital nerves). These nerves can be blocked individually and in combination to provide postoperative analgesia for a wide variety of procedures; see text for details. **A,** Posterior view. **B,** Anterolateral view. **C,** Axial view. *a*, artery; *C2*, *C3*, *C4*, cervical sensory branches of the nerve roots; *n*, nerve; *SCM*, sternocleidomastoid muscle; V_1, V_2, V_3, branches of the trigeminal nerve. FIGURE 42.10 A, Supraorbital and supratrochlear nerve block. The supraorbital notch is palpated by running a finger from the midline laterally along the eyebrow. **B,** A 27-gauge needle is inserted into the supraorbital notch perpendicularly; bupivacaine (1 mL, 0.25% with 1:200,000 epinephrine) is injected into the space after careful aspiration. To block the supratrochlear nerve, the needle is withdrawn to skin level and then directed medially several millimeters toward the apex of the nose; bupivacaine (1 mL, 0.25% with 1:200,000 epinephrine) is injected. This block provides postoperative pain relief for children undergoing frontal craniotomies or frontal ventriculoperitoneal shunt insertion.

notch is usually located in line with the pupil with the eye in midline position). The skin is prepared with povidone-iodine or chlorhexidine and care is taken to avoid spilling the solution into the eye. A 27-gauge needle is inserted in the proximity of the supraorbital notch; 0.5 to 1.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected into the space after careful aspiration to prevent intravascular placement (see Fig. 42.10B). To block the supratrochlear nerve, the needle is withdrawn to the skin level and then directed and advanced several millimeters medially toward the apex of the nose; 0.5 to 1.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected (Video 42.5).

COMPLICATIONS. Because of the loose adventitious tissue of the eyelid, gentle pressure should be applied to the supraorbital area; this prevents the dissection of the local anesthetic into the eyelid and supraorbital tissue, and may reduce the potential for ecchymosis and/or hematoma.

Greater Occipital Nerve Block

The greater occipital nerve block is used to diagnose and treat occipital pain. If this technique is used for the diagnosis of occipital neuralgia, a careful history and physical examination is performed to rule out other pathologic causes of headaches, including posterior fossa tumors and Arnold-Chiari malformation.[324] It can also be used to treat postoperative pain in the posterior fossa after posterior fossa surgery, and in children undergoing posterior ventriculoperitoneal shunt revisions.[325]

ANATOMY. The cervical spinal nerves innervate the posterior head and neck. The dorsal rami of C2 end in the greater occipital nerve, which provides the cutaneous innervation to the major portion of the posterior scalp (Fig. 42.11A). The nerve becomes subcutaneous slightly inferior to the superior nuchal line by passing above the aponeurotic sling; here it is in close proximity and medial to the occipital artery.

TECHNIQUE. With the child supine and the head laterally rotated or with the child prone, the occipital artery is palpated at the level of the superior nuchal line. The occipital artery is usually located at approximately one-third of the distance from the external occipital protuberance to the mastoid process on the superior nuchal line (see Fig. 42.11B). A total volume of 2 mL of bupivacaine (0.25% with 1:200,000 epinephrine) is injected SC (Video 42.6). A recent technique using ultrasound guidance has been used in children for performing occipital nerve blocks.[326]

COMPLICATIONS. It is rare to see complications with this block because of the superficial location of the nerve. One has to bear in mind the close proximity to the spinal canal, particularly in children who have had surgery in the area. Thus the needle must remain just beneath the skin during injection of local anesthetic. It is more difficult to perform this block at the C2 nerve root without the aid of either ultrasonography or fluoroscopy and hence it cannot cover the entire distribution of the greater occipital nerve. Intravascular injection may be avoided with incremental injection and frequent aspiration.

Infraorbital Nerve Block

ANATOMY. The infraorbital nerve is the termination of the second division of the trigeminal nerve, the maxillary nerve (Fig. 42.12A). This nerve is entirely sensory in function. It leaves the skull through the foramen rotundum and enters into the pterygopalatine fossa. It then enters the infraorbital groove and passes through the infraorbital canal. The nerve emerges in front of the maxilla through the infraorbital foramen and then divides into four branches: the inferior palpebral, the external nasal, the internal nasal, and the superior labial. The anatomic location of the infraorbital foramen has been studied using CT scans: the average distance from the midline (in millimeters) is 21.3 + 0.5 × age (years).[327,328] The branches of the infraorbital nerve innervate the lower eyelid, the lateral inferior portion of the nose and its vestibule, the upper lip, the mucosa along the upper lip, and the vermilion. This block is effective for surgery of the upper lip and the vermilion after a cleft lip repair,[329] for reconstructive procedures on the nose (including septal reconstruction and rhinoplasty),[330] and for endoscopic sinus surgery.[331] There are two approaches to the infraorbital nerve: intraoral and extraoral.

INTRAORAL APPROACH. This is our preferred method for this block. The infraorbital foramen is located by palpation of the

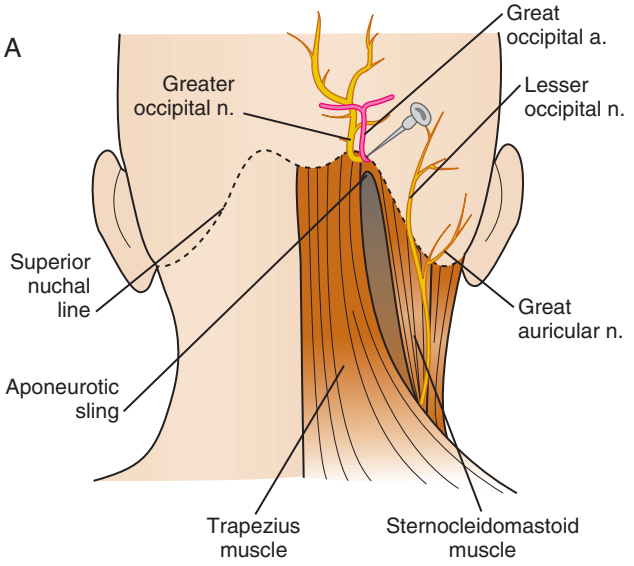

FIGURE 42.11 A, Greater occipital nerve and site of block. **B,** With the patient supine and with the head turned to one side or with the patient prone, the occipital artery is palpated at the level of the superior nuchal line. The occipital artery is located about one-third of the distance from the external occipital protuberance (*dashed line,* part **A**) to the mastoid process on the superior nuchal line. A total volume of 2 mL of bupivacaine (0.25% with 1:200,000 epinephrine) is injected subcutaneously to form a skin wheal. Frequent aspiration and incremental injection may avoid intravascular injection. This block is used to diagnose occipital neuralgia and as a means for providing postoperative pain relief for children undergoing posterior fossa tumor resection or posterior ventriculoperitoneal shunt insertion. *a,* artery; *n,* nerve. (Modified from Brown DL, Wong GY. Occipital nerve block. In: Waldman S, Winnie AP, eds. *Interventional Pain Management.* Philadelphia: WB Saunders; 1996:228.)

infraorbital notch. After folding back the upper lip, a 27-gauge needle is inserted through the buccal mucosa approximately parallel to the maxillary second molar and passed SC with the tip of the needle directed toward the infraorbital foramen. It is important to place a finger over the infraorbital foramen so as to palpate the progress of the needle beneath the skin and prevent unintended passage of the needle into the orbit. With the tip of the needle at the level of the infraorbital foramen and after careful aspiration, 0.5 to 1.0 mL of local anesthetic is injected (see Fig. 42.2B and Video 42.7). Bupivacaine (0.25% with epinephrine 1:200,000) provides prolonged postoperative analgesia with this block.

EXTRAORAL APPROACH. The infraorbital ridge of the maxillary bone should be identified and the infraorbital foramen palpated. A 27-gauge needle is advanced toward the foramen at a 45-degree angle to the maxilla (see Fig. 42.12C). After careful aspiration, 0.5 to 1.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected.

COMPLICATIONS. Because of the loose adventitious tissue, children can develop ecchymosis and swelling. Pressure should be applied to the infraorbital area to retain the solution within the infraorbital foramen, prevent dissection of the local anesthetic into the periorbital area, and reduce the potential for the formation of a hematoma or ecchymosis. Care should be taken to avoid direct injection into the orbit or eye. Intravascular injection may be avoided with incremental injection and frequent aspiration. This block can be achieved with low volumes in infants and toddlers; hence every attempt should be made to decrease the volume of the local anesthetic solution. Using other additives, including clonidine, may be helpful, although there are no randomized controlled trials to demonstrate the improved efficacy of this block using additives.

Great Auricular Nerve Block

The great auricular nerve supplies the sensory innervation to the mastoid area and the external ear. It is a branch of the superficial cervical plexus. Cervical plexus blocks were first performed by Halstead in 1884. This block has been used to provide postoperative analgesia in children undergoing otoplasty repair,[332] as well as in tympanomastoid surgery.[333] We found that the great auricular nerve block decreases the incidence of nausea and vomiting, which is a major morbidity associated with tympanomastoid surgery.[333] It provides surface analgesia but not muscle relaxation and hence can be used for intraoperative analgesia despite the need for facial nerve monitoring in children undergoing tympanomastoid procedures.

ANATOMY. The cervical plexus is formed by the anterior primary division of the anterior and posterior roots of cervical nerves C2-4. The great auricular nerve is derived from C3, which was described by McKinney. The anatomic location of the nerve for blockade has been described as the McKinney point.[334] The great auricular nerve wraps around the belly of the sternocleidomastoid muscle at the level of the cricoid cartilage and emerges to supply the area of the mastoid and external ear (Fig. 42.13A).

TECHNIQUE. With the child under general anesthesia, the cricoid cartilage is identified. A line is drawn from the superior margin of the cricoid cartilage laterally to the posterior border of the sternocleidomastoid muscle (McKinney point). Bupivacaine (2–3 mL, 0.25% with epinephrine 1:200,000) is injected superficially at this point (see Fig. 42.13B and Video 42.8).

COMPLICATIONS. Deep rather than superficial injection can result in a deep cervical plexus block and the risk of Horner syndrome, phrenic nerve block, or unintended central neuraxial blockade. A small erythematous area may be seen at the site of the needle injection. Intravascular injection may be avoided by incremental injection of the solution and frequent aspiration.

Nerve of Arnold (Auricular Branch of Vagus)

The auricular branch of the vagus supplies the sensory nerve that supplies the innervation to the auditory canal, as well as the inferior portion of the tympanic membrane. This is useful for providing analgesia to the tympanic membrane after myringotomy and tube placement, as well as for tympanoplasty surgery. In a

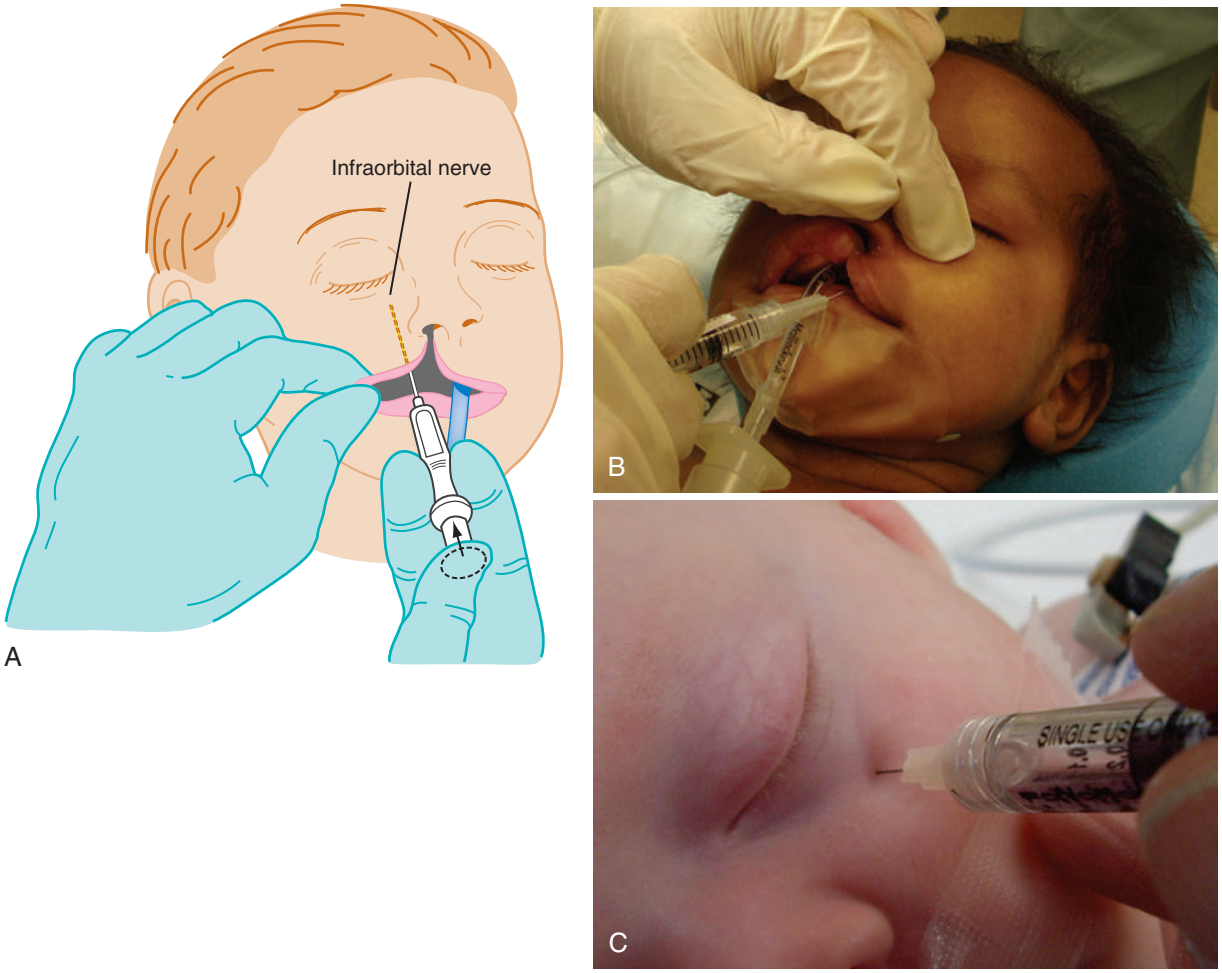

FIGURE 42.12 A, Infraorbital block (intraoral approach): The infraorbital foramen is located by palpation of the infraorbital notch (right-sided block). **B,** The lip is folded back and a 27-gauge needle is inserted through the buccal mucosa approximately parallel to the maxillary second molar. The tip of the needle is directed toward the infraorbital foramen. A finger is placed over the infraorbital foramen to avoid accidental placement of the needle into the orbit. After careful aspiration to avoid intravascular injection, 0.5 to 1.0 mL of bupivacaine (0.25% with 1:200,000 epinephrine) is injected (left-sided block). **C,** For the extraoral approach (left-sided block) the infraorbital ridge of the maxillary bone should be identified and the infraorbital foramen is palpated. A 27-gauge needle is advanced toward the foramen at a 45-degree angle to the maxilla (midpupillary point). After careful aspiration, 0.5 to 1.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected. This block is used to provide postoperative pain relief for children undergoing upper lip or cleft lip repair, reconstructive procedures of the nose (e.g., rhinoplasty), and endoscopic sinus surgery.

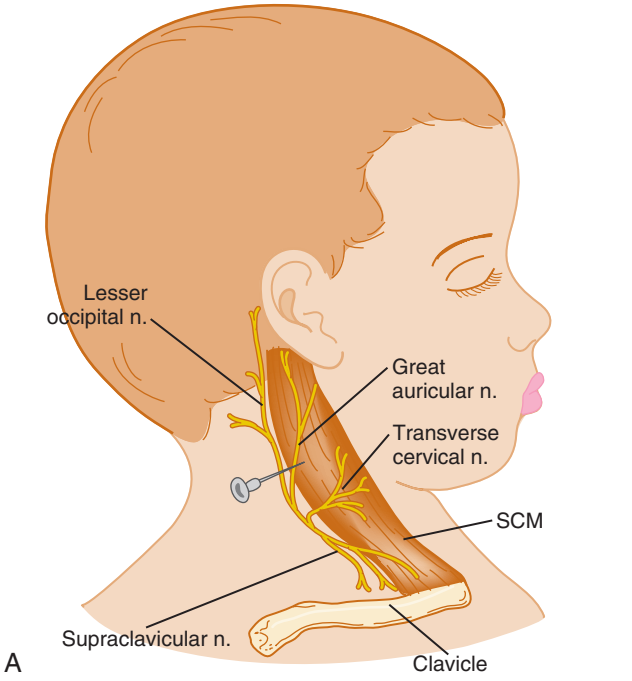
randomized controlled trial, intranasal fentanyl and blockade of the auricular branch of the vagus provided equivalent analgesia without adverse effects.[335]

INDICATIONS. This block is used to provide analgesia for myringotomy and tube placement, and for tympanoplasty.

TECHNIQUE. After induction of anesthesia, and with the child turned to one side, the tragus is cleaned and reflected laterally, a 30-gauge needle is inserted into the tragus to pierce the cartilage; after aspiration, 0.2 mL of local anesthetic solution is injected (Video 42.9). Mild pressure is applied to prevent any bleeding following the procedure.



COMPLICATIONS. It is rare to see complications, although occasionally there can be some brisk bleeding from the needle entry site, which can be offset by applying pressure.

TRUNCAL BLOCKS

Truncal blocks are performed in children for a variety of different surgical procedures. The most common blocks include intercostal blocks,[46] ilioinguinal blocks, penile blocks, rectus sheath blocks, and paravertebral blocks.

Intercostal Nerve Block

Intercostal blocks after thoracotomy are useful in reducing opioid requirements, optimizing respiratory mechanics, and encouraging early ambulation.[46,336,337] Their major disadvantage is the limited duration of analgesia. Currently, we more commonly use epidural blockade for this purpose. The development of degradable bupivacaine microspheres and the recent approval of liposomal encapsulated bupivacaine, which produce analgesia of dramatically

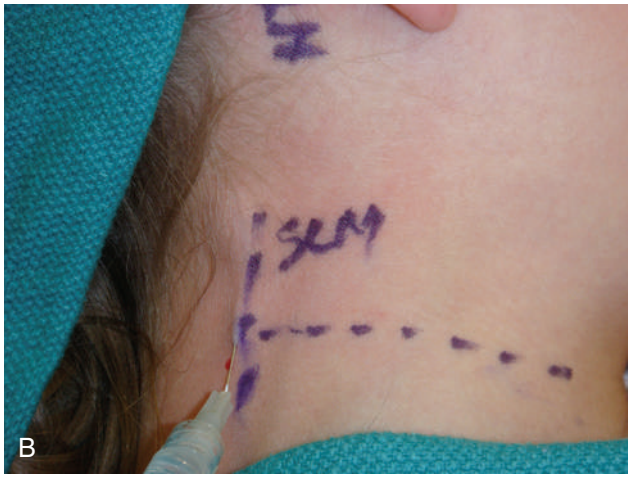


FIGURE 42.13 A, Great auricular nerve block. The cricoid cartilage is identified. **B,** A broken line drawn from the superior border of the cricoid cartilage laterally to the posterior border of the sternocleidomastoid (*SCM*) (McKinney point) is identified; bupivacaine (2–3 mL, 0.25% with 1:200,000 epinephrine) is injected subcutaneously at this point. Gentle massage after the injection allows spread of the local anesthetic in the injected site. This block is used to provide postoperative analgesia for children undergoing tympanomastoid surgery or otoplasty. *n*, nerve. (Modified from Brown DL, ed. *Atlas of Regional Anesthesia*. Philadelphia: WB Saunders; 1999:185.)

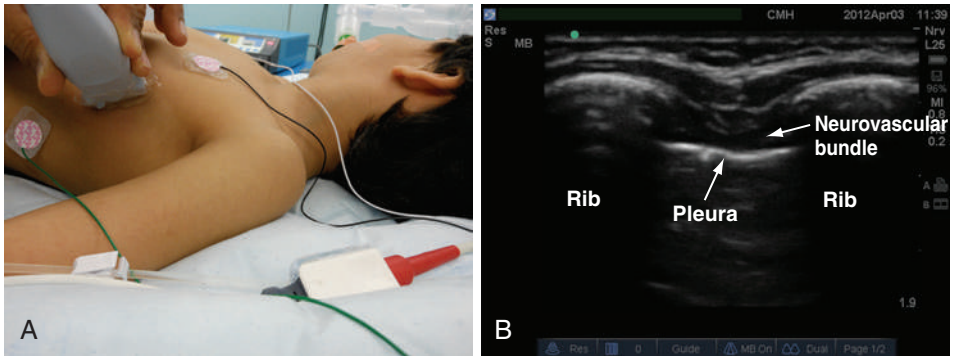
greater duration, may change this practice in the future.[52,61–63,69,338] There are, however, still situations in which intercostal blocks are useful, particularly in children who cannot have a neuraxial catheter placed.

The uptake of local anesthetic after intercostal blocks is the most rapid of all sites of regional anesthesia, yielding the greatest plasma concentrations of local anesthetics after any other regional block. Furthermore, plasma concentrations in children increase more rapidly than after identical blocks in adults.[339] For this reason, epinephrine (1:200,000) should always be added to reduce the absorption of local anesthetic. We commonly use 1 to 5 mL of 0.25% bupivacaine with epinephrine to block each intercostal nerve, depending on the size of the child and the number of ribs to be blocked. A maximum of 2 mg/kg of bupivacaine is used, although this amount should be reduced by about 30% for infants younger than 6 months of age. The concentration of bupivacaine should be decreased to provide adequate volume for the desired number of intercostal blocks while avoiding the risk of systemic toxicity.



ANATOMY. The intercostal nerves are derived from the ventral rami of the first through the twelfth thoracic nerves. There are four branches. The first is the gray rami communicans, which goes to the sympathetic ganglion. The second branch arises as the posterior cutaneous branch, which supplies the skin in the paravertebral area. The third branch, the lateral cutaneous branch, arises anterior to the midaxillary line and sends subcutaneous branches both anteriorly and posteriorly. The final branch provides cutaneous innervation to the midline of the chest and abdomen. The dura mater and the arachnoid membrane fuse with the epineurium as they exit the vertebral foramen. This could lead to subarachnoid block if the posterior paravertebral approach is used.

TECHNIQUE. The site of injection may be either paravertebral or in the midaxillary line. The lower rib margin is located, and the skin is retracted cephalad (Fig. 42.14A). The needle is inserted perpendicular to the skin over the rib and advanced until the rib is encountered (see Fig. 42.14B). The skin through which the needle is passed is allowed to retract caudally, and the needle is then walked off the lower edge of the rib a distance of 2 to 3 mm (see Fig. 42.14C). This method may reduce the potential for pneumothorax, because the needle strikes the rib and is not advanced more than half of the thickness of the rib. A distinct pop may be felt as the needle enters the neurovascular sheath. After negative aspiration for blood, an appropriate volume of anesthetic is injected. Recently, with the use of ultrasound guidance, we can visualize the pleura, thereby avoiding puncturing the pleura because it can be adequately visualized while performing the block (E-Fig. 42.6; see also Fig. 43.11).

COMPLICATIONS. Pneumothorax has been reported after intercostal blockade, with an incidence of approximately 0.07% in adults.[340] However, the majority of the blocks in that study were performed by residents in training. If a small pneumothorax occurs, reabsorption is facilitated with the use of oxygen. Placement of a chest tube is indicated only if breathing is compromised. A more significant complication is the toxic effect of absorbed local anesthetic drugs. Using smaller volumes of more dilute local anesthetic may reduce the risk of achieving toxic plasma concentrations. The risk of intravascular injection may be reduced with incremental injection and frequent aspiration. A third complication is a high subarachnoid block, usually associated with the posterior paravertebral approach.

Inguinal Block (Ilioinguinal and Iliohypogastric Nerves)

Inguinal block, supplemented by wound infiltration, is sometimes used in adult patients undergoing inguinal hernia repair. However, in children, an inguinal nerve block is used almost exclusively as an adjunct to general anesthesia and to manage postoperative pain. This block is as effective as caudal anesthesia for inguinal repairs.[341,342] Blockade of the ilioinguinal and iliohypogastric nerves is very successful for this purpose and has few associated complications, although injection into the femoral vessels and potential femoral nerve block are possible adverse outcomes.[343,344] The risks of toxicity from excessive drug doses may be greater than previously recognized, as discussed earlier, but ultrasound guidance has

E-FIGURE 42.6 Intercostal nerve block. **A,** A linear ultrasound probe is placed overriding the ribs. **B,** The innermost intercostal muscle is identified, a needle is placed using an off-plane approach, and, after negative aspiration, 2 mL of local anesthetic is injected. Spread of the local anesthetic solution in the innermost intercostal signifies blockade of the intercostal nerves.

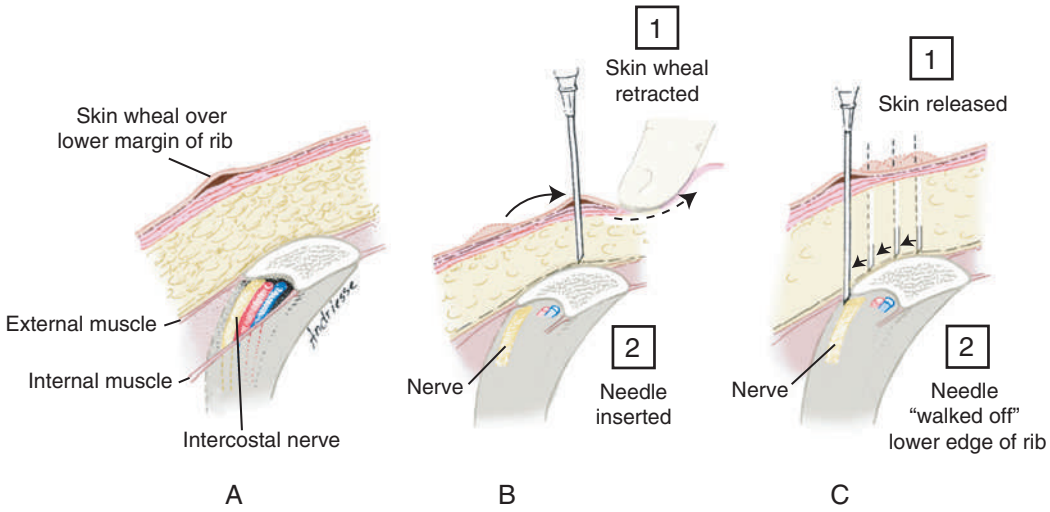


FIGURE 42.14 Intercostal block. **A,** A skin wheal is inserted on the lower rib margin. **B,** The skin wheal is retracted over the body of the rib, and a needle is inserted until contact is made with the rib. **C,** The skin is released, and the needle is carefully "walked" off the edge of the rib margin. After negative aspiration for blood, the appropriate volume of drug is injected. This block is used for postoperative analgesia for thoracotomy or chest tube insertion (see also E-Fig. 42.6).

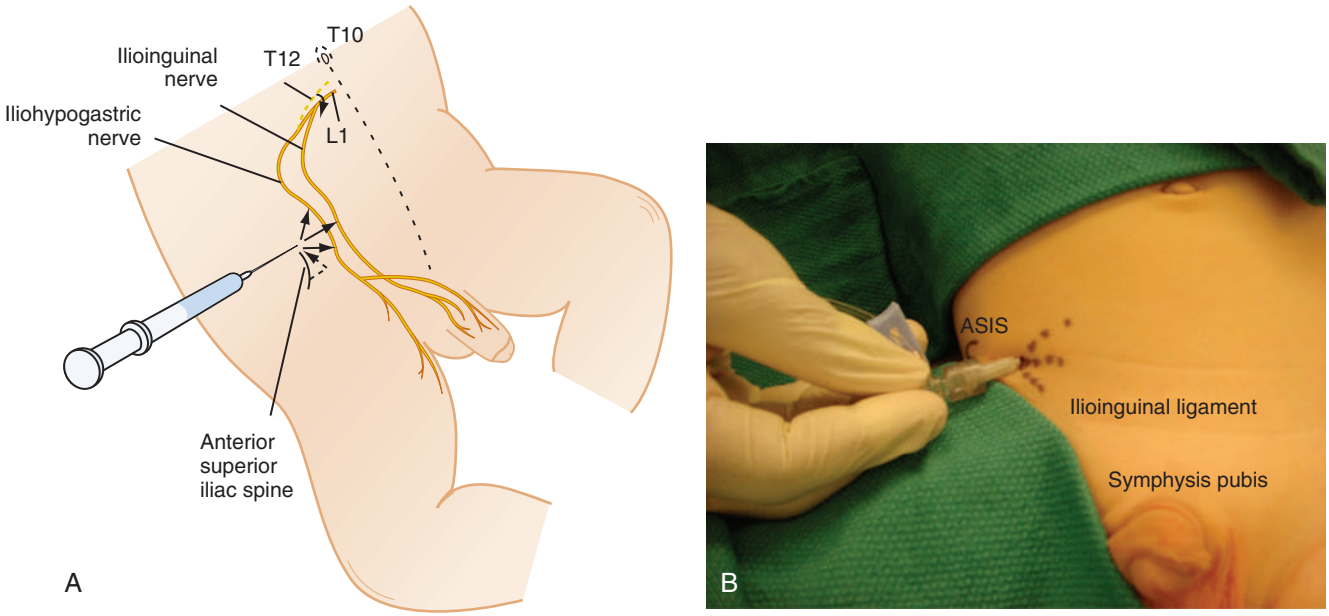

FIGURE 42.15 Ilioinguinal and iliohypogastric nerve blocks. **A** and **B,** The anterior superior iliac spine *(ASIS)* is palpated, and a point 1.0 to 1.5 cm cephalad and toward the midline is located (*dashed line*). A 22-gauge needle is passed through the external and internal oblique muscles, and 1.0 to 5.0 mL of local anesthetic is deposited in a fan-like fashion cephalad toward the umbilicus, medially, and caudad toward the groin (*solid arrows*). Just before removal from the skin, another 0.5 to 1.0 mL of local anesthetic is injected subcutaneously to block the iliohypogastric nerve. Blockade of these nerves provides postoperative analgesia for inguinal hernia and orchiopexy procedures (see also E-Fig. 42.7).

demonstrated adequate analgesia with reduced doses of local anesthetic solution because the drug is placed in the optimal location.[345] This block may be (and commonly is) performed in conjunction with infiltration of the wound. The use of ultrasound may also avoid the risk of bowel perforation (see also Chapter 43, and Figs. 43.34 and 43.35).[346]

ANATOMY. The inguinal area is innervated by the subcostal nerve (T12) and the iliohypogastric and ilioinguinal nerves (derived from L1). These nerves lie in close proximity to each other medial and superior to the anterior superior iliac spine (Fig. 42.15A). After piercing the internal oblique 2 to 3 cm medial to the anterior superior iliac spine, the nerve then lies between the internal oblique

and the external oblique aponeurosis. Here it accompanies the spermatic cord (in males) to the genital area.

TECHNIQUE. The block may be performed either at the beginning of surgery or before the end of general anesthesia. If bupivacaine is used, a minimum of 15 minutes is usually required from the completion of the block until maximal analgesia is obtained. Thus blocks placed at the beginning of the surgical procedure (our preference) are usually more effective than those performed at the end of surgery. Blocks performed before skin incision may also provide "preemptive analgesia," although the evidence for this is still under debate and somewhat confusing.[347–350] The duration of postoperative analgesia is unaffected by the timing of placing the block at the beginning of the procedure, assuming that the surgical procedure is not of more than 1.5 hours in duration or at the end. A short-bevel 27-gauge needle is inserted at a 45-degree angle at a point one-fourth of the way toward the midline along a line drawn from the anterior superior iliac spine to the umbilicus (1.0–1.5 cm cephalad and toward the midline from the anterior superior iliac spine in a 10- to 15-kg child). As the needle is advanced through the external and internal oblique muscles (see Fig. 42.15B), two pops are elicited and provide useful guides of proper needle placement. Negative aspiration should be confirmed several times during the incremental injection of local anesthetic. A volume of 0.3 mL/kg of local anesthetic solution is injected in a fan-like fashion, cephalad toward the umbilicus, caudad toward the groin, and medially. Before removal of the needle from the skin, an additional 0.5 to 1.0 mL of local anesthetic is injected SC to block the iliohypogastric nerve (Video 42.10). Care must be taken to avoid entering the peritoneum, which has been reported after the blind injection approach.[346] For inguinal herniorrhaphy, orchiopexy, or other inguinal procedures, local anesthetic deposited directly into the wound before it is closed has also proved effective for postoperative analgesia.[342] The volume of drug used by this approach, like the volume of drug used for wound infiltration, must be accounted for when calculating the maximal dose of local anesthetic that can be used. It is important to note that this block will not provide pain relief for scrotal procedures because this is supplied by the genitofemoral nerve and hence it is important to have the surgeon infiltrate the scrotum for complete pain relief after orchiopexy or any other scrotal procedures. As mentioned earlier, an ultrasound-guided technique may be easier to perform and is associated with fewer complications (E-Fig. 42.7).[345]

COMPLICATIONS. Complications are rare. Care should be taken not to enter the peritoneal cavity. Intravascular injection may be avoided by incremental injection with frequent aspiration.

Penile Block

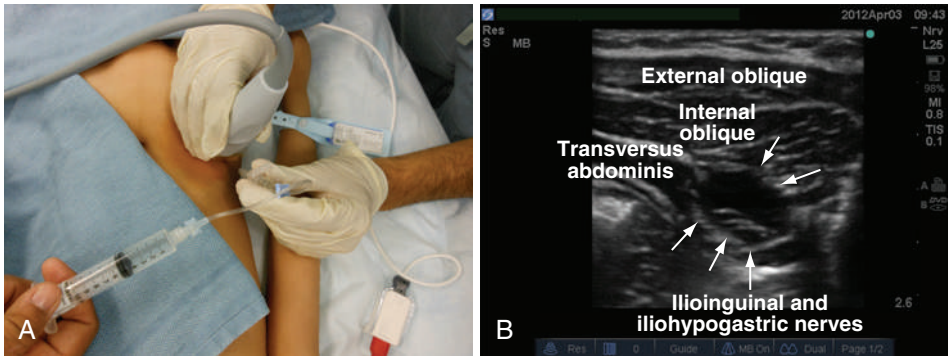
A penile block is used for anesthesia and postoperative analgesia for circumcision, urethral dilatation, and hypospadias repair. Caudal anesthesia is superior for proximal shaft or penoscrotal hypospadias repair because a penile block provides analgesia only for the distal two-thirds of the penis.[265,351,352] The block is easily performed with very good success. Bupivacaine, levobupivacaine, and ropivacaine are the most useful agents because of their prolonged duration of action. *Epinephrine is avoided for this block because the dorsal artery of the penis is an end artery and vasospasm caused by epinephrine could cause necrosis.*

ANATOMY. The nerve supply of the penis is from the pudendal nerve and the pelvic plexus (Fig. 42.16A). Along the dorsal artery to the penis are two dorsal nerves that separate at the level of the symphysis pubis; they supply the sensory innervation to the penis.

TECHNIQUE. There are two commonly used techniques for penile block: (1) a ring block and (2) blockade of the dorsal nerve. One investigation compared the efficacy of these techniques and concluded that the ring block provided analgesia of prolonged duration, although both techniques provided analgesia superior to EMLA cream.[353] The ring block is performed by inserting a 27-gauge needle at the base of the penis and, after negative aspiration, injecting the local anesthetic without epinephrine in a ring-shaped pattern around the base of the penile shaft. The needle may be inserted once in the midline and then redirected to each side (see Fig. 42.16B). The alternate dorsal nerve block is performed with a 27-gauge needle inserted 1 cm above the symphysis pubis, in the midline, at a 30-degree angle and directed caudally (see Fig. 42.16C). The needle is advanced 1 cm after it pierces the penile fascia. After negative aspiration for blood, 1 to 4 mL of local anesthetic *without epinephrine* is injected slowly. There is a small risk of injury to the adjacent neurovascular structures.

COMPLICATIONS. The major complication is compromise of organ blood flow. *Vasoconstrictors, such as epinephrine, must never be used for this block.* Applying pressure after the injection may minimize hematoma formation. Intravascular injection may be avoided with incremental injection and frequent aspiration.

Rectus Sheath Block



Although reported almost 20 years ago,[354] this block has recently become popular for children undergoing repair of an umbilical hernia.[355–357] The rectus sheath contains the thoracic intercostal nerves (T10) that can be blocked at the paraumbilical area using a small volume of local anesthetic solution.

TECHNIQUE. On either side of the umbilicus, about 1 cm from midline a needle is inserted into the rectus sheath (Fig. 42.17). A pop can be felt as the needle advances beyond the anterior rectus sheath, through the rectus abdominis muscle, and then just anterior to the posterior rectus sheath. After aspiration, a volume of 0.1 mL/kg of local anesthetic solution is injected (Video 42.10). This provides excellent analgesia for most umbilical area surgery, including laparoscopic surgery. Use of ultrasound may facilitate performing this block[358] (see Figs. 42.17A and B; see also Chapter 43, and E-Figs. 43.3 and 43.4).

Paravertebral Block

This block is also gaining some popularity for use in children. The main advantage is that deposition of local anesthetics in the paravertebral space will lead to strict unilateral anesthesia of one or more adjacent dermatomes (Fig. 42.18); the main indications for a paravertebral nerve block are unilateral thoracic or abdominal surgical procedures.

ANATOMY. The paravertebral space is a triangular wedge-shaped area situated in the angle between the lateral border of the vertebral body and the anterior surface of the transverse process (Fig. 42.19). The paravertebral space exists only between T1 and T12. Below T12 the space is sealed off by the origin of the psoas muscle from the vertebral body and the transverse process.[359] Cranially the space appears to communicate with fascial planes in the neck, because an upper thoracic paravertebral block may cause Horner syndrome. The communication of different thoracic levels of the paravertebral space is the foundation for spread of local anesthetic to multiple segments (see Fig. 42.18). The medial boundary of the paravertebral space is the lateral part of the vertebral body and disk, the dorsal limitation is the transverse process and costotransverse ligament, and the anterolateral boundary is the

E-FIGURE 42.7 A, Ultrasound-guided ilioinguinal nerve block: a linear ultrasound probe is placed along the superior margin of the iliac crest. (Orientation: thorax at the bottom of the figure, legs at the top.) **B,** The internal oblique and the transversus abdominis are visualized. The ilioinguinal nerve and the iliohypogastric nerves are located between the two muscle layers. Using an in-plane approach, the nerves are accessed and 0.1 mL/kg of local anesthetic solution is injected.

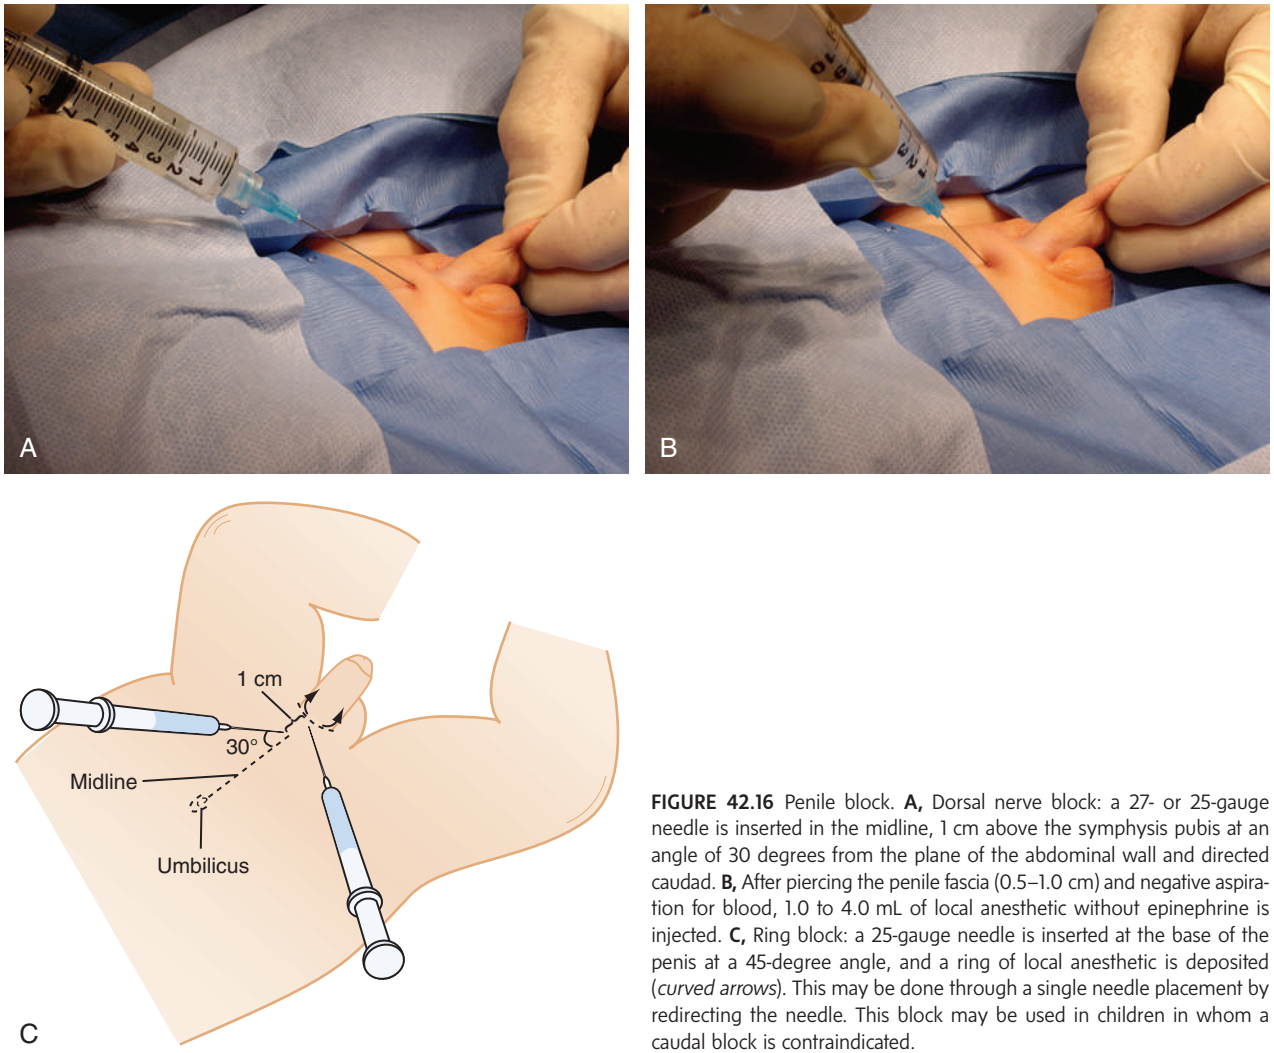


FIGURE 42.16 Penile block. **A,** Dorsal nerve block: a 27- or 25-gauge needle is inserted in the midline, 1 cm above the symphysis pubis at an angle of 30 degrees from the plane of the abdominal wall and directed caudad. **B,** After piercing the penile fascia (0.5–1.0 cm) and negative aspiration for blood, 1.0 to 4.0 mL of local anesthetic without epinephrine is injected. **C,** Ring block: a 25-gauge needle is inserted at the base of the penis at a 45-degree angle, and a ring of local anesthetic is deposited (*curved arrows*). This may be done through a single needle placement by redirecting the needle. This block may be used in children in whom a caudal block is contraindicated.

parietal pleura. Structures that pass through the paravertebral space include the spinal nerve root–intercostal nerve, the sympathetic chain, and the intercostal vessels. The paravertebral space is not like the epidural space, because the pleura are very adhesive to the other structures but should instead be viewed as a "potential space." This accounts for the slight difficulty in introducing a percutaneous catheter into the paravertebral space. In the lumbar region a paravertebral block is still possible but each individual space must be blocked separately because there are no communications between adjacent lumbar levels.

TECHNIQUE. Three approaches to perform a paravertebral block in children have been described:

Loss-of-Resistance Technique[359]: The skin is punctured laterally to the spinous process and the needle is advanced in a perpendicular manner until contact is made with the transverse process. A Tuohy needle (19- to 20-gauge if the child is younger than 1 year of age, 18-gauge if older than 1 year of age) is then "walked" below (underneath) the transverse process and by means of a loss-of-resistance technique the costotransverse ligament is pierced and the paravertebral space located. Alternatively, the needle can be "walked" above (over the top of) the transverse process, but by using this approach there is the risk of striking the neck of the rib before entering the paravertebral space. Occasionally this will redirect the needle, making it virtually impossible to obtain access to the paravertebral space. The approach from below the transverse process is clearly advantageous.

Once in the paravertebral space, the bolus dose of local anesthetic can be injected after careful aspiration to exclude the presence of blood or air. If a continuous technique is preferred, a catheter can be introduced 1 to 2 cm into the paravertebral space through the Tuohy needle. The insertion of the catheter frequently needs manipulation of the Tuohy needle to be successful, and occasionally one will have to make the injection of the bolus dose to "open up" or "create" a space to allow catheter insertion. One should not insert more than 1 to 2 cm of the catheter into the paravertebral space because further advancement may cause the catheter to migrate into the spinal canal through the intervertebral foramen (causing an epidural distribution of the block) or to go laterally, following the path of the intercostal nerve (giving a dense block of only one dermatome).

An estimate of the distance from the spinous process to the skin puncture site (spinous process to paravertebral space distance) and the distance from the skin to the paravertebral space can be approximated by the following equations[360,361]:

$$\text{Spinous process to paravertebral space distance (mm)} = 0.12 \times \text{kg} + 10.2$$

$$\text{Skin to paravertebral space distance (mm)} = 0.53 \times \text{kg} + 21.2.$$

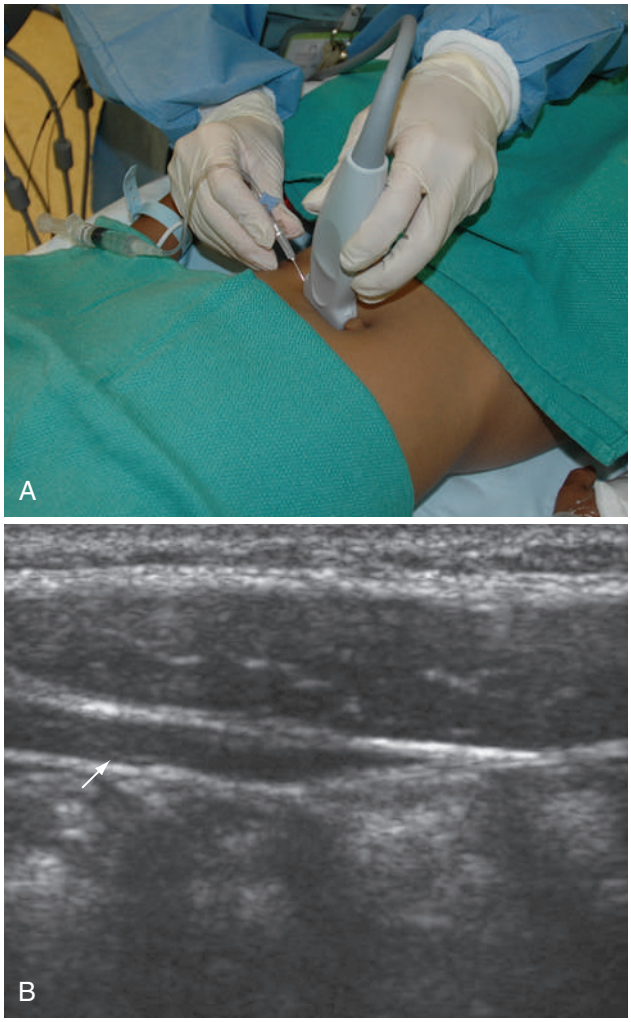

FIGURE 42.17 Rectus sheath block. The rectus sheath is encompassed between the rectus abdominis muscle anteriorly and the posterior rectus sheath. **A,** A linear ultrasound probe is placed lateral to the umbilicus, and the anterior rectus sheath, the rectus abdominis muscle, and the posterior rectus sheath are identified. **B,** With the use of an in-plane approach, a 27-gauge needle is inserted through the rectus abdominis muscle anterior to the posterior rectus sheath and 0.1 mL/kg of local anesthetic solution is injected (*arrow*).

The level of the puncture depends on the surgical intervention, but for a thoracotomy the puncture is best performed at T5-6 and for renal surgery at T9-10.

Nerve-Stimulator–Guided Technique.[362] The intervertebral lines corresponding to the specific dermatomes are determined by manual palpation. The site of injection is marked 1 to 2 cm laterally from the midline on the intervertebral line according to the child's weight. A 21-gauge insulated needle of appropriate length, attached to a nerve stimulator (initial stimulating current: 2.5–5 mA, 1 Hz), is introduced perpendicularly to the skin in all planes. A contraction of the paraspinal muscles is initially observed, and the needle is advanced until the costotransverse ligament is reached. At this point the contraction of the paraspinal muscles will disappear. After piercing the costotransverse ligament, muscle contractions of the corresponding level are sought and the needle tip is manipulated into a position allowing continued muscular contractions while reducing the stimulating current to 0.4 to 0.6 mA; the desired local anesthetic dose and volume is injected. Manipulation of the needle tip within the paravertebral space is not an "in and out" movement but is rather an angular manipulation and circumferential rotation around the axis of the needle to reach an optimal position of the needle tip with regard to the nerve within the paravertebral space.

Ultrasound-Aided Approach. With the aid of ultrasound the position of the transverse processes and the depth to the paravertebral space can be determined; ultrasound is very helpful regardless of whether a loss-of-resistance or nerve-stimulator–guided technique is used.

SELECTION OF DRUG. After a negative aspiration test and administration of a test dose, 0.5 mL/kg of the local anesthetic (levobupivacaine 0.25% with epinephrine 1:200,000, bupivacaine 0.25% with epinephrine 1:200,000, or lidocaine 1% with epinephrine 1:200,000) is injected in toddlers and older children. This dose will usually spread to cover at least five dermatomes. A typical distribution of the block will be unilateral analgesia of the trunk ranging from T4 to T12 (see Fig. 42.18). In neonates and infants, slightly modified dosage regimens are recommended;[363-365] these dosages have been found to be both effective and associated with acceptable plasma concentrations of bupivacaine.[363]

COMPLICATIONS. The use of a percutaneous loss-of-resistance technique in a mixed adult and pediatric population was found to be associated with an overall failure rate of approximately 10%, and the complications experienced were hypotension (5%; only adults), vascular puncture (4%), pleural puncture (1%), and pneumothorax (0.5%).[366] The risk for block failure is reduced to less than 5% when a nerve-stimulator–guided technique is used, and this technique also appears to be associated with a reduced risk for complications.[362,367] Use of ultrasound may further improve success while reducing complications.

UPPER EXTREMITY BLOCKS

Brachial Plexus Block

Of the four techniques used to block the brachial plexus (axillary, infraclavicular, supraclavicular, and interscalene), the axillary approach is most commonly used in children when using nerve stimulation or landmark approaches.[368] Advantages include ease of insertion, a high rate of success in experienced hands, and low morbidity. The block is also well suited for orthopedic or plastic surgical repairs on the hand or forearm in a child with a full stomach.[369,370] In the latter situation, the child is at greater risk for aspiration of gastric contents with deeper levels of sedation, an intravascular injection, or a drug overdose. Because it is unnecessary to elicit a sensory paresthesia, the block can also be performed in an anesthetized child for postoperative pain management. Toxicity is avoided if the dose of bupivacaine is less than 2.5 mg/kg.

With the use of ultrasound guidance, infraclavicular, supraclavicular and interscalene blocks have largely supplanted the axillary block in children. The infraclavicular block is our preferred technique for the placement of a continuous catheter in the postoperative period. Unintentional block of the phrenic and recurrent laryngeal nerves is much more common in young children because these nerves are close to the site of injection, especially with an interscalene block. Data suggest that some degree of phrenic nerve blockade is present in all children who receive interscalene blocks.[371,372] Phrenic nerve blockade may cause respiratory failure in very young children whose breathing depends almost completely on the diaphragm, whereas blockade of the recurrent laryngeal nerve will paralyze the vocal cords and increase airway resistance. The risk of pneumothorax is greater because the apex of the lung is situated more rostral in infants and small children.

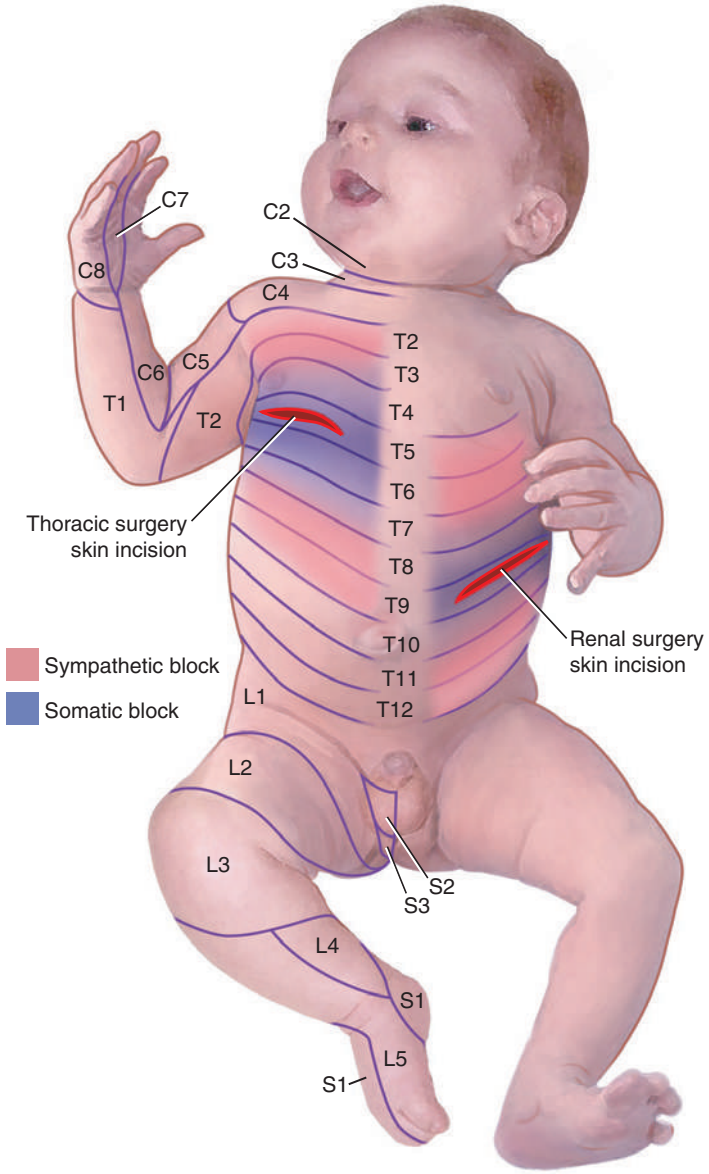

FIGURE 42.18 Distribution of somatic and sympathetic blockade after thoracic paravertebral blocks. *Blue shading* indicates the approximate spread of somatic blockade and *pink shading* indicates the approximate extent of sympathetic blockade. (See text for details.) (From Lönnqvist PA, Richardson J. Use of paravertebral blockade in children. *Tech Region Anesth Pain Manage*. 1999;3[3]:184–188.)

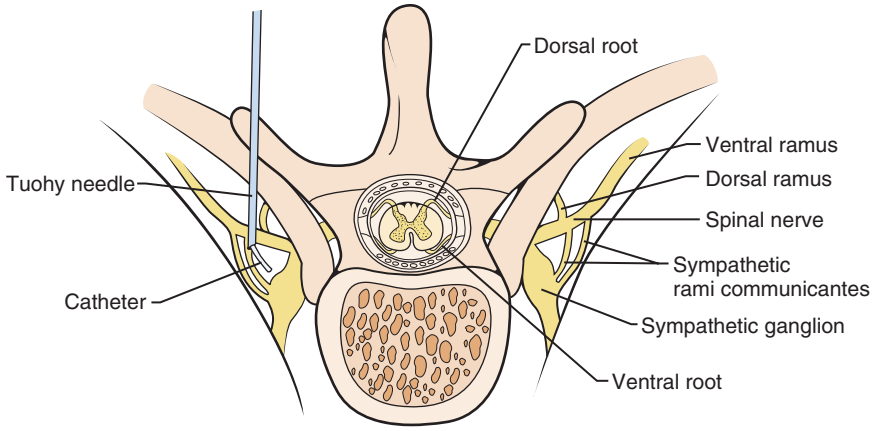

FIGURE 42.19 Anatomic relationship of the paravertebral block and correct position of Tuohy needle and catheter. (From Lönnqvist PA, Richardson J. Use of paravertebral blockade in children. *Tech Region Anesth Pain Manage*. 1999;3[3]:184–188.)

Total spinal anesthesia is also more likely with the interscalene approach to axillary plexus blockade.[373]

ANATOMY. The brachial plexus arises in the neck from spinal nerves C5, C6, C7, C8, and T1, passes between the clavicle and first rib, and extends into the axilla. At that point, the axillary artery is surrounded by a narrow fascial sheath that contains the median nerve anteriorly, the ulnar nerve posteriorly, and the radial nerve on the posterolateral aspect (Fig. 42.20A). In children, the axillary artery and, at times, the axillary sheath itself may be palpable.

TECHNIQUE. Several techniques can be used to establish that the needle is within the axillary sheath. The first is by eliciting a sensory paresthesia with the needle, but this has little application in pediatric practice, particularly in young children and in those who are anesthetized. The use of a nerve stimulator allows precise placement of the needle in the neurovascular sheath without either the cooperation of the child or the need for painful sensory paresthesias (see Fig. 42.2). In thin children, the sheath can often be palpated as a cord-like structure inferior to the coracobrachialis muscle, allowing the placement of the needle in the sheath by "feel." A transarterial approach can also be used.[374] With all techniques, it is useful to attach a short piece of extension tubing between the needle and syringe to facilitate precise handling during needle placement, aspiration, and drug injection.

The use of a nerve stimulator for the axillary approach to the brachial plexus is best accomplished by abducting the arm to 90 degrees (see E-Fig. 42.2). Care should be taken not to hyperabduct the arm, obscuring the axillary pulse. The artery is palpated in the axilla, and a short beveled needle is advanced toward it (see Fig. 42.20B and C). When using a nerve stimulator, a distal motor response is elicited in the distribution of the radial, ulnar, or median nerves at a threshold of less than 0.2 mA (see E-Fig. 42.2). If one is not using a nerve stimulator, the needle is advanced until a distinct pop is felt as the needle pierces the axillary sheath. The axillary sheath may be divided into fascial compartments for each nerve, and these may limit the spread of local anesthetic within the axillary sheath. Although distinct paresthesias to the distribution of all three nerves may be elicited with the nerve stimulator, and divided doses of anesthetic may be administered to each of those locations, in practice it becomes extremely difficult to find the second and third motor paresthesias after the administration of even a very small amount of local anesthetic with the first injection (Video 42.12). Alternatively, the transarterial technique, which involves direct puncture of the axillary artery, allows deposition of local anesthetic at two sites within the sheath. The needle is aimed directly toward the axillary pulse. As soon as blood is aspirated, the needle is advanced through the posterior wall of the artery. When blood can no longer be aspirated, half of the dose of local anesthetic is deposited posterior to the artery. The needle is withdrawn through the anterior wall of the artery, and the remainder of the dose is deposited anterior to the artery after reconfirming a negative aspiration for blood. Regardless of technique, the local anesthetic is administered in incremental quantities with intermittent aspiration to confirm that the needle is still outside the blood vessel. It is sometimes difficult to block the musculocutaneous nerve, which carries sensory fibers to the radial aspect of the forearm, because it exits the brachial plexus proximal in the axillary fossa. Therefore, some practitioners advocate applying a tourniquet distal to the site where the block is to be performed. Applying a tourniquet promotes proximal spread of local anesthetic and enhances the chances of a successful block of this nerve. Alternatively, the musculocutaneous nerve may be blocked by infiltrating 1 to 3 mL (proportional to the size of the child) of local anesthetic into the body of the coracobrachialis muscle. Regardless of the technique chosen, an additional 1 to 3 mL of local anesthetic is deposited as a subcutaneous cuff to block the intercostobrachial nerve and its communications with the musculocutaneous nerve. These additional quantities of local anesthetic must be accounted for when calculating the total drug dose. An ultrasound may also be used in conjunction with a nerve stimulator to further improve the localization of each nerve bundle (see Figs. 42.20D, 43.16, and 43.21).[370]

SELECTION OF DRUG. Local anesthetics commonly used in our practice include lidocaine and bupivacaine (see Table 42.2). As with other regional techniques that involve larger volumes of local anesthetic, the addition of both levobupivacaine and ropivacaine to the armamentarium is likely to prove beneficial in reducing the risk of toxicity from local anesthetics. Because it is desirable to have a prolonged duration of postoperative analgesia, longer-acting agents are usually used in place of lidocaine. To help ensure block of the musculocutaneous nerve, we use large volumes (0.5 mL/kg), diluting the concentration of local anesthetic with normal saline solution as needed to avoid toxicity. Care must always be taken not to exceed the maximal allowable doses of bupivacaine on a milligram per kilogram basis (2.5 mg/kg).[375] Adding epinephrine (1:200,000) may decrease vascular absorption and the potential for toxicity. Sodium bicarbonate (1 mEq/10 mL of local anesthetic) added to the local anesthetic will speed the onset of blockade by increasing the pH of the solution; this is particularly the case with the premixed anesthetic-epinephrine formulations that have a reduced pH.

COMPLICATIONS. All of the nerves of the brachial plexus occupy a neurovascular bundle and hence are prone to unintended injection into a blood vessel. A hematoma may form at the site of injection. If it is large enough, the hematoma may compress the neurovascular bundle, rendering the limb ischemic. Hence it is important to know the child's coagulation status before attempting the block. Intravascular injection may be avoided with incremental injection and frequent aspiration. Intraneural injection may be minimized by use of a nerve stimulator. Practitioners may feel the importance to check the viability of the radial, median, and ulnar nerves before injecting local anesthetic solution. This block can be carried out in the recovery room after the function of the nerves is determined. A simple rule of thumb is to check the radial nerve (extension of the thumb), median nerve (flexion of the proximal interphalangeal joint of the thumb), and ulnar nerve (scissoring of the fingers) (Video 42.13). This can functionally check the nerves before injection of local anesthetic solution.[376]

INFRACLAVICULAR APPROACH. This approach to the brachial plexus is very helpful, particularly in children who may have fractures making it painful to abduct the arm. A vertical approach to the infraclavicular brachial plexus is performed using the coracoid process as a landmark to access the nerve.[377] We routinely use this technique in children who require continuous infusions of local anesthetic solution in the postoperative period.

TECHNIQUE. With the arm in abduction, the acromial process is palpated. A line drawn 2 cm below and medial to the coracoid process is usually where the needle is introduced (Fig. 42.21A). At this level, the pleura is not usually affected. A sheathed needle with a nerve stimulator is introduced, and the nerve is stimulated at about 1 mA. Any stimulation other than forearm flexion is taken as a positive stimulation of the brachial plexus. Forearm flexion denotes stimulation of the musculocutaneous nerve. The needle should then be directed medial to provide a blockade of the cords of the brachial plexus (see Fig. 42.2B). An ultrasound-guided

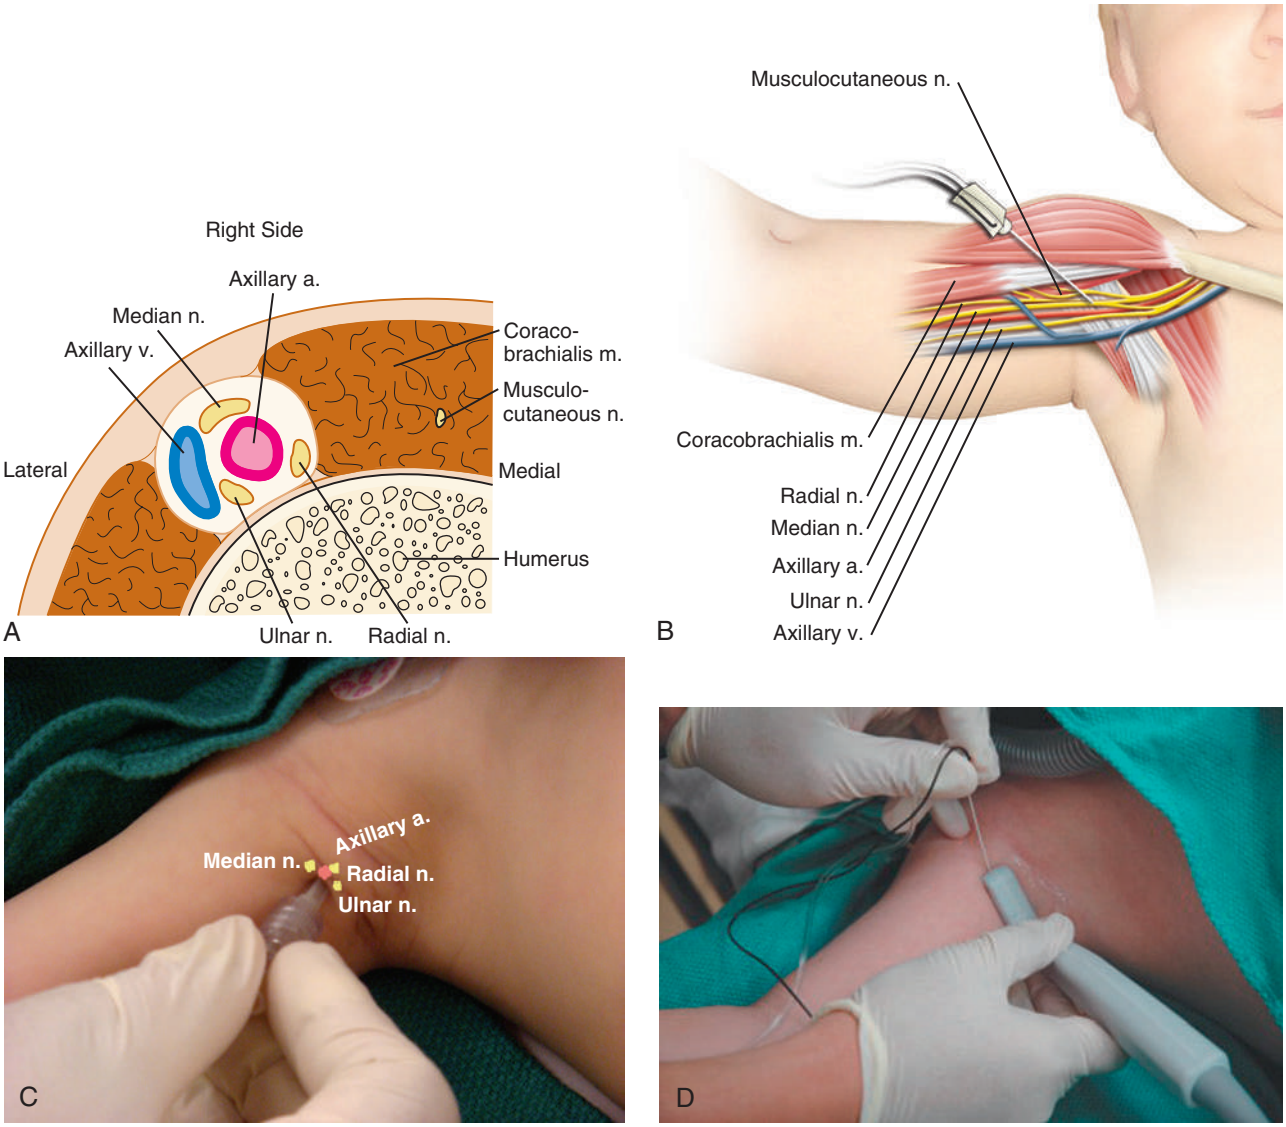

FIGURE 42.20 A and **B,** The anatomic relationships of the brachial plexus are presented. Note that the fascial sheath envelops the nerves and the axillary artery and vein; the musculocutaneous nerve lies within the body of the coracobrachialis muscle. Local anesthetic injected within the sheath (on either side of the axillary artery) produces a satisfactory block. There may be septation within the sheath in some individuals (not pictured). **C,** The axillary artery is palpated with the arm in abduction in the axilla. A needle is introduced superior to the pulsation to block the median nerve. If a nerve stimulator is used, opposition of the thumb can be elicited as the median nerve is stimulated. The needle is then gently positioned below the artery; the ulnar nerve can be blocked in this position. If a nerve stimulator is used, flexion of the fifth finger is elicited. For blocking the radial nerve situated posterior to the artery, it may be necessary to pass the needle posterior to the artery while constantly aspirating to avoid intravascular placement. If the needle does encounter the axillary artery, continue to advance the needle so that the aspirate is negative while the needle is situated posterior to the artery. If a nerve stimulator is used, biceps flexion may be observed. A total volume of 0.1 to 0.15 mL/kg in divided doses between all three nerves will provide an adequate blockade of the nerves. If the axillary artery is encountered while accessing the radial nerve, it is imperative to apply pressure after the block is placed to avoid hematoma formation. **D,** An ultrasound is particularly useful for successful placement of an axillary block. A linear ultrasound probe or a hockey stick probe is placed on the axilla. With the use of an in-plane approach, the median nerve (located anterior to the artery), then the radial nerve (located posterior to the axillary artery), and then the ulnar nerve (located below the artery) are blocked individually. Careful aspiration before injection may prevent intravascular injection. *a*, artery; *m*, muscle; *n*, nerve; *v*, vein.

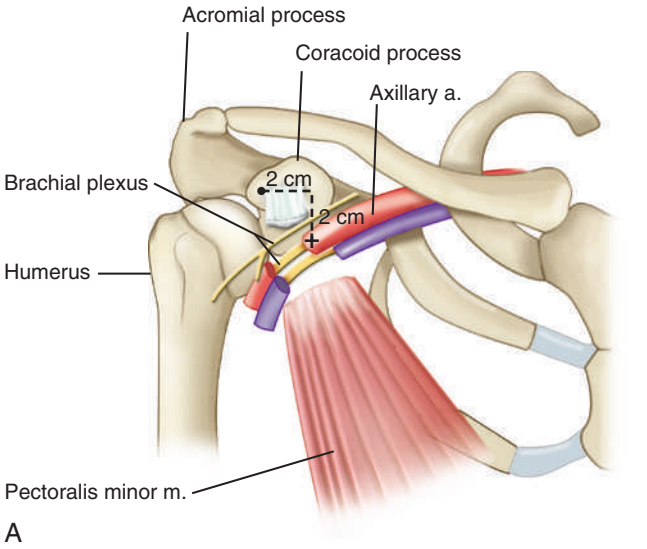

FIGURE 42.21 A, Anatomic landmarks for the infraclavicular approach to the brachial plexus. Note that the arm is in an abducted position, which may be quite useful for children with fractures. **B,** The coracoid process is palpated. With the arm abducted, a needle is inserted 2 cm medial and inferior to the coracoid process. A nerve stimulator is used and stimulation is initiated at 1 mA and then decreased to 0.4 mA as the nerve is accessed. Elicitation of hand flexion or extension is used as an indicator of being close to the nerve. After aspiration, 0.2 mL/kg of local anesthetic solution is injected. Use of ultrasound may also improve the success of this block. *a*, artery; *m*, muscle. (Modified from Wilson JL, Brown DL, Wong GY, et al. Infraclavicular brachial plexus block: parasagittal anatomy important to the coracoid technique. *Anesth Analg.* 1998;87[4]:870–873.)

technique may also be used and is preferred (see also Chapter 43 and Figs. 43.17 to 43.19).

COMPLICATIONS. There is the potential for intrapleural injection and pneumothorax, especially if the needle is directed medially. Because of the proximity of the plexus to the subclavian vein and artery, it is imperative that the procedure not be attempted on children who have coagulation abnormalities.

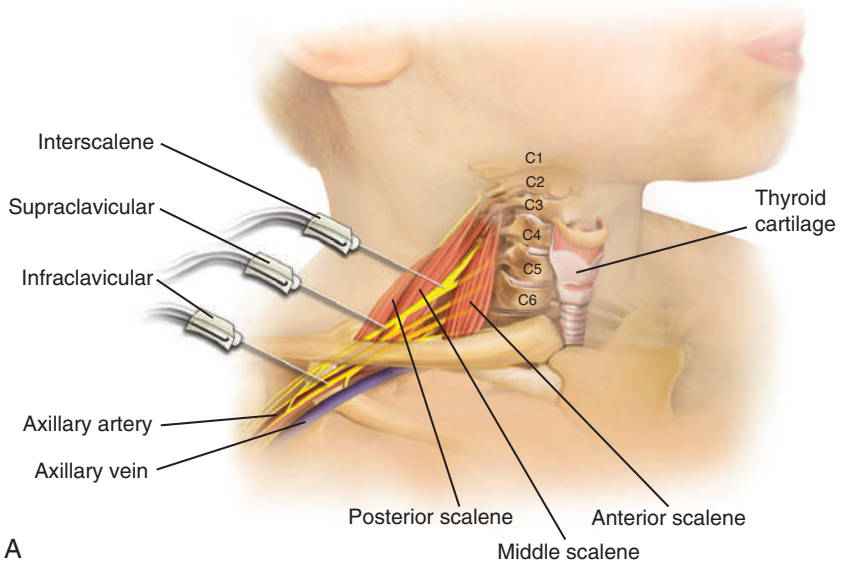
SUPRACLAVICULAR APPROACH. This is an easy approach to the brachial plexus in children and can be readily performed, particularly with the aid of ultrasound guidance. The risk with performing this procedure without ultrasound guidance is the potential for injection into the vertebral artery. It can be used for most procedures performed on the upper arm and forearm. The cervical pleura is also located close to the supraclavicular plexus; thus caution should be exercised while performing this block. The entire brachial plexus, including the musculocutaneous and the axillary nerves, is located lateral to the artery. Occasionally, the suprascapular nerve may leave the upper trunk more cranially.

INDICATIONS. This block is used for analgesia or anesthesia for upper arm surgery and can be performed with either a single injection or catheter technique.

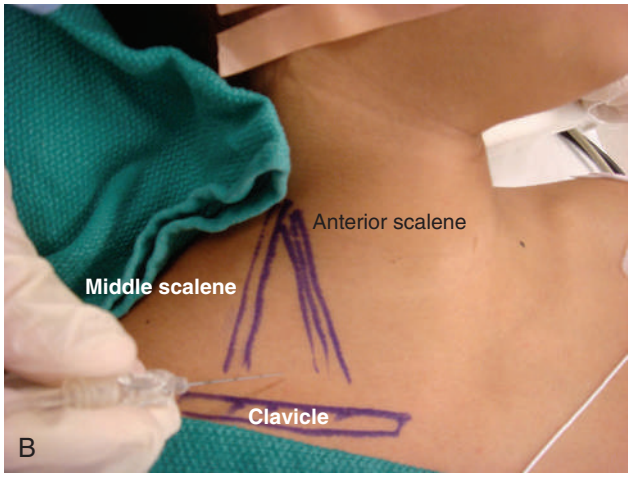
TECHNIQUE. The supraclavicular plexus is located above the clavicle and is approximately at the middle of the sternocleidomastoid. A stimulating needle (1 mA) is passed above the clavicle lateral to the arterial pulsation and close to the inferior margin of the anterior scalene. The plexus is located superficially and can be easily stimulated as soon as the skin is pierced. Any movement of the child's fingers or arm is accepted as an adequate stimulation to the plexus. The energy is reduced to 0.4 mA and, if continued response to the stimulation is observed, 0.15 to 0.2 mL/kg of local anesthetic solution is injected in graduated doses after careful aspiration.

The ultrasound-guided technique is now our preferred method for blocking the supraclavicular plexus. We use a linear probe or a hockey stick probe and, using the in-plane technique, pass the needle close to the plexus. If a stimulating needle is used, the needle is advanced until we see movement of the hand. We have been able to decrease the dose of local anesthetic solution to 0.15 to 0.2 mL/kg (Fig. 42.22 and Video 42.14; see also Fig. 43.16).

COMPLICATIONS. Pleural puncture and intravascular injection can occur from misplacement of the needle.



Interscalene Approach



This approach is not commonly used in children. The main indication for this technique is for children undergoing shoulder surgery; this approach is generally reserved for the older teenager or young adult.

ANATOMY. The interscalene groove is formed by the anterior and middle scalene muscles and is located in most children at the lateral border of the sternocleidomastoid muscle (see Fig. 42.22A). The upper three nerve roots are superficial, whereas the lower two roots are in a deeper position. In children the lower nerve roots are close to the pleura, which may increase the potential for a pneumothorax. The phrenic nerve is also close to the nerve roots and may often be unintentionally blocked on the side of the intended nerve block. Therefore this block is clearly avoided in children who may have a compromised pulmonary system. The vertebral artery is located in close proximity to the lower nerve roots (C7) and hence it is important to aspirate and ensure that the needle is not in a vessel.

INDICATIONS. Shoulder and upper arm surgery and ensuing postoperative analgesia can be provided with this block.

Conventional Techniques. Dalens and associates reported a technique of parascalene brachial plexus blockade for pediatric shoulder surgery using an extended head position and placing the puncture between the lower and middle thirds of the line extending from the center of the clavicle to the C6 transverse process (Chassaignac tubercle; see Fig. 42.22A).[378] The rationale for selecting this puncture site was to avoid the vertebral artery and pleura. With the use of a perpendicular needle orientation, the lower roots (C8 and T1) are not blocked at all or require very large amounts of local anesthetic to be successfully blocked. Ultrasound guidance is greatly advantageous in this situation because it paves the way for safe blockade of both roots (C8 and

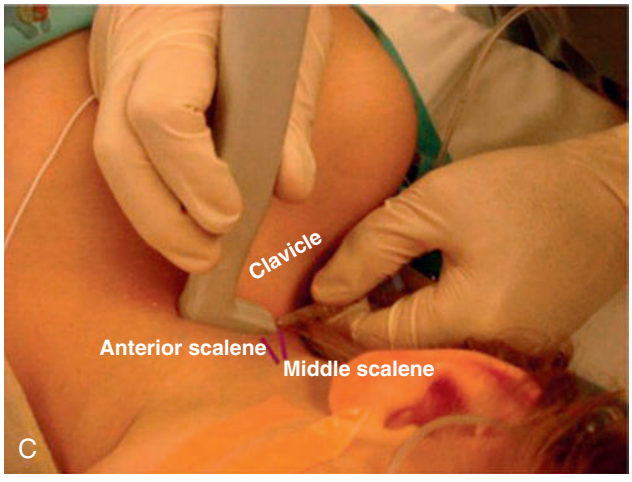


FIGURE 42.22 A right-sided supraclavicular block (landmark technique): The supraclavicular block is used frequently in children for most procedures on the hand and elbow. **A,** The divisions and cords are located around the carotid artery cephalad to the clavicle at the inferior margins of the scalene muscles. **B,** A stimulating needle, using 0.5 mA of energy, is introduced at the inferior border of the anterior scalene muscle. Any movement of the patient's fingers (including flexion or extension) suggests adequate positioning of the needle. After aspiration to avoid intravascular injection, 0.15 mL/kg of local anesthetic solution is injected. **C,** Supraclavicular block with ultrasound guidance. A linear ultrasound probe or a hockey stick probe is placed lateral to the suprasternal notch and above the clavicle. The carotid artery is identified. The supraclavicular plexus is located around the carotid artery at this location like a "bunch of grapes." A needle is placed in an in-plane approach (along the axis of the probe), and the plexus is penetrated. Injection of local anesthetic solution will be seen as a hypoechoic spread around the plexus.

T1). With the use of a nerve stimulator, diaphragmatic stimulation may be observed as a result of ventromedial needle position (the phrenic nerve runs ventral to the body of the anterior scalene muscle).

Ultrasound-Guided Technique (see Chapter 43). To visualize the anatomic structures of a child's neck, a high-frequency linear ultrasound probe is used. The process is facilitated by slightly turning the child's head to the contralateral side. The probe should be oriented from the medial to the lateral aspect. Medially, the thyroid gland and the major vessels in the neck area (carotid artery and internal jugular vein) are easily identified. Then the probe is moved along the sternocleidomastoid muscle until its lateral border is reached. At the same time, the transducer is moved in a caudal direction such that the posterior scalene gap and the upper anterior roots (C5-7) of the brachial plexus become visible between the anterior and medial scalene muscles. In very small children, all roots of the brachial plexus (C5-T1) can be simultaneously visualized. The puncture is performed in a tangential direction relative to the neck above the transducer. The C5 nerve root will be encountered superficially, within a few millimeters. As a rule, the needle should be oriented lateral to the C7 root, which will ensure that the neck vessels remain at an adequate distance from the needle insertion site. As soon as the local anesthetic has been injected, it will spread toward the C5 root, which can be visualized in the ultrasound image. Depending on the blockade required, the needle can be advanced to a deeper level for injection after the deep roots (C8 and T1) have been visualized. If the local anesthetic fails to spread adequately in a medial direction, the needle is retracted toward the subcutaneous level and is then repositioned on the medial side of the posterior scalene gap in the area of the C7 root. In the majority of cases, however, the local anesthetic will spread in an adequate manner even when the needle is in a lateral position. The injected volume of local anesthetic should not exceed the amount necessary to fully cover the root surfaces. It is, therefore, inappropriate to recommend a specific volume. In general, however, complete blockade via the interscalene route can be expected with local anesthetic volumes of 0.15 to 0.25 mL/kg.

COMPLICATIONS. Pneumothorax, intravascular injection, and temporary phrenic nerve injury are risks of this block.

Intravenous Regional Anesthesia

IV regional anesthesia was first described in 1908 by August Bier and is frequently referred to as the Bier block.[379] This technique has been advocated for upper extremity procedures lasting 30 to 60 minutes in children because of its rapid onset of anesthesia and its ease of performance.[380–382] *Only dilute lidocaine (0.25% or 0.5%) can be used because of the risk of local-anesthetic toxicity, particularly if the tourniquet is deflated early or inadvertently.* This can be a useful block for upper extremity fracture reduction or suture of a large laceration in children with a full stomach. It is also helpful for chronic painful conditions, including complex regional pain syndrome type 1, in children and adolescents.[383] The exsanguination and manipulation of the limb before administering the local anesthetic may prove to be unduly painful for children with a fracture, and many children may not tolerate the discomfort of the tourniquet without significant sedation. Another disadvantage is the possibility of toxic reactions in the event of tourniquet failure. Strict attention to detail–elevation or exsanguination of the extremity to be blocked, proper application of a double pneumatic cuff, careful attention to anesthetic dose, and care not to deflate the tourniquet until 30 minutes after injection of the local anesthetic–is important to avoid serious complications and provide a successful block. This block is unsuitable for infants (those younger than 1 year of age) because of the risk of toxic reactions in infants. This technique may also be contraindicated in children in whom the prolonged use of a tourniquet is inadvisable.

TECHNIQUE. A small-gauge IV cannula is inserted in a vein on the dorsum of the hand. Exsanguination of the arm is accomplished either by wrapping the limb with an Esmarch bandage, or by elevating the limb if wrapping is too painful. The proximal compartment of a double tourniquet is inflated to a pressure of 200 to 250 mm Hg, although some have recommended that it be inflated to 150 mm Hg greater than the child's systolic blood pressure. If tourniquet pain develops during the course of the procedure, the distal cuff may be inflated, followed by deflation of the proximal cuff. The tourniquet must remain inflated for a minimum of 30 minutes to prevent a rapid IV infusion of lidocaine and sequelae. It is best to deflate the tourniquet incrementally. Because no residual blockade persists after the tourniquet is released, supplementary analgesia must be considered (e.g., IV opioids, local infiltration with a long-acting local anesthetic).

SELECTION OF DRUG. Use 1 mL/kg of *preservative-free* 0.25 to 0.5% lidocaine without epinephrine for this block because the duration of the block is limited by the tourniquet time and because of the greater potential for cardiac toxicity with longer-acting agents. A very low dose of a nondepolarizing neuromuscular blocking agent, such as rocuronium (0.03 mg/kg), may improve the quality of the motor blockade.[384–386]

COMPLICATIONS. Unintended deflation of the tourniquet results in release of drug into the intravascular compartment; hence, only a short-acting local anesthetic, such as lidocaine, should be used. *Bupivacaine should never be used for this block because of the risk of cardiotoxicity.*

Peripheral Blocks at the Elbow

There is usually no great advantage to blocking the peripheral nerves at the elbow compared with blocking them at the wrist for analgesia or anesthesia of the hand because the forearm is supplied by cutaneous branches that originate in the upper arm. However, on some occasions (e.g., to avoid injections into surgical fields or areas of infection), anesthesia of the hand may be achieved by blocking the appropriate nerves at the elbow because the cutaneous nerve supply to the hand arises at the elbow.

Radial Nerve

ANATOMY. The radial nerve supplies the radial side of the dorsum of the hand and the proximal parts of the radial three-and-a-half digits. Block at the elbow is useful for the provision of anesthesia for an arteriovenous fistula. It is also useful to supplement an inadequate brachial plexus block at the axillary level. The radial nerve passes over the anterior aspect of the lateral epicondyle (Fig. 42.23A).

TECHNIQUE. The intercondylar line is marked. After identification of the biceps tendon, a 27-gauge needle is inserted directly toward the bone of the lateral epicondyle toward the lateral margin; 2.0 to 5.0 mL (depending on the child's weight) of bupivacaine (0.25% with epinephrine 1 : 200,000) is injected into the area (see Fig. 42.23B). Ultrasound guidance can help with determination of the exact location of the nerve in the forearm (see Chapter 43 and Figs. 43.22 and 43.23).

COMPLICATIONS. Intravascular injection and intraneural injections are potential complications. The use of a nerve stimulator or ultrasound can reduce unintended intraneural injection.

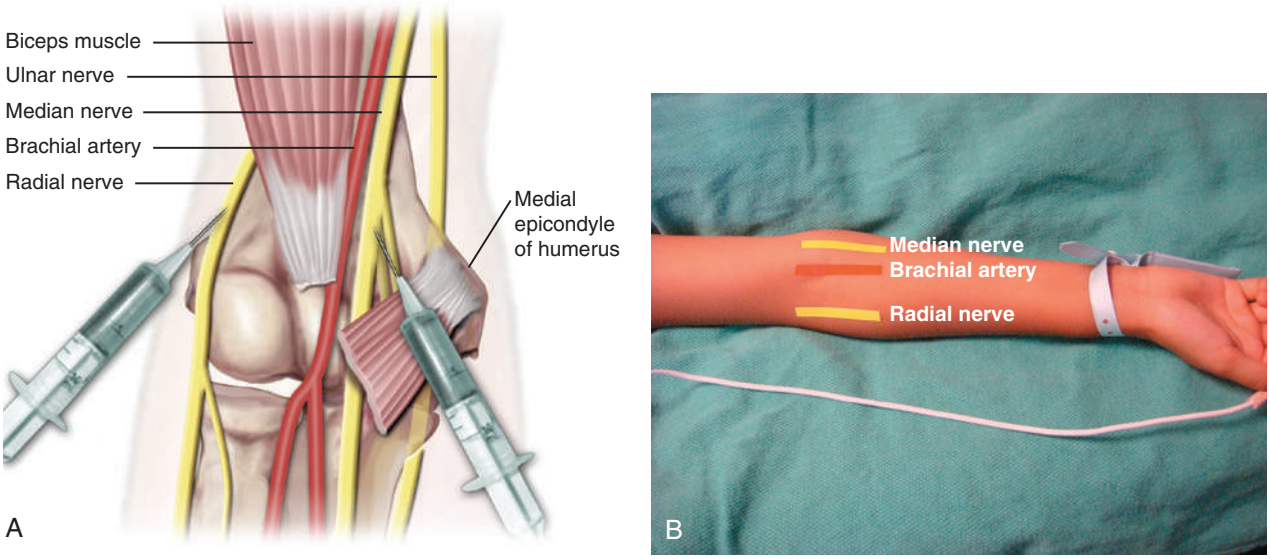

FIGURE 42.23 A, Anatomic relationship of the nerves around the elbow. **B,** Radial nerve block: the intercondylar line is marked. After identification of the biceps tendon, a 27-gauge needle is inserted directly toward the bone of the lateral epicondyle toward the lateral margin; 2.0 to 5.0 mL (depending on the patient's weight) of bupivacaine (0.25% with epinephrine 1:200,000) is injected into the area. To block the median nerve, the brachial artery is palpated at the elbow crease. The median nerve is located immediately medial to the brachial artery. A nerve stimulator is used, and flexion of the patient's fingers denotes adequate localization of the nerve.

Intravascular injection may be avoided with incremental injection and frequent aspiration.

Median Nerve

ANATOMY. This nerve supplies the radial side of the palm and the three-and-a-half digits of the palmar aspect (see Fig. 42.23A). It accompanies the brachial artery in its course down the arm. It is initially lateral and then crosses the ventral side of the artery and eventually lies medial to the artery at the bend of the elbow. It is deep to the bicipital fascia and superficial to the brachialis muscle.

TECHNIQUE. The arm is abducted and the forearm supinated. After marking the intercondylar line between the medial and the lateral epicondyle of the humerus, the brachial artery is palpated (see Fig. 42.23A). A 27-gauge needle is inserted just medial to the artery and directed perpendicular to the skin; 2.0 to 5.0 mL (depending on the child's weight) of bupivacaine (0.25% with epinephrine 1:200,000) is injected into the site. Caution must be exercised to avoid the artery because it is in close proximity to the nerve. Surface mapping using a nerve stimulator probe generating 5 mA or greater can be used to locate the nerve in the forearm if there is difficulty in palpating the artery (see Fig. 42.23A).[387] An ultrasound-guided technique may also be used for this block (see Chapter 43 and Fig. 43.22).

COMPLICATIONS. Intravascular injection and intraneural injections are potential complications. The use of a nerve stimulator can prevent the unintended intraneural injection. Intravascular injection may be avoided with incremental injection and frequent aspiration.

Ulnar Nerve

ANATOMY. The ulnar nerve is the superficial nerve to the arm and the ulnar side of the forearm and the hand. It is the terminal continuation of the medial cord of the brachial plexus. At the elbow, it pierces the medial intermuscular septum and follows along the medial head of the triceps to the groove between the olecranon and the medial epicondyle of the humerus. It is covered only by skin and fascia and can be easily palpated and blocked at this level (see Figs. 42.13 and 42.24A and B).

TECHNIQUE. With the child supine, the elbow is flexed. The medial epicondyle and the ulnar groove are palpated (see Fig. 42.24). A 27-gauge needle is advanced perpendicular to the skin along the line of the nerve; 1 to 3 mL (depending on the child's weight) of bupivacaine (0.25% with epinephrine 1:200,000) is injected into the area. An ultrasound-guided technique may also be used for this block (see Chapter 43 and Fig. 43.22).

COMPLICATIONS. Intravascular injection and intraneural injections are potential complications. Because this is a very superficial nerve, injection just after the skin is pierced in the area of the ulnar nerve usually produces a good block. Intravascular injection may be avoided with incremental injection and frequent aspiration.

Wrist Blocks

Blocking the median, radial, and ulnar nerves at the wrist can be easily achieved. These blocks provide very good analgesia and, because they are easy to perform, they generally have a predictable successful outcome.

Radial Nerve

The cutaneous branches of the radial nerve supply the radial side of the dorsum of the hand and the proximal parts of the radial three-and-a-half digits.

ANATOMY. The superficial branch of the radial nerve runs along the lateral border of the forearm under the brachioradialis muscle. In the distal third of the forearm it angles dorsally under the tendon of the brachioradialis toward the dorsum of the wrist. It pierces the deep fascia and divides into two branches: (1) the lateral branch supplies the radial side and the tip of the thumb

FIGURE 42.24 Ulnar nerve block at the elbow. The olecranon process is palpated. The ulnar nerve is located in the olecranon groove; after aspiration, 1 to 3 mL of local anesthetic solution is injected. It is important not to deposit the local anesthetic deep into the olecranon groove because the nerve is superficial and can be easily blocked by a subcutaneous injection.

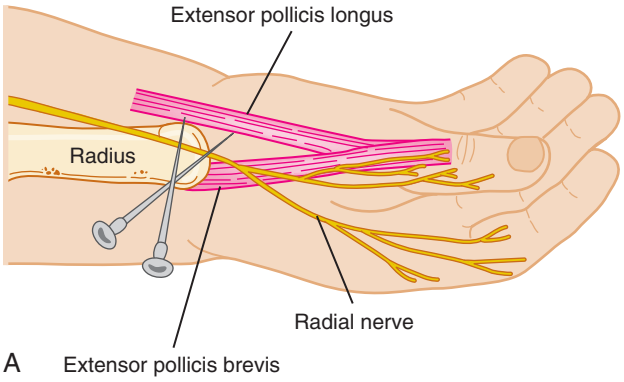

FIGURE 42.25 Wrist block: radial nerve. **A,** This is a superficial block of the terminal branches of the radial nerve. An attempt to make the "anatomic snuffbox" prominent by extension of the thumb before anesthesia is desirable. The extensor pollicis and brevis tendons are marked. **B,** A 27-gauge needle is inserted close to the dorsal radial tubercle over the extensor longus tendon; bupivacaine (2 mL, 0.25% with 1:200,000 epinephrine) is injected subcutaneously. Fanning the local anesthetic in the anatomic snuffbox helps to distribute the local anesthetic over the radial nerve. (Modified from Raj P, Pai U. Techniques of nerve blocking. In: Raj P, ed. *Handbook of Regional Anesthesia*. New York: Churchill Livingstone; 1985:185.)

and (2) the medial branch communicates with the dorsal branch of the ulnar nerve. This then divides into the four digital nerves that supply the ulnar side of the thumb, the radial side of the index finger, and the space between the index finger and thumb. A communicating branch with the ulnar nerve supplies the adjacent sides of the middle and ring finger (Fig. 42.25A).

TECHNIQUE. This is essentially a field block of the superficial terminal branches. An attempt to make the "anatomic snuffbox" prominent by extension of the thumb before anesthesia is desirable. The extensor pollicis and brevis tendons are marked. A 27-gauge needle is inserted close to the dorsal radial tubercle over the extensor longus tendon, and 2.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected SC. An attempt to fan the local anesthetic in the anatomic snuffbox helps to distribute the local anesthetic over the radial nerve (see Fig. 42.25B).

COMPLICATIONS. Intravascular injection may be avoided with incremental injection and frequent aspiration. Post–nerve block dysesthesia may be occasionally experienced with a radial nerve block and is usually self-limited.

Median Nerve

ANATOMY. In the palm of the hand, the median nerve is very superficial and is covered only by skin and the palmar aponeurosis and rests on the tendons of the flexor muscles. It emerges from under the retinaculum and splits into muscular and digital branches. The muscular division of the median nerve supplies the muscles of the thenar eminence. The palmar digital nerve supplies the thumb, index finger, middle finger, and ring finger. These nerves also supply the lumbricals (Fig. 42.26A).

TECHNIQUE. The palmaris tendon is identified. This may be done before general anesthesia by asking the child to flex the wrist against resistance. The radial border of the tendon is identified. Cutaneous landmarks include both distal wrist skin creases. A 27-gauge needle is inserted at the level of the second skin crease (1–1.5 cm proximal to the distal crease in teenagers) perpendicular to the skin. The nerve is at a depth of less than 1 cm in the teenager and less in younger children; 1.0 to 2.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected into the area (see Fig. 42.26B). If the child is awake, it is better to elicit paresthesias because the needle may be anterior to the neurovascular bundle and the nerve could be missed altogether.

COMPLICATIONS. Intravascular placement should be avoided by repeated aspiration before injection.

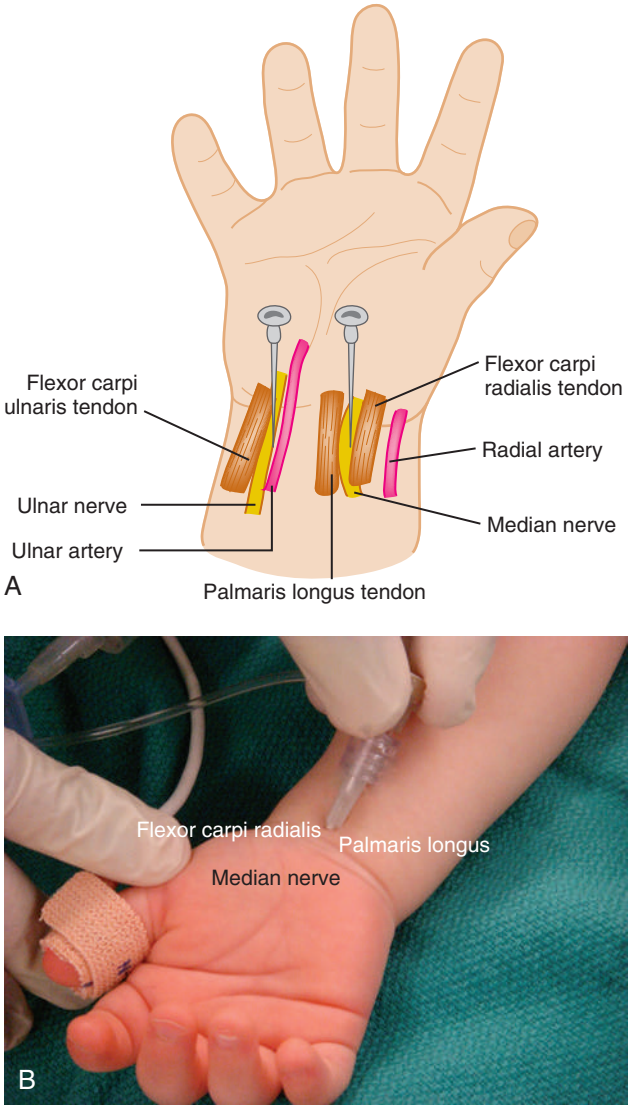

FIGURE 42.26 Wrist block: median and ulnar nerves. **A,** Median nerve: identify the palmaris tendon by asking the child to flex the wrist against resistance. Distal skin creases are identified. **B,** A 27-gauge needle is inserted at the level of the distal skin crease perpendicular to the skin. The nerve is at a depth of less than 1 cm in teenagers and less than that in younger children; 1.0 to 2.0 mL of bupivacaine (0.25% with 1:200.000 epinephrine) is injected in the area. If the child is awake, it is better to elicit paresthesias because the needle may be anterior to the neurovascular bundle, which can be missed altogether. Ulnar nerve: identify the flexor carpi ulnaris tendon, which lies proximal to the pisiform bone. A 27-gauge needle is inserted just proximal to the pisiform bone and directed radially a distance of approximately 0.5 cm. Bupivacaine (2–3 mL, 0.25% with epinephrine 1:200,000) is injected. (Modified from Raj P, Pai U. Techniques of nerve blocking. In: Raj P, ed. *Handbook of Regional Anesthesia*. New York: Churchill Livingstone; 1985:185.)

Ulnar Nerve

ANATOMY. The palmar cutaneous branch of the ulnar nerve arises near the middle of the forearm and accompanies the ulnar artery into the hand (see Fig. 42.26A). It then perforates the flexor retinaculum and ends in the skin of the palm communicating with the palmar branch of the median nerve. There are two dorsal digital nerves and a metacarpal communicating branch. The more medial digital nerve supplies the ulnar side of the little finger and the digital branch supplies the adjacent sides of the little and ring finger. The palmar or the terminal portion of the ulnar nerve crosses the ulnar border of the wrist in company with the ulnar artery.

TECHNIQUE. Blocking the ulnar nerve at the wrist is easier than at the elbow. The nerve is blocked at the wrist, where it lies under cover of the flexor carpi ulnaris tendon just proximal to the pisiform bone. The best way to access the nerve is to approach it from the ulnar side of the tendon. A 27-gauge needle is inserted just proximal to the pisiform bone and directed radially a distance of approximately 0.5 cm; 2.0 to 3.0 mL of bupivacaine (0.25% with epinephrine 1:200,000) is injected (see Fig. 42.26A).

COMPLICATIONS. The ulnar artery runs in close proximity to the ulnar nerve; every possible effort should be made to avoid intravascular placement. Intravascular injection may be avoided with incremental injection with frequent aspiration.

Digital Nerve Blocks: Hand

Digital nerve blocks are useful for providing pain relief to children who are undergoing procedures to individual fingers. These are useful for postoperative analgesia in procedures, such as trigger finger release, and also for the provision of pain relief in children undergoing laser therapy for warts on their fingers.[388]

ANATOMY. The common digital nerves are derived from the median and ulnar nerves and divide in the palm to volar digital nerves that supply the fingers. All digital nerves are usually accompanied by digital vessels. There are three digital nerves derived from the median nerve. The first common digital nerve divides into three palmar digital nerves that supply the sides of the thumb; the second common digital nerve supplies the web between the index and middle finger; and the third common palmar digital nerve communicates with a branch of the ulnar nerve and supplies the web space between the middle and ring fingers. These common digital nerves then become the proper digital nerves (digital collaterals) that supply the skin of the palmar surface and the dorsal side of the terminal phalanx of their respective digits. All digital nerves ultimately terminate in two branches: one ramifies in the skin of the fingertips and the other ends in the pulp under the nail. Smaller digital nerves are derived from the radial and ulnar nerves and supply the back of the fingers. These tend to lie on the dorsolateral aspect of the finger. There are four dorsal digital nerves: (1) ulnar side of the thumb; (2) radial side of the index finger; (3) adjacent sides of index and middle fingers; and (4) communication to the adjacent sides of middle and ring finger.

TECHNIQUE. There are two techniques for blockade of the digital nerves.

For blockade at the base of the thumb (Fig. 42.27A and B), with the thumb extended, on the palmar surface of the hand, a 27-gauge needle is inserted into the web space between the index finger and thumb. The needle is advanced to the junction of the web space and the palmar skin of the hand, a distance of about 1 cm; 0.5 mL of bupivacaine *without epinephrine* is injected. A second needle is inserted into the thenar eminence on the radial aspect of the thumb; 1.0 mL of bupivacaine *without epinephrine* is injected. Caution has to be exercised if the child has collagen vascular disease, because this may precipitate acute vascular spasm that may not be relieved.

Blockade of the other fingers is accomplished at the bifurcation between the metacarpal heads (see Fig. 42.27B and C). With the fingers extended, a 27-gauge needle is inserted into the web about 3 mm proximal to the junction between the web and the palmar

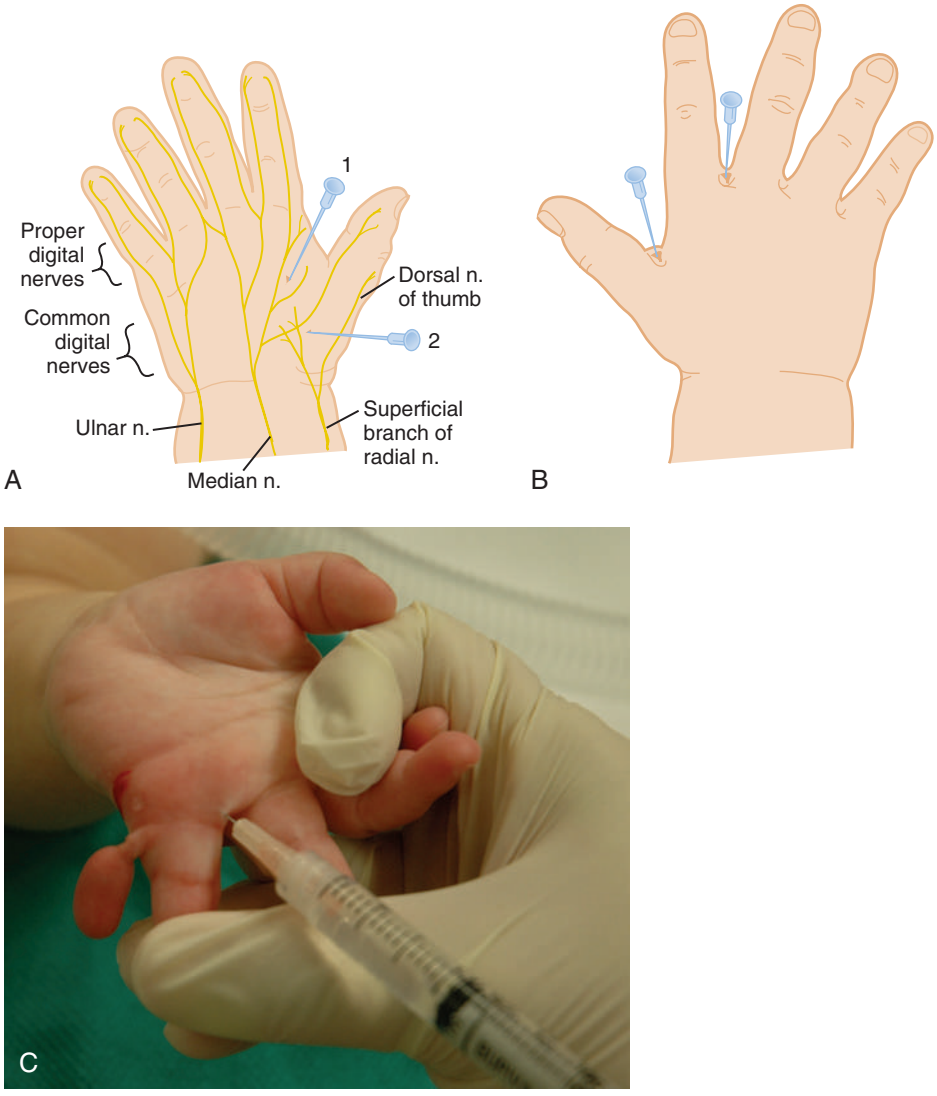

FIGURE 42.27 Digital nerve blocks. **A,** Blockade of the thumb: with the thumb extended, on the palmar surface of the hand, a 27-gauge needle is inserted into the web space between the index finger and thumb (*1*). The needle is advanced to the junction of the web space and the palmar skin of the hand a distance of about 1 cm; bupivacaine (0.5 mL, *without epinephrine*) is injected. A second needle is inserted into the thenar eminence on the radial aspect of the thumb, and 1.0 mL of bupivacaine *without epinephrine* is injected (*2*). Caution has to be exercised if the patient has collagen vascular disease because this may precipitate acute vascular spasm that may not be relieved. **B,** Blockade of other digits: blockade of the other fingers is accomplished at the bifurcation between the metacarpal heads. With the fingers widely extended, a 27-gauge needle is inserted into the web about 3 mm proximal to the junction between the web and the palmar skin; bupivacaine (1.0 to 2.0 mL, *without epinephrine*) is injected. **C,** This can be performed either from a dorsal approach or a volar approach. The web on either side will have to be blocked to provide analgesia for each finger to be anesthetized. *n*, nerve.

skin; 1.0 to 2.0 mL of bupivacaine *without epinephrine* is injected. This can be performed either from a dorsal approach or a volar approach.

Caution: Vasoconstrictors are avoided when blocking digital nerves because these are end vessels and acute vasospasm caused by epinephrine can lead to permanent damage or necrosis of the digits. The use of dilute epinephrine concentrations (1 : 100,000–1 : 200,000) in digital nerve blocks may be undergoing a renaissance as epinephrine with local anesthetics have been in used in almost 3000 digital blocks without sequelae.[389]

COMPLICATIONS. Large volumes of local anesthetic are contraindicated because of the possibility of pressure and vascular compromise. Vasoconstrictors are generally avoided because they may cause necrosis of the digit. Intravascular injection may be avoided with incremental injection and frequent aspiration.

LOWER EXTREMITY BLOCKS

The major use of nerve blocks of the lower extremity in children is for managing postoperative pain and as an adjunct to general anesthesia. When considering the sensory and cutaneous innervation of the lower extremity (Fig. 42.28), it is not surprising that few surgical procedures can be accomplished under single nerve blocks. However, combinations of sciatic, femoral, and lateral femoral cutaneous blockade can provide both excellent postoperative

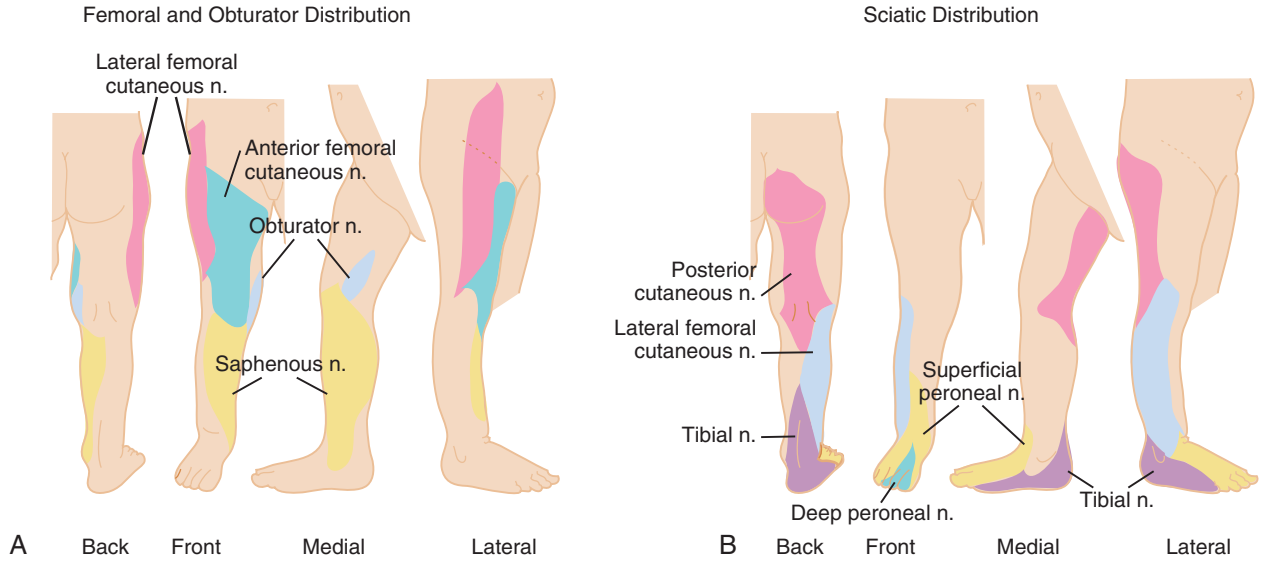

FIGURE 42.28 The sensory innervation of the lower extremity is presented. Note that anesthesia of the lower extremity requires block of the femoral nerve **(A)** (and its branches), as well as the sciatic nerve **(B).** *n*, nerve.

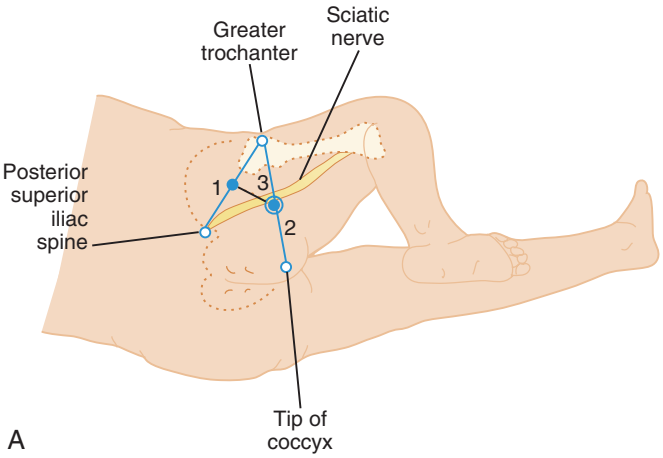
analgesia and surgical anesthesia for selected operations; the fascia iliaca block produces anesthesia of multiple nerves with a single injection. Continuous peripheral nerve blocks extend the duration of postoperative analgesia with a good safety profile (https://www.asra.com/advisory-guidelines/article/1/anticoagulation-3rd-edition.ia). In a large review of peripheral nerve blocks, with lower extremity blocks accounting for 85% of blocks, the incidence of complications was 12.1% (95% CI 10.7%–13.5%), most commonly catheter malfunction, block failure, superficial infection, and vascular puncture; there were no reports of persistent neurologic problems, catheter malfunctions, or toxicity.[390]

Sciatic Nerve Block



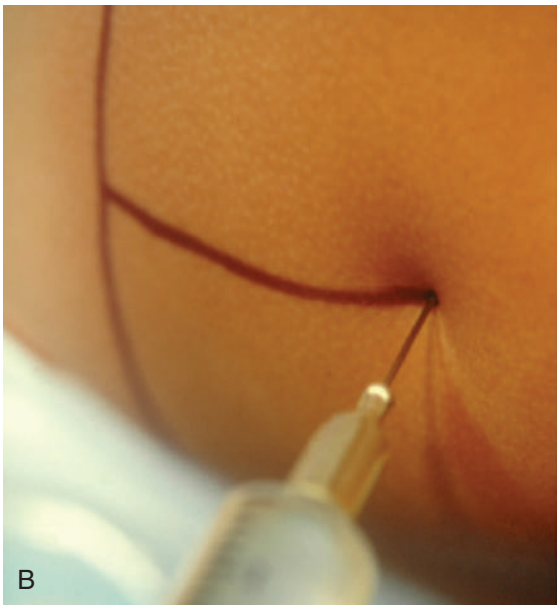
ANATOMY. The sciatic nerve arises from the L4 through S3 roots of the sacral plexus, passes through the pelvis, and becomes superficial at the lower margin of the gluteus maximus muscle. It then descends into the lower extremity in the posterior aspect of the thigh, supplying sensory innervation to the posterior thigh, as well as to the entire leg and foot below the level of the knee, except for the medial aspect, which is supplied by the femoral nerve (see Fig. 42.28A). Although a sciatic nerve block alone is useful for few surgical procedures, it can be combined with a femoral nerve block for operations below the knee and for postoperative pain relief. There are multiple approaches to the sciatic nerve.[391] All blocks in the absence of ultrasound guidance, are performed with the aid of a nerve stimulator to elicit a motor paresthesia in the foot, and, if the block is performed in a lightly sedated trauma victim, the approach that places the child in a greater position of comfort should be chosen. Ultrasound guidance improves the performance of the nerve block (see Chapter 43). A newer approach to the sciatic nerve using a lateral approach to the popliteal fossa has been described. This offers the additional advantage of being able to provide the block in the supine position. An infragluteal-parabiceps approach is another easy method of providing a sciatic nerve block in children.[392]

APPROACH OF LABAT (POSTERIOR APPROACH). The child is placed in the lateral decubitus position lying on the nonoperative leg. The leg to be blocked is flexed and the lower leg is extended (Fig. 42.29A). A line is drawn from the posterior superior iliac spine to the greater trochanter of the femur. Another line is drawn from the greater trochanter to the coccyx. The first line is bisected, and a perpendicular line is drawn from that point to the second line; the point at which it intersects the second line is the site of needle insertion (see Fig. 42.29B). A 22-gauge insulated needle is advanced in the perpendicular plane until it strikes bone. It is possible for the needle to pass through the sciatic notch without either encountering bone or causing a paresthesia. In that case, the needle is redirected in a cephalad direction until bone is encountered. A motor paresthesia is then sought using an organized grid-like approach, fanning medially to laterally.

ANTERIOR APPROACH. As the sciatic nerve emerges from the lower border of the gluteus maximus to extend down the thigh, it passes medial and deep to the lesser trochanter of the femur (Fig. 42.30A; see also Figs. 42.31 and 42.32).

With the child in the supine position, a line is drawn from the anterior superior iliac spine to the pubic tuberosity. The greater trochanter is then located, and another line is drawn parallel to the first line (see Fig. 42.30B); at the medial one-third of the first line, a perpendicular is dropped to the second line. The point of intersection with the line originating at the greater trochanter marks the point of needle entry. The needle is inserted in a perpendicular plane until bone is encountered. It is then partially withdrawn and redirected medially. When the needle is posterior to the medial margin of the femur, ease of injection is determined after negative aspiration for blood. This approach carries a greater risk of unintended puncture of the femoral vessels, and repeated negative aspirations must precede incremental injection. If the needle is in muscle or a fascial bundle, resistance to injection will be felt. In this case, the needle is advanced until minimal resistance to injection is felt. Motor paresthesia is a helpful indicator.

For the previous two techniques, a dose of 0.2 mL/kg of bupivacaine (0.25% with epinephrine 1:200,000) is the dose usually administered for children older than 6 months of age. If the sciatic nerve block is used in conjunction with a femoral nerve block, consideration should be given to diluting the local anesthetic



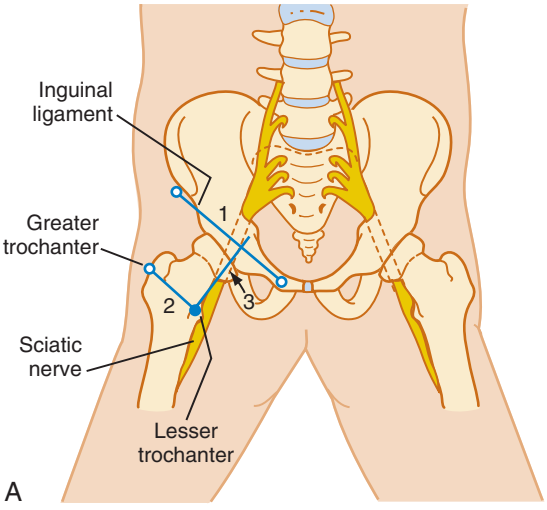


FIGURE 42.29 A, Sciatic nerve block (approach of Labat). The patient is placed in a lateral position with the lower leg extended and the upper leg, the one to be blocked, flexed; a line is drawn from the greater trochanter of the femur to the posterior superior iliac spine (*blue line 1*). A second line is drawn from the greater trochanter to the coccyx (*blue line 2*). Line 1 is bisected, and a perpendicular line is drawn from that point to line 2 (*black line 3*); the point at which the perpendicular broken line intersects line 2 (*encircled dot*) is the point of needle insertion. **B,** A 22-gauge needle is advanced perpendicular to the skin until it strikes bone or, if the child is awake, a paresthesia is elicited. Use of a nerve stimulator will produce either plantar flexion or dorsiflexion of the foot.

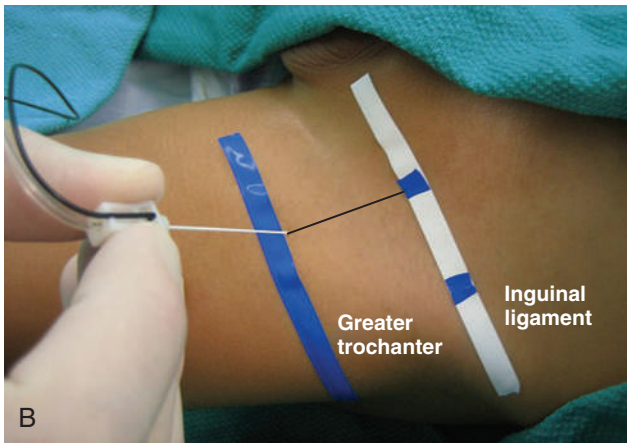

FIGURE 42.30 A, Sciatic nerve block (anterior approach). With the patient supine, a line is drawn from the anterior iliac spine to the pubic tuberosity (*line 1*). The greater trochanter is located, and another line is drawn parallel to the first (*line 2*). A perpendicular line is drawn from line 1 at a point one-third the distance laterally from the pubic tuberosity to the anterior iliac spine (*solid line 3*). **B,** Left sciatic nerve block. A needle is inserted at the intersection of line 2 and the perpendicular line (in **A,** *solid circle*) until bone is encountered. The needle is redirected off the edge of the femur to the approximate posterior margin of the femur and, after negative aspiration for blood, ease of injection is ascertained. Resistance to injection indicates that the needle is within muscle or fascial bundle; the needle should be advanced until there is minimal resistance to injection or until a paresthesia is elicited.

concentration further to limit the injected dose to 2.5 mg/kg of bupivacaine.[393]

Lateral Popliteal Sciatic Nerve Block

This approach to the sciatic nerve can be performed with the child in the supine position.[394] This block provides postoperative analgesia in children undergoing surgery to the foot and knee, such as clubfoot repair or triple arthrodesis, and in children having knee surgery, particularly when combined with a femoral nerve block.[395] It has the advantage of preserving hamstring function and allows early ambulation with crutches.

ANATOMY. The popliteal fossa is a diamond-shaped area located behind the knee. It is bordered by the biceps femoris laterally, medially by the tendons of the semitendinosus and semimembranosus muscles, and inferiorly by the heads of the gastrocnemius muscle. The sciatic nerve, after its formation from L4 through S5, innervates all areas of the leg and foot below the knee except the anteromedial cutaneous areas of the leg and foot, which are supplied by the femoral nerve. The sciatic nerve divides into two branches, the larger tibial nerve located medially and the common peroneal nerve located laterally. The nerves are together at the apex of the popliteal fossa, where they are in close proximity to

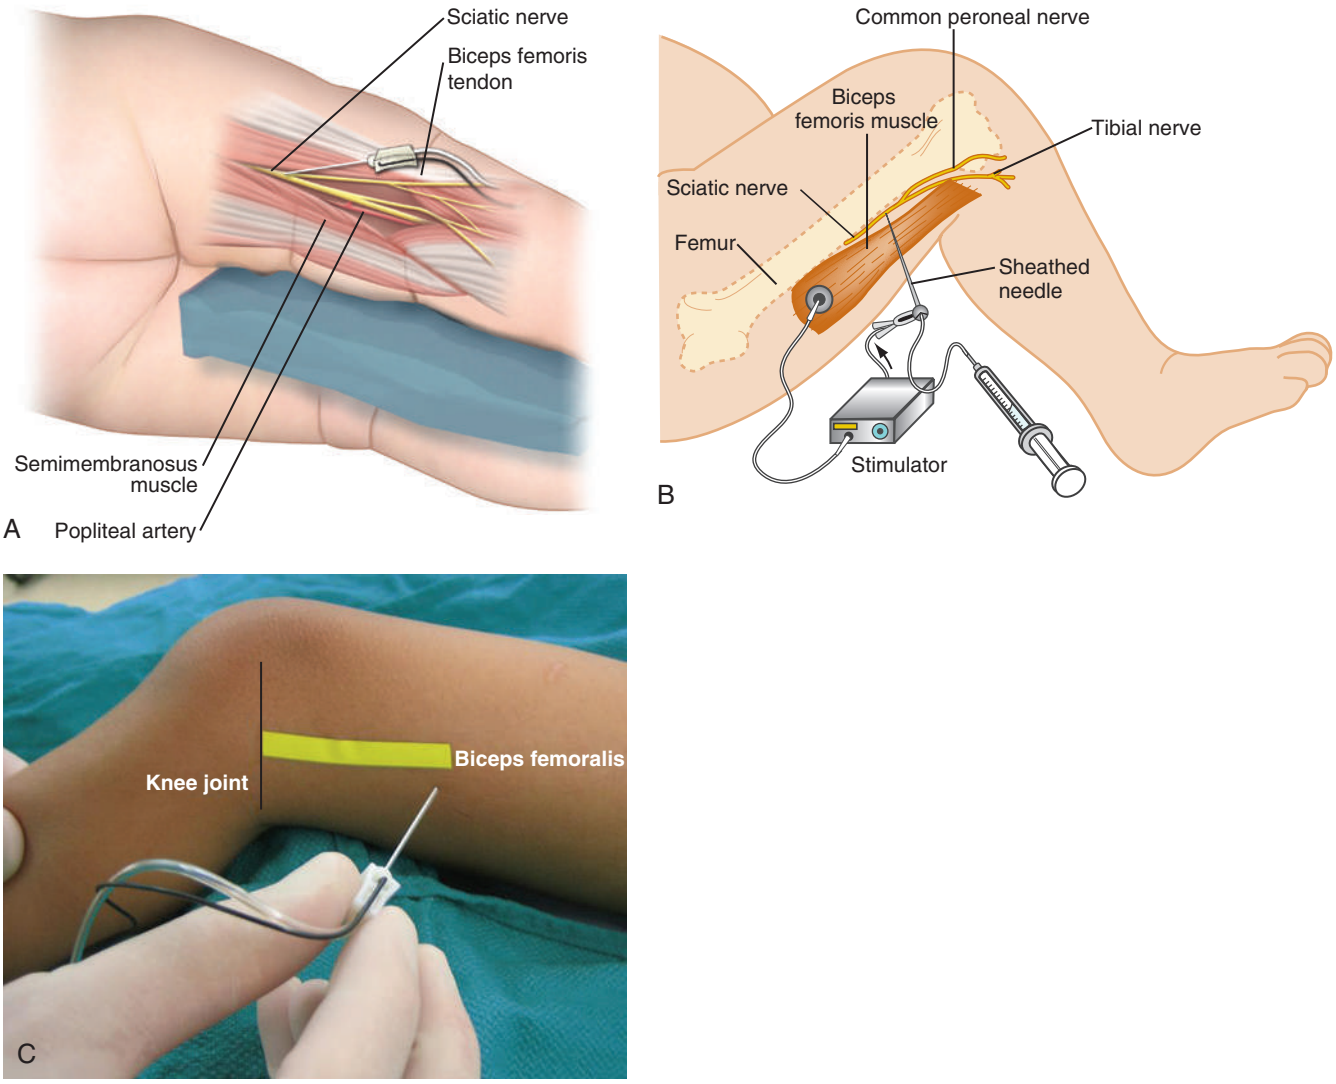

FIGURE 42.31 Lateral popliteal sciatic nerve block. **A,** Anatomy for lateral popliteal approach to the sciatic nerve. The calf is elevated on a pillow and the biceps femoris tendon is palpated. The tendon is traced proximally for 3 to 5 cm. **B,** A 22-gauge insulated needle is inserted anterior to the tendon in a horizontal plane with a cephalad angulation. A nerve stimulator is attached to the needle and with low-voltage stimulation (0.2–0.5 mV), the foot is observed for plantar flexion or dorsiflexion. With injection of the test dose of 1.0 mL of bupivacaine (0.25% with 1:200,000 epinephrine), the twitching is abolished. This confirms the correct placement of the needle. **C,** Then 5 to 10 mL of additional local anesthetic is injected.

each other and are enclosed in a connective tissue sheath for a few more centimeters before dividing into the component nerves (see Fig. 42.31A).

TECHNIQUE. After induction of general anesthesia, the calf is elevated on a pillow. The biceps femoris tendon is palpated. The tendon is then traced upward for 3 to 5 cm. A 22-gauge insulated needle is inserted anterior to the tendon in a horizontal plane with a cephalad angulation (see Fig. 42.31B). A nerve stimulator is attached to the sheathed needle and with low-voltage stimulation (0.2–0.5 mV), the foot is observed for plantar flexion or dorsiflexion. On injection of a test dose of 1 mL bupivacaine (0.25% with epinephrine 1:200,000), the twitching is abolished. This confirms the correct placement of the needle (see Fig. 42.31C); 5 to 10 mL of additional local anesthetic is then injected (see Video 42.1). In adult studies, it has been shown that the sciatic nerve block is longer lasting than an ankle block or subcutaneous infiltration, and it provides excellent postoperative analgesia.[394] Continuous catheter techniques can be used to provide effective analgesia in children in the postoperative period.[396] An ultrasound-guided technique may also be used (see Chapter 43 and Figs. 42.30 and 43.31).

COMPLICATIONS. Intraneural injection must be avoided. Using a low-voltage nerve stimulator ensures the proper placement of the needle. It is rare to see intravascular placement of the needle with this approach. Intravascular injection may be avoided with incremental injection and frequent aspiration.

Infragluteal-Parabiceps Approach

This approach is a simple way to access the sciatic nerve.[392] It offers an advantage over the popliteal fossa technique because

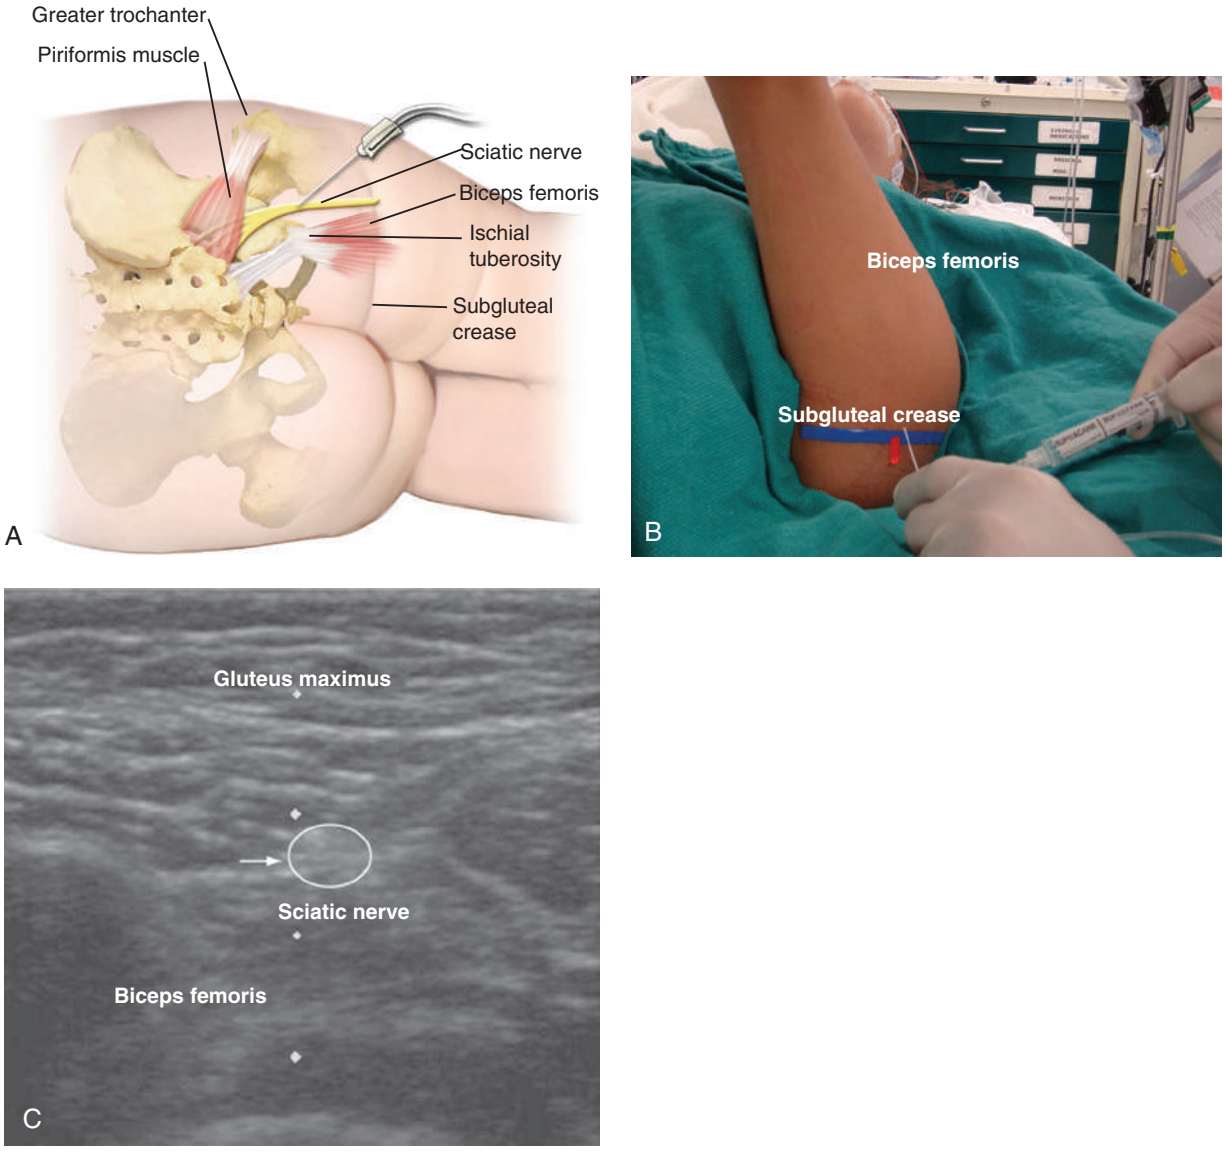

FIGURE 42.32 A, Artist's rendering of infragluteal-parabiceps block. **B,** The gluteal crease is identified (left leg) in the prone or supine position. The biceps femoris muscle is identified (distal portion not illustrated) and followed cephalad to the gluteal crease. A stimulating needle is inserted at the level of the gluteal crease along the medial border of the biceps femoris muscle *(blue line);* with stimulation at 0.5 mA, plantar flexion or extension or inversion or eversion denotes adequate positioning of the needle. After aspiration to rule out intravascular injection, 0.2 mL/kg of local anesthetic solution is injected to provide an adequate blockade of the sciatic nerve. **C,** An ultrasound technique may also be used. A linear ultrasound probe is placed along the inferior border of the gluteus maximus along the gluteal crease. The biceps femoris muscle and the semitendinosus muscle are identified. The sciatic nerve is seen as a hyperechoic shadow *(arrow).* In this location, the nerve may be isoechoic. This may require mild rotation or movement of the ultrasound probe to recognize the nerve completely. With the use of an in-plane approach, the needle is advanced close to the sciatic nerve. After aspiration, 0.2 mL/kg of local anesthetic solution is injected. A "donut sign" is seen as the nerve is surrounded by the local anesthetic solution.

the posterior cutaneous nerve supplying the posterior portion of the thigh can be blocked with this approach.

TECHNIQUE. The child is placed in the supine position or a lateral position to perform this block. The biceps femoris tendon is palpated and traced cephalad to the distal crease of the buttocks (Fig. 42.32A). A stimulating needle is then inserted perpendicular to the femoral shaft, along the biceps femoris tendon (parabiceps) until a twitch is obtained (see Fig. 42.31B). Either inversion or eversion of the foot is a reasonable response for localization of the nerve. Next, 0.2 mL/kg of local anesthetic solution is injected into the area (Video 42.15). An ultrasound-guided approach may facilitate this block (see also Chapter 43 and Figs. 42.30 to 42.32).[397]

COMPLICATIONS. Profound motor block can be seen in most children after a subgluteal (infragluteal) parabiceps sciatic nerve block. If the child is discharged home, caution should be exercised because of the motor weakness produced. More recently, we have used continuous catheters in hospitalized children having major lower extremity surgical procedures, with very good results.[398]

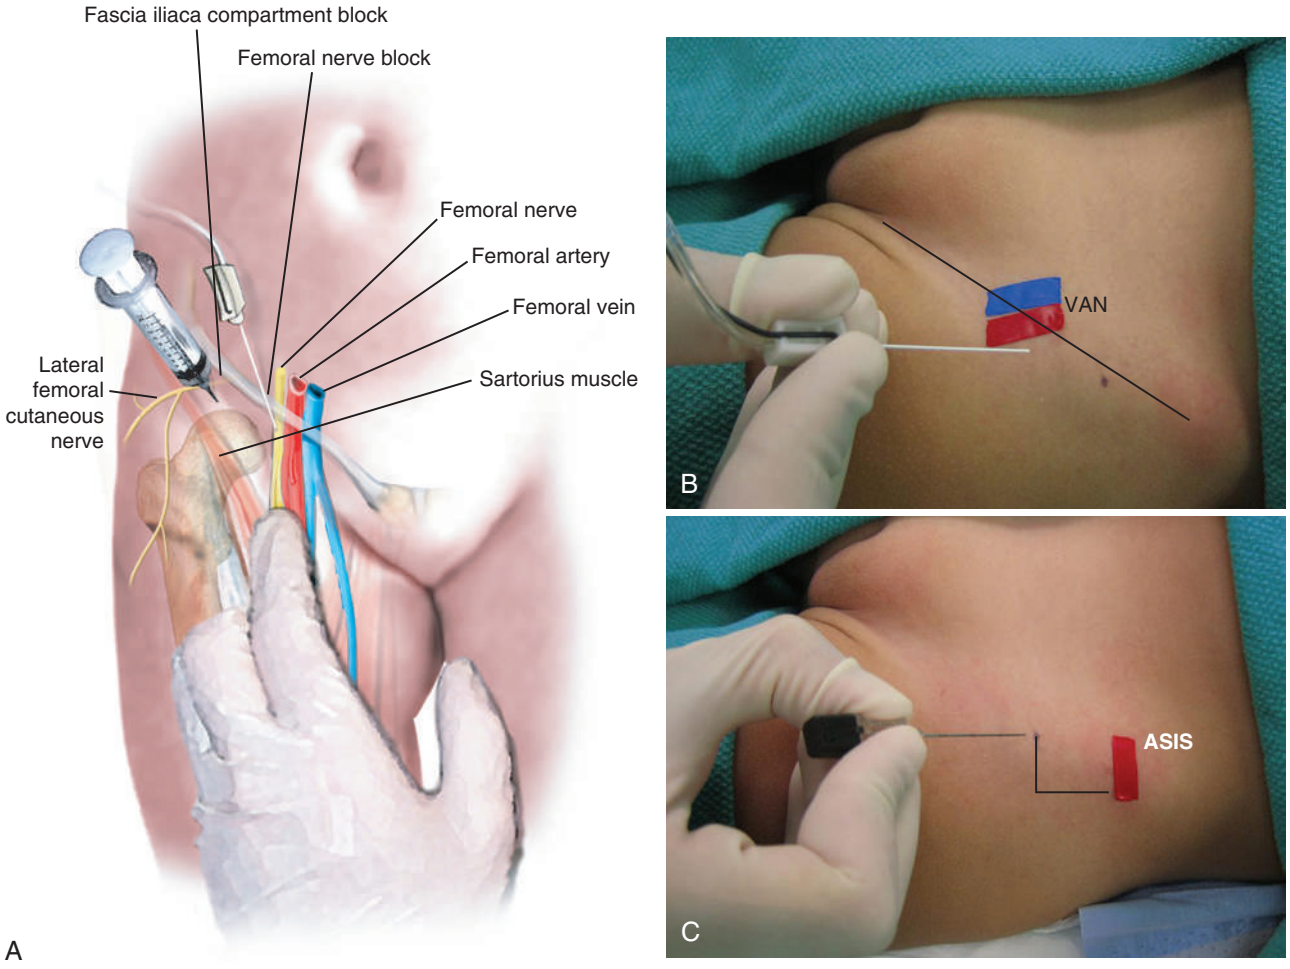

FIGURE 42.33 A, Right femoral nerve block and fascia iliaca compartment block. Note that the femoral nerve lies lateral to the femoral artery. The appropriate dose of local anesthetic is administered while maintaining pressure on the nerve sheath distal to the site of injection just below the inguinal ligament; local anesthetic is thus forced proximally. **B,** For a left femoral nerve block, the point of injection is lateral to the pulse, over the site of the nerve (*V,* vein; *A,* femoral artery; *N,* femoral nerve) (black line indicates inguinal ligament). **C,** The left lateral femoral cutaneous nerve is blocked by injecting 1.0 to 2.0 mL of local anesthetic 1 to 2 cm medial and caudal to the anterior superior iliac crest (*ASIS*). A caudal needle is used so as to better feel the "pop" through tissue planes. For the fascia iliaca block, the point of injection is just lateral to the site depicted for the femoral nerve block, 1 cm inferior to the lateral and middle thirds of the inguinal ligament. An injection at this location will bathe all three nerves in the compartment, resulting in blockade with a single injection.

Femoral Nerve Block

A femoral nerve block is particularly useful in children with a fractured femoral shaft so that transport, radiographic, and other manipulations are not painful.[399–401] This block provides analgesia and relieves muscle spasms around the fracture site.

ANATOMY. The femoral nerve is located immediately lateral to the femoral artery and deep to both the fascia lata and fascia iliaca (Fig. 42.33A).

TECHNIQUE. A 22-gauge blunt B-bevel needle is advanced lateral to the pulsation of the femoral artery. Two fascial planes can be located by the distinct pop that is felt as the needle traverses these fascial tissues. The nerve is blocked by depositing an appropriate volume (5–10 mL) of local anesthetic lateral to the femoral pulse and deep to the fascia iliaca. The needle is advanced in a perpendicular plane (see Fig. 42.33B and Video 42.16). It is not necessary to elicit a motor paresthesia, provided that the two fascial planes are penetrated. Performance of this block may, on occasion, produce a fascia iliaca block. Repeated aspiration and incremental injection should be used to avoid injection into the femoral artery. With ultrasound guidance, the femoral nerve can be easily visualized and can be blocked (see also Chapter 43 and Fig. 43.26).[397] A catheter can be placed to provide continuous analgesia in the postoperative period.[399]

COMPLICATIONS. It may be preferable to avoid this technique in children who are taking anticoagulants or who may have blood dyscrasias, owing to the close proximity of the nerve to the femoral artery. Intravascular injection may be avoided with incremental injection and frequent aspiration.

Lateral Femoral Cutaneous Nerve

ANATOMY. The lateral femoral cutaneous nerve arises from the L2 and L3 roots of the lumbar plexus. It emerges from the

lateral border of the psoas muscle and passes obliquely under the fascia iliaca to enter the thigh 1 to 2 cm medial to the anterior superior iliac crest (see Fig. 42.33A). The nerve innervates the lateral aspect of the thigh. One of its anterior branches forms part of the patellar plexus; thus it must be blocked for regional anesthesia of the knee. Blockade is also indicated for supplementation of femoral and sciatic nerve blocks to provide relief of tourniquet pain. It is also suitable for anesthetizing the lateral aspect of the thigh as a donor site for small skin grafts, fascia iliaca grafts, or muscle biopsy for muscular disorders.[402,403] This block can also be used for both diagnostic and therapeutic purposes in treating meralgia paresthetica, a condition that leads to chronic pain along the lateral aspect of the thigh.[404,405] In most cases, a fascia iliaca block will block this nerve along with the femoral and obturator nerves, thus obviating the need for performing an isolated lateral femoral cutaneous block.

TECHNIQUE. A point approximately 2 cm caudal and 2 cm medial to the anterior superior iliac spine is located (see Fig. 42.33C). A blunt needle is then advanced through the skin and then through the fascia lata. A distinct pop is felt at this point. The fascia lata and fascia iliaca compartments are entered as two distinct pops can be felt as the needle advances into the fascia iliaca compartment. Two to 10 mL of local anesthetic, depending on the size of the child, is deposited in a fan-like fashion (Video 42.17). Recently we have used an ultrasound-guided technique that allows us to visualize the fascia iliaca compartment as it fills up with the local anesthetic solution on injection.

COMPLICATIONS. It is rare to see any complications associated with a lateral femoral cutaneous nerve block. However, care must be taken to avoid an intraneural placement of the local anesthetic solution. Intravascular injection may be avoided with incremental injection and frequent aspiration.

Fascia Iliaca Block

This block is particularly useful in children to provide unilateral anesthesia or analgesia of the lower extremity. The block has been reported to be less reliable in adults than in children.[406] It produces blockade of the femoral, lateral femoral cutaneous, and obturator nerves with a single injection of local anesthetic.

ANATOMY. The compartment is bounded superficially by the fascia iliaca and iliacus muscle, superiorly by the iliac crest, and deeply by the psoas muscle (see Fig. 42.33A). It has the advantage of producing blockade without requiring the needle to be in close proximity to any major nerves or blood vessels. One study reported a greater than 90% success rate and found it far superior in children to the "3 in 1" block described by Winnie.[406]

TECHNIQUE. The injection is made approximately 1 cm inferior to the junction of the outer and middle thirds of the inguinal ligament (see Fig. 42.33A). As the needle is inserted at a perpendicular angle of about 75 degrees to the skin, two characteristic pops are felt as the needle pierces the fascia lata and then the fascia iliaca. Slight pressure on a fluid-filled syringe attached to the needle may aid in placement of the block by producing a subtle loss of resistance when the fascia iliaca compartment is entered. The angle of needle insertion is decreased and directed cephalad, and the local anesthetic is incrementally injected. One should feel little resistance to injection. Digital pressure is exerted distally to the site during the injection and for a short time afterward, and the swelling produced in the groin by the volume of local anesthetic is massaged to promote proximal flow of the drug. A long-acting local anesthetic, such as bupivacaine, ropivacaine, or levobupivacaine, is usually chosen so that postoperative blockade can provide prolonged analgesia. A volume of 0.3 to 0.5 mL/kg is sufficient in most cases. An ultrasound-guided technique similar to that for the lateral femoral cutaneous block may also be used for this block.

COMPLICATIONS. Because of the larger volume required to provide an adequate block, care has to be taken to not exceed the maximum dosage of the local anesthetic. Intravascular injection may be avoided with incremental injection and frequent aspiration.

Saphenous Nerve Block

The saphenous nerve, the terminal sensory branch of the femoral nerve, provides sensory innervation to the medial aspect of the leg and foot. When blocked in the thigh, as it courses through the adductor canal, it can provide excellent analgesia following operations on the knee while minimizing the weakness of the quadraceps muscle produced by a femoral nerve block (Video 42.18).[406a]

ANATOMY. The nerve lies below the sartorius muscle, and bounded laterally by the vastus medialis and medially by the femoral artery.

An echogenic needle is advanced medially in plane at the mid-thigh level through the sartorius muscle. A pop is felt as the needle exits its investing fascia. The nerve lies lateral to the femoral artery.

COMPLICATIONS. Arterial puncture.

Ankle Block

Block of the nerves of the foot at the ankle is a technique that is valuable to produce both surgical anesthesia and postoperative analgesia for procedures on the foot.

ANATOMY. Three nerves can be blocked from the dorsal aspect of the foot. The deep peroneal nerve (L4, L5, S1, and S2) innervates the web space between the great and second toes. This nerve extends down the anterior aspect of the leg medial to the extensor hallucis longus and lateral to both the anterior tibial muscle and the anterior tibial artery. It is blocked at the level of the ankle crease in the lower part of the leg by inserting a 25-gauge needle through the skin until it contacts the tibia (Fig. 42.34A). Two to three milliliters of local anesthetic are injected, and then an additional amount as the needle is being withdrawn. The superficial peroneal nerve (L4, L5, S1, and S2) innervates the medial and lateral aspects of the dorsum of the foot. Its anatomic course passes through the crural fascia on the anterior aspect of the distal two-thirds of the leg and subcutaneously along the lateral aspect of the foot. It is blocked immediately above the talocrural joint. It can be blocked by subcutaneous infiltration of local anesthetic from the anterior border of the tibia to the lateral malleolus. The last nerve that lies on the dorsal aspect of the foot is the saphenous nerve, which innervates the skin over the medial malleolus. It is blocked by subcutaneous infiltration around the great saphenous vein at the level of the medial malleolus. The tibial and the sural nerves are blocked using a posterior approach. The tibial nerve (L4, L5, S1, S2, and S3) lies posterior to the posterior tibial artery and divides into the medial and lateral plantar branches, which innervate their respective aspects of the sole of the foot. It is blocked at the level of the posterior medial malleolus.

TECHNIQUE. It is not necessary to elicit paresthesias, and an ankle block can be satisfactorily performed in sedated children without the use of a nerve stimulator. Five principal nerves must be blocked to provide analgesia to the entire foot: (1) the deep peroneal, (2) superficial peroneal, (3) saphenous, (4) tibial, and (5) sural nerves (see Fig. 42.34). The technique is the same as in

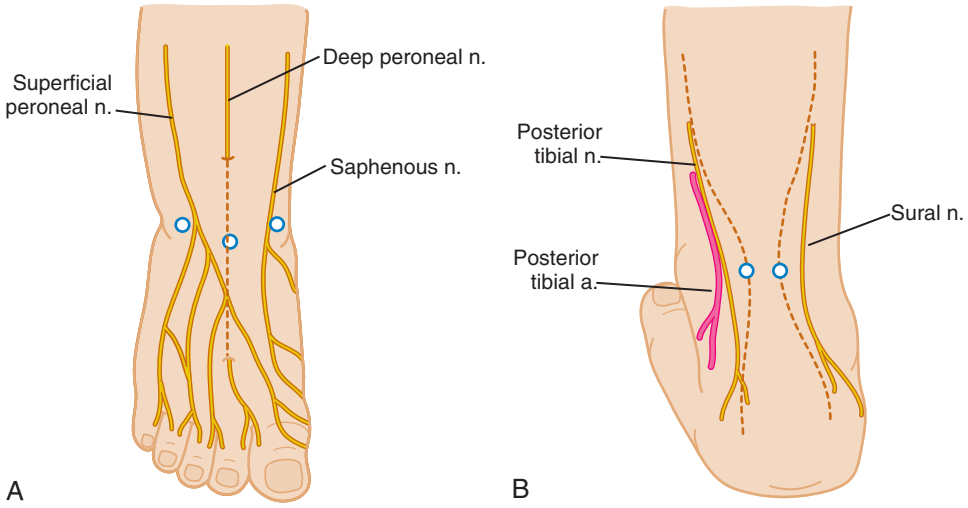

FIGURE 42.34 Ankle block. Block of the ankle generally requires five separate nerves to be blocked. Three nerves can be blocked from the dorsal aspect of the foot **(A)** and two on either side of the Achilles tendon **(B).** Sites of injection are indicated by the *circles*. *a*, artery; *n*, nerve.

the adult. It should be noted that there might be some variation in the precise distribution of distal innervation from child to child. A 25-gauge needle is inserted at a 90-degree angle to the posterior aspect of the tibia and is directed lateral to the posterior tibial artery until the tibia is contacted. Several milliliters of local anesthetic are deposited at this level and several more are injected as the needle is withdrawn. The sural nerve innervates the heel. It is blocked by subcutaneous infiltration of local anesthetic from the Achilles tendon to the lateral malleolus (see Fig. 42.34B). The deep peroneal nerve is located next to the extensor hallucis longus tendon. Usually it can be located by palpating the dorsalis pedis artery. The needle is inserted lateral to the extensor hallucis longus tendon and is advanced until it meets the periosteum of the metatarsal. It is then withdrawn a few millimeters. After careful aspiration, a volume of 2 to 3 mL of local anesthetic is injected. The superficial peroneal nerve is located under the dorsum of the foot. A superficial injection from the lateral malleolus to the extensor hallucis longus tendon area blocks all the branches of the superficial peroneal nerve.

COMPLICATIONS. It is very rare to see complications from an ankle block. However, the use of vasoconstrictors can theoretically cause necrosis of the toes. Care should be taken to avoid the use of an ankle block in children who may have compromised blood flow to the lower extremity.[407]

Digital Nerve Blocks: Foot

This is an easy block to perform and is useful for surgeries that include trauma to the nails and toes, ingrown toenail surgery, and laser treatment of warts.[388]

ANATOMY. The digital nerves of the foot are derived from the plantar cutaneous branches of the tibial nerve. The proper digital nerve of the great toe pierces the plantar aponeurosis posterior to the tarsal-medial joint and supplies the medial side of the great toe. The three common digital nerves pass between the divisions of the plantar aponeurosis and split into two proper digital nerves each. The first supplies the adjacent areas of the great and second toes; the second supplies the adjacent sides of the second and third toes; the third supplies the adjacent sides of the third and fourth toes. Each proper digital nerve gives off cutaneous and articular filaments that terminate at the tip of the toe. The superficial peroneal nerve gives off branches that supply the dorsum of the foot. They are derived from two nerves: (1) the dorsal cutaneous divides into two branches, a medial one that supplies the great toe and a lateral one that supplies the adjacent sides of the second and third toes; and (2) the intermediate dorsal cutaneous nerve, which passes along the lateral part of the foot supplying the lateral part of the dorsum of the foot and communicating with the sural nerve. This latter nerve terminates by dividing into two dorsal digital branches, one of which supplies the adjacent sides of the third and fourth toes and another one that supplies the adjacent sides of the fourth and little toes.

TECHNIQUE. Placement of the needle for this block can be initially difficult owing to the thickness of the overlying skin. We prefer using an approach in which we access the nerve from the web space or at the dorsolateral aspect of the toe. Bupivacaine *without epinephrine* is injected (1-2 mL) after aspiration to rule out intravascular placement. These blocks should be avoided in children with already compromised blood flow to the toes.

COMPLICATIONS. Large volumes of local anesthetic are contraindicated because this may cause pressure and vascular compromise. *Vasoconstrictors should be avoided because this may cause necrosis of the digit.*[389] Intravascular injection may be avoided with incremental injection with frequent aspiration.

Summary

Most regional techniques that are suitable for adults can be used in children. Although in most children sedation or general anesthesia is necessary in addition to the regional anesthetic, in certain neonates, regional anesthesia is often used as the sole technique and may reduce the incidence of early but not late postanesthetic apnea in former preterm infants. In addition to the intraoperative benefits, regional anesthesia may improve postoperative analgesia and may offer some improvement to postoperative respiratory function in selected children. Regional anesthesia is particularly useful in outpatient surgery, providing postoperative analgesia with rapid emergence and a low incidence of side effects. It is

important to realize, however, that the anatomic, physiologic, and pharmacologic factors unique to children can affect the performance and safety of regional anesthetic techniques. The advent of ultrasound guidance for placement of peripheral, as well as central, neuraxial blockade may increase the use of these blocks. Continuous catheter techniques can also increase the postoperative pain control in these children, with fewer adverse effects related to opioid use.[408] Once these differences are understood, regional anesthesia can be safely and effectively used in children of all ages, either as the sole anesthetic or as a supplement to general anesthesia, to provide a smooth intraoperative course and pain-free awakening.

ACKNOWLEDGMENT

The authors wish to thank Per-Arne Lönnqvist, MD, DEAA, FRCA, PhD, for his generous contribution to the paravertebral block section of this chapter.

ANNOTATED REFERENCES

A laboratory study documenting both the efficacy of lipid emulsion in treating local anesthetic systemic toxicity in infancy, as well as the risk of adding the usual resuscitation doses of epinephrine in this condition. Lipid is more efficacious than epinephrine.

Polaner DM, Taenzer AH, Walker BJ, et al. Pediatric Regional Anesthesia Network (PRAN): a multi-institutional study of the use and incidence of complications of pediatric regional anesthesia. *Anesth Analg*. 2012;115(6):1353-1364.

The first paper from the Pediatric Regional Anesthetic Network, this is the most comprehensive prospective look at regional anesthesia practice in the United States. The PRAN database now contains 10 times this number of cases and still has documented similarly low numbers of adverse events.

Rosenberg PH, Veering BT, Urmey WF. Maximum recommended doses of local anesthetics: a multifactorial concept. *Reg Anesth Pain Med*. 2004;29(6):564-575, discussion 524.

A scientific and pharmacologic approach to local anesthetic toxicity that describes the important concept that a simple dose per kilogram is insufficient to determine how much drug is safe to administer.

Suresh S, Long J, Birmingham PK, De Oliveira GS Jr. Are caudal blocks for pain control safe in children? An analysis of 18,650 caudal blocks from the Pediatric Regional Anesthesia Network (PRAN) database. *Anesth Analg*. 2015;120(1):151-156.

Caudal block is still the most commonly performed regional anesthetic in children. This analysis demonstrates that it has a high degree of safety, but that one must be careful in choosing the dose.

Taenzer AH, Walker BJ, Bosenberg AT, et al. Asleep versus awake: does it matter? Pediatric regional block complications by patient state: a report from the Pediatric Regional Anesthesia Network. *Reg Anesth Pain Med*. 2014;39(4):279-283.

A landmark study that presents the first prospective data that administering regional blocks in children under general anesthesia does not increase risk. Previous admonitions about the risk of this practice were based on a few case reports. These data show that administering regional anesthesia in anesthetized pediatric patients is at least as safe, and possibly safer, than in awake or sedated children.

Walker BJ, Long JB, De Oliveira GS, et al. Peripheral nerve catheters in children: an analysis of safety and practice patterns from the pediatric regional anesthesia network (PRAN). *Br J Anaesth*. 2015;115(3):457-462.

Peripheral nerve catheters are being increasingly used for ambulatory surgery of the extremities. These catheters can be safely managed at home as long as well-designed follow-up systems are in place. Accidental catheter dislodgment remains the primary problem.

Williams RK, Adams DC, Aladjem EV, et al. The safety and efficacy of spinal anesthesia for surgery in infants: the Vermont Infant Spinal Registry. *Anesth Analg*. 2006;102(1):67-71.

This report from the world's largest database of spinal anesthetics in infants documents a high degree of safety and efficacy, although a minority of patients did require some brief supplementation with general anesthesia or sedation during highly stimulating portions of the operations. The success rate was very high.

Summary

PERIPHERAL NERVE BLOCKS ARE frequently performed in children to provide anesthesia or analgesia during the perioperative period.[1–3] Success depends on the ability to accurately place the needle—and thereby the local anesthetic—close to the target nerve without causing injury to the nerve or adjacent structures. Peripheral nerve blocks are not without risk and can pose a serious challenge even to the experienced anesthesiologist because they are usually performed after the child is anesthetized. In the past, clinicians relied on anatomic landmarks,[1–3] fascial clicks,[4] loss of resistance,[5] or nerve stimulation[6] to position the needle in the vicinity of the nerve. Anatomic landmarks provide valuable clues to the position of the nerve, but they are surrogate markers, lack precision,[7] vary among children of different ages, and may be difficult to locate in obese children. Even nerve stimulation, which has been recommended as the gold standard for nerve localization, may not always elicit a motor response[8] and its use does not guarantee success or preclude complications.[9] Moreover, the accuracy of needle placement cannot be predicted with any of these methods, which may lead to multiple attempts to place the needle that may result in pain and possibly an incomplete or failed nerve block.

Various imaging modalities, such as fluoroscopy,[10] computed tomography (CT),[11] and magnetic resonance imaging (MRI),[7] improve the accuracy of block placement in adults. However, these adjuncts are rarely used in children and are not practical in the operating room. The use of ultrasound (US) to guide peripheral and central neuraxial blocks has improved both accuracy and safety in both adults and children.[12–21] In this chapter, the basic principles of US imaging and US-guided regional anesthesia (USGRA) in children are described. It is assumed that the reader has a basic understanding of common landmark-based nerve block techniques in children (see Chapter 42).

The use of US for regional anesthesia dates back to 1978, when La Grange et al. used a Doppler flow detector to locate the subclavian artery and guide supraclavicular brachial plexus blocks.[22] In 1994, Kapral and colleagues published the first report on direct sonographic visualization in regional anesthesia.[23] They used US to directly visualize the brachial plexus and observe the spread of the local anesthetic in real time during supraclavicular brachial plexus block. Today, US is commonly used to guide regional anesthesia techniques in both adults and children. Improvements in US technology and the availability of portable US machines with high-resolution imaging capabilities allow direct visualization of the peripheral nerves and central neuraxial structures in children; this can be compared to removing a blindfold from

FIGURE 43.1 Sound wave.

TABLE 43.1 Propagation Velocity of Sound in Body Tissues

Tissue	Propagation Velocity of Sound (m/second)[a]
Bone	4080
Muscle	1580
Blood	1570
Kidney	1560
Liver	1550
Soft tissue (average)	1540
Water	1480
Fat	1450
Lung	600
Air	330

[a]Medical ultrasound device measurements are based on an assumed average propagation velocity of 1540 m/second.

the anesthesiologist performing regional anesthesia. Currently, outcome data that prove US increases the safety and efficacy of regional anesthesia in children are rapidly accumulating.[20,21,24]

Principles of Ultrasound

Sound is a form of mechanical energy that propagates through a medium as a wave of alternating pressure, causing local regions of compression and rarefaction (Fig. 43.1). The frequency (f) of sound is the number of cycles of oscillations per second made by the sound source and the particles in the medium through which it moves. It is expressed in hertz (Hz, cycles per second). Sound waves propagate symmetrically away from the source at a constant velocity (v), which is the speed of sound in the medium. Distance between the wavefronts is the wavelength (λ) of the sound. The speed of sound through a medium can thus be represented as:

$$v = f \times \lambda$$

Amplitude is the strength of a sound wave, and the unit used to describe it is decibels (dB). The velocity of transmission of sound through a medium depends on its acoustic impedance and is determined by factors such as the stiffness, elasticity, and density of the medium. This accounts for the varying velocity of sound transmission through different tissues in the human body (Table 43.1). The average velocity of sound transmission through biologic tissue is 1540 m/second. If the time taken by the US signal to return to the transducer is known, the distance of the target from the transducer (depth) can be computed.

The human ear can detect sound between 20 and 20,000 Hz. US is sound with a frequency beyond 20,000 Hz (20 KHz). For medical imaging, US typically uses a frequency between 1 million and 15 million Hz (megahertz [MHz]) and is produced by a piezoelectric crystal (element) within the transducer. When an electrical field is applied to the surface of an element in a transducer, it undergoes dimensional changes that cause it to vibrate and produce sound. The element is typically driven by a pulsed alternating voltage. This results in the generation of short pulses of US that are emitted into body tissues. Between successive short pulses of US generation, the transducer does not transmit but rather functions as a receiver of the reflected US energy (i.e., the echoes). The percentage of time that a transducer is transmitting is termed the *duty factor* and is typically less than 1%. The US transducer thus has a dual function—it functions as both a transmitter and a receiver.

The emitted US signal travels through the tissue medium, and when it encounters a tissue interface it is reflected back. The degree of reflection of US from tissues is related to the changes in acoustic impedance (Z) between two tissue interfaces. The reflected echoes are detected by the transducer and converted into electrical energy; they are then processed by the US machine according to their strength and displayed as dots on the monitor. The brightness of each dot corresponds to the strength of the echo signal. Strong echoes produce bright white dots, weak echoes produce gray dots, and anatomic structures that do not reflect US appear as black dots. The position of the dot on the monitor represents the depth from which the echo is received. When all of these dots are combined, they produce a complete image of the area scanned.[25–27]

MODES OF ULTRASOUND

B-Mode (Brightness) or Two-Dimension Mode

B-mode (brightness) or two-dimensional (2D) mode, is the most commonly used US mode. In this mode, the echo is converted to a dot and the brightness of the dot represents the amplitude of the returning signal.[25–27] The position of the dot on the display represents the depth from which the signal is returning and depends on the round-trip time of the US signal. Multiple scan lines across a plane are combined to produce a single 2D gray-scale image. A series of frames are then displayed in rapid succession to give the impression of constant motion, the quality of which depends on the number of images displayed per second, that is, the *frame rate*.

M-Mode (Motion)

Motion, or M-mode, US is directed along a single scan line (sample line), and reflected signals along this scan line are converted to a brightness scale and displayed against a time axis. Because M-mode is produced from US signals along a single scan line, the 2D anatomy of the underlying body tissues should be studied first using the 2D mode. M-mode is of particular interest when time resolution is necessary, such as when examining a target with rapid movement (e.g., the mitral valve during echocardiography).[28]

Doppler Ultrasound

Doppler US (based on the Doppler principle) detects a shift in frequency between the emitted US waves and their echoes. It is

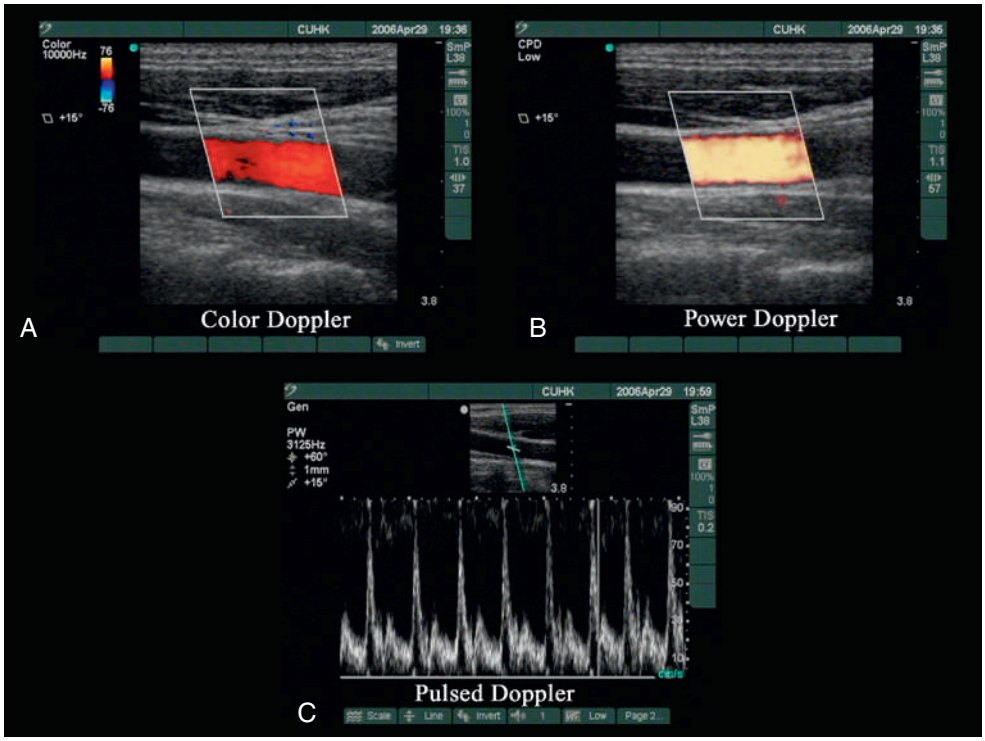

FIGURE 43.2 Doppler ultrasound. **A,** Color Doppler. **B,** Power Doppler. **C,** Pulsed Doppler.

used to detect and measure blood flow, and the major reflector for this purpose are red blood cells.[29–32] Several modes are available:

- *Color Doppler* measures and color codes the direction and magnitude of the mean Doppler frequency shifts that occur in moving red blood cells and superimposes a color depiction of these data on the gray-scale image (Fig. 43.2A).
- *Power color Doppler* depicts the amplitude, or power, of the Doppler signals (Fig. 43.2B). This allows better sensitivity for visualization of small vessels, but at the expense of directional information.
- *Pulsed Doppler* allows a sampling volume (or gate) to be positioned in a vessel visualized on the gray-scale image and displays a spectrum of the full range of blood velocities within the gate plotted as a function of time (Fig. 43.2C).

THE ULTRASOUND MACHINE

US machines are made up of the following components: a *monitor* (where the clinical images are displayed), the *US unit* (where the signals are processed), the *control panel* (with the knobs and controls), one or more *transducers*, and a *data storage device*.[33–35] For an anesthesiologist's first encounter with a US machine the wide array of knobs and controls available may be confusing. However, several controls are common in most US machines, and a clear understanding of their function—that is, *knobology*—is essential for optimal imaging.

Presets

Most US machines have a number of presets, which are factory set, to allow optimal US imaging of a specific area of the body or type of examination. Some of the categories of presets that are available include small part, vascular, breast, nerve, musculoskeletal, abdominal, and so on. For example, if a small part preset is chosen, the US machine assumes that the operator is scanning for small, relatively superficial structures and automatically adjusts the depth, power, focus, gain, and time-gain compensation (TGC) to allow optimal imaging of superficial structures. Some US machines also allow customized presets according to clinical requirements. Power output is the amount of energy transmitted from the US transducer. In most machines, the power cannot be adjusted by the operator but is automatically set when a particular preset is chosen.

Frequency

This control is used to select the desired frequency, within certain limits, of a broadband transducer—that is, a transducer that serves a range of frequencies. In some US systems (Edge, SonoSite Inc., Bothell, WA), this is available as an image optimization control. In the "Res" (resolution) setting the highest frequency of the broadband transducer is selected; in the "Pen" (penetration) setting the lowest frequency is selected; and in the "Gen" (general) setting an intermediate frequency is selected.

Gain

The gain control adjusts the amplification of the returning acoustic signals and is used to optimize the US image (Fig. 43.3A). Reduced gain produces a dark image (Fig. 43.3B) and detail is masked. In contrast, too much gain produces a white image and detail is saturated (Fig. 43.3C). Some US machines have separate controls for overall gain and gain for the near and far fields. "Auto-gain," by which the US machine automatically adjusts the gain, is also available in some machines.

Time-Gain Compensation

US energy is progressively attenuated as it travels through tissue. Therefore signals returning from reflectors at a depth are weaker in strength. By selectively amplifying the echoes from greater

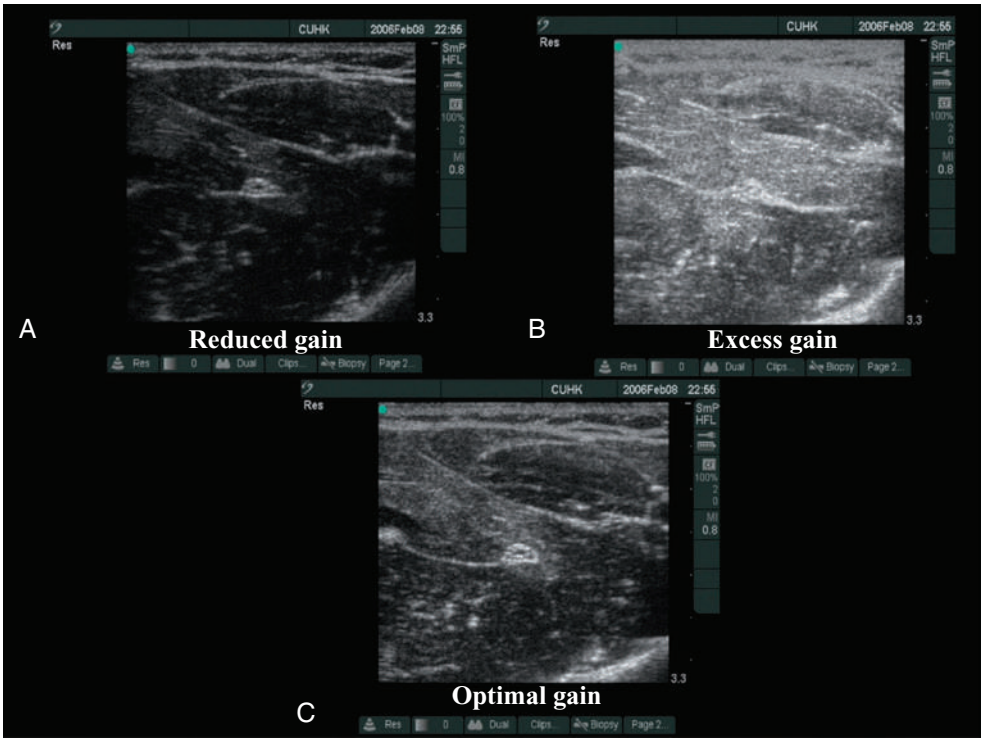

FIGURE 43.3 Transverse sonogram of the forearm demonstrating **A,** reduced gain, **B,** excess gain, and **C,** optimal gain.

depths, using the TGC method or depth-gain compensation (DGC), equal reflectors at unequal depths are displayed as structures of equal brightness on the monitor. TGC is preset to a large degree, and the operator can make fine adjustments if necessary. The TGC control is presented as a series of sliders arranged in a vertical fashion on the control panel. Each of the sliders adjusts the amplification of the returning US signals at a specific image depth.

Depth

Adjustment in the displayed depth may be necessary, depending on the location of the target, the patient's body size, or other anatomic factors. A depth greater than necessary should not be chosen because this reduces the frame rate and resolution of the image.

Focus (Focal Zone)

The focus of the US signal occurs at a point at which the beam is at its narrowest width. It is also the region where lateral resolution is the best. The focus point should therefore be positioned at the depth at which the relevant anatomic structures are located. In some US machines, the operator can select multiple focal zones, but this markedly reduces the frame rate and thus should not be routinely used.

Freeze and Unfreeze

The "freeze" function allows the operator to lock a static image on the monitor. A number of frames (usually 20 or more) are also simultaneously stored in a memory bank. These stored frames can be scrolled back and forth. The selected still image can then be used for annotation, documentation, storage, review, or teaching. Pressing the freeze button once again will unfreeze the image.

Ultrasound Transducers

The transducer functions both as a transmitter and a receiver of the ultrasound signal.[33–35] Three types of transducers are currently used (Fig. 43.4): (1) in a linear-array transducer, the piezoelectric crystals are arranged in a linear fashion and sequentially fired to produce parallel beams of ultrasound in sequence, creating a field of view that is rectangular and as wide as the footprint of the transducer (Fig. 43.4A); (2) a curved linear-array transducer has a curved surface, creating a field of view that is wider than the footprint of the probe (Fig. 43.4B), but at the cost of reduced lateral resolution in the far field as the scan lines diverge; (3) a phased-array transducer has a small footprint, but the ultrasound beam is steered electronically to produce a sufficiently wide far field of view. The ultrasound beam diverges from virtually the same point in the transducer (Fig. 43.4C). Phased-array transducers are routinely used for transthoracic echocardiography.[34] The footprints of these transducers are small enough to fit between the ribs and still produce a wide far field of view to image the heart. US transducers are typically broadband and can serve a range of frequencies. For example, a transducer with the notation HFL38/13-6 indicates that it is a high-frequency broadband (13-6 MHz) linear transducer with a 38-mm footprint. Note that the nomenclature used for transducers varies among manufacturers of US devices.

Ultrasound Transducer Selection

Resolution is the ability to distinguish two objects that are close together. *Axial resolution* is the ability to distinguish two objects that are along the axis of the US beam, and *lateral resolution* is the ability to distinguish two objects that are side by side. High-frequency US (13-6 MHz) has a higher axial and lateral

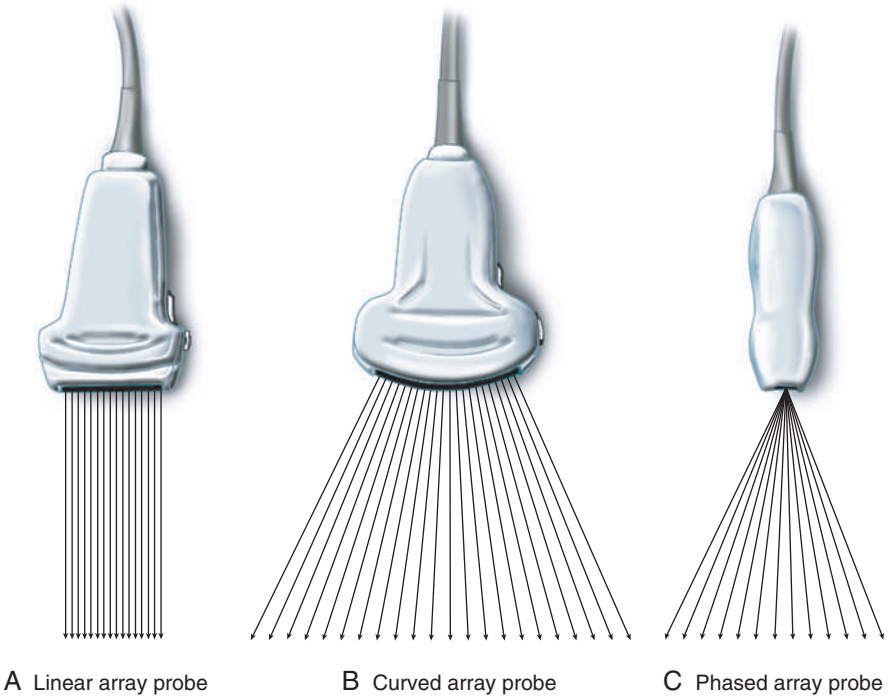

FIGURE 43.4 Schematic diagram illustrating the different types of ultrasound transducers. Note how the ultrasound beam is emitted from each of these transducers.

resolution compared with low-frequency US but cannot penetrate as deeply into body tissue. Therefore high-frequency US is used to image superficial structures such as the brachial plexus in the interscalene groove or supraclavicular fossa. A lower-frequency US transducer (10-5 MHz) is suited for slightly deeper structures, such as the brachial plexus in the infraclavicular fossa, whereas a low-frequency US transducer (5-2 MHz) is used to image deep structures, such as the lumbar plexus or the sciatic nerve. Broadband transducers allow a single transducer to be used for scanning over a wide range of depths. Because regional blocks are performed at relatively shallow depths in neonates, infants, and young children, high-frequency linear transducers are used for most procedures. High-frequency linear transducers with a small footprint (13-6 MHz, 25 mm), in either a hockey stick or linear configuration, are particularly suited for young children.

Essentials of Musculoskeletal Ultrasound Imaging

AXIS OF SCAN

In diagnostic ultrasonography, scans are performed in the transverse, longitudinal (sagittal), oblique, or coronal axis. During a transverse (axial) scan the transducer is oriented at right angles to the target, producing a cross-sectional display of the structures (Fig. 43.5A). During a longitudinal scan, the transducer is oriented parallel to and along the long axis of the target (e.g., a blood vessel or nerve) (Fig. 43.5 B). During USGRA procedures, US scans are most commonly performed in the transverse axis. In this axis, the nerves, the adjoining structures, and the circumferential spread of the local anesthetic are easily visualized.

PROBE AND IMAGE ORIENTATION

The US image must be properly oriented to accurately identify the anatomic relations of the various structures on the monitor. To facilitate this, all US probes have an orientation marker, which is usually represented by a groove or a ridge on one side of the transducer and corresponds to a green dot (or a logo) on the monitor. By convention, the orientation marker on the transducer is directed cephalad when performing a longitudinal scan and directed toward the right side of the patient when performing a transverse scan. This way the orientation marker on the left upper corner of the monitor always represents the cephalad end during a longitudinal scan or the right side of the patient during a transverse scan. The top of the display monitor therefore represents superficial structures and the bottom of the monitor the deep structures.

ECHOGENICITY

Certain terms are frequently used to describe the sonographic appearance of musculoskeletal structures (Fig. 43.6):

- *Echogenic*: A bright white structure against a dark background
- *Reflective*: Synonymous with an echogenic structure
- *Isoechoic*: A shade of gray that is of the same brightness or echogenicity as the surrounding tissues
- *Hyperechoic*: A shade of gray that is bright white or brighter than the surrounding tissues
- *Hypoechoic*: A shade of gray that is dark or less bright than the surrounding tissues
- *Anechoic*: An absence of echoes, hence blackness

AXIS OF INTERVENTION

The plane of US imaging is approximately 1 mm thick (Fig. 43.7); for a needle to be visible during US imaging it must lie within

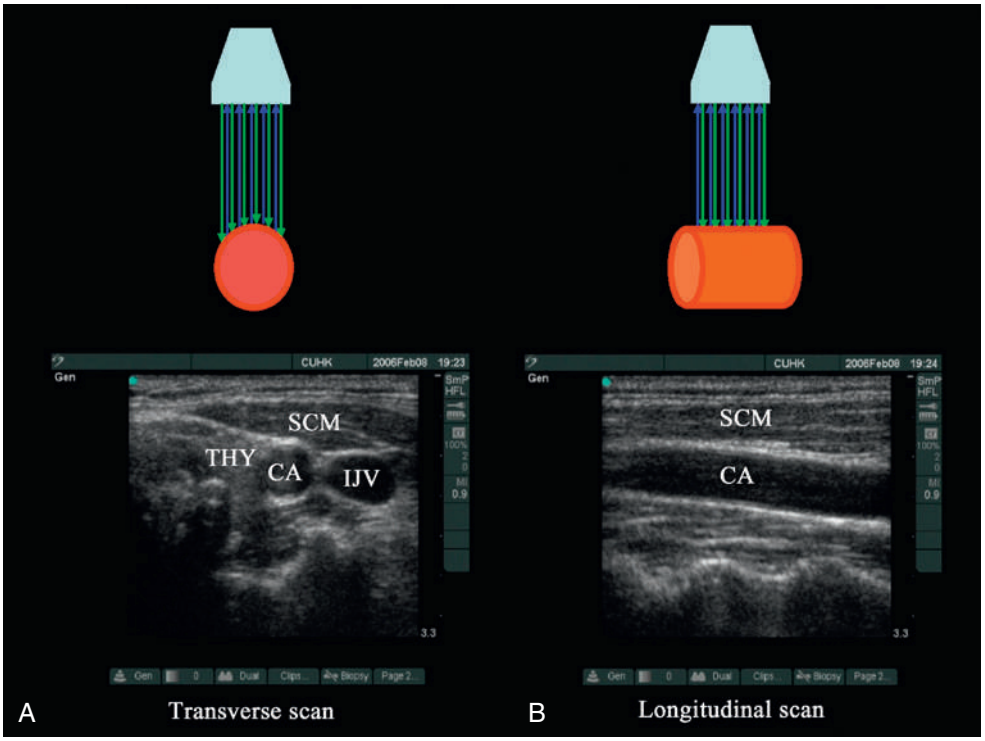

FIGURE 43.5 Axis of scan. **A,** Transverse scan. **B,** Longitudinal scan. *CA,* carotid artery; *IJV,* internal jugular vein; *SCM,* sternocleidomastoid muscle; *THY,* thyroid.

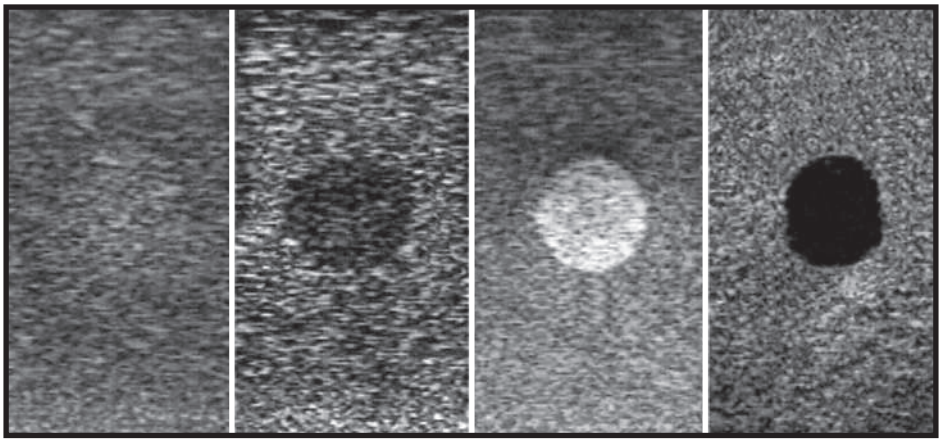

FIGURE 43.6 Schematic diagram to demonstrate the relative echogenicity of various tissues.

this narrow plane of imaging. During USGRA procedures, the block needle is inserted either outside of the plane (out-of-plane approach) (Fig. 43.8A) or within the plane of the US beam (in-plane approach) (Fig. 43.8B). In the out-of-plane approach, the needle is inserted in the short axis and is initially outside the plane of imaging and therefore not visible. It becomes visible only when the needle crosses the plane of imaging and is seen as an echogenic dot on the monitor (Fig. 43.8A). It is important to note that this echogenic dot may be just the cross-sectional image of the shaft of the needle as it passes through the plane of the US beam and thus may not represent the tip of the needle. In the in-plane approach, the needle is inserted along the long axis of the transducer in the plane of imaging and therefore both the shaft and tip of the needle are visible.

Both approaches are commonly used, and no data have shown that one is better than the other. Proponents of the out-of-plane approach[13,14,36] have had great success with this method and claim that it causes less needle-related trauma and pain because the needle is advanced through a shorter distance to the target. However, critics express concerns that the inability to reliably visualize the needle and to use tissue movement as a surrogate marker to locate the needle tip during a procedure can lead to complications. The needle is better visualized in the in-plane approach,[37,38] but this requires good hand–eye coordination.

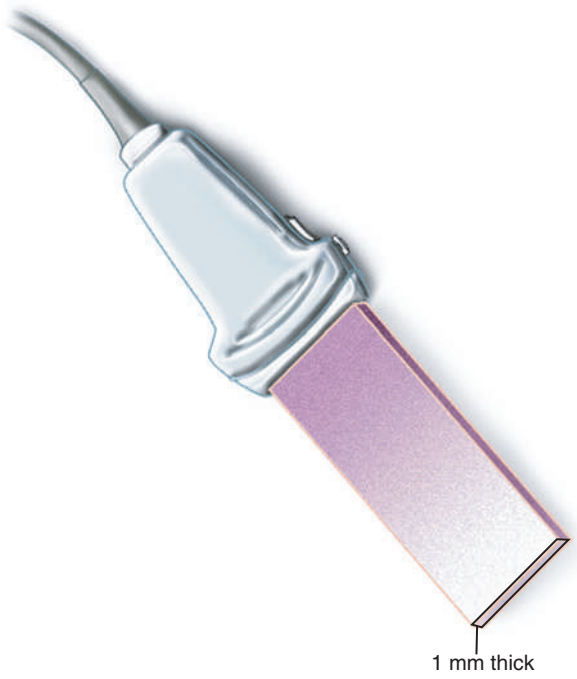

FIGURE 43.7 The plane of ultrasound imaging. Note that the ultrasound beam is only 1 mm thick and for a needle to be visible during an ultrasound-guided intervention it must lie within this plane of imaging.

Moreover, there are claims that the in-plane approach also causes more discomfort in awake patients because longer needle insertion paths are required.[13,14,36]

NEEDLE VISIBILITY

The ability to visualize the needle during a US (USG) procedure is critical for precision, safety, and success. However, this is often limited by the dispersion of the reflected US signals away from the transducer. Several factors have been identified that can influence needle visibility.[39–41] The shaft of the needle is better visualized in the long axis than in the short axis, and its visibility decreases linearly with steep angles of insertion and smaller needle diameters. The needle tip is better visualized when it is inserted in the long axis for shallow angle of insertion (<30 degrees) and in the short axis when the angle of insertion is steep (>60 degrees). To overcome the effect of angle on needle visibility, some US machines allow the operator to steer the US beam toward the needle ("beam steering") during steep needle insertions.[42] However, this requires experience and decreases in needle visibility can still occur. Manufacturers have incorporated microscopic glass beads or reflectors onto the surfaces of block needles, or have laser-etched the tips of block needles to improve their visibility (echogenic needle).[43–45]

The anesthesiologist's skill in aligning the needle along the plane of imaging is by far the most important factor influencing needle visibility because minor deviations of even a few millimeters from this plane will result in inability to visualize the needle. Even with experience, needle tip visibility is a problem

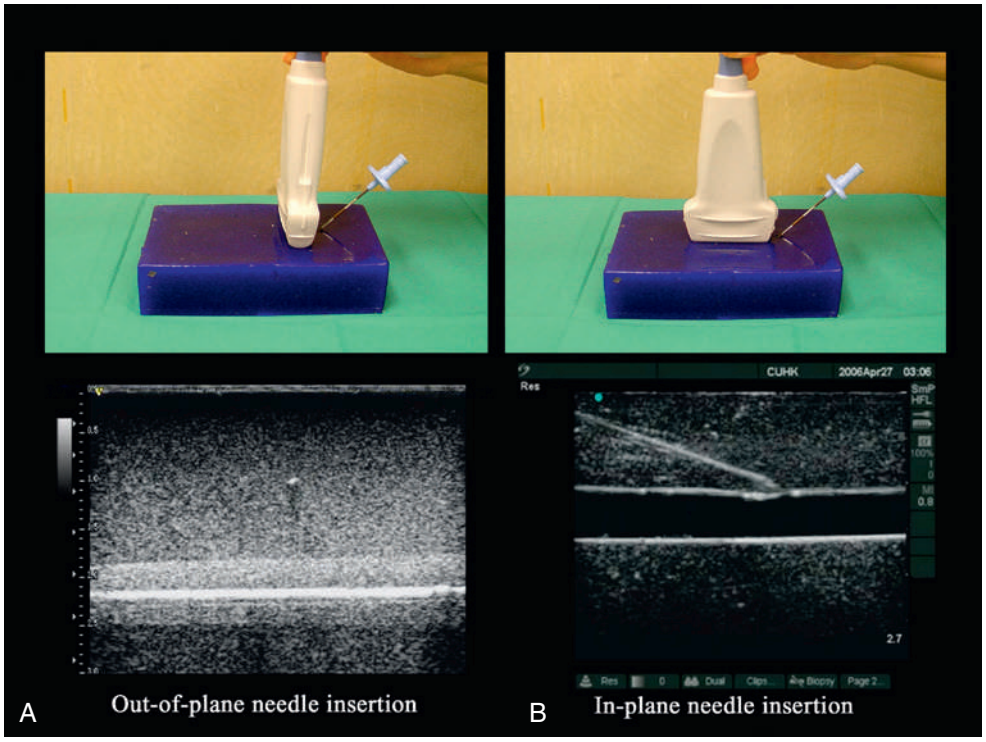

FIGURE 43.8 Axis of intervention. **A,** Out-of-plane and **B,** in-plane techniques.

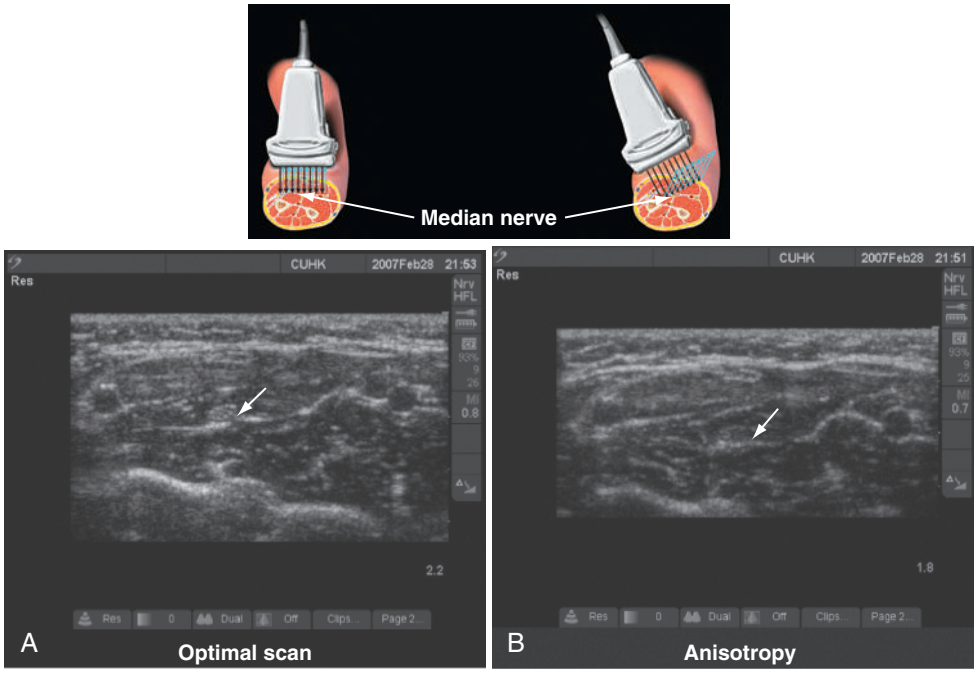

FIGURE 43.9 Anisotropy. Note how a small change in the angle of the ultrasound beam from the neutral position (**A**) has affected the visibility of the median nerve (*white arrow,* **B**) in the forearm.

when performing blocks at a depth in areas that are rich in fatty tissue. Under such circumstances, gently jiggling (rapid in-and-out movement) the needle and observing tissue movement or performing a test injection of saline solution or 5% dextrose (0.5–1 mL) and observing tissue distention can help locate the position of the needle tip. Five percent dextrose is preferred for the latter when nerve stimulation is used because it does not increase the electric current required to elicit a motor response.[46]

ANISOTROPY

Anisotropy, or angular dependence, is a term used to describe the change in echogenicity of a structure with a change in the angle of insonation of the incident US beam (Fig. 43.9).[47] It is frequently observed during scanning of nerves, muscles, and tendons. This occurs because the amplitude of the echoes returning to the transducer varies with the angle of insonation. Nerves are best visualized when the incident beam is at right angles (Fig. 43.9A); small changes in the angle away from the perpendicular can significantly reduce their echogenicity (Fig. 43.9B). Therefore during USGRA procedures, the transducer should be tilted, from side to side, to minimize anisotropy and optimize visualization of the nerve.[48]

Identification of Nerves, Tendons, Muscle, Fat, Bone, Fascia, Blood Vessels, and Pleura

NERVES

On a transverse scan, nerves appear round, oval, triangular, lip-shaped, or even flat.[49] Nerves also assume different shapes along their course, depending on the surrounding structures. The echogenicity of nerves also varies and depends on the nerve and area scanned. They are generally hyperechoic and stand out in the background of the hypoechoic muscles (Fig. 43.10A), but they can also appear hypoechoic with a hyperechoic rim (Fig. 43.10B). They also have been described to have a fascicular or honeycomb appearance (i.e., echogenic structures with internal punctate, echo-poor spaces) (Fig. 43.10C). On longitudinal scan, the appearance of peripheral nerves has been likened to a "tram track"; that is, parallel hyperechoic lines are seen against a background of echo-poor space (Fig. 43.10D).

TENDONS

Tendons appear to have numerous fine, parallel hyperechoic lines separated by fine hypoechoic lines (fibrillar pattern) on long-axis scans.[50] Compared with nerves, tendons have more hyperechoic lines and move more than adjacent nerves when the corresponding muscle is contracted or passively stretched.

MUSCLE

Muscle fibers are hypoechoic, but the connective tissue structure enveloping the entire muscle (epimysium) is hyperechoic.[51,52] The perimysium that envelops individual muscle fascicles is also hyperechoic. Muscle fibers converge to become tendons or aponeurosis.

FAT

Fat lobules appear as round to oval hypoechoic nodules separated by fine hyperechoic septa. Fat tends to be superficially distributed (subcutaneous fat), slightly compressible, and similar on transverse and longitudinal scans.

BONE

Bone reflects most of the US energy. Therefore it appears bright and has a hyperechoic edge on US imaging, with a large anechoic shadow (acoustic shadow) distal to it (Fig. 43.11).

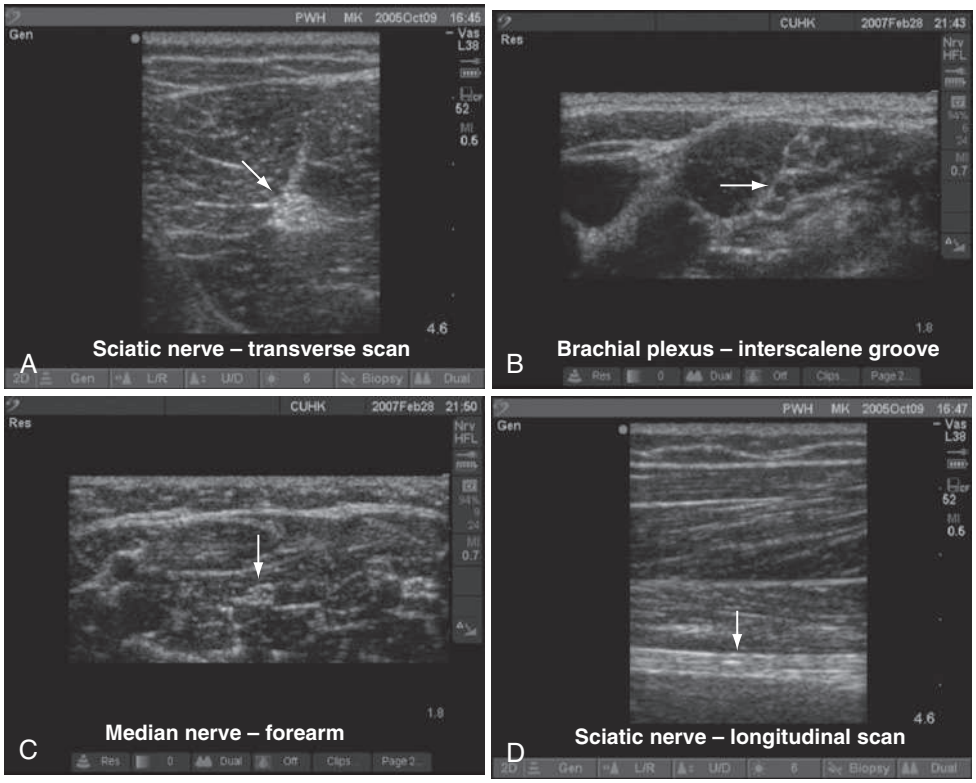

FIGURE 43.10 Ultrasound appearance of peripheral nerves. **A,** Transverse sonogram of the sciatic nerve in the thigh. **B,** Transverse sonogram of the brachial plexus in the interscalene groove. **C,** Transverse sonogram of the median nerve in the forearm. **D,** Longitudinal sonogram of the sciatic nerve in the thigh.

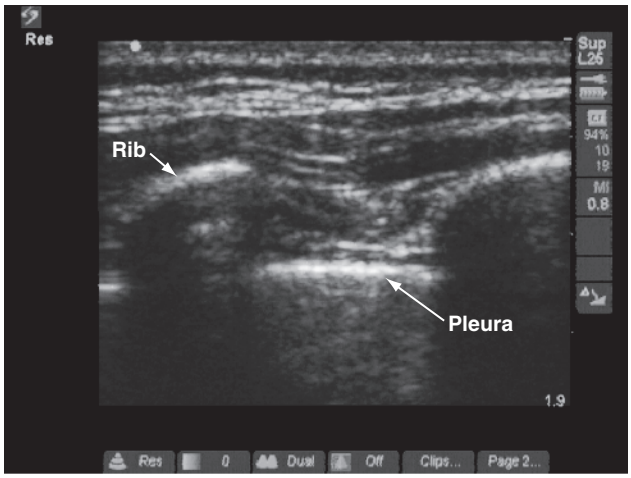

FIGURE 43.11 Longitudinal sonogram of the intercostal space demonstrating the ultrasound appearances of bone and pleura.

FASCIA

Fascia, peritoneum, and aponeurosis appear as thin hyperechoic layers on US imaging.

BLOOD VESSELS

Arteries are identified by their pulsatility, are not easily compressible, and have anechoic lumens. Veins are not pulsatile, are easily compressible, and have anechoic lumens. Color Doppler or power Doppler modes can also be used to demonstrate blood flow pattern and differentiate arteries from veins (see Fig. 43.2).

PLEURA

The pleura appear as a hyperechoic line on US imaging (see Fig. 43.11).[53–55] During scanning of the intercostal space, the pleural line is located slightly below the hyperechoic ribs. "Comet-tail" artifacts may be present as a series of vertical lines arising from the pleura. On real-time imaging, lung sliding movement between the parietal and visceral pleura can be discerned from movement of the comet-tail artifacts ("lung sliding sign").

Special Techniques

TISSUE HARMONIC IMAGING

The term *harmonic* refers to frequencies that are integral multiples of the frequency of the transmitted pulse (which is also called the fundamental frequency or first harmonic). The second harmonic has a frequency of twice the fundamental frequency. Harmonics are generated in the tissues by the nonlinear propagation of sound.[56–58] Tissue harmonic imaging (THI) is a technique in which the harmonic signals reflected from tissue interfaces are selectively displayed. This results in reduced image artifacts, haze, and clutter and improved contrast resolution (Fig. 43.12).

COMPOUND IMAGING

US imaging depends on the reflection of the US from tissue interfaces. Not all tissues are good reflectors, and certain structures

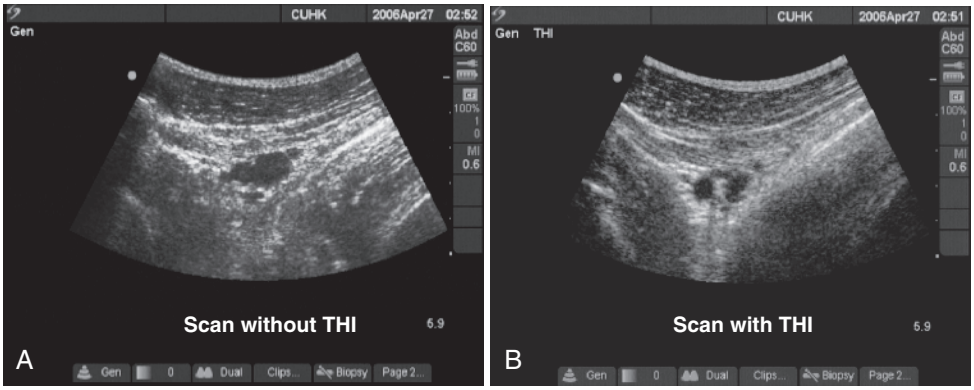

FIGURE 43.12 Tissue harmonic imaging *(THI)*. Sagittal sonogram of the infraclavicular fossa. **A,** Conventional scan. **B,** Conventional scan with THI.

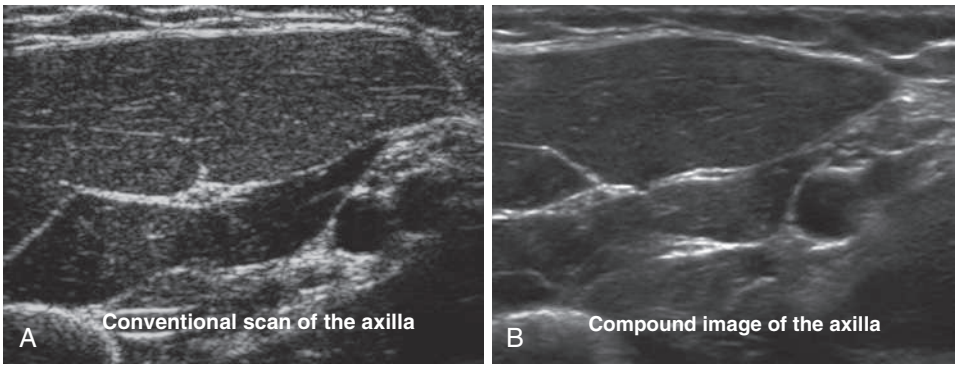

FIGURE 43.13 Compound imaging. Transverse sonogram of the axilla. **A,** Conventional scan. **B,** Conventional scan with compound imaging.

also cause scattering of the US signals. Unlike reflected signals, scattered signals radiate in all directions. As a result, only a small amount of energy is reflected back to the transducer. The scattering of the US signal results in speckle artifacts, also described as noise, which reduces image resolution and makes the US image appear grainy or noisy. Compound imaging is a technique used to improve resolution by reducing the contrast-to-noise ratio.[59] The US beam from the transducer is electronically steered, and the same structure is imaged from several different angles. The returning echoes are then processed with simultaneous filtering of the artifacts in real time, producing a composite image that has reduced noise or speckle and improved definition (Fig. 43.13).

PANORAMIC IMAGING

B-mode (2D) ultrasonography has a limited field of view and allows visualization of only a small portion of any large structure. Panoramic imaging, as the name implies, is a technique used to extend the field of view so that larger structures and their surrounding tissues can be visualized together.[60] During a panoramic scan, the operator slowly slides the US transducer across an area of interest. During this motion, multiple images are acquired from many different transducer positions across the area of interest. The registered image data are accumulated in a large buffer and then combined to form the composite panoramic image (Fig. 43.14). Although useful for annotation, documentation, teaching, and research, it is rarely used in children during USGRA procedures.

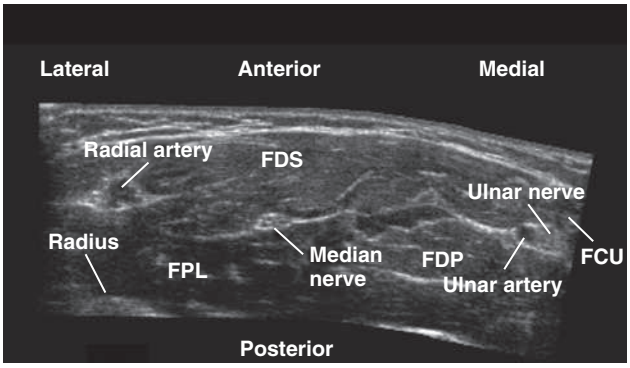

FIGURE 43.14 Panoramic imaging. Transverse panoramic scan of the forearm. *FCU,* flexor carpi ulnaris; *FDP,* flexor digitorum profundus; *FDS,* flexor digitorum superficialis; *FPL,* flexor pollicis longus.

ARTIFACTS

US artifacts are structures that are visible in the US image that do not correlate with any anatomic structure.[61] The US machine makes the following assumptions when generating an image:

1. The US beam is considered to travel only in a straight line, with a constant rate of attenuation.
2. The average speed of sound through body tissue is considered to be 1540 m/second.

3. The US beam is assumed to be infinitely thin, with all echoes originating from its central axis.
4. The depth of a reflector is calculated by determining the round-trip time of the US signal.

When a deviation from any of these assumptions occurs, the US machine is unable to determine it. This results in the display of an echo that has no relation with the interface that actually produced the echo; that is, an artifact is produced. Some artifacts are undesirable and interfere with interpretation, whereas others help identify certain structures. It is essential to recognize them to avoid misinterpretation. Therefore when a structure appears abnormal on ultrasonography, it must be examined in two planes to avoid making a wrong interpretation. Real anatomic structures are visible in both planes of imaging, whereas artifacts are visible in only one plane.

Contact Artifact

The contact artifact is the most common artifact produced when loss of acoustic coupling occurs between the skin and the transducer. This could occur because the transducer is not touching the skin, but more frequently it is due to air bubbles that are trapped between the skin and the transducer. Therefore it is prudent to apply liberal amounts of gel to exclude air from the skin and transducer interface.

Reverberation Artifact

Reverberation artifacts, also known as repetitive echoes, occur when repeated reflection of US occurs between two highly reflective surfaces.[62] Some of the US signals returning to the transducer are reflected back, then strike the original interface, and are reflected back toward the transducer a second time. As a result, the first reverberation artifact is twice as far from the skin surface as the original interface. A second or third reverberation artifact also may be seen. Because of attenuation, the intensity of the artifacts decreases with increasing distance from the transducer. Reverberation artifacts are frequently seen during USG axillary brachial plexus block, particularly when the needle is inserted in the long axis.

Mirror Image Artifact

Mirror image artifact is a type of reverberation artifact that occurs at highly reflective interfaces.[63] The first image is displayed in the correct position, and a false image is produced on the other side of the reflector because of its mirrorlike effect.

Propagation Speed Artifact

Propagation speed artifacts occur when the medium through which the US beam passes does not propagate at 1540 m/second, resulting in echoes that appear at incorrect depths on the monitor. An example of propagation speed artifact is the "bayonet artifact," which has been reported during a USG axillary brachial plexus block.[64] The shaft of the needle appeared bent when it accidentally traversed the axillary artery. This happens because of the difference in the velocity of sound between whole blood (1580 m/second) and soft tissue (1540 m/second).

Acoustic Shadowing

Acoustic shadow is an echo-free area behind surfaces that are highly reflective or attenuating, such as bone (see Fig. 43.11) or metallic implants. The implication for regional anesthesia is that tissues in the area of the shadow cannot be imaged.

TABLE 43.2 Scanning Routine

1.	Turn on the ultrasound machine.
2.	Select a scanning mode.
3.	Select an appropriate transducer.
4.	Dim the lights in the room.
5.	Assume a comfortable position.
6.	Apply liberal amount of ultrasound gel.
7.	Perform a scout scan.
8.	Orient the transducer and image.
9.	Select the appropriate ultrasound settings (preset, frequency—for broadband transducers, depth, gain, and focus point).
10.	Mark the position of the transducer on the patient's skin once an optimal image is obtained before the intervention.

SCANNING ROUTINE

Being able to consistently produce high-quality images of the area scanned is vital for safety and success during any USGRA procedure. Without optimal images, it is not possible to accurately identify musculoskeletal structures or perform interventions with precision. We have found that following a "scanning routine," or a set of simple steps that are repeatable, is essential for optimal imaging; the routine that we follow is outlined in Table 43.2. Although the suggested routine may appear complicated at first, with repetition these steps are gradually internalized. Attaching a card with the scanning routine to the US machine facilitates easy recall.

Scout Scan

The aim of the scout scan, or the preintervention scan, as the name implies, is to examine the area of interest before the intervention. This has also been referred to as a "mapping scan." During the scout scan, steps 8 and 9 described in Table 43.2 are performed, the sonoanatomy of the area is visualized, and the image is optimized. Once an optimal view with the target structure is obtained and the best possible site for needle insertion is determined, it is advisable to mark the position of the transducer on the patient's skin so the transducer can be returned to the same position after sterile preparations have been completed. It is common to diagnose anatomic variations during the scout scan.[65] The operator can then decide whether to continue with the block in the same location or to choose an alternative approach or technique that may be safer. This assessment of anatomic variation is one of the major benefits of using US for regional anesthesia.

GENERAL CONSIDERATIONS IN CHILDREN

Preparations for a USG nerve block should begin during the preoperative visit by adequately explaining the technique, its benefits and risks, and, more importantly, the possibility of a failed block to the parents. In the event of failure, a contingency plan to quickly convert to general anesthesia or another form of postoperative analgesia must always be in place. In children, most regional anesthetic procedures are performed while the child is anesthetized. However, in a cooperative child or under special circumstances, such as in a child with difficult airway or a child predisposed to malignant hyperthermia, it is possible to perform the block after light sedation. We find that it is easy to explain the procedure to children who are older than 8 years of age. Some of them may even express a wish to stay awake and observe the US images during the block. Eutectic mixture of local anesthetic

(EMLA) cream applied an hour before the procedure to the skin over the area where the block needle and the intravenous catheter are to be inserted helps reduce needle-related pain. Parental presence during the nerve block may also be helpful. In older children, allowing the child to listen to favorite music through a personal stereo or watch a video are useful distraction techniques that make the whole experience a more pleasant one for the child. We have connected a DVD player to our US machine, and this is used to play movies or cartoons through the monitor during the surgical procedure (E-Fig. 43.1).

Before any USGRA procedure, intravenous access is established, standard monitoring is applied, and equipment and drugs appropriate for the child are prepared. Aseptic precautions are maintained, and the skin over the needle puncture site is prepared with antiseptic solution in the usual fashion. The US probe is placed inside a custom-designed sterile transducer plastic cover.[66]

TIPS AND TRICKS FOR SUCCESS

Certain steps are common to all USG procedures, and, if followed, they may increase success. The lights in the room must be dimmed to avoid any glare or reflection from the US monitor. The operator must assume a comfortable position (Fig. 43.15).[67] For upper extremity blocks, the operator sits at the ipsilateral head end of the child, and the US machine is placed directly in front. For lower extremity blocks, such as femoral nerve block, the operator stands on the ipsilateral side of the child, and the US machine is placed on the opposite side. For lower extremity or central neuraxial blocks in the lateral position, the operator sits behind the child, and the US machine is placed in front, with the monitor in the line of view of the operator. Because of the small muscle bulk in young children the nerves are relatively superficial and can most frequently be easily visualized using high-frequency linear transducers. The exact choice of transducer depends on the area scanned, but a high-frequency linear transducer with a small footprint (13-6 MHz, 25-mm footprint) is particularly suited for young children. The 15-6–MHz broadband linear-array transducer is also useful for most blocks in young children. In older children, a 10-7–MHz broadband linear-array transducer, which allows greater flexibility with the depth of scan, is adequate for most procedures. Low-frequency (5-2 MHz) curved-array transducers are rarely used in children but are useful for imaging deeper structures such as the lumbar plexus and sciatic nerve in older children.

To improve dexterity, hold the transducer with the nondominant hand and perform interventions with the dominant hand. Holding the transducer steady for even short periods can be quite trying. We have found that gently resting the hand that is holding the transducer on the child during a block helps to keep the transducer steady (see Fig. 43.15). It is important to maintain light contact between the transducer and the skin because excessive pressure will cause the veins to collapse or distort the anatomy of the area of interest. Always apply liberal amounts of US gel to maintain adequate acoustic coupling between the skin and the transducer because even small amounts of air trapped between the two can result in artifacts. We use sterile US gel from single-use sachets for all USG peripheral nerve blocks. At any given time during a USG intervention either the transducer or the needle must be moved. It is impossible to maintain the needle within the plane of imaging if both are moving, a common error by novices. This results in an inability to visualize the needle. If the needle is not visible in the US image, a good strategy is to keep the needle steady and manipulate the transducer (slide, tilt, or rotate) until the needle becomes visible on the monitor. Thereafter the transducer should be held steady and the needle should be gently advanced to the target nerve, maintaining it in the imaging plane. When the angle of insertion of the needle is steep (>60 degrees), it is preferable to introduce the needle in the short axis using the out-of-plane technique. However, if the in-plane approach is used for all USG interventions, as in our case, inserting the needle a few centimeters away from the edge of the transducer may improve needle visibility by decreasing the angle between the needle and the imaging plane.

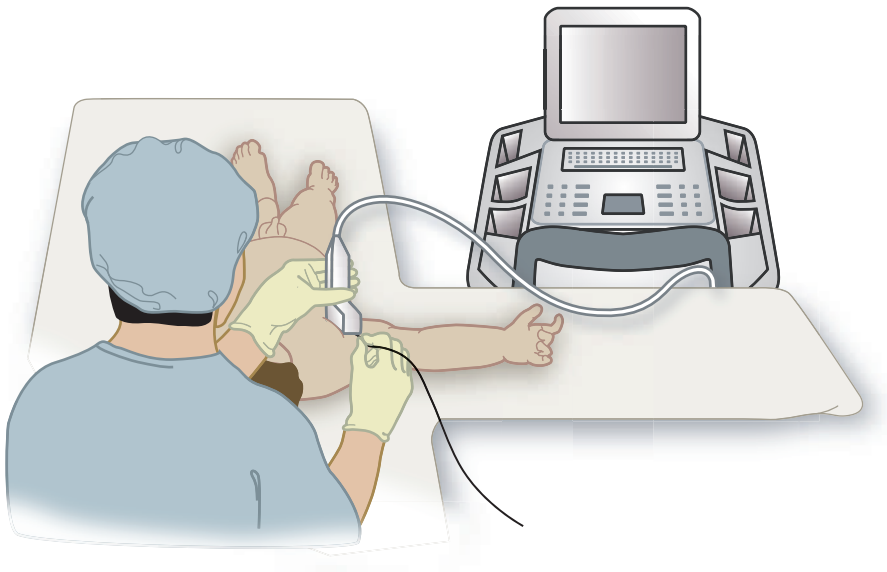

FIGURE 43.15 Position of the child, anesthesiologist, and ultrasound machine during an ultrasound-guided regional anesthesia procedure.

E-FIGURE 43.1 The monitor of the ultrasound machine is being used to display a cartoon from a DVD player while a child is undergoing surgery under regional anesthesia.

Injecting air into the area of the intervention must be avoided because air bubbles will degrade the image. We routinely purge the block needle with saline solution or local anesthetic to remove air before proceeding with the block. An assistant aids with the injection. When the needle tip is close to the target nerve, the assistant gently aspirates to exclude unintended intravascular placement. The assistant must avoid generating excessive negative pressure because small blood vessels are prone to collapse. A short length of extension tubing attached between the needle and the local anesthetic syringe allows the operator to hold the needle steady while the assistant performs the injection.[68] We routinely perform a test injection with 0.5 to 1 mL of saline solution or 5% dextrose (when nerve stimulation is also used)[46] and visualize the distribution of the injectate in real time before injecting the local anesthetic. Failure to visualize the injectate in the US image indicates that the needle is not in the plane of imaging or it is intravascular until proven otherwise. No further injection should be made until the needle is repositioned and the distribution of the injectate is confirmed.

ANCILLARY EQUIPMENT

Most single-shot peripheral nerve blocks can be performed with a standard short-bevel needle designed for regional anesthesia; an echogenic block needle is preferred because the echogenic coating allows it to be more easily identified. In older children, a 22-gauge block needle is a good choice. Most block needles also allow the use of peripheral nerve stimulation together with US-guidance. Indwelling catheters also can be placed under US guidance. A standard continuous peripheral nerve block kit (stimulating catheter with echogenic introducing needle) of an appropriate size can be used for catheter placement.

Specific Ultrasound-Guided Nerve Blocks

UPPER EXTREMITY BLOCKS

Supraclavicular Brachial Plexus Block

The supraclavicular brachial plexus block in children[69] is rarely used because of fear of pleural puncture and pneumothorax. However, USG supraclavicular brachial plexus block has been performed in children younger than 6 years.[70] Even though the brachial plexus and cervical pleura are clearly delineated using US in the supraclavicular fossa, this technique should be performed by experienced operators because of the close proximity between the cervical pleura and the brachial plexus.

The child's head rests on a head ring and is slightly turned to the contralateral side, and a small roll is placed between the scapula. For a right-sided block, a right-handed operator stands or sits at the head end of the child, and the US machine is placed directly in front on the ipsilateral side (see Fig. 43.15). The position of the operator and US machine is reversed for a left-sided block. In the supraclavicular fossa, the subclavian artery lies on top of the first rib. The trunks and divisions of the brachial plexus are superficial and lateral to the subclavian artery and sandwiched between the scalenus anterior and scalenus medius muscle (Fig. 43.16). A linear-array transducer (13-10 MHz) is used to perform the block; the hockey stick probe or a linear-array transducer with a small footprint (25 mm) is particularly suited for this block.

During the scout scan the transducer is positioned parallel to and against the clavicle and the subclavian artery is identified. The trunks and divisions of the brachial plexus often resemble a bunch of grapes on the superficial and lateral aspect of the subclavian artery (see Fig. 43.16). The cervical pleura and lung are deep to the first rib. The operator should bear in mind that the acoustic shadow of the first rib can obscure the view of the pleura and lung. The block needle is inserted in the long axis (in-plane) of the transducer in a lateral to medial direction, keeping the pleura in view. A test injection with saline solution is performed to ensure optimal needle position, after which the calculated dose of local anesthetic is injected in aliquots.

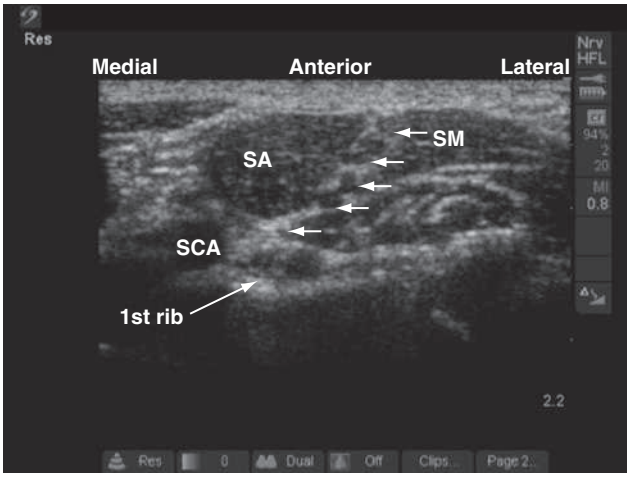

FIGURE 43.16 Sonographic appearance of the brachial plexus *(white arrows)* in the supraclavicular fossa. *SA,* scalenus anterior; *SCA,* subclavian artery; *SM,* scalenus medius.

Infraclavicular Brachial Plexus Block

USG infraclavicular brachial plexus block is performed with the child in the supine position. The block can be performed with the arms by the side, but it is preferable to abduct the arm (to 90 degrees) whenever possible because it elevates the lateral part of the clavicle, which makes more space available below the clavicle for transducer placement. The operator sits at the ipsilateral head end of the child, and the US machine is positioned directly in front. Because the cords of the brachial plexus are relatively superficial in the infraclavicular fossa in children, a linear-array transducer (13-10 MHz in young children and 10-7 MHz in the older child) is used to perform the block. The transducer is positioned in the sagittal plane over the deltopectoral region, medial and inferior to the coracoid process, with its orientation marker directed cephalad.

During the scout scan the second part of the axillary artery and the axillary vein are identified deep to the pectoral muscles (Fig. 43.17). The axillary artery is located superior to the vein, and the cords of the brachial plexus are closely related to the axillary artery at this level. The medial cord is situated caudal to the axillary artery, often between the axillary artery and vein, whereas the posterior and lateral cords are posterior and cephalad to the artery, respectively (Fig. 43.17A). Despite this relation, in most cases it is not easy to identify all three cords of the brachial plexus in a single plane of imaging. If the transducer is moved medially, the pleura usually comes into view (Fig. 43.17B). In infants and young children, the margin of safety between the cords of the brachial plexus and the pleura is relatively small and pleural puncture is a risk if the block is performed in this medial position. Therefore we recommend that the infraclavicular brachial plexus block be performed laterally where the pleura is not visible in the US image.

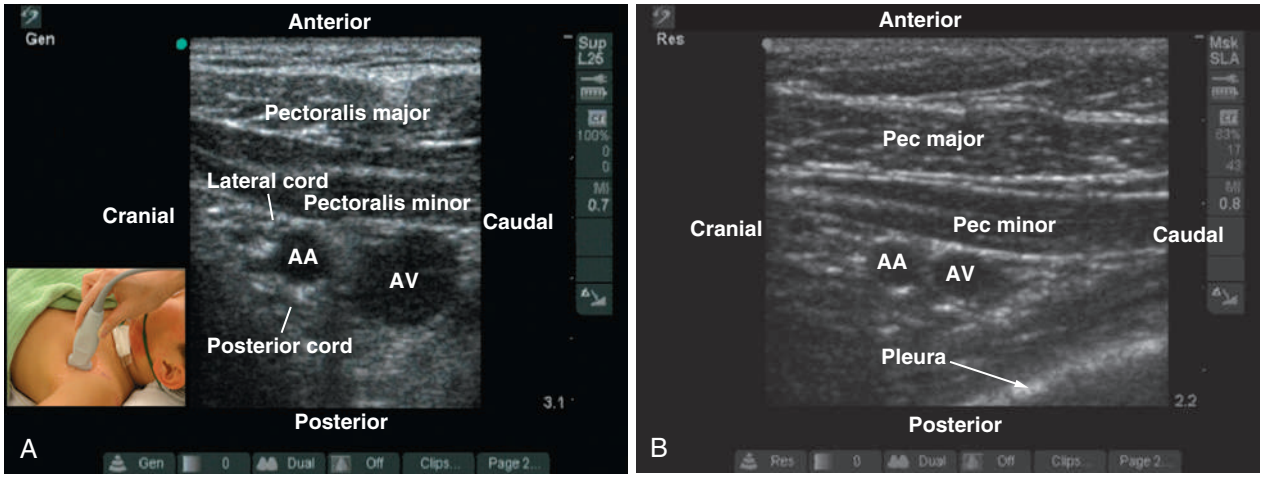

FIGURE 43.17 **A,** Sagittal sonogram of the left infraclavicular fossa. **B,** Sagittal sonogram of the infraclavicular fossa with the transducer positioned medially. Note the hyperechoic pleura in the lower right corner of the image *(arrow)*. *AA,* axillary artery; *AV,* axillary vein; *Pec,* pectoralis.

We prefer to perform multiple injections targeting the areas where the three cords of the brachial plexus are located. The aim is to produce a circumferential spread of the local anesthetic around the axillary artery, the "doughnut sign" (Fig. 43.18), which correlates well with successful brachial plexus anesthesia. This perivascular injection technique is best visualized by imagining the transverse image of the axillary artery as a clock face with its 12-o'clock position in its anterior aspect and the 6-o'clock position in the posterior aspect of the artery (Fig. 43.19). The block needle is inserted in-plane and from a cranial to caudal direction (see Fig. 43.19), and one-third of the total dose of local anesthetic is injected close to each of the posterior (6-o'clock position), lateral (9-o'clock position), and medial (3-o'clock position) cords.[71–77] Because the angle of needle insertion is fairly steep with this approach, the needle is rarely seen on the US image, and the operator has to gently jiggle the needle to locate the needle tip. A subtle pop may be felt as the needle tip traverses the epimysium of the pectoralis minor muscle. A test injection with 1 mL of saline solution should be performed before the local anesthetic injection to ensure optimal needle position and distribution of the injectate (Video 43.1) (see also Fig. 42.20 for landmark-guided techniques).

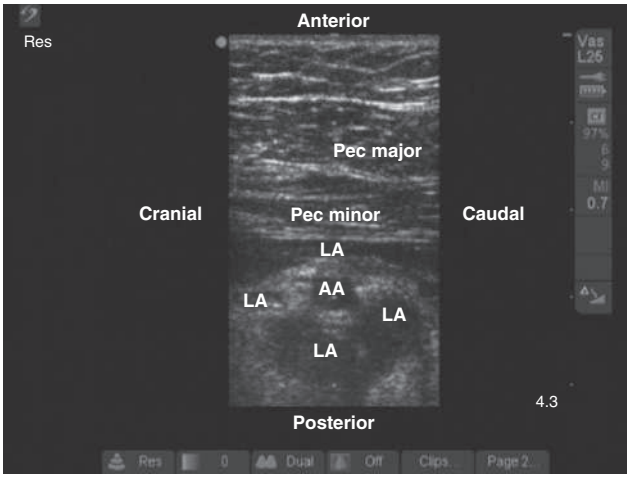

FIGURE 43.18 Infraclavicular brachial plexus block. Sagittal sonogram of the infraclavicular fossa after local anesthetic injection demonstrating the circumferential spread of local anesthetic around the axillary artery—the "doughnut sign." *AA,* axillary artery; *LA,* local anesthetic; *Pec,* pectoralis.

Axillary Brachial Plexus Block

USG axillary brachial plexus block is typically performed with the child in the supine position.[78–80] The arm is abducted (to 90 degrees) and externally rotated so that the palm of the hand is facing up. The operator sits at the ipsilateral head end of the child, and the US machine is positioned directly in front (see Fig. 43.15). Because the nerves of the brachial plexus are relatively superficial in the axilla, a high-frequency linear-array transducer (13-6 MHz) is used. During the scout scan, the transducer is positioned just below the lateral border of the pectoralis major muscle, with its orientation marker directed laterally (Fig. 43.20). The resultant image on the monitor is a transverse scan of the axillary structures. The pulsatile vessel in the image is the axillary artery. The axillary vein is medial to the artery; it is common to see more than one vein (see Fig. 43.20).

At this level, the three major nerves of the brachial plexus (the median, ulnar, and radial nerves) lie very close to the axillary artery. In adults, when the arm is abducted and externally rotated, the median nerve is located on the anterior or anterolateral side of the axillary artery (97.9%), the ulnar nerve is located on the anteromedial side of the artery (91.3%), and the radial nerve is located posterior to the axillary artery (89.9%)[81] (Fig. 43.21). To accurately identify these three nerves it may be necessary to trace the nerve distally along its course. The musculocutaneous nerve frequently courses between the coracobrachialis and the biceps muscle or within the substance of the coracobrachialis muscle (see Fig. 43.21).[82,83] Occasionally, the musculocutaneous nerve also may be located very close to the median nerve, and local anesthetic injected close to the median nerve may affect the musculocutaneous nerve. The shape of the musculocutaneous nerve varies along its course, and it may appear oval, round, elliptical, or even triangular.

We prefer the in-plane approach for needle insertion during axillary brachial plexus block in both sedated and anesthetized

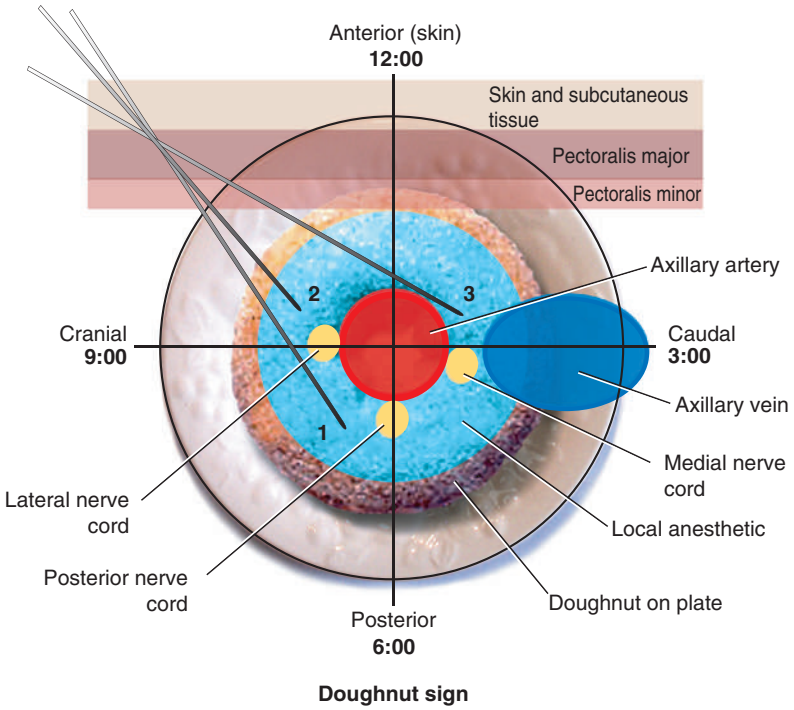

FIGURE 43.19 Infraclavicular brachial plexus block (oriented as with a wall clock). Schematic diagram showing the positions of the cords of the brachial plexus and the sites at which the local anesthetic is injected: (**1**) posterior cord, (**2**) lateral cord, and (**3**) medial cord.

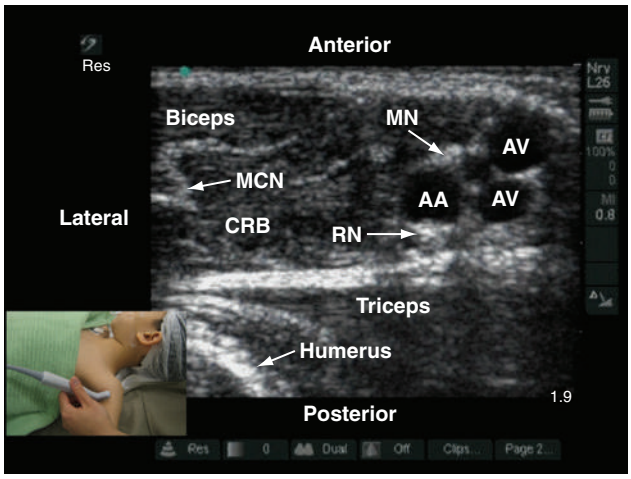

FIGURE 43.20 Transverse sonogram of the left axilla. *AA,* axillary artery; *AV,* axillary vein; *CRB,* coracobrachialis muscle; *MCN,* musculocutaneous nerve; *MN,* median nerve; *Res,* resolution; *RN,* radial nerve.

children. The block needle is inserted from the lateral to the medial side of the arm, keeping it within the plane of the US imaging. A subtle pop is often felt when the tip of the needle traverses the epimysium of the biceps muscle and enters the fascial plane containing the neurovascular bundle. Multiple injections are required to block the median, radial, and ulnar nerves. The objective is to produce a circumferential spread of local anesthetic around the artery (i.e., "the doughnut sign" in the US image). To achieve this, local anesthetic is injected close to the anterior (12-o'clock position), posterior (6-o'clock position), and lateral

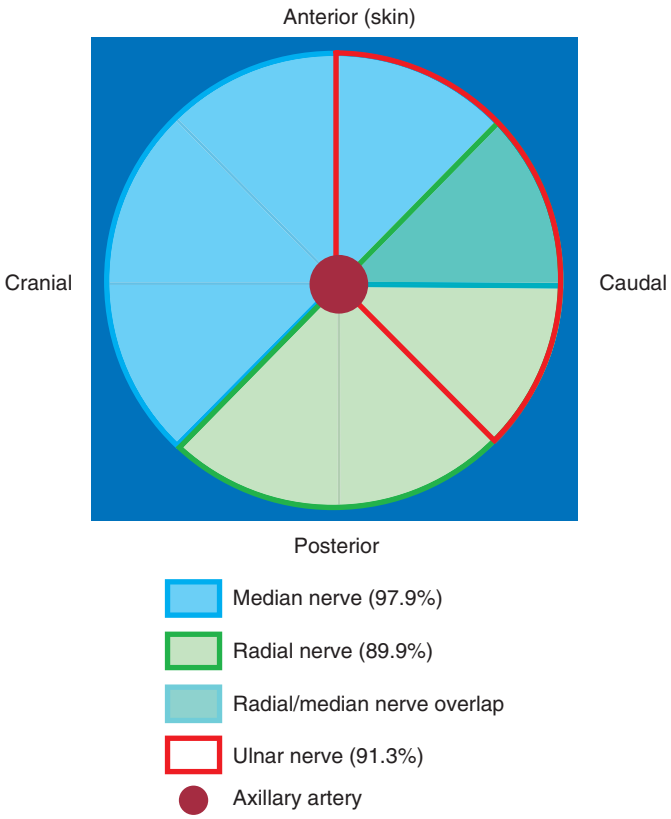

FIGURE 43.21 Schematic diagram showing the positions of the three main nerves (median, radial, and ulnar) of the brachial plexus in relation to the axillary artery, as identified on transverse ultrasonography, at the axilla.

(9-o'clock position) aspects of the axillary artery. The musculocutaneous nerve is then identified and selectively blocked using a few milliliters of local anesthetic. We have found this approach to be technically simple, safe, and effective in producing brachial plexus blockade in children (Video 43.2) (see also Fig. 42.19 in Chapter 42 for landmark-guided techniques).

SELECTIVE PERIPHERAL NERVE BLOCKS OF THE UPPER EXTREMITY

Selective blockade of the nerves of the upper extremity can be used to rescue incomplete or partial axillary brachial plexus block or provide analgesia or anesthesia over a specific dermatome.[84] It has been successfully used in the emergency department for pain control and interventions involving the hand after trauma.[85] We have also found it to be useful for USG differential nerve blockade in children undergoing ambulatory hand surgery. This technique combines an axillary brachial plexus block with a short-acting local anesthetic agent such as lidocaine and a peripheral nerve block (e.g., a median or ulnar nerve block, depending on the dermatomes involved) in the forearm using a long-acting drug (bupivacaine or ropivacaine). Because of the shorter duration of action of lidocaine compared with bupivacaine or ropivacaine, the child regains protective motor function of the elbow fairly quickly after surgery (2–4 hours) while still enjoying prolonged postoperative analgesia from distal nerve blockade. All of the major nerves of the upper extremity (median, ulnar, and radial) can be identified using high-frequency linear-array transducers (13-10 MHz), and it is possible to selectively block these nerves at various sites along their course with only 1 to 2 mL of local anesthetic. In an adult study, the mean 95% effective dose (ED95) of 1% mepivacaine to block the ulnar nerve at the forearm is only 0.7 mL.[86] We prefer the in-plane needle insertion technique and use a short-beveled nerve block needle.

Median Nerve

The median nerve is closely related to the brachial artery throughout its course in the arm. Proximally it is lateral to the artery; in the middle of the upper arm it crosses to the medial side and then continues on the medial side distal to the elbow. In the antecubital fossa, the median nerve lies medial to the brachial artery, behind the bicipital aponeurosis, and in front of the brachialis muscle (Fig. 43.22A). In the forearm, the median nerve is deep to the flexor digitorum superficialis and on the surface of the flexor digitorum profundus (Fig. 43.22B) and accompanied by the median artery that is a branch of the anterior interosseous artery. Pulsations of the latter can occasionally be observed on the US image. A few centimeters proximal to the wrist, the median nerve becomes superficial and lies between the tendon of the flexor carpi radialis (laterally) and the flexor digitorum superficialis (medially) and may also be overlapped by the tendon of the palmaris longus.

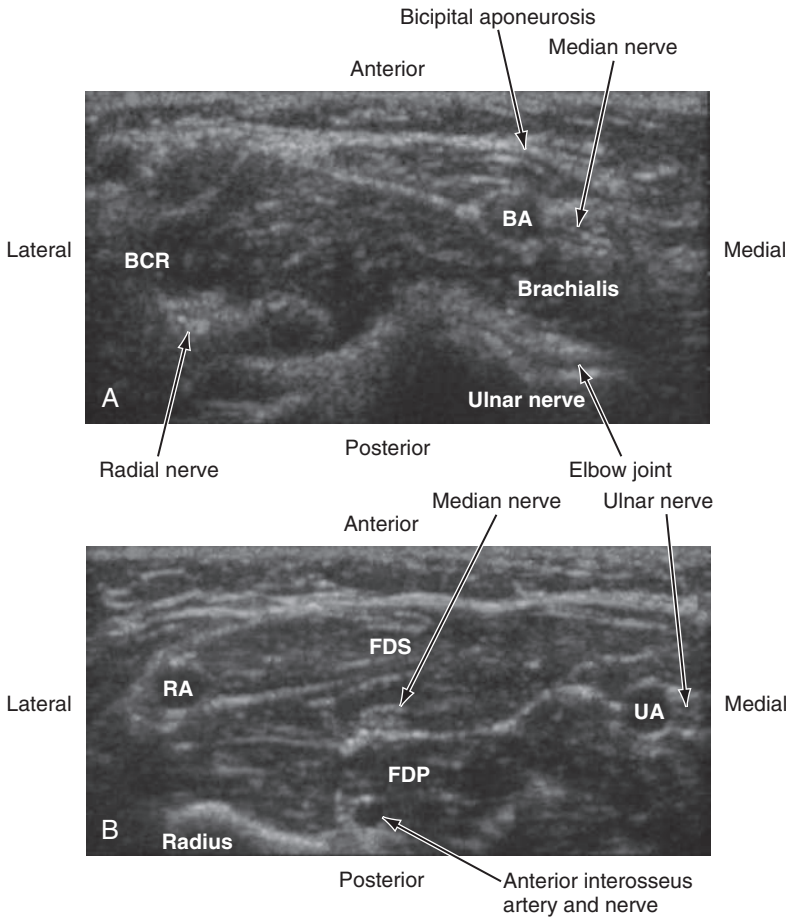

FIGURE 43.22 A, Transverse sonogram of the cubital fossa. **B,** Transverse sonogram of the forearm. *BA,* brachial artery; *BCR,* brachioradialis. *FDP,* Flexor digitorum profundus; *FDS,* flexor digitorum superficialis; *RA,* radial artery; *UA,* ulnar artery.

Because the nerve is superficial at this level and it can be difficult to differentiate the nerve from the tendons, we prefer to perform median nerve block at the midforearm, where it is clearly delineated (Video 43.3) (see also Fig. 42.25 for landmark-guided techniques).

Ulnar Nerve

Proximally, the ulnar nerve runs medial to the brachial artery to about the midhumeral level or the insertion of the coracobrachialis muscle, where it pierces the medial intermuscular septum and enters the posterior compartment of the arm. At the elbow, it passes behind the medial epicondyle to enter the ulnar nerve sulcus. Although the nerve is palpable and superficial at the sulcus, it is often difficult to visualize using US because of bony and contact artifacts. The ulnar nerve then enters the proximal forearm and runs between the flexor digitorum profundus (posterior) and the flexor digitorum superficialis (laterally) muscles, and in the distal forearm it is accompanied by the ulnar artery (lateral) (see Fig. 43.22B). Close to the wrist, the ulnar nerve is lateral to the flexor carpi ulnaris muscle. The ulnar artery may be used as a reference to locate the ulnar nerve. Once the artery is located, the nerve is traced backward and the local anesthetic injected away from the artery (see Video 43.3) (see also Fig. 42.25 for landmark-guided techniques).[87]

Radial Nerve

Proximally the radial nerve is posterior to the brachial artery. It then diverges from the artery to enter the radial (spiral) groove on the back of the arm, where it is accompanied by the profunda brachii artery. In the distal arm the radial nerve pierces the lateral intermuscular septum and enters the anterior compartment. In the antecubital fossa it is lateral to the biceps tendon and lies in an intermuscular gap between the brachialis (medially), the brachioradialis, and the extensor carpi radialis longus (laterally) (Fig. 43.23). At the level of the lateral epicondyle the radial nerve gives off the posterior interosseous nerve (deep branch of the radial nerve), which leaves the fossa by piercing the supinator muscle. In the forearm, the radial nerve (superficial branch of the radial nerve) continues as a pure cutaneous nerve and supplies the radial half of the dorsum of the hand and the proximal parts of the dorsal surfaces of the thumb and index finger. The radial nerve is best blocked before its division in the antecubital fossa (see also Fig. 42.22 for landmark-guided techniques).[84]

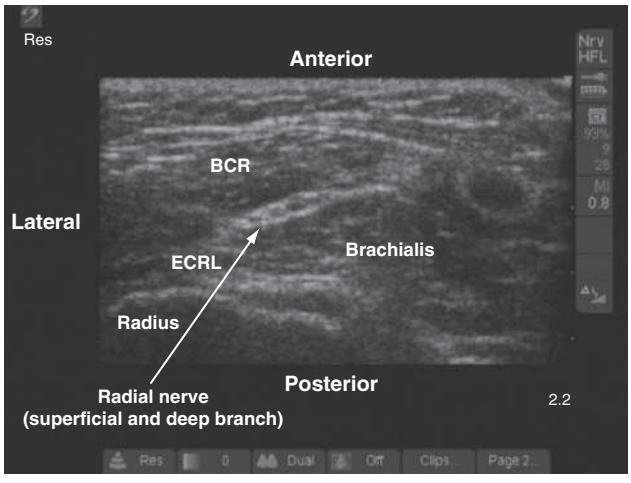

FIGURE 43.23 Transverse sonogram of the arm, just above the elbow, showing the radial nerve. *BCR*, brachioradialis; *ECRL*, extensor carpi radialis longus.

LOWER EXTREMITY BLOCKS

Lumbar Plexus Block

The lumbar plexus results from the union of the ventral rami of the first four lumbar spinal nerves within the substance of the psoas major muscle. The plexus may also receive contributions from the 12th thoracic nerve or the 5th lumbar nerve. In adults, the plexus is located between the fleshy anterior part of the psoas major muscle, which arises from the anterolateral part of the vertebral bodies and the intervertebral disk, and the accessory posterior part of the muscle that originates from the anterior surface of the transverse process. Local anesthetic injected into this intramuscular plane, also referred to as the psoas compartment, produces an ipsilateral lumbar plexus block.

A US scan for the lumbar plexus block can be performed in the transverse or sagittal axis at the L3-4 vertebral level. The child is positioned in the lateral position with the side to be blocked uppermost with the hip and knees flexed. A linear-array transducer (10-5 MHz) is adequate for imaging in young children, whereas in the older child (>6 to 8 years) a curved-array transducer (8-5 or 5-2 MHz) is required.

For a transverse scan, the US transducer is positioned approximately 2 to 3 cm lateral to the lumbar spine at the L3-4 vertebral level, with its orientation marker directed laterally. We also prefer to align the transducer slightly medially to produce a paramedian oblique transverse scan (PMOTS) of the lumbar paravertebral region.[88–92] Also during a PMOTS of the lumbar paravertebral region, the US beam can be insonated either at the level of the transverse process (PMOTS-TP, Fig. 43.24A) or through the gap between the two adjacent transverse process (i.e., the intertransverse space [ITS]), producing a PMOTS-ITS scan (Fig. 43.24B). In a typical PMOTS-ITS sonogram of the lumbar paravertebral region, the erector spinae muscle, the vertebral body, the psoas major muscle, the quadratus lumborum muscle, and the anterolateral surface of the vertebral body are clearly visualized (Fig. 43.24B). The inferior vena cava (on the right side) and the aorta (on the left side) are also identified anterior to the vertebral body. The lower pole of the kidney is closely related to the anterior surfaces of the quadratus lumborum and psoas muscle and is seen as an oval structure that moves with respiration in the retroperitoneal space. The lumbar plexus is not sonographically visualized in all patients, but when it is visualized, it appears as an oval hyperechoic structure in the posterior part of the psoas muscle (see Fig. 43.24B) and close to the intervertebral foramen. In contrast, because the acoustic shadow of the transverse process obscures the posterior part of the psoas muscle and the area close to the intervertebral foramen during a PMOTS-TP, the lumbar plexus is rarely visualized in this US scan window (see Fig. 43.24A). Therefore if a transverse scan is performed during a USG lumbar plexus block, it is our recommendation to use the PMOTS-ITS.[91,92]

For a sagittal scan of the lumbar paravertebral region, the US transducer is positioned approximately 2 to 3 cm lateral and parallel to the lumbar spine, with its orientation marker directed cranially. In a typical sagittal sonogram of the lumbar paravertebral region, the L2, L3, and L4 transverse processes with their acoustic shadow produce what we refer to as the "trident sign" (Fig. 43.25) because of its similarity to the trident (Limia tridens or tridentis) that is often associated with Poseidon (the god of the sea in Greek mythology) and the trishula of the Hindu god Shiva.[93] The hypoechoic psoas muscle is seen between the transverse processes,

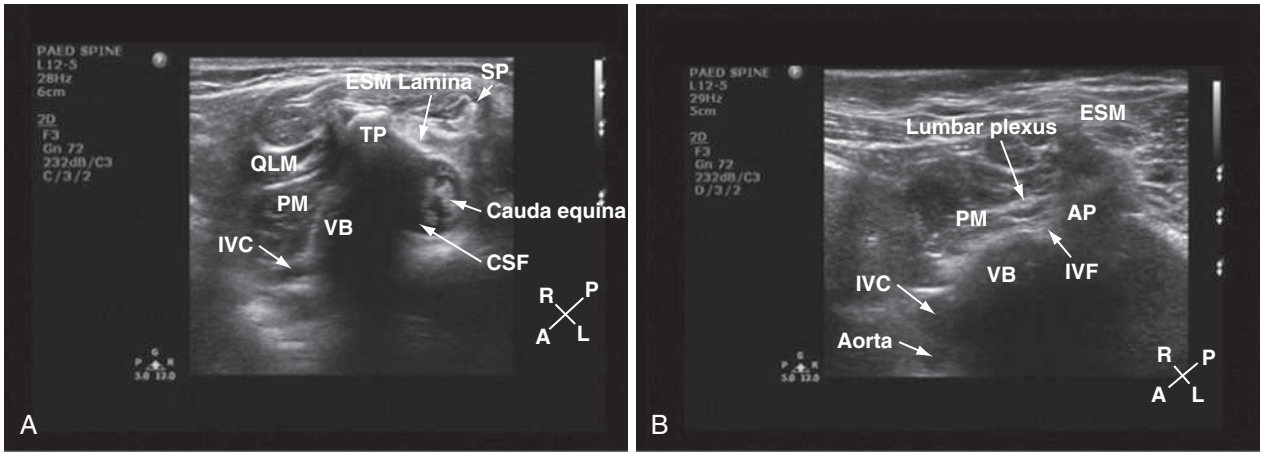

FIGURE 43.24 A, Paramedian oblique transverse scan of the right lumbar paravertebral region at the level of the transverse process (PMOTS-TP) in an 11-month old infant. Note how the acoustic shadow of the transverse process *(TP)* obscures the posterior part of the psoas muscle *(PM)* and how parts of the spinal canal and neuraxial structures (dura, intrathecal space, and cauda equina) are seen through the interlaminar space. **B,** Paramedian oblique transverse scan of the right paravertebral region through the gap between two adjacent transverse processes (PMOTS-ITS) in a 14-month old child. Note the intervertebral foramen *(IVF)*, articular process *(AP)*, and the lumbar plexus in the posterior part of the PM. *A,* anterior; *CSF,* cerebrospinal fluid; *ESM,* erector spinae muscle; *IVC,* inferior vena cava; *L,* left; *P,* posterior; *PM,* psoas muscle; *QLM,* quadratus lumborum muscle; *R,* right; *SP,* spinous process; *VB,* vertebral body.

and the lumbar plexus is identified as hyperechoic longitudinal striations within the posterior aspect of the muscle. A laterally positioned transducer will produce a suboptimal scan without the trident, and the lower pole of the kidney, which can reach the L4-5 level in young children, will come into view.

Once an optimal image of the lumber paravertebral region is obtained, the insulated block needle is inserted in the plane of the US beam. The needle is inserted from the medial side of the transducer when a PMOTS-ITS is used or from the caudal end of the transducer when a sagittal scan is used. The needle is slowly advanced under ultrasound guidance to the posterior part of the psoas muscle, and the correct position of the needle tip close to the lumbar plexus is confirmed by observing ipsilateral quadriceps muscle contraction. After negative aspiration, an appropriate dose of local anesthetic is injected in aliquots over 2 to 3 minutes and the patient is closely monitored.

Femoral Nerve Block

The femoral nerve is the largest branch of the lumbar plexus and is the major nerve of the anterior (extensor) compartment of the thigh. It is formed by the dorsal division of the anterior primary rami of spinal nerves L2, L3, and L4. It exits the pelvis and enters the femoral triangle in the thigh by passing under the inguinal ligament just lateral to the femoral artery. In the thigh it lies in the groove between the iliacus and the psoas major muscle, outside the femoral sheath, and lateral to the femoral artery. A high-frequency (13-10 MHz) linear-array transducer is used to scan the femoral nerve. On a transverse sonogram the femoral nerve is seen as an oval or triangular hyperechoic structure lateral to the femoral artery (Fig. 43.26). The femoral nerve exhibits marked

anisotropy, and it may be necessary to tilt or rotate the transducer during the scan before it can be visualized.[48] In young children one must avoid exerting too much pressure during the scan because it is easy to compress the femoral vein.

A femoral nerve block is used to provide postoperative analgesia after femoral fractures. It is performed with the child in the supine position. The ipsilateral lower limb is slightly abducted and externally rotated, and the knee is also slightly flexed. A right-handed operator stands on the right side of the child, and the US machine is positioned directly in front on the contralateral side. The sides of the operator and the US machine are reversed for a left-handed operator. The scout scan is performed with the transducer positioned parallel and just below the inguinal ligament. This ensures that the femoral nerve is scanned before its division. Once an optimal view of the femoral nerve is obtained, the block needle is inserted in the long axis (in-plane) of the US transducer from the lateral to medial side and directed to the lateral aspect of the femoral nerve.[48,94] A test injection with saline solution is performed before the local anesthetic is injected to confirm that the needle is deep to the fascia iliaca and to observe the distribution of the injectate in relation to the femoral nerve (see also Fig. 42.32 for landmark-guided techniques).

Subsartorial Saphenous Nerve Block

The saphenous nerve is a branch of the anterior division of the femoral nerve and supplies the skin on the medial aspect of the leg and foot up to the ball of the big toe. In the thigh, the saphenous nerve is located in the subsartorial canal, and local anesthetic injected into this intramuscular space produces a saphenous nerve block. The subsartorial canal is also referred to as the adductor canal or Hunter canal and is situated on the medial side of the middle one third of the thigh and extends from the apex of the femoral triangle, above, to the tendinous opening in the adductor magnus muscle, below. The canal is triangular in cross-section, and its anterior wall is formed by the vastus medialis muscle, the posterior wall or floor is formed by the adductor longus, and the medial wall or roof is formed by a strong fibrous membrane that is overlapped by the sartorius muscle (Fig. 43.27). The subsartorial canal contains the following structures: femoral artery and vein, saphenous nerve, nerve to vastus medialis, and the two divisions

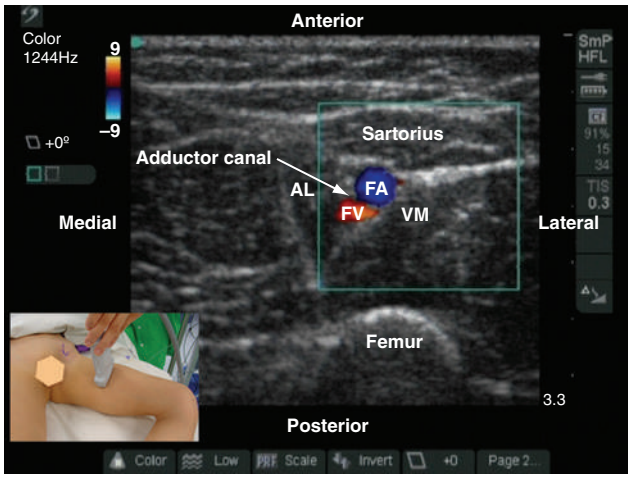

FIGURE 43.27 Transverse sonogram of the thigh showing the adductor canal. *AL,* adductor longus; *FA,* femoral artery; *FV,* femoral vein; *VM,* vastus medialis.

of the obturator nerve. The femoral vein lies posterior to the artery in the upper part and lateral to the artery in the lower part of the canal. The saphenous nerve crosses the femoral artery anteriorly from the lateral to the medial side in the canal.[95–98]

A high-frequency (13-6 MHz) linear-array probe is used to scan the saphenous nerve in the subsartorial canal with the child the supine position. The ipsilateral lower limb is slightly abducted and externally rotated, and the knee is also slightly flexed. For a right-sided block, a right-handed operator stands on the right side of the patient, and the US machine is positioned directly in front on the contralateral side. The transducer is positioned in the transverse axis over the middle one-third of the thigh. The triangular subsartorial canal can be identified between the epimysium of the vastus medialis (closely related to the femur), the adductor longus, and the sartorius muscles. The pulsatile femoral artery lies anterior to the vein in the canal, and the saphenous nerve is seen as a round or oval hyperechoic structure anterior to the artery (12-o'clock position). Because the saphenous nerve is a small nerve, it may not always be visible on US imaging in children. However, owing to the close relation of the saphenous nerve to the femoral artery in the subsartorial canal, a perivascular (arterial) injection in the canal will produce a saphenous nerve block. The block needle is inserted in the long-axis (in-plane) of the US transducer from the medial to lateral side and is directed to the anterior aspect of the femoral artery. A test injection of saline solution (1 mL) is performed to confirm that the tip of the needle is in the canal, after which the local anesthetic is injected.

Sciatic Nerve Block

The sciatic nerve is the largest mixed nerve in the body, arising from the lumbosacral plexus (L4, L5, S1-3). It innervates the posterior aspect of the thigh and the entire lower limb below the knee except for a small patch of skin on the medial aspect of the leg and ankle, which is innervated by the saphenous nerve. A sciatic nerve block is frequently used to provide analgesia for foot (clubfoot) and leg surgery in children. Several different approaches to the sciatic nerve have been described; most rely on surface anatomic landmarks (anterior, transgluteal, infragluteal, lateral, posterior subgluteal, proximal thigh, or at the popliteal fossa). USG sciatic nerve block also has been described[99–110]; a proximal approach is selected when surgery involves the hip (rare in children) or block of the posterior cutaneous nerve of the thigh is warranted. Because a sciatic nerve block is most frequently used for foot (clubfoot) surgery in children, a distal approach to the sciatic nerve at the popliteal fossa is usually preferred (see also Fig. 42.30 for landmark-guided techniques).

Sciatic Nerve Block at the Subgluteal Space

The sciatic nerve exits the pelvis through the greater sciatic foramen, between the piriformis and the superior gemelli muscles, and enters the subgluteal space below the piriformis muscle. It then descends over the dorsum of the ischium, lying on the dorsal surface of the superior gemellus muscle, tendon of obturator internus, inferior gemellus muscle, and quadratus femoris muscle (in a cranial to caudal relation) before it enters the hollow between the greater trochanter and the ischial tuberosity and then goes on to the posterior compartment of the thigh. The anterior surface of the gluteus maximus covers the upper part of the sciatic nerve; immediately distal to its lower border (infragluteal position), the sciatic nerve is fairly superficial. In between the greater trochanter and the ischial tuberosity, the sciatic nerve lies in the subgluteal

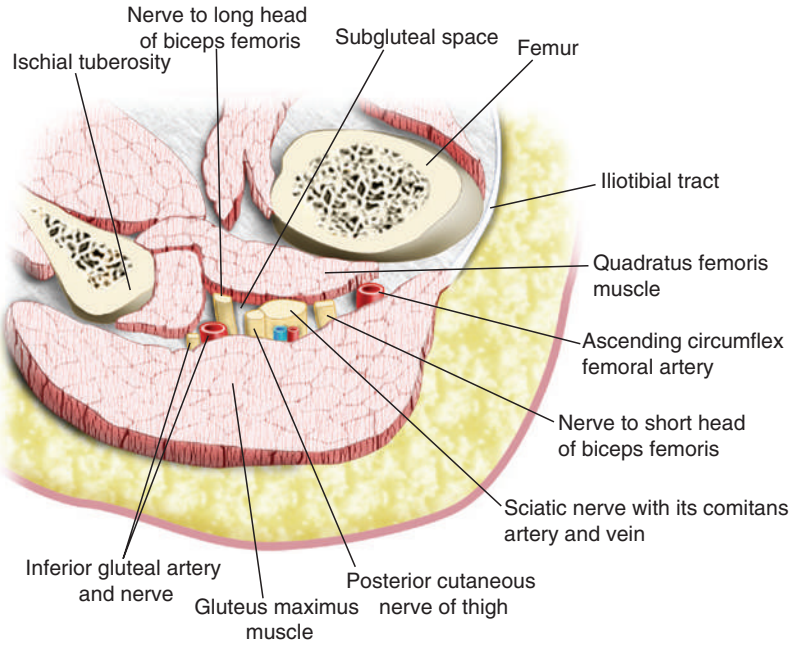

FIGURE 43.28 Transverse section through the gluteal region at the level of the quadratus femoris muscle showing the subgluteal space and its contents.

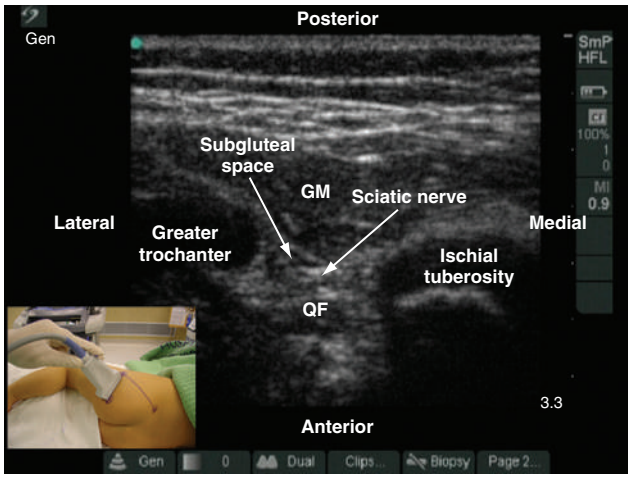

FIGURE 43.29 Transverse sonogram between the greater trochanter and the ischial tuberosity showing the hypoechoic subgluteal space between the hyperechoic perimysium of the gluteus maximus and the quadratus femoris muscle. The sciatic nerve is seen as a hyperechoic structure in the medial aspect of the subgluteal space. *GM,* gluteus maximus; *QF,* quadratus femoris.

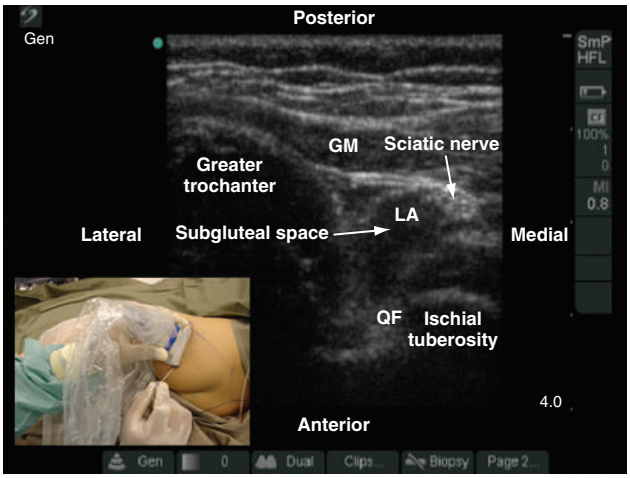

FIGURE 43.30 Transverse sonogram of the sciatic nerve at the subgluteal space after local anesthetic injection. Note the distention of the subgluteal space caused by the local anesthetic and the distribution of local anesthetic around the sciatic nerve. *GM;* gluteus maximus; *LA,* local anesthetic; *QF,* quadratus femoris.

space, which is a well-defined anatomic space between the anterior surface of the gluteus maximus and the posterior surface of the quadratus femoris muscle (Fig. 43.28).[99] Other structures present in the subgluteal space include the posterior cutaneous nerve of the thigh, the inferior gluteal vessels and nerve, the nerve to the short and long head of the biceps femoris, the comitans artery and vein of the sciatic nerve, and the ascending branch of the medial circumflex artery (Fig. 43.29). Local anesthetic injected into the subgluteal space blocks the sciatic nerve and the posterior cutaneous nerve of the thigh, which is useful when anesthesia over the posterior aspect of the thigh is needed.

USG sciatic nerve block at the subgluteal space is performed with the child in the lateral position. The side to be anesthetized is placed uppermost, and the hip and knees are flexed (Fig. 43.30). The operator sits or stands behind the child, and the US machine is positioned directly in front. In young children, a linear-array transducer (10-5 MHz) is adequate for imaging the sciatic nerve; in children older than 6 to 8 years, the sciatic nerve can also be imaged using a curved linear array transducer (8-5 or 5-2 MHz) (preferred) because the increased depth of scan required (as a result of increased muscle bulk) limits the field of vision when a linear transducer is used.

The greater trochanter and the ischial tuberosity are identified, and a line is drawn between these two landmarks. The US transducer is placed parallel to this line, with its orientation marker directed toward the greater trochanter to obtain a transverse scan of the sciatic nerve and the subgluteal space.[99–101] It may be necessary to slide the transducer slightly cephalad or caudad before an optimal image of the sciatic nerve in the subgluteal space can be obtained. On a transverse sonogram, the subgluteal space is seen as a hypoechoic area between the hyperechoic epimysium of the gluteus maximus and quadratus femoris muscle (see Fig. 43.30) extending from the greater trochanter laterally to the ischial tuberosity medially. The subgluteal space is not so well delineated in young children and is better visualized in older children. The sciatic nerve is seen as an oval or triangular hyperechoic structure within the subgluteal space (see Fig. 43.30). The medial limit of the space is obscured by the attachments of the semimembranosus, semitendinosus, and biceps femoris muscles to the ischial tuberosity. Pulsations of the inferior gluteal artery often can be detected medial to the sciatic nerve on the sonogram.

The block needle is inserted using an in-plane technique from the ischial tuberosity side and advanced slowly toward the sciatic nerve.[99,102] Once the block needle is deemed to be in the subgluteal space, the position is confirmed by injecting 1 to 2 mL of saline solution and observing a distention of the subgluteal space (i.e., separation of the epimysium of the gluteus maximus and quadratus femoris muscle) on the US image (Fig. 43.31). However, if the test injection of saline solution spreads posterior to the epimysium of the gluteus maximus muscle, it indicates that the tip of the needle is not in the subgluteal space. The needle should be reoriented and advanced a little farther until the typical distention of the subgluteal space to the saline solution test injection is seen. Occasionally, a subtle pop is felt when the needle tip traverses the epimysium of the gluteus maximus muscle and enters the subgluteal space. Local anesthetic is then injected in aliquots over 2 to 3 minutes while observing for the distention of the subgluteal space and the spread of local anesthetic in relation to the sciatic nerve. It is also easy to pass a catheter into the subgluteal space when a continuous sciatic nerve block is planned. Because the catheter is inserted into an anatomic space, the catheter is also more likely to stay in situ (Video 43.4) (see also Figs. 42.28–42.30. for landmark-guided techniques).

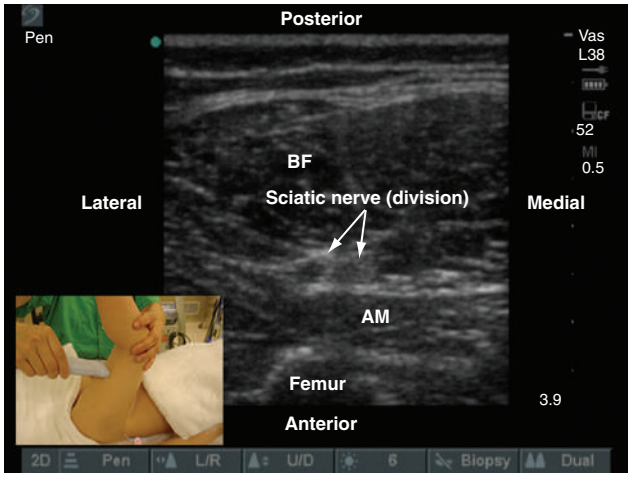

FIGURE 43.31 Popliteal sciatic nerve block. Transverse sonogram of the sciatic nerve at the apex of the popliteal fossa. *AM,* adductor magnus; *BF,* biceps femoris.

Sciatic Nerve Block at the Popliteal Fossa

The sciatic nerve block at the popliteal fossa is the preferred approach for children undergoing foot surgery. The popliteal fossa is a diamond-shaped space lying behind the knee joint, the lower part of the femur, and the upper part of the tibia. It is bound superolaterally by the biceps femoris tendon, superomedially by the semitendinosus and the semimembranosus tendons, inferolaterally by the lateral head of the gastrocnemius, and inferomedially by the medial head of the gastrocnemius. The sciatic nerve enters the posterior aspect of the thigh at the lower border of the gluteus maximus and runs vertically downward to the apex of the superior triangle of the popliteal fossa, where it terminates by dividing into the tibial and the common peroneal nerve, usually 3 to 7 cm above the popliteal crease in adults.[103–106] The division of the sciatic nerve into its terminal branches may, however, takes place anywhere above this level. This accounts for the occasional sparing of either division of the sciatic nerve after distal sciatic nerve block techniques using a nerve stimulation.

Although the classic teaching is to perform a popliteal sciatic nerve block with the patient in the prone position, it is very commonly performed in children with the child in the supine position with the leg elevated by an assistant (Fig. 43.32). During USG popliteal sciatic nerve block the operator sits on the ipsilateral side facing the head of the patient, and the US machine is positioned directly in front. In young children, a linear-array transducer (10-5 MHz) is adequate for imaging the sciatic nerve in the popliteal fossa; in the adolescent child or children with muscular thighs, a curved-array transducer (8-5 MHz) may be preferable. The transducer is positioned just above the apex of the upper triangle of the popliteal fossa in the transverse axis (see Fig. 43.29). It may be necessary to first scan for the sciatic nerve in the middle of the thigh and then trace it distally to the popliteal fossa, where the sciatic nerve is seen as a round, hyperechoic structure. Division of the sciatic nerve into the tibial and common peroneal nerves varies widely but can be visualized in children.[107] In the popliteal fossa and proximal to the popliteal crease, the tibial and common peroneal nerves are seen as hyperechoic structures superficial and lateral to the popliteal artery.

The block needle is inserted using in-plane technique from the lateral aspect of the thigh with its point of entry being anterior to the tendon of the biceps femoris (if it is palpable). This places

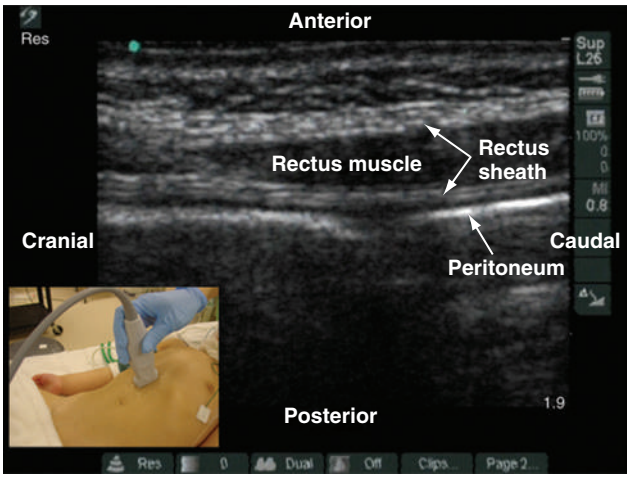

FIGURE 43.32 Longitudinal sonogram of the rectus muscle showing the anterior and posterior rectus sheath.

the needle in the same orientation as for the lateral approach to the sciatic nerve at the popliteal fossa. The exact point of needle entry will depend on where the sciatic nerve is best visualized. The needle is gradually advanced under US guidance, and the tip is positioned just posterior to the sciatic nerve. This is confirmed by injecting 1 to 2 mL of saline solution through the needle, after which half of the calculated dose of local anesthetic is injected. The same process is repeated by repositioning the tip of the needle anterior to the sciatic nerve. This ensures that the local anesthetic spreads optimally around the sciatic nerve (see also Fig. 42.30 for landmark-guided techniques).

TRUNCAL BLOCKS

Rectus Sheath Block

The rectus sheath block is the technique of injecting local anesthetic into the potential space between the rectus muscle and the posterior rectus sheath. This produces anesthesia of the ventral rami of the intercostal nerves as they traverse the rectus muscle to supply the skin of the anterior abdominal wall on either side of the midline. Because the seventh and eighth intercostal nerves also provide motor innervation to the rectus abdominis muscle, a rectus sheath block at this level should also produce relaxation of the muscle. Bilateral rectus sheath blocks are frequently used in children to provide perioperative analgesia during umbilical and paraumbilical hernia repair.[108,109] We have also found it to be useful for analgesia after laparoscopic procedures in children in whom the port insertion sites are close to the midline.

The rectus abdominis muscle arises as two tendinous heads from the lateral part of the pubic crest and the anterior pubic ligament. The fibers run vertically upward and are inserted to the front of the chest wall through the xiphoid process and the fifth, sixth, and seventh costal cartilages. The muscle is enclosed in a fibrous aponeurotic sheath, the rectus sheath, which is formed by the aponeurosis of the external oblique, internal oblique, and transversus abdominis muscles. The anterior rectus sheath is complete and covers the muscle from end to end. However, the posterior rectus sheath is incomplete, being deficient above the costal cartilage and below the arcuate line (or the fold of Douglas), which is located midway between the umbilicus and the pubic symphysis. The rectus sheath on both sides is held together in the midline by a raphe, the linea alba, which is formed by the fusion of the fibers of the three aponeuroses that form the rectus sheath. The ventral rami of the 7th to 12th intercostal nerves pass anteriorly and downward from the intercostal spaces and pierce the posterolateral aspect of the rectus sheath before passing anteriorly through the muscle to supply the skin of the anterior abdominal wall. Three transverse fibrous bands (tendinous insertions)–one at the level of the umbilicus, one at the level of the xiphoid process, and one midway between the two–divide the rectus muscle into three smaller parts. These fibrous bands are adherent to the anterior rectus sheath and traverse only the anterior half of the rectus muscle. Therefore a potential space exists between the rectus muscle and the posterior rectus sheath that communicates from the xiphisternum to the pubic crest. Local anesthetic injected into this space can spread up and down the sheath and is the basis of a rectus sheath block.

A linear-array transducer (13-10 MHz) with a small footprint (25 mm) is used for imaging in children (see Fig. 43.32). The operator stands or sits on one side of the anesthetized child, and the US machine is positioned directly opposite on the contralateral side. The transducer is positioned in the longitudinal axis midway between the umbilicus and the xiphisternum. The rectus muscle is seen as a hypoechoic structure between the hyperechoic anterior and posterior rectus sheath (see Fig. 43.32). Deep to the posterior rectus sheath the hyperechoic peritoneum can be recognized by its typical peritoneal sliding movement and the comet-tail artifacts produced. The fibrous bands (tendinous insertions) in the rectus sheath can also be recognized in the longitudinal sonogram as hyperechoic areas on the anterior surface of the hypoechoic muscle that do not traverse the whole muscle belly.[110–112] The linea alba can be recognized on a transverse sonogram, and the posterior deficiency of the rectus sheath is also readily recognized below the level of the arcuate line.

The block needle is inserted using the in-plane technique in a caudal to cranial direction (Fig. 43.33A and B). When the tip of the needle is visualized in the potential space between the rectus muscle and the posterior rectus sheath, a test injection of saline solution (1–2 mL) is performed to confirm the longitudinal spread of the injectate between the muscle and the rectus sheath and the widening of the space (Fig. 43.33 C and D). Injection into the muscle will offer resistance to injection and is readily recognized in the sonogram. The needle should be repositioned, and the typical spread of the test injection under the rectus muscle should be confirmed before a calculated dose of the local anesthetic is injected.[113] For umbilical hernia surgery, bilateral rectus sheath blocks are performed just above the umbilicus on either side.

Ilioinguinal and Iliohypogastric Nerve Blocks

Ilioinguinal and iliohypogastric nerve blocks are used to provide analgesia after inguinal hernia repair, orchidopexy, or hydrocele surgery. The analgesia is comparable to caudal epidural analgesia, and it offers the advantage of not affecting micturition after surgery, making it ideal for an outpatient procedure. Currently anatomic landmarks and tactile sensations are relied upon to perform the block, which unfortunately can result in failure in up to 20% to 30% of cases. Moreover, it can also lead to complications such as femoral nerve palsy, pelvic hematoma, and bowel perforation.[114] A USG ilioinguinal iliohypogastric nerve block has been compared with the traditional landmark-based method; USG ilioinguinal iliohypogastric nerve block is more accurate, uses smaller volumes of local anesthetic, and has a greater success rate.[115]

The ilioinguinal and iliohypogastric nerves are branches of the primary ventral ramus of L1, which arises from the lumbar plexus. It also receives contributions from the T12 spinal nerve. Superomedial to the anterior superior iliac spine (ASIS), the two nerves pierce the transversus abdominis muscle to lie between it and the internal oblique muscle. The iliohypogastric nerve is situated superior to the ilioinguinal nerve and continues inferomedially for a short distance, after which their ventral rami transverse the internal oblique muscle to lie between the internal and external oblique muscles before giving off branches that pierce the external oblique muscle to provide cutaneous sensation. The iliohypogastric nerve supplies sensory innervation to the skin over the inguinal region. The ilioinguinal nerve continues anteroinferiorly with the spermatic cord or the round ligament in the inguinal canal and becomes superficial by emerging through the superficial inguinal ring to innervate the skin of the upper medial aspect of the thigh and either the skin of the upper part of the scrotum and the root of the penis or the skin covering the labia majora and mons pubis.

A linear-array transducer (13-10 MHz) is used for imaging the ilioinguinal and iliohypogastric nerves, which are best visualized close to the ASIS.[115–117] The operator stands on the ipsilateral side to be blocked, and the US machine is positioned directly opposite

on the contralateral side. The transducer is positioned close to the ASIS and parallel to a line joining the ASIS and the umbilicus (Fig. 43.34). The ilioinguinal and iliohypogastric nerves are identified as two small, rounded structures lying side by side between the internal oblique and transversus abdominis muscle (see Fig. 43.34). The external oblique is frequently identified only as a hyperechoic aponeurotic layer at the point of needle insertion. Deep to the transversus abdominis muscle, the peritoneum and the bowel are also visualized (see Fig. 43.34).

The block needle is inserted in the long axis (in-plane) of the US beam in a medial to lateral direction (Fig. 43.35). We prefer this orientation because it facilitates visualization of the needle (in-plane) and, in the event that the needle is inadvertently inserted too deep, further passage is obstructed by the iliac bone, thus reducing the potential for a major complication such as bowel perforation.[114] When the tip of the needle is close to the two nerves, a test injection is performed with 0.5 to 1 mL of normal saline solution. Correct position of the needle tip is confirmed by

observing the widening of the tissue plane between the internal oblique and transversus abdominis muscles. A calculated dose of a long-acting local anesthetic (e.g., 0.4 mL/kg) is then injected and the spread of local anesthetic to both nerves visualized (Video 43.5) (see also E-Fig. 42.8B for landmark-guided techniques).

Transversus Abdominis Plane Block

The sensory supply of the abdominal wall is provided by the anterior rami of the T7 to L1 thoracolumbar nerves. T7 to T9 innervate the skin above the umbilicus, T10 innervates the skin around the umbilicus, and T11, T12 (cutaneous branches of the subcostal nerve), and L1 (iliohypogastric and ilioinguinal nerves) innervate the skin below the umbilicus. These nerves pass infero-anteriorly in a plane between the internal oblique and transversus abdominis muscles, also known as the transversus abdominis plane (TAP). The lateral cutaneous branch is given off at the midaxillary line and innervates the abdominal wall up to the lateral edge of the rectus abdominis muscle. The segmental nerve then courses anteriorly and medially toward the midline in the TAP to penetrate the lateral margin of the rectus sheath and emerge anteriorly through the rectus muscle as the anterior cutaneous branch. The lateral and anterior cutaneous branches of the thoracolumbar nerves supply the skin from the midline to the anterior axillary line. The thoracolumbar nerves, as they course through the TAP, also supply muscular branches to the abdominal musculature.

Local anesthetic injected into the TAP plane produces sensorimotor blockade (segmental) of the abdominal wall. TAP block techniques can be classified according to the site of needle insertion (i.e., the posterior, lateral, and subcostal TAP blocks).[118] The posterior TAP block is discussed together with the quadratus lumborum block (QLB) in the next section. For the lateral TAP block, local anesthetic is injected in the TAP plane between the iliac crest and the costal margin at the midaxillary line; for a subcostal TAP block the local anesthetic is injected into the TAP plane just below the costal margin at the mid-clavicular line.[119] Anesthesia and analgesia produced by a TAP block is unilateral; thus it is useful for surgical procedures (e.g., orchidopexy, herniotomy, appendectomy) in which the incision does not cross the midline. Bilateral TAP blocks are indicated for abdominal surgical procedures in which the surgical incision is in the midline or crosses the midline. It is also the authors' practice to perform bilateral TAP blocks for laparoscopic procedures.[120–122] However, since TAP blocks do not produce visceral analgesia, they should be used as part of a multimodal analgesic regimen for perioperative analgesia. TAP blocks may be useful as an alternative when central neuraxial blocks are contraindicated (e.g., in children with underlying coagulopathy or spinal dysraphism).

For a lateral TAP block, a high-frequency linear array transducer (15-7 MHz) is placed midway between the iliac crest and the costal margin along the midaxillary line (Fig. 43.36A). For infants and young children, a linear transducer with a small footprint (25 mm) is preferred. The operator stands or sits on one side of the child, and the US machine is positioned directly opposite on the contralateral side. The various layers of the abdominal wall are identified on the sonogram (Fig. 43.36B). From superficial to deep, they include a layer of subcutaneous tissue and fat and the three abdominal muscles with their fascial layers (i.e., the external oblique, internal oblique, and the transversus abdominis muscles, respectively). Deep to the transversus abdominis muscle the hypoechoic peritoneum is also visualized (Fig. 43.36B). The block

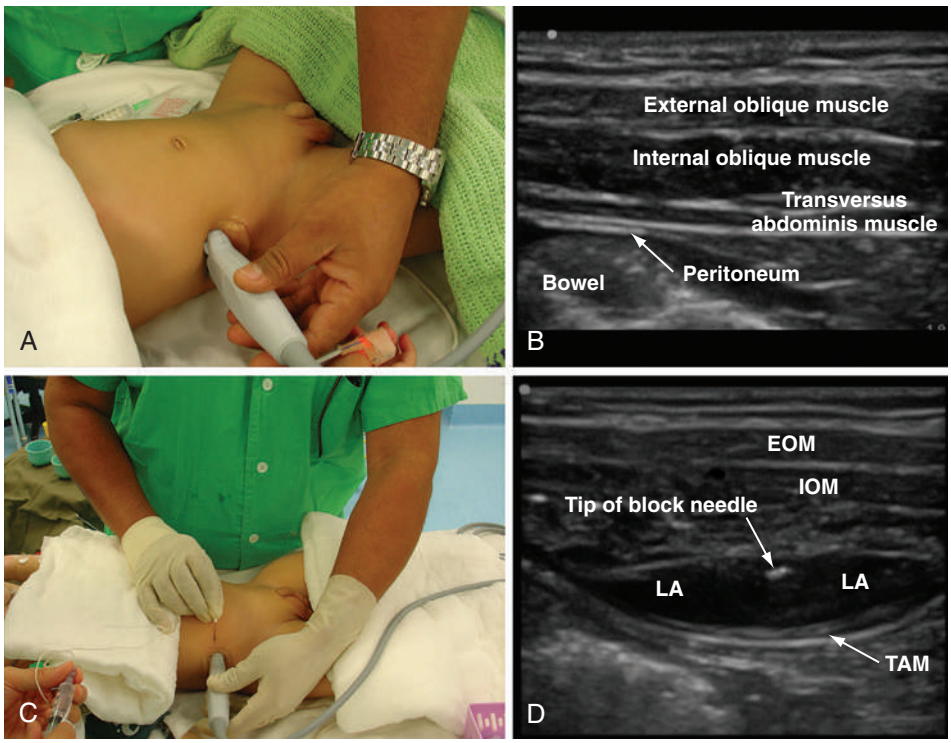

FIGURE 43.36 Posterior transverse abdominis plane (TAP) block. **A,** Note how the ultrasound transducer is positioned between the iliac crest and the costal margin along the mid-axillary line. **B,** The three layers of the abdominal musculature. **C,** In-pane needle insertion during a posterior TAP block. **D,** Distention of the TAP by the injected local anesthetic (*LA*). *EOM,* external oblique muscle; *IOM,* internal oblique muscle; *TAM,* transversus abdomen muscle.

needle (50 mm) is inserted 1 to 2 cm medial to the medial edge of the ultrasound transducer (Fig. 43.36C) in the plane of the US beam. Because the abdominal wall in infants and young children is relatively thin, and to avoid inadvertent deep needle insertion and visceral puncture, it is the authors' practice to initially insert the block needle directed toward the US transducer rather than in an anteroposterior direction. Once the needle tip penetrates the skin and enters the abdominal muscle, it is redirected and slowly advanced under direct vision and penetration of the tip through the external oblique and internal oblique muscles, and finally the TAP is identified between the internal oblique and transversus abdominis muscles. A test injection (1 mL) of saline solution is performed to confirm correct needle placement in the TAP, which is indicated by distention of the TAP by the hypoechoic fluid. A calculated dose of a long-acting local anesthetic is then injected through the needle, while distention of the TAP is visualized in real time (Fig. 43.36D) (Video 43.6).

For a subcostal TAP block, a high-frequency linear-array transducer (15-6 MHz) is placed immediately below the costal margin along the midclavicular line and the block needle (50–80 mm) is inserted in the plane of the US beam and from a medial to lateral direction until the tip is identified to be in the TAP. Saline solution 1 to 2 mL is injected to confirm correct needle placement in the TAP. A calculated dose of local anesthetic is then injected, and as the local anesthetic hydro-dissects the TAP plane, the block needle is advanced posteriorly in the TAP to improve spread of the local anesthetic. Bilateral subcostal TAP blocks are indicated for midline upper abdominal incisions. Currently, published data on the use of subcostal TAP blocks in children are limited, and its role in children is still not defined.

Quadratus Lumborum Block (QLB)

The QLB is a recently introduced abdominal wall field block in which the local anesthetic is injected into a fascial plane located deep to the fascia transversalis (the deep fascia of the abdominal wall) and on the anterolateral aspect of the quadratus lumborum muscle (Fig. 43.37).[123–127] The point of injection is believed to approximate to the landmark-based technique of performing posterior TAP block at the lumbar triangle of Petit.[128,129] Several USG techniques for QLB or their variations have been described in the literature, QLB-I, QLB-II, and transmuscular QLB (Fig. 43.38), but the optimal technique or the best site of injection is still not known.[130–132]

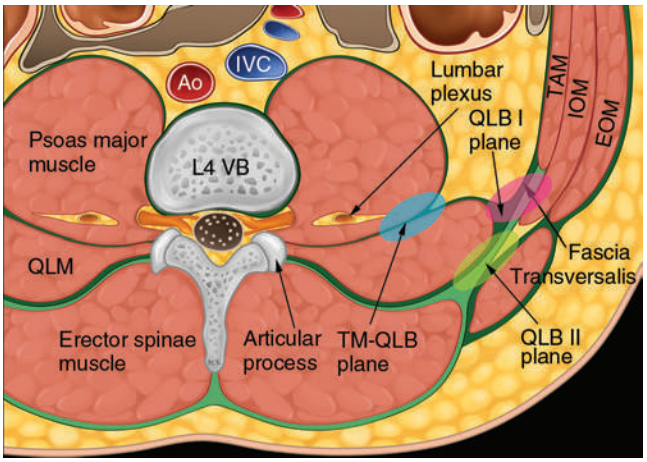

FIGURE 43.37 Cross-sectional anatomy at the L4 level illustrating the anatomy relevant for quadratus lumborum block (*QLB*). The QLB I block involves injecting the local anesthetic at the anterolateral aspect of the quadrates lumborum muscle (*pink region*). QLB II involves injection posterior to the quadratus lumborum muscle (*green region*). QLB III block, also known as transmuscular QLB (*TM-QLB*), involves advancing the needle through the quadratus lumborum muscle and injecting the local anesthetic between the quadratus lumborum and psoas muscle (*blue region*). *Ao,* aorta; *EOM,* external oblique muscle; *IOM,* internal oblique muscle; *IVC,* inferior vena cava; *QLM,* quadratus lumborum muscle; *TAM,* transversus abdominis muscle; *VB,* vertebral body.

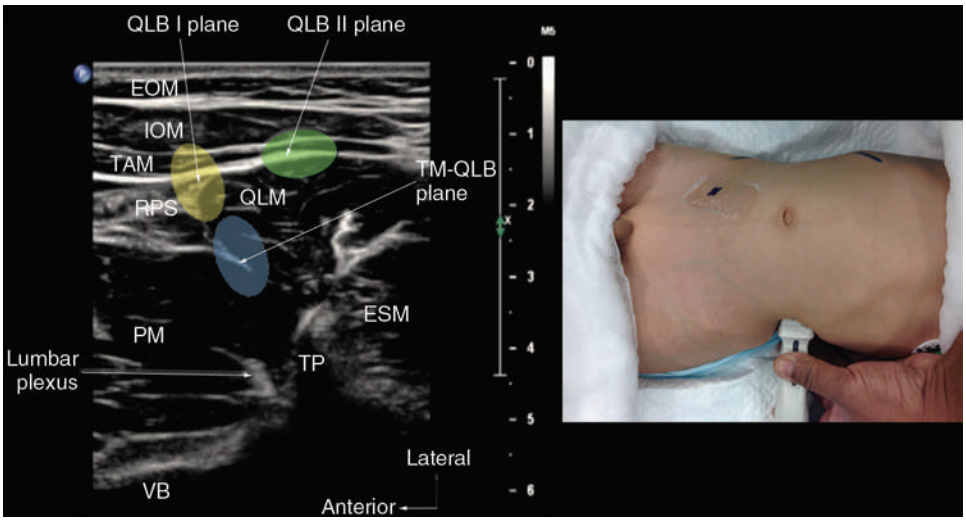

FIGURE 43.38 Quadratus lumborum block in a child. Note how the ultrasound transducer is positioned in the posterior flank immediately above the iliac crest. Transverse sonogram demonstrating the relevant sonoanatomy and the anatomic planes for local anesthetic injection during a quadratus lumborum block. *EOM,* external oblique muscle; *ESM,* erector spinae muscle; *IOM,* internal oblique muscle; *PM,* psoas major; *QLM,* quadratus lumborum muscle; *RPS,* retroperitoneal space; *TAM,* transversus abdominis muscle; *TM-QLB,* transmuscular quadratus lumborum block; *TP,* transverse process; *VB,* vertebral body.

The fascia transversalis of the abdominal wall blends medially with the anterior layer of the quadratus lumborum fascia and the psoas fascia (psoas sheath) (see Fig. 43.37). The subcostal (T12), iliohypogastric (L1), and ilioinguinal (L1) nerves course anterior to and in close contact with the quadratus lumborum muscle and the lateral femoral cutaneous nerve of the thigh (L2, L3) crosses the lateral border of the psoas muscle at the level of the inferior border of the L4 vertebra in this fascial plane.

Currently there are limited data on QLB in children,[124,125,127,133] but studies in adults show that a QLB produces multidermatomal ipsilateral anesthesia of the thoracolumbar nerves. A bilateral single-injection QLB (20 mL of 0.375% ropivacaine on each side) produces loss of sensation to cold from (T7–L1)[134] compared with bilateral lateral TAP blocks (T10–T12).[130–132] Also the duration of analgesia after a bilateral QLB in adults is significantly greater (attributed to paravertebral spread of local anesthetic) than that produced by bilateral lateral TAP blocks.[134] QLB may also produce ipsilateral sympathetic blockade since paravertebral spread of contrast has been demonstrated. Therefore QLB may be effective in relieving sympathetic-mediated visceral pain, which is otherwise not affected by a lateral TAP block. However, since there is a paucity of data on the use of bilateral QLB for major abdominal surgery in children, no recommendations can be made at this time, but QLB holds promise as a technique for perioperative pain management.

A QLB is performed with the child in the lateral or supine position (see Fig. 43.38). The lateral position is preferable for unilateral QLB because the transmuscular approach can be easily performed. For bilateral QLBs the child is placed in the supine position (see Fig. 43.38). The abdomen is exposed between the costal margin and the iliac crest. The operator stands on one side of the subject, and the ultrasound machine is placed directly opposite on the contralateral side. A high-frequency (13-8 MHz) linear-array transducer is used in young children; a curved-array transducer (5-1 MHz), which produces a wider field of view, may be used in older or obese children. The transducer is placed in the transverse orientation in the flank immediately above the iliac crest. The operator then gently slides the transducer posteriorly, aiming to identify the anterolateral surface of the vertebral body and the transverse process in the transverse sonogram. Once the transverse process is located and the relevant anatomy is identified, the operator tilts or slides the transducer slightly caudally to perform the transverse scan through the ITS. The acoustic shadow of the transverse process will now no longer be visible and will be replaced by the hyperechoic articular process. On the transverse sonogram the vertebral body and transverse process of the vertebra appear as hyperechoic structures with a corresponding acoustic shadow (see Fig. 43.38). The psoas major, quadratus lumborum, and erector spinae muscles are easily recognized surrounding the transverse process. Also, depending on the side scanned, the inferior vena cava (on the right) and aorta (on the left) are visualized anterolateral to the vertebral body. The arrangement of the three muscles around the transverse process—that is, the psoas muscle lying anterior, the erector spinae muscle lying posterior, and the quadratus lumborum muscle lying at the apex—produces a sonographic pattern that has been likened to a "shamrock" with the muscles representing the three leaves.[135] Superficial and anterior to these three muscles, the external oblique, internal, and transversus abdominis muscles are identified. In the transverse sonogram through the lumbar ITS, the acoustic shadow of the transverse process is no longer visualized, and the intervertebral foramen and spinal canal may also be visualized in addition to the psoas major, quadratus lumborum, and erector spine muscles (Fig. 43.39).

A 22-G (50- to 80-mm) nerve block needle is inserted in-plane from the anterior to posterior direction, and the needle tip is positioned between the anterior border of QLM and its fascia (QLB-I) (see Fig. 43.37 to Fig. 43.39). Correct needle tip position is confirmed by injection of 1 to 2 mL of normal saline solution and observing the spread of the injectate in relation to the quadratus lumborum muscle (see Fig. 43.39). After negative aspiration, a calculated dose of local anesthetic (e.g., 0.2–0.3 mL/kg per side) is injected. It is prudent to identify the lower pole of the kidney and the limits of the peritoneal cavity during the scout scan to avoid deep needle insertion and visceral injury (Video 43.7).

Thoracic Paravertebral Block

A thoracic paravertebral block (TPVB) is the technique of injecting local anesthetic alongside the thoracic vertebra close to the

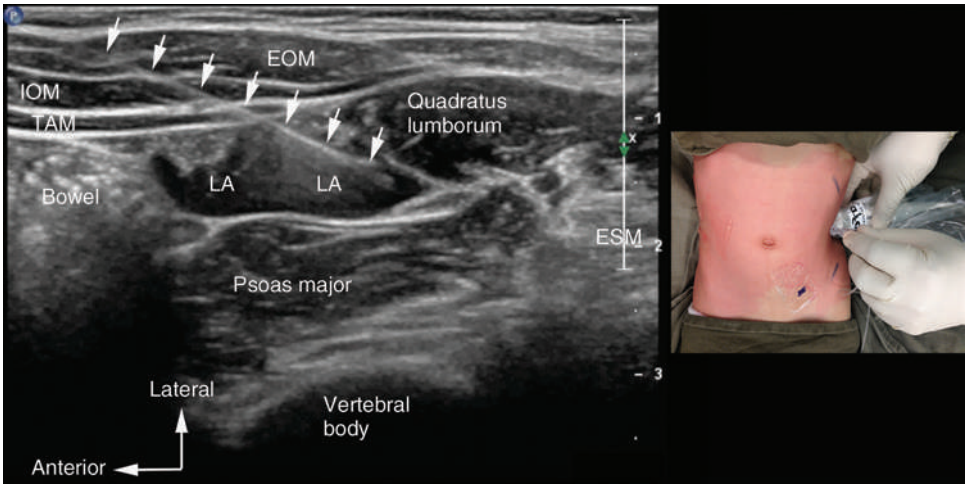

FIGURE 43.39 Quadratus lumborum block II with the patient in the supine position. Note the needle is inserted in-plane and advanced into a fascial plane deep to the fascia transversalis and on the anterolateral aspect of the quadratus lumborum muscle. *EOM,* external oblique muscle; *ESM,* erector spinae muscle; *IOM,* internal oblique muscle; *LA,* local anesthetic; *TAM,* transversus abdominis muscle.

intervertebral foramen. This produces ipsilateral, segmental, somatic, and sympathetic nerve blockade that is effective for relieving postoperative pain of unilateral origin from the chest and abdomen. Traditionally, TPVB is performed using surface anatomic landmarks or a catheter is placed in the thoracic paravertebral space (TPVS) under direct vision during thoracic surgery. Currently, there is a paucity of data on USG TPVB in children.[136,137] The following section describes how the authors perform real-time, in-plane USG TPVB and paravertebral catheter placement in young infants and children.[138–141]

USG TPVB is performed with the child in the lateral position and with the side to be blocked uppermost (Fig. 43.40). The operator sits or stands behind the child, and the US machine is positioned directly in front on the opposite side of the operating table. In most children a 15-6 or 13-8 MHz linear-array transducer is adequate for imaging the paravertebral anatomy. However, a high-frequency linear-array transducer with a small footprint (25 mm) is ideal for USG TPVB in neonates and young infants.

The thoracic paravertebral region can be imaged in the transverse or sagittal axis. We prefer the transverse axis, and the ultrasound scan is performed by sequentially imaging three contiguous sites at the target thoracic level (Fig. 43.41). Each of the three transverse ultrasound scan windows produces a very distinct sonogram, reflecting the different osseous (Fig. 43.42A-C) and musculoskeletal

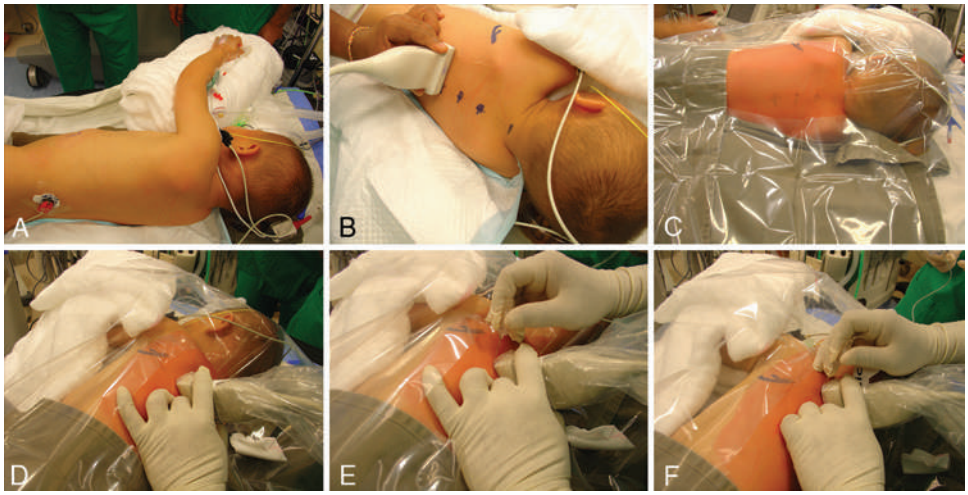

FIGURE 43.40 Ultrasound-guided thoracic paravertebral block in a child. **A,** The child is positioned in the lateral position with the side to be blocked uppermost. **B,** Transverse scan using a 13–8 MHz linear-array transducer. **C,** Aseptic precautions. **D,** The ultrasound transducer is placed inside a sterile cover. **E,** In-plane needle insertion, **F,** Local anesthetic is injected by an assistant.

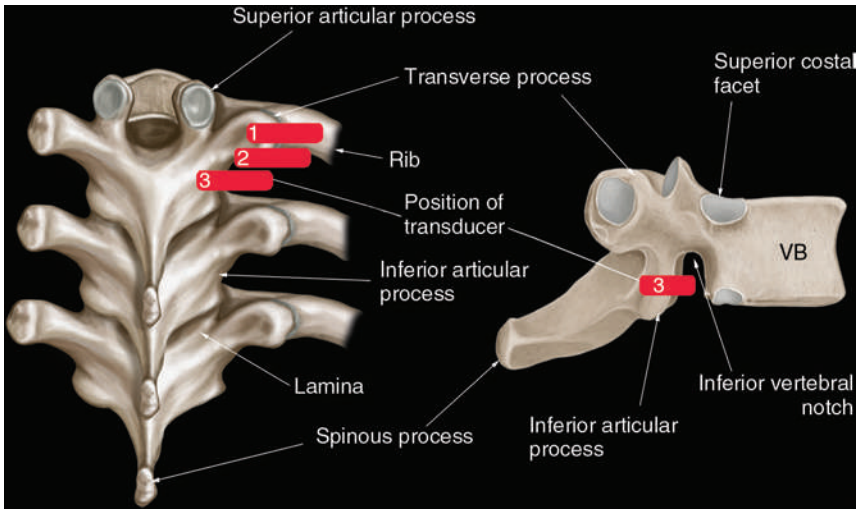

FIGURE 43.41 Schematic diagram showing the positions of the ultrasound transducer at the three contiguous sites over the paravertebral region relevant for thoracic paravertebral block. *Position 1,* The ultrasound transducer is placed over the ipsilateral spinous process, lamina, transverse process, and the rib. *Position 2,* The ultrasound transducer is placed over the ipsilateral lamina and transverse process. *Position 3,* From position 2 the ultrasound transducer is gently slid or tilted caudally until the inferior articular process of the vertebral body is visualized medially.

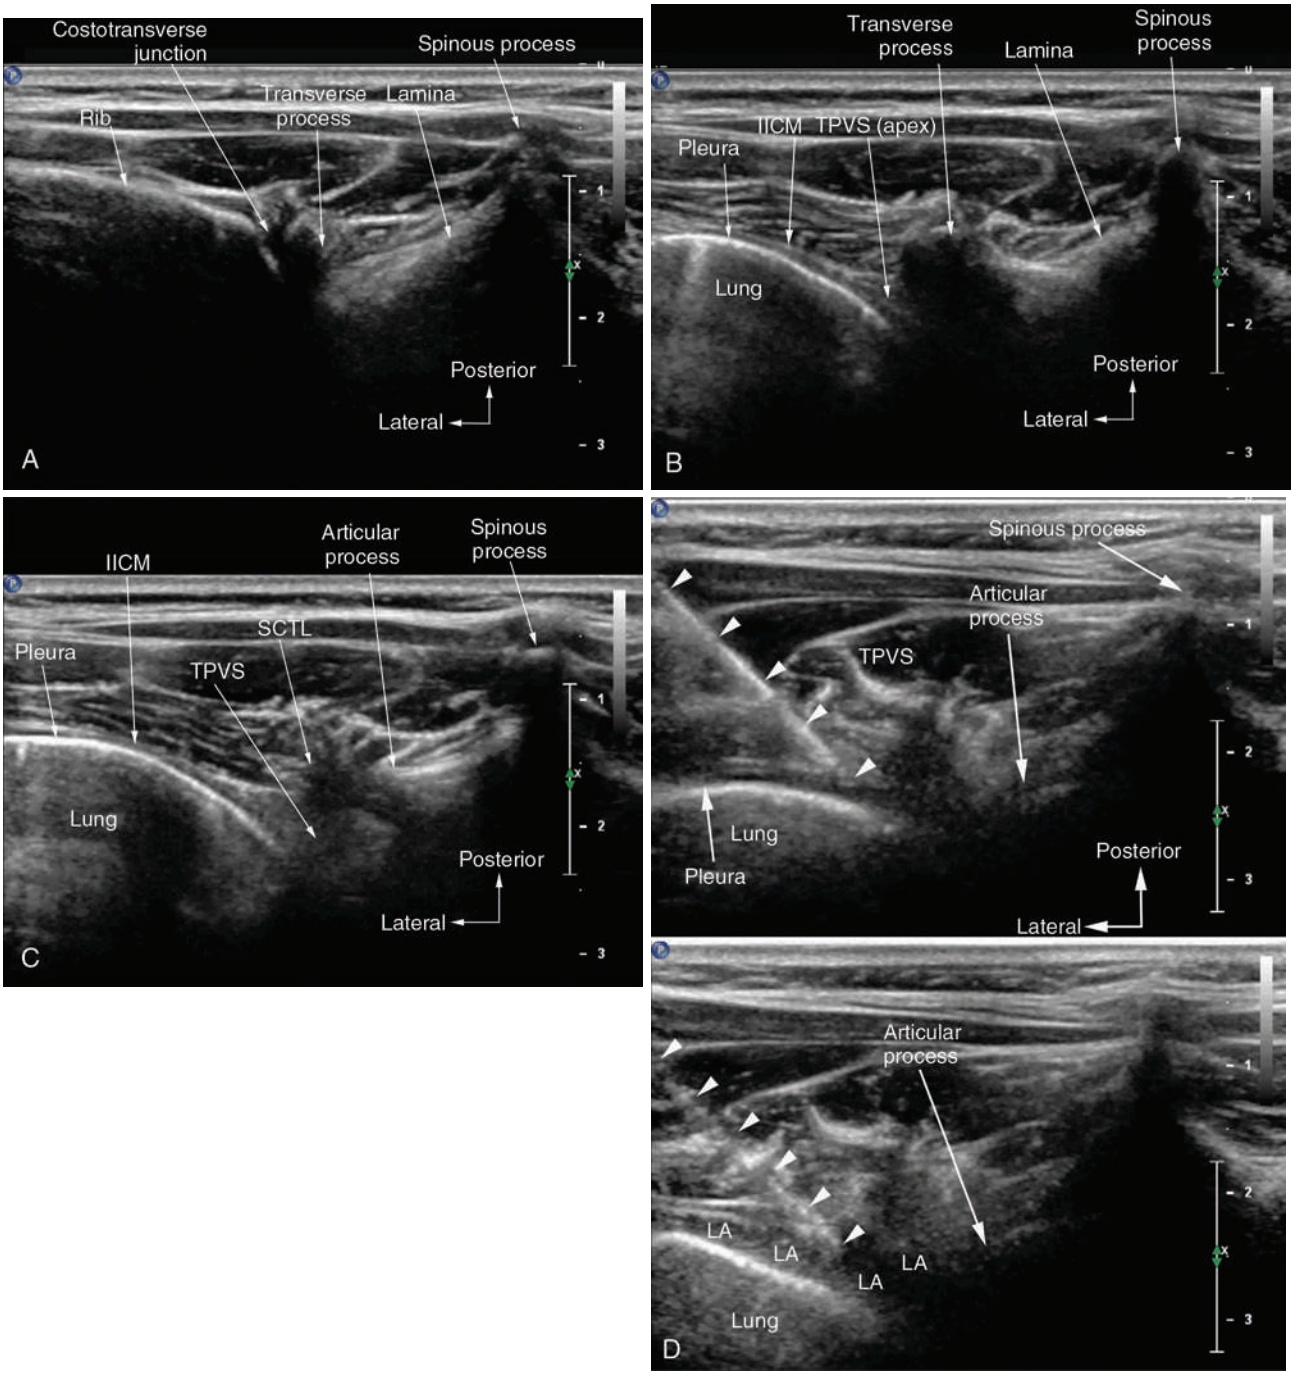

FIGURE 43.42 A, Transverse sonogram of thoracic praravertebral region at the T5 level with the ultrasound transducer placed over position 1 (Fig. 43.41). The hyperechoic outlines of the ipsilateral spinous process, lamina, transverse process, and the rib with their corresponding acoustic shadow anteriorly are clearly delineated from a medial to lateral direction. **B,** Transverse sonogram of thoracic paravertebral block region at the T5 level with the ultrasound transducer placed over position 2 (Fig. 43.41). The hyperechoic outline of transverse process and the lamina with their acoustic shadow are visualized medially. **C,** Transverse sonogram of thoracic paravertebral block region at T5 level with the ultrasound transducer placed over position 3 (Fig. 43.41). Note the acoustic shadow of the transverse process is no longer visualized and the hyperechoic inferior articular process is visualized medially. The outlines of the thoracic paravertebral space are also clearly delineated. **D,** Ultrasound guided thoracic paravertebral block with the block needle being inserted in plane and at the level of the articular process in the transverse sonogram; *arrowheads* indicate the path of the needle. Note the anterior displacement of the parietal pleura and distention of the paravertebral space after the local anesthetic *(LA)* injection. *IICM,* internal intercostal membrane; *SCTL,* superior costotransverse ligament; *TPVS,* thoracic paravertebral space.

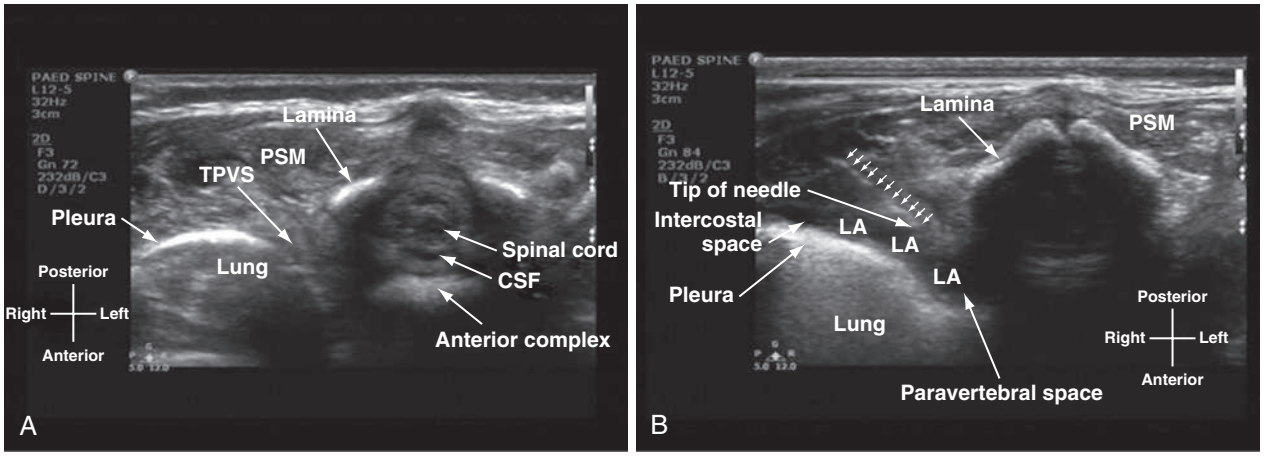

FIGURE 43.43 A, Transverse sonogram demonstrating the sonoanatomy of the right thoracic paravertebral region in a neonate. Note the hyperechoic pleura anteriorly and the hypoechoic apical part of the thoracic paravertebral space *(TPVS)* posterior to the pleura. Also note the large acoustic window resulting from incomplete ossification of the posterior spinal elements that allows visualization of the neuraxial structures within the spinal canal. **B,** Transverse sonogram of the right thoracic paravertebral region in a neonate after an ultrasound-guided thoracic paravertebral block. structures that are visualized in the sonograms. On a transverse sonogram with the ultrasound beam being insonated over the ipsilateral spinous process, lamina, transverse process, and the rib (position 1, Fig. 43.42A), the hyperechoic outlines of the osseous structures with their corresponding acoustic shadows are clearly delineated from a medial to lateral direction. This ultrasound window does not demonstrate the paravertebral anatomy per se but is the initial ultrasound window that one should acquire after which identification of the transverse sonoanatomy of the paravertebral region becomes relatively simple. From position 1, one can gently slide or tilt the transducer caudally until the acoustic shadow of the rib is no longer visualized (position 2) (see Fig. 43.41), and the hyperechoic outline of the lamina and transverse process with their acoustic shadow are seen (see Fig. 43.42B). Lateral to the transverse process the hyperechoic pleura and lung are visualized anteriorly, the hyperechoic internal intercostal membrane (IICM) posteriorly, and a hypoechoic triangular space that represents the apex of the TPVS is interposed between the two (see Fig. 43.42B). If one now gently slides or tilts the ultrasound transducer slightly more caudally (position 3) (see Fig. 43.41), the acoustic shadow of the transverse process disappears and the hyperechoic inferior articular process is visualized medially (see Fig. 43.42C). The thick superior costotransverse ligament (SCTL), parietal pleura, lung, and the apical part of the paravertebral space are also delineated. Continuation of the SCTL to the IICM laterally can also be delineated in some children (see Fig. 43.42C). However, since the acoustic shadow of the transverse process is no longer visualized, outlines of the entire TPVS can now be seen (see Fig. 43.42C). The location of the intervertebral foramen, which lies anteromedial to the inferior articular process, can also be defined (Video 43.8).

Currently the majority of the published data on USG TPVB in children exclusively use the transverse axis, and the scan is performed at the level of the transverse process (position 2, see Fig. 43.42B).[136,137] There are also no data describing the use of the transverse ultrasound scan window at the level of the articular process for TPVB. The latter is our preferred ultrasound window for imaging and needle insertion during USG TPVB because it not only delineates the entire TPVS but there is also less bony obstruction during needle insertion. Furthermore, one can also accurately define the location of the intervertebral foramen, "a no-go zone" during TPVB (position 3) (see Fig. 43.42C).

For a USG thoracic paravertebral block, a transverse view of the paravertebral space at the target level and at the articular process level, is obtained (see Fig. 43.42C). The block needle (50 mm) is inserted lateral to the US transducer and advanced toward the apical part of the paravertebral space in the plane of the US beam (Fig. 43.42D). The advancing needle is visualized in real time, and entry into the TPVS is confirmed using a test bolus injection (1 mL) of saline solution. Correct placement of the needle in the paravertebral space is indicated by anterior displacement of the parietal pleura, distention of the paravertebral space, and increased echogenicity of the parietal pleura (see Fig. 43.42D). A calculated dose of local anesthetic (e.g., 0.4 mL/kg) is then injected with the needle in situ before a catheter is inserted through the needle, leaving approximately 2 cm of catheter in situ if a continuous thoracic paravertebral block is planned. The technique described above can also be used for USG TPVB in young infants and neonates (see Fig. 43.43 A and B and Video 43.9) (see also Figs. 42.18 and 42.19 for landmark-guided techniques).

CENTRAL NEURAXIAL BLOCKS

Spinal Sonography

Since the early 1980s, spinal ultrasonography has been used as a diagnostic screening tool in neonates and infants suspected of having a spinal dysraphism and for detecting spinal tumors, vascular malformations, and trauma.[142–147] Today it is considered the first-line screening test for spinal dysraphism, with a diagnostic sensitivity comparable to that of MRI. Spinal ultrasonography is possible in neonates and infants because the incomplete ossification of the predominantly cartilaginous posterior spinal elements creates an acoustic window that allows the transmission of the US beam.

The overall visibility of neuraxial structures decreases with age. Neuraxial structures are best visualized in neonates and infants younger than 3 months of age; progressive ossification of the posterior spinal elements makes detailed sonographic evaluation of the spine difficult beyond 6 months of age unless the child has a persistent posterior spinal defect. Some reports have demonstrated that neuraxial structures can be visualized in older children, although their details are limited. The overall visibility of neuraxial structures also decreases as one progresses up the spine, with the best visibility in the sacral level followed by the lumbar and then at the thoracic level.

In diagnostic radiology, spinal US is most frequently performed with the child in the prone position, whereas in an anesthetized child it is generally performed with the child in the lateral position. Because the neuraxial structures are relatively superficial in children, they are best visualized using high-frequency (10-5 MHz) transducers, which also produce better images than sector transducers. Scans are obtained in both the transverse (axial) and longitudinal (sagittal) axes, and they are performed either through the midline or parallel and lateral (paramedian) to the spinous processes. The paramedian scan is preferable in older children because it avoids the ossified spinous processes that can interfere with US transmission. In neonates and young infants, the spinal canal can be scanned with the transducer placed directly over the spinous processes (i.e., a median longitudinal scan). Beyond this age group a paramedian longitudinal scan provides the best overall view of neuraxial structures.

On a longitudinal sonogram, the neonatal spinal cord is seen as a hypoechoic tubular structure with hyperechoic anterior and posterior walls. A thin strip of variable intense echo, "the central echo complex" (Fig. 43.44A), extends longitudinally through the center of the spinal cord and represents the area between the myelinated ventral white commissure and the central portion of the anterior median fissure. This produces the "triplet echoes" that are characteristic of the spinal cord at all levels (Fig. 43.44B). The diameter of the spinal cord varies, being largest in the cervical and lumbar regions and smallest at the thoracic region. Anterior and posterior to the spinal cord are two well-defined linear and hyperechoic echoes that represent the arachnoid-dural layer (see Fig. 43.44A). The ligamentum flavum, which is relevant for epidural access, is also readily visualized in young children and appears less echogenic than the dura (see Fig. 43.44B). The dural layers taper distally to close the thecal sac at the S2 level. The epidural space is the hypoechoic area between the dura and the ligamentum

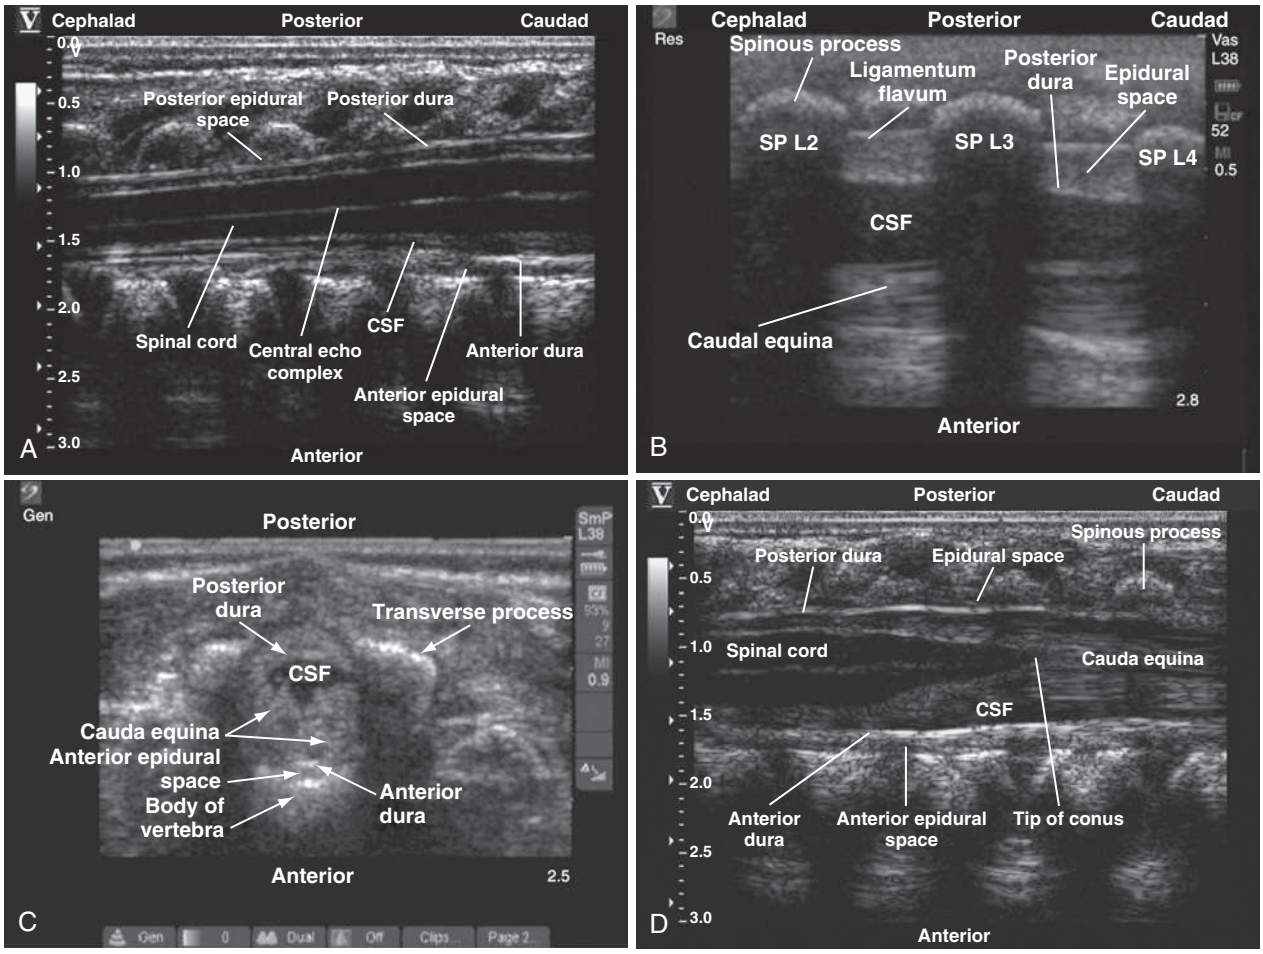

FIGURE 43.44 **A,** Longitudinal paramedian sonogram of the thoracic spine in a neonate. **B,** Longitudinal midline sonogram of the lumbar spine in a neonate. **C,** Transverse sonogram of the lumbar spine in a neonate showing the cauda equina. **D,** Longitudinal paramedian sonogram of the thoracolumbar spine in a neonate showing the termination of the spinal cord. *CSF,* cerebrospinal fluid; *SP L2,* spinous process of L2; *SP L3,* spinous process of L3; *SP L4,* spinous process of L4.

flavum (see Fig. 43.44B) and arterial pulsations also may be visible on US between these two layers. The cerebrospinal fluid (CSF) surrounds the spinal cord as an anechoic layer between the dura and spinal cord (Fig. 43.44C). The vertebral bodies are seen as echogenic structures anterior to the spinal cord. The spinal cord tapers distally to form the conus medullaris (Fig. 43.44D) at the level of the first and second lumbar vertebral bodies. The conus medullaris is continuous with the filum terminale, which extends into the sacral canal as a hyperechoic structure. It is surrounded by the roots of the cauda equina, which appear as multiple parallel echogenic lines surrounding the filum terminale (Fig. 43.45A). Differentiation of the filum terminale from the roots of the cauda equina can sometimes be difficult. The cauda equina typically lies in the anterior half of the spinal canal when the child is in the prone position, but it moves freely within the CSF with change in position and with crying. Slight anteroposterior movement of the spinal cord, superimposed on the arterial pulsations, is commonly seen during real-time imaging.

On a transverse (axial) sonogram, the spinal cord is seen as a round or oval hypoechoic structure, with its bright central echo complex (see Fig. 43.45B). The spinal cord is fixed laterally by the dentate ligament (see Fig. 43.45B), which represents the transversely oriented, echogenic arachnoid duplications that are seen in parts of the thoracic spinal canal. Paired (ventral and dorsal) echogenic nerve roots are seen below the L2 level. Farther caudally in the lumbar region, a transverse scan shows the filum terminale surrounded by the nerve roots of the cauda equina (see Fig. 43.45C). The arachnoid–dura mater complex is hyperechoic and forms the anterior and posterior border of the subarachnoid space in the lumbar region (see Fig. 43.45C). The vertebral bodies are the hyperechoic structures anterior to the spinal canal. The vertebral arches are also echogenic and cast an acoustic shadow anteriorly (see Fig. 43.45C). The paraspinal muscles appear hypoechoic on US.

Caudal Epidural Anesthesia

Single-shot caudal epidural injection is the most frequently used regional anesthetic technique in children and almost always is used in combination with general anesthesia for surgery involving the lower thoracic, lumbar, and sacral dermatomes.[148–150] Several methods are used to perform a caudal epidural injection.

Detecting the characteristic pop or give as the needle traverses the sacrococcygeal ligament to enter the caudal epidural space is by far the most commonly used method in children. However, even in experienced hands it can result in failure, and the overall failure rate varies between 2.8% and 11%. US has been used to guide caudal epidural injection in children,[151–153] providing correct

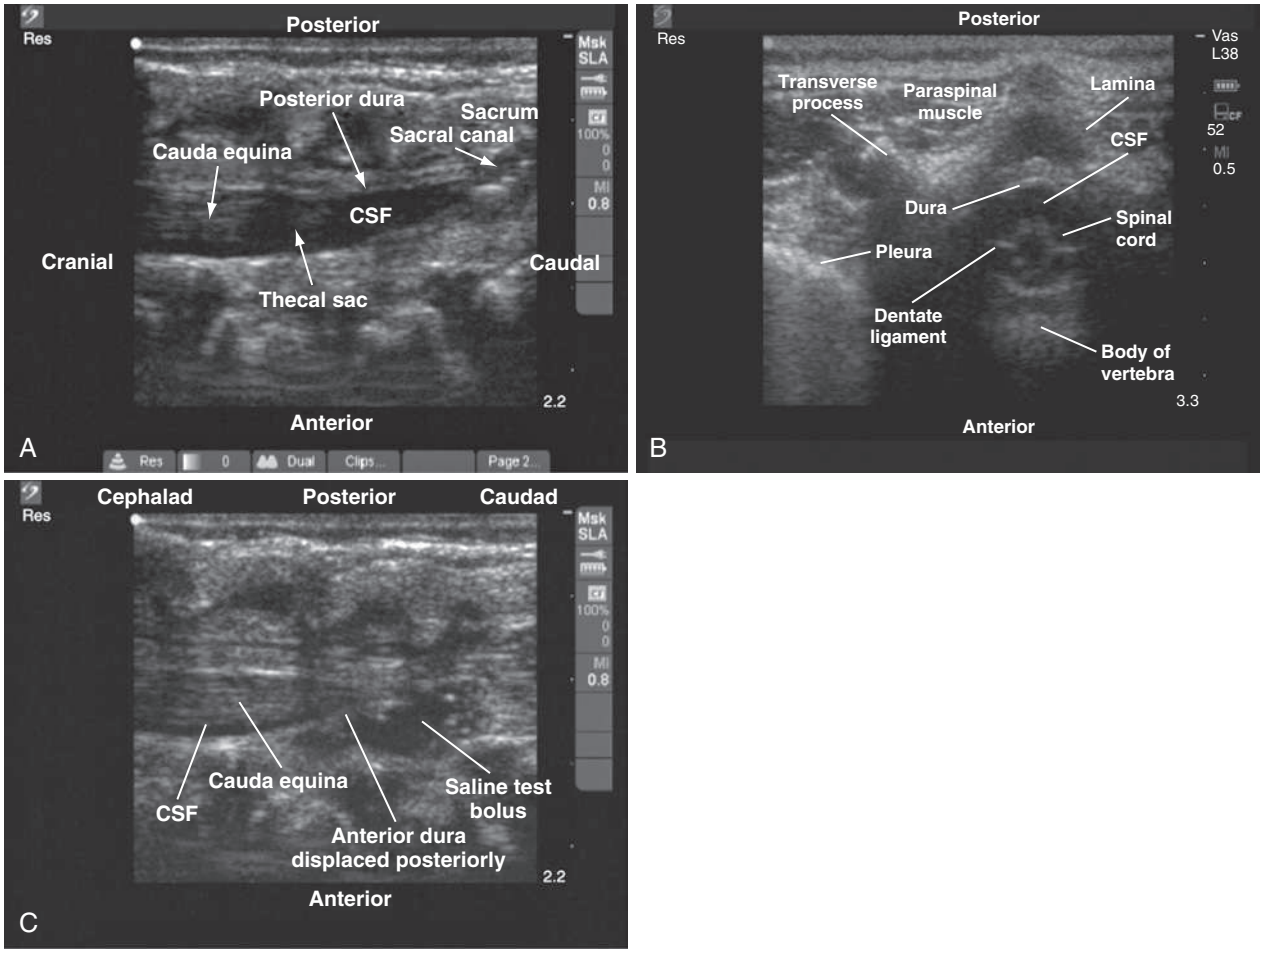

FIGURE 43.45 **A,** Longitudinal sonogram of the sacrum showing the tapered end of the thecal sac. **B,** Transverse sonogram of the thoracic spine in a neonate. **C,** Longitudinal sonogram of the sacrum after a test bolus injection of saline solution through an indwelling caudal catheter during a single-shot caudal epidural injection. FIGURE 43.46 **A,** Transverse sonogram of the sacrum ("frog-eye sign"). **B,** Longitudinal sonogram of the sacrum.

needle or catheter positioning in the caudal epidural space confirmed by real-time US visualization in the sacral canal, or by observing dural displacement after a saline solution test bolus (1–10 mL) injection.

The anesthetized child is positioned in the lateral position with the knee and hips flexed. The operator sits or stands behind the child, and the US machine is positioned directly in front. A linear-array transducer (13-10 MHz) is used to image the sacrum. A transducer with a wide footprint is preferable because it allows a greater length of the spine to be examined in a single view. The transducer is initially positioned directly over the sacral cornua in the transverse axis (Fig. 43.46A). On a transverse sonogram at the level of the sacral hiatus, the sacral cornua are seen as two hyperechoic reverse U-shaped structures, one on either side of the midline. Connecting the two sacral cornua and deep to the skin and subcutaneous tissue is a hyperechoic band, the sacrococcygeal ligament (see Fig. 43.46A). Anterior to the sacrococcygeal ligament is another linear hyperechoic structure, which represents the posterior surface of the sacrum. The hypoechoic area between the sacrococcygeal ligament and the bony posterior surface of the sacrum is the sacral hiatus. The two sacral cornua and the posterior surface of the sacrum produce a US image that we refer to as the "frog-eye sign" because of its resemblance to the eyes of a frog. On a longitudinal sonogram of the sacrum, the sacrococcygeal ligament, the base of the sacrum, and the sacral hiatus can be clearly seen (Fig. 43.46B). In neonates and young infants the tapered end of the thecal sac with CSF, the anterior and posterior epidural space filled with fat, and the cauda equina may be visualized in the sacral canal (see Fig. 43.46B) (Video 43.10).

For USG caudal epidural injection, either the in-plane or out-of-plane technique can be used. We prefer the in-plane approach, and the needle is advanced under real-time guidance into the sacral canal through the sacrococcygeal ligament. During insertion, the needle is maintained at an angle (approximately 20 degrees) so that it is parallel to the posterior surface of the sacrum. Correct position of the needle in the caudal epidural space is confirmed objectively by performing a test bolus injection of saline solution and observing in real time the displacement of the dura (Fig. 43.47) (Video 43.11). Anterior displacement of the posterior dura is more frequently seen than posterior displacement of the anterior dura. If dural displacement is not seen in the US image, it implies that the needle or catheter is not in the correct position, the needle or catheter is not in the plane of US imaging, or the needle is intravascular. The needle should be withdrawn and the procedure repeated until the typical dural displacement is visualized. The calculated dose of local anesthetic is then injected in aliquots. The cephalad spread of the local anesthetic within the epidural space also can be visualized in real time.[154] Depending on the volume of local anesthetic injected, progressive widening of the epidural space and a resultant compression of the thecal sac occur (see Fig. 43.47). These changes are visualized in the sacral canal and at the lumbar and thoracic levels. In some cases the thecal sac is almost completely obliterated in the sacral and lumbar region. Because the compression and obliteration of the thecal sac occurs in a caudal to cranial direction, it indicates that there is a net cranial displacement of CSF (Video 43.12).

US guidance during a caudal epidural injection in children offers several advantages. It is safe, noninvasive, radiation free, simple, and quick to perform; it provides real-time images that are easy to interpret; and, unlike the nerve stimulation technique, is not affected by the use of neuromuscular blocking drugs or epidural local anesthetics. Moreover, US can demonstrate the underlying caudal anatomy, which is useful in children with cutaneous markers of dysraphism when it can be used to screen the underlying spinal anatomy. Thus many children who may have otherwise been excluded from a caudal block can benefit from its effects (see also Fig. 42.6 and E-Fig. 42.6 for landmark-guided techniques).

Epidural Catheterization

Continuous epidural analgesia via an indwelling epidural catheter is a well-established method of providing perioperative analgesia in children. The loss-of-resistance technique is the most frequently used method of identifying the epidural space. Although popular, this technique relies on the operator's tactile sensation and can occasionally result in dural puncture or serious neurologic complication (e.g., a spinal cord injury). Alternative methods for identifying the epidural space in children have been described but have not gained widespread acceptance. Epidural catheters have been successfully placed in young children under US guidance.[155–157] Compared with the traditional loss-of-resistance method, when epidural catheterization is performed using the loss-of-resistance method in conjunction with US guidance, fewer bony contacts occur during the procedure, and the time required for catheter placement is reduced. The spread of local anesthetic in the epidural

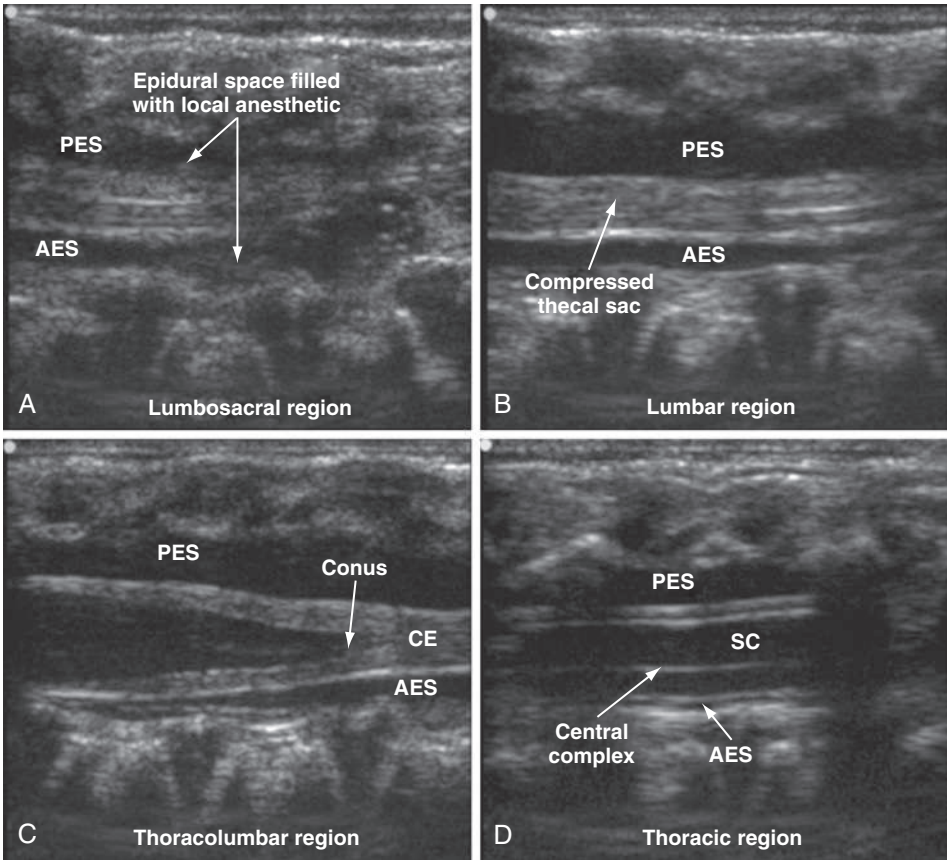

FIGURE 43.47 Longitudinal sonogram of the spine after a single-shot caudal epidural injection at the **A,** lumbosacral, **B,** lumbar, **C,** thoracolumbar, and **D,** thoracic levels. Note the displacement of the anterior and posterior dura, widening of the epidural space, and the compression of the thecal sac at the various levels. *AES,* anterior epidural space; *CE,* cauda equina; *PES,* posterior epidural space; *SC,* spinal cord.

space can also be visualized in real time. In addition, the underlying anatomy and the depth from the skin to the ligamentum flavum, dura, and epidural space can be assessed before needle insertion. However, epidural catheterization under US guidance requires two anesthesiologists who are familiar with epidural anesthesia and spinal sonography in children. The first anesthesiologist performs the scan in the longitudinal paramedian axis and maintains a steady image while the second anesthesiologist performs the needle insertion through the midline. Entry of the needle into the epidural space is confirmed by the loss of resistance to saline solution and observing the local sonographic changes resulting from the saline solution injection (i.e., anterior displacement of the posterior dura, widening of the epidural space, and compression of the thecal sac). USG epidural catheterization in young children is a very demanding procedure and requires a great deal of skill and dexterity; it should be undertaken only by those with adequate training and skill in USG regional anesthesia.

Assessment of Indwelling Epidural Catheters

For optimal epidural anesthesia or analgesia, the epidural catheter tip must be located in the correct dermatomal level. This is often achieved by directly placing the catheter in the desired level via the lumbar or thoracic route. Even with this approach, and in particular when loss of resistance is used to locate the epidural space, it is not possible to determine with any certainty the exact location of the catheter tip. Epidurography can locate the catheter tip, but this exposes the child to radiation and the risk of anaphylaxis from the contrast medium (see Fig. 42.8).[158,159] An epidural catheter inserted via the caudal route can be advanced to the lumbar or thoracic epidural space. However, this is technically difficult in children older than 1 year of age, and even in children younger than 6 months of age, the catheter can be misplaced in the sacral, lumbar, and even the cervical region. Greater success has been reported with styletted catheters.[160] Even if a catheter is successfully advanced to the thoracic epidural space, a radiographic can confirm the position of the catheter tip.[158,159] Electric nerve stimulation through an indwelling styletted epidural catheter and observation of myotomal contractions have been used to locate the position of the catheter tip.[161] In experienced hands this technique has a success rate of 89%. However, this test cannot be performed if neuromuscular blocking drugs or local anesthetics have been administered. Epidural electrocardiography also can be used to locate the position of a thoracic epidural catheter and is not affected by the use of neuromuscular blocking drugs or local anesthetics in the epidural space.[162] This method relies on matching the evolving electrocardiogram (ECG) recorded from the tip of a specially adapted epidural catheter, as it is advanced, to the surface ECG recorded at the target vertebral level. However, this method is not specific because even a subcutaneous electrocardiographic electrode at the same position relative to the heart will produce a similar electrocardiographic pattern.

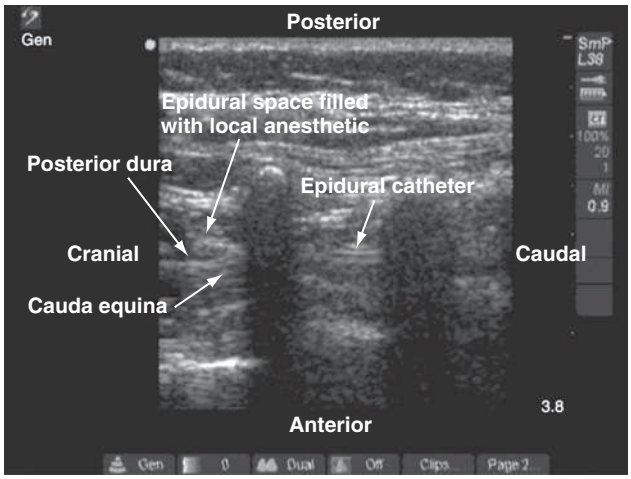

FIGURE 43.48 Longitudinal paramedian sonogram of the lumbar spine demonstrating an indwelling epidural catheter.

US has been used to directly visualize the position of epidural catheters in children (Fig. 43.48).[163,164] US localization noninvasively provides real-time images of the catheter during placement. However, not all epidural catheters or their tips can be identified using US, and it may be limited by the acoustic window available for scanning in children of different ages. Gently jiggling the catheter and observing tissue movement within the epidural space also has been used to facilitate epidural catheter localization. Injecting saline solution with air bubbles may improve catheter localization using US, but the use of air in the injectate can lead to inadvertent air embolism or a patchy block.[165] A small volume of contrast material may be injected under x-ray guidance as well to localize the tip of the catheter. Therefore it is suggested that observing surrogate markers such as the widening of the epidural space, dural displacement, and compression of the thecal sac, subsequent to a saline solution test injection, may be more accurate in locating the position of an epidural catheter in children (Video 43.13).

ADVANTAGES OF ULTRASOUND IMAGING

USG regional anesthetic blocks appear to offer several advantages. US imaging is noninvasive and simple to use and does not involve exposure to radiation. It allows the target nerves and the surrounding structures to be directly visualized during block placement, which is particularly advantageous in children with difficult or variant anatomy, obesity, or amputated limbs in whom the evoked motor responses cannot be visualized. US is also useful in young children because the majority of regional anesthetic procedures in this age group are performed with the child under general anesthesia when the use of a muscle relaxant makes nerve stimulation impractical. US guidance also helps determine the best possible site and maximum safe depth for needle insertion, allows real-time guidance of the needle and needle tip to the target site, avoids unintended vascular or pleural puncture, and allows visualization of the spread of the injected local anesthetic in real time. Together, these should lead to fewer needle insertions, improved comfort during block placement in awake and sedated children, reduced complications, improved quality of block, and greater success rates. Evidence (from adults and children) suggests that US speeds the execution of peripheral nerve and central neuraxial blocks, reduces the discomfort experienced during block placement, reduces the amount of local anesthetic required, speeds the onset of sensory blockade, improves the quality of sensorimotor blockade, and prolongs the duration of sensory blockade.[24,166–168]

Education and Training

Learning USG nerve block techniques takes time and patience. The state of the art of regional anesthesia demands a high degree of manual dexterity and hand–eye coordination and an ability to conceptualize 2D information into a 3D image. In addition, to produce good-quality US images, the anesthesiologist must also possess a sound knowledge of anatomy, the physical principles of US, and musculoskeletal imaging. Therefore individuals who intend to perform USGRA should start by learning the basics of US and USG interventions by attending a course or workshop[169–173] and by working with individuals who already possess these skills. Initial experience of musculoskeletal scanning can also be acquired in volunteer situations, and USG interventions can be practiced using a US phantom. Once the basic skills are acquired, it is best to start by performing superficial peripheral nerve blocks (e.g., axillary brachial plexus block, femoral and sciatic nerve block) under supervision before attempting deeper blocks (e.g., lumbar plexus block), which can be technically demanding even for an experienced operator. Whenever possible, it is advisable to use a peripheral nerve stimulator in conjunction with US during the learning phase of USG nerve blocks. With proficiency, it is possible to perform most techniques without nerve stimulation. Fortunately, the learning curve is steep,[174,175] and most anesthesiologists are able to acquire the required skills very quickly. It is preferable to perfect these techniques in adults or older children before performing them in young children.

Summary

USGRA is a promising alternative to anatomic landmark-guided techniques, and almost all regional anesthetic techniques that are commonly performed in children can be performed using US guidance. US allows the anesthesiologist to visualize the target nerves and surrounding structures in real time during block placement. There is increasing evidence to support the routine use of US for regional anesthesia in children. We believe that anesthesiologists who care for children must acquire the skills necessary to perform USGRA and embrace this technology. US guidance is rapidly becoming the standard of care in pediatric regional anesthesia.[176]

Summary

THE PRACTICE OF PAIN MANAGEMENT in children continues to advance. Since the early 1980s, clinicians have recognized that neonates and infants experience pain and process those learning experiences. Research has demonstrated long-term adverse consequences of unrelieved pain, including harmful neuroendocrine responses, disrupted eating and sleep cycles, and increased pain perception during subsequent painful experiences.[1–3] Adequate pain control is second only to correct diagnosis when parents are surveyed about their priorities and concerns surrounding hospital admission.[4] Disparities in pain treatment led organizations, such as the Agency for Healthcare Research and Quality (AHRQ) and the American Pain Society (APS), to provide guidelines and the Joint Commission (formerly the Joint Commission on Accreditation of Healthcare Organizations) to issue mandates that further enhanced pediatric pain management.[5–7] The availability of reliable and valid pain assessment tools for children and governmental incentives encouraged the inclusion of children in analgesic drug trials. Many children's hospitals have dedicated multidisciplinary teams that manage acute and chronic pain. The increasing use of regional analgesia techniques led to the development of the Pediatric Regional Anesthesia Network (PRAN), a registry of practice patterns and complications of regional anesthetics in children. An enormous expansion of the breadth of techniques for acute pain management in children, the establishment of pediatric pain services, and the investigation and introduction of innovative modalities of therapy all attest to the importance accorded to this aspect of perioperative care.

Developmental Neurobiology of Pain

Nociceptive pathways in the periphery, spinal cord, and brain develop in a series of stages through the second and third trimester in humans. By 26 weeks postconception age, there is sufficient maturation of peripheral and spinal afferent transmission for the late-gestation fetus or preterm neonate to respond to tissue injury or inflammation with withdrawal reflexes, autonomic arousal, and hormonal metabolic stress responses. There are also changes in responsiveness after injury or repetitive stimulation indicative of central sensitization. In general, preterm neonates have reduced thresholds for withdrawal to noxious thermal and mechanical stimuli and immature descending inhibitor pathways that are necessary for modulating the pain response compared with older infants and children. One mechanism that may contribute to these low-threshold responses involves projections of low-threshold peripheral afferents to superficial as well as deep laminae in the spinal dorsal horn; later in development these afferents project only to deeper dorsal horn laminae. Most of the neural pathways that conduct nociception from the periphery through the central nervous system (CNS) are present and functional at 24 weeks gestational age, although the central connections, particularly in the thalamocortical pathways that are involved in the integration and perception of conscious pain, are not as well developed.[8–10] Controversy remains as to the meaning and implications of this neural immaturity. Opioid receptors and responses are present in the spinal cord at the time of birth, although spinal glial inflammatory mechanisms are immature. Because these mechanisms are central to the cyclooxygenase (COX-1 and COX-2) responses, this may imply that there is limited or no analgesic response to nonsteroidal antiinflammatory drugs (NSAIDs) and COX inhibitors in preterm infants or neonates, whereas opioid responses are active. γ-Aminobutyric acid (GABA) receptors and associated pathways, which play an important role in the effects of analgesics and anesthetics, can be either excitatory or inhibitory, depending on the stage of development.[11] The neuroplasticity that is characteristic of these infants may be a double-edged sword. Animal models and some clinical evidence suggest that repeated noxious stimuli may result in heightened sensitivity to nociceptive input and adverse behavioral sequelae.[2,12–16] On the other hand, nerve injury in infant animals may result in less pain than in older animals.[15,16] In humans, the neural injury to the brachial plexus after shoulder dystocia during delivery rarely results in chronic pain. It may be that there are both vulnerable periods and periods of greater resiliency during development, so that the consequences of pain in young children may not be easily predictable.

Investigators have examined indexes suggestive of cortical activation, including near-infrared spectroscopy[17] and electroencephalography,[18] in response to noxious events. Using near-infrared spectroscopy, a unilateral heel stick (performed for clinical purposes) produces signal changes suggestive of contralateral cortical activation.[17–19] Despite these lines of evidence, the nature of pain in neonates, viewed as conscious suffering, remains unknown. Other investigators have looked for long-term consequences of painful events (with or without treatment) in humans and in animal models. Despite attempts by these investigators to correct for confounding factors, in our view, the interpretation of these studies, especially in humans, should be quite cautious. Neonates who undergo painful procedures are commonly those who are more medically ill. It appears difficult to distinguish consequences of pain per se from the consequences of other factors, such as prematurity, critical illness (including episodes of hypoxia or ischemia), deprivation of tactile and social contact, and nutritional deprivation. Many clinicians and investigators have adopted the view that, in the absence of better information about either the nature of suffering experienced by neonates or the potential adverse consequences of pain in terms of long-term development, caregivers should err on the side of providing, rather than withholding, analgesia. Although this is a compelling perspective, it is important to highlight three concerns: (1) in general, available studies have had difficulty showing effects of routine administration of analgesia (e.g., morphine infusions) on immediate behavioral indexes of distress in neonates undergoing intensive care; (2) repeated or prolonged administration of anesthetics and sedatives in animal models have been shown to have deleterious effects on brain development, (the human implications of these animal studies remain unclear at this time [see also Chapters 7 and 25])[12,20–25]; and (3) as detailed later, younger organisms develop tolerance to opioids and benzodiazepines more rapidly than older organisms, so that the management of tolerance and withdrawal has now become a nearly universal consequence of prolonged administration of these medications to critically ill neonates, infants, and children.

Pain Assessment

The International Association for the Study of Pain (IASP) has defined *pain* as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or *described* in terms of such damage. The IASP and others have acknowledged that the inability to communicate verbally, as in the preverbal, nonverbal, or the cognitively impaired, does not preclude the possibility that an individual is experiencing pain and is in need of appropriate pain management.[26,27] Table 44.1 summarizes various pain assessment tools in terms of appropriate age, target population, ease of use, and practicality; commonly used scales are discussed in more detail later.

Consensus guidelines have been published with recommendations for appropriate tools to use for research studies, many of which are simple to use in routine clinical settings.[28] It should be emphasized that pain intensity is only one of many factors that should be considered when performing a global pain assessment. Other important outcomes include functional recovery, patient satisfaction, adverse effects, emotional recovery, and economic factors. The Revised American Pain Society Patient Outcomes Questionnaire (APS-POQ-R) consists of 12 questions pertaining to multiple pain outcomes.[29] A study is currently under way to validate a modified version in children. Although this tool is likely too cumbersome for daily use, it can be helpful for quality assurance and research studies.

SELF-REPORT METRICS

Self-report metrics in which a patient is asked to quantify the severity of the pain between 0 (no pain) and 10 (maximum pain) most accurately reflect acute pain because pain is a subjective experience. Because many children lack the cognitive skills to use such scales, pain assessment metrics have been developed to include developmentally appropriate self-report tools, behavioral-observational tools, and physiologic-biologic measures (see Table 44.1). Given the multidimensional nature of the individual pain experience, and the complexity and inherent biases associated with self-report, the use of unidimensional numeric scales alone to reflect pain is overly simplistic.[30–33] Therefore, regardless of the metric used, it must be emphasized that a complete pain assessment is more than just a number attempting to quantify the severity of pain. Estimating the impact of pain on the suffering and the quality of the individual's life and recovery process, targeting appropriate therapeutic metrics, and evaluating the efficacy and side effects of such measures are additional key components of a global and ongoing pain assessment and treatment strategy.

For children to use numeric scales, they must understand the concepts of magnitude and ordinal position—that is, they must be able to identify which of different-sized objects is bigger and place them in order from smallest to largest. They must also be able to arrange geometric figures or numbers in a series *(seriation)*. These skills are typically not present until about 7 years of age; thus pain assessment tools that use graphic facial displays representing different degrees of pain expression are used to facilitate self-report of pain in young children.

Faces Pain Scales

Faces pain scales consist of a series of line diagrams of faces with expressions of increasing distress.[34–39] Some versions have a smiling face, whereas others, notably the Faces Pain Scale and Faces Pain Scale-Revised (FPS-R), have a neutral face to represent the "no pain" end of the scale (Fig. 44.1).[39,40] Unlike the numeric scales, the faces scales do not require the concept of magnitude or seriation and can therefore be used by preschool-aged children. The Wong-Baker Faces Pain Scale has been extensively studied and its reliability and validity confirmed in children 3 to 18 years of age. Strong correlations have been reported between the Wong-Baker Scale scores and other faces scales, the Visual Analog Scale (VAS), as well as nurses' ratings based on behavior.[41–44] Data suggest that versions with the smiling face at the no-pain end of the spectrum, such as the Wong-Baker Scale, may overestimate pain because children without pain, but with distress from other sources, may be reluctant to choose the smiling face.[39] The Wong-Baker Scale was preferred by children to the numeric rating scale, the graphic rating scale, and the Color Analog Scale.[34,36,42,45] Overall, the FPS-R is the faces scale with the largest support for its validity.[46] The International Association for the Study of Pain (IASP) has the FPS-R available in dozens of languages on its website (http://www.iasp-pain.org/education).

Numeric Scales

Visual Analog Scale

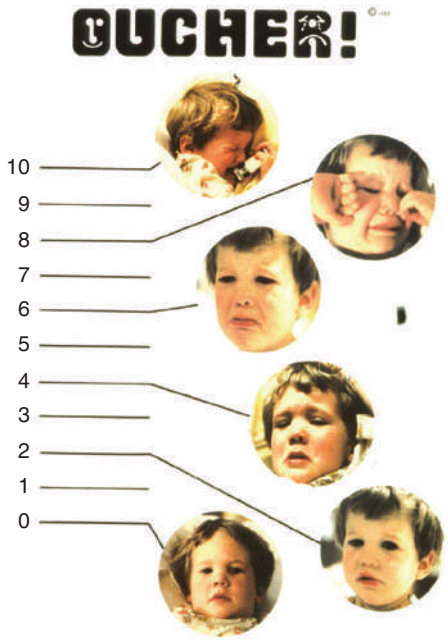
Several versions of the VAS are available, including horizontal and vertical lines, word anchors representing extremes of pain, and lines with divisions and numeric values (Fig. 44.2). When using the vertical versions of this scale, the severity of the pain

TABLE 44.1 Appropriate Pain Assessment Measures by Age Group: Self-Report, Observational/Behavior, and for the Cognitively Impaired

Self-Report Tools	Appropriate Age Groups	Comments
Faces Pain Scale	3–18 years	Simple and quick to use; extensively validated in healthy school children with postoperative and cancer pain
Oucher	3–18 years	Photographic for ≥3-year-olds, numeric 0–10 scale for ≥6-year-olds; less clinical utility and feasibility compared with other faces scales
Manchester Pain Scale	3–18 years	Panda bear faces eliminate gender and ethnic bias; tested in emergency department setting
Computer Face Scale	4–18 years	Offers option for continuous rather than categorical format; good construct validity; preferred by children over the Wong-Baker Faces Scale; further testing needed
Sydney Animated Facial Expression Scale (SAFE)	4–18 years	Animated version of Faces Pain Scale; rated by children as easiest to use; no psychometric advantage compared with other scales
Visual Analog Scale (VAS)	6–18 years	Simple and quick to use; requires the concepts of order, magnitude, and seriation (the ability to place or visualize in series); widely used across settings; preferred to other self-report tools by children ≥8 years old and adolescents
Numeric Rating Scale (NRS)	7–18 years	Simplest and most commonly used in clinical as well as research settings
Observational/Behavioral Measures		
Comfort Scale	0–18 years	Developed for use in intensive care settings; useful in mechanically ventilated children and in the postoperative setting
Face, Legs, Activity, Cry, Consolability (FLACC)	2 months–7 years	Excellent pragmatic and psychometric qualities; widely adopted in clinical and research settings; has been translated into several languages other than English
Children's Hospital of Eastern Ontario Pain Scale (CHEOPS)	1–7 years	Good psychometric properties; lengthy with inconsistent scoring among categories; cumbersome; extensively used both in clinical and research settings
Cognitively Impaired Children		
Revised FLACC	All ages	Allows for scoring individualized pain behaviors; good psychometric properties; highest clinical utility compared with the Non-Communicating Children's Pain Checklist–Postoperative Version (NCCPC-PV) and Nursing Assessment of Pain Intensity (NAPI)
Non-Communicating Children's Pain Checklist (NCCPC)	All ages	Requires 5-minute observation period; comprehensive but cumbersome; used in clinical and research setting
University of Wisconsin Pain Scale	All ages	Inconsistent scoring style compared with other clinical scoring systems; scoring style may permit flexibility but limits precision
The Pain Indicator for Communicatively Impaired Children	All ages	Useful for pain assessment in cognitively impaired children in the home setting.

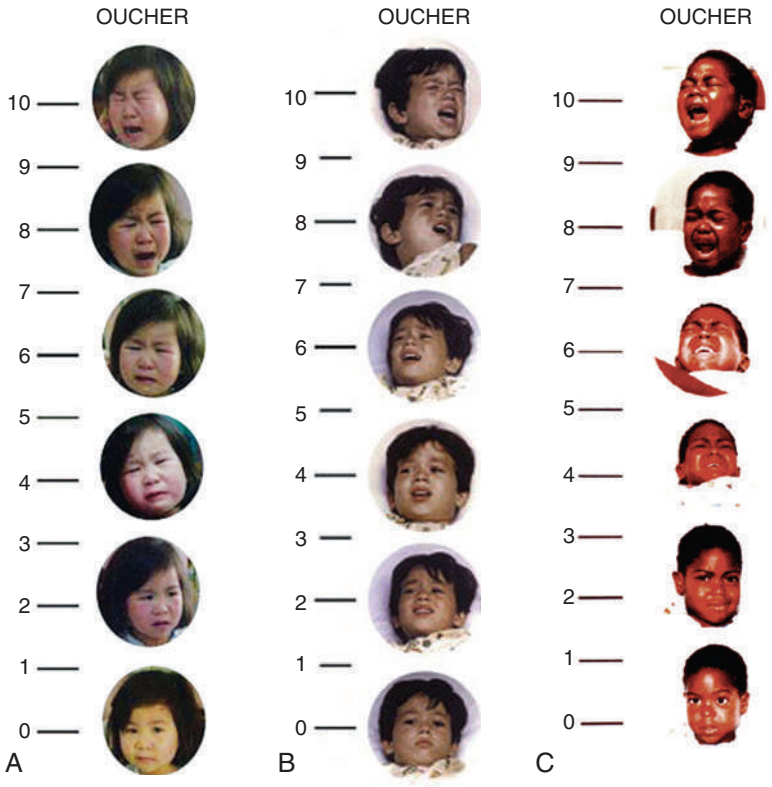
increases as one ascends the ladder. Although moderate to strong correlations have been reported between the VAS, faces pain scales, the Oucher (E-Fig. 44.1), and ethnic versions of the Oucher (E-Fig. 44.2),[47,48] the effect of user age on VAS ratings are conflicting.

Numeric Rating Scale



The Numeric Rating Scale (NRS) is the simplest and most commonly used numeric scale in which the child rates the pain from 0 (no pain) to 10 (worst pain). Its validity has been established with good correlations between NRS and FPS-R scores in children 7 to 17 years of age and NRS and VAS scores in children 9 to 17 years of age.[49] The NRS also correlates well with perceived need for analgesia, pain relief, and patient satisfaction in children.[50] An important caveat when using numeric scales is to verify the denominator that the child is using. For example, a pain score of 9 on a 0 to 100 scale would reflect mild pain and may not require treatment, whereas a score of 9 on a 0 to 10 scale would reflect severe pain that warrants aggressive treatment.

Selection Criteria



Selection of a self-report tool for a child requires careful consideration of the age and cognitive and developmental level. Fig. 44.3 depicts the percentages of children of different ages who can self-report their pain and the tools most appropriate for various age ranges. Children who are unable to use a self-report tool may be able to report their pain intensity using simple words, such as "small," "medium," and "big." However, self-reports of pain are subject to the modulating influences of many factors, including the child's previous pain experience and response to treatment, psychosocial factors, and parental preferences and influences. Consequently, in many cases, it may be necessary to complement self-reported pain scores with behavioral observations, particularly in preschool-aged children. Regardless of the tool selected, assessment of postoperative pain is greatly facilitated by the introduction of the concept of rating pain and of the tool itself during the preoperative preparation of the child.

Novel Self-Report Tools

These self-report tools use a categorical format and the static faces do not allow for "fine-tuning" of the ratings before a final assessment regarding the severity of pain is reached.[51] In recent years, there has been interest in developing computer-based self-report assessment tools that use a continuous rather than categorical format.[52]

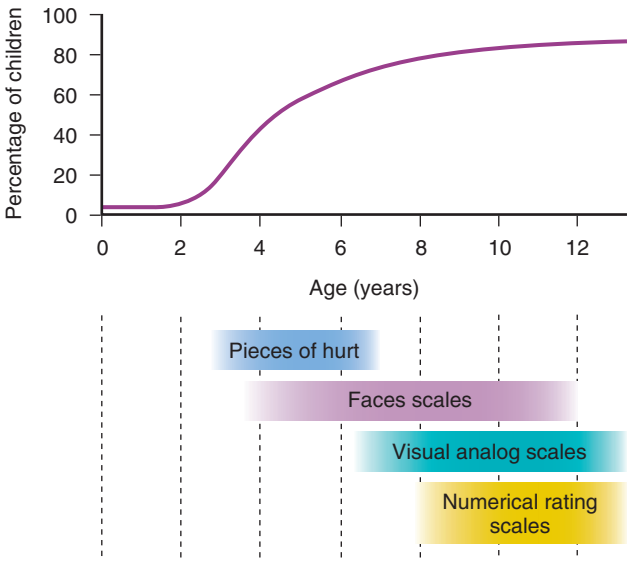

FIGURE 44.3 Self-report tools most appropriate for different age ranges. The percentage of children at different ages who can self report their pain is shown in the upper panel. The lower panel shows suitable pain measure for different ages.

The Computer Face Scale allows the child to adjust the shape of the mouth of a cartoon face from smiling to frowning and simultaneously to adjust the eyes from completely open to completely closed.[51,53] The suggested benefits of this scale include increased sensitivity (given the ability to select from a wide range of faces) and computerized storage of the results, with ready access and data display. Preliminary work with this scale has demonstrated its construct validity, and it was preferred by children over the Wong-Baker Faces Scale.[51]

The Sydney Animated Facial Expression Scale (SAFE) is an animated version of the Faces Pain Scale[54] and consists of a series of 101 faces. To administer this scale, the child pushes the left or right arrow key on a computer, causing the expression of the single face to change until it corresponds with the child's pain intensity (http://www.usask.ca/childpain/research/safe). At this point, a keystroke records a score between 0 and 100. The SAFE scale was rated to be easiest to use by children aged 4 to 16 years compared with other scales, including the Faces Pain Scale, the Color Analog Scale, and Pieces of Hurt,[55] although it offered no psychometric advantage over the other scales. Further research with this tool is needed before its role can be clearly defined.

OBSERVATIONAL-BEHAVIORAL MEASURES

Despite the availability of several age-appropriate methods for self-reporting, assessing pain in children who are unable or unwilling to self-report depends on observations of their behaviors. Five behaviors shown to be reliable, specific, and sensitive when predicting analgesic requirements are facial expression, vocalization or

cry, leg posture, body posture, and motor restlessness.[56] Variations in these behaviors have been used in several observational pain tools. Table 44.2 describes the content validity of some commonly used observational tools. Behavior checklists provide a list of pain behaviors that are marked as present or absent, and the extent of pain is estimated on the basis of the number of behaviors present at the time of the assessment.[57,58] Behavior rating scales also incorporate a rating of the intensity or frequency and duration of each behavior.[59] Global rating scales provide a rating of the observer's overall impression of the child's pain.

Children's Hospital of Eastern Ontario Pain Scale

The Children's Hospital of Eastern Ontario Pain Scale (CHEOPS), one of the earliest behavioral rating scales (Table 44.3),[60] incorporates six categories of behavior scored individually from 0 to 2 or 1 to 3 and then sums them to provide a pain score ranging from 4 to 13. Scores of 6 or less indicate no pain. Its validity and reliability for brief painful events and for postoperative pain has been well established, with good to excellent correlations with faces pain scales and the VAS.[48,61] However, the time required to complete the evaluation and inconsistent scoring among categories of the CHEOPS make it cumbersome and impractical to use in a busy clinical setting.

TABLE 44.2 Content Validity of Behavioral Pain Tools: Categories of Behavior in Pain Assessment Tools

FLACC	CHEOPS	OPS	TPPPS	Büttner/ Finke
Face	Facial expression		Facial pain expression	Facial expression
Legs	Leg movement	Movement		Leg position
Activity	Torso movement	Agitation	Bodily pain expression	Position of torso
				Motor restlessness
Cry	Cry	Cry	Vocal pain expression	Cry
Consolability	Touching of the wound	Blood pressure		Consolability
	Verbal report of pain	Verbal complaint and body language		

CHEOPS, Children's Hospital of Eastern Ontario Pain Scale; *FLAAC*, Face, Legs, Activity, Cry, Consolability scale; *OPS*, Objective Pain Scale; *TPPPS*, Toddler Preschool Preoperative Pain Scale.

TABLE 44.3 Children's Hospital of Eastern Ontario Pain Scale (CHEOPS)[a]

Item	Behavioral	Score	Definition
Cry	No cry	1	Child is not crying.
	Moaning	2	Child is moaning or quietly vocalizing silent cry.
	Crying	2	Child is crying, but the cry is gentle or whimpering.
	Scream	3	Child is in a full-lunged cry; sobbing; may be scored with complaint or without complaint.
Facial	Composed	1	Child has neutral facial expression.
	Grimace	2	Score only if definite negative facial expression.
	Smiling	0	Score only if definite positive facial expression.
Child Verbal	None	1	Child is not talking.
	Other complaints	1	Child complains, but not about pain, e.g., "I want to see mommy" or "I am thirsty."
	Pain complaints	2	Child complains about pain.
	Both complaints	2	Child complains about pain and about other things, e.g., "It hurts; I want my mommy."
	Positive	0	Child makes any positive statement or talks about others things without complaint.
Torso	Neutral	1	Body (not limbs) is at rest; torso is inactive.
	Shifting	2	Body is in motion in a shifting or serpentine fashion.
	Tense	2	Body is arched or rigid.
	Shivering	2	Body is shuddering or shaking involuntarily.
	Upright	2	Child is in a vertical or in upright position.
	Restrained	2	Body is restrained.
Touch	Not touching	1	Child is not touching or grabbing at wound.
	Reach	2	Child is reaching for but not touching wound.
	Touch	2	Child is gently touching wound or wound area.
	Grab	2	Child is grabbing vigorously at wound.
	Restrained	2	Child's arms are restrained.
Legs	Neutral	1	Legs may be in any position but are relaxed; includes gentle swimming or discrete movements.
	Squirming/kicking	2	Definitive uneasy or restless movements in the legs and/or striking out with foot or feet.
	Drawn up/tensed	2	Legs tensed and/or pulled up tightly to body and kept there.
	Standing	2	Standing, crouching, or kneeling.
	Restrained	2	Child's legs are being held down.

[a]Recommended for children 1 to 7 years old; a score greater than 6 indicates pain.

Face, Legs, Activity, Cry, Consolability Scale

The Face, Legs, Activity, Cry, Consolability (FLACC) scale was developed in an effort to improve on the pragmatic qualities of the existing behavioral pain tools by providing a simple framework for quantifying pain behaviors in children.[59] This tool includes five categories of behaviors previously found to reliably correlate with pain in young children: facial expression, leg movement, activity, cry, and consolability (Table 44.4).[56] The acronym FLACC facilitates recall of these categories, each of which is scored from 0 to 2 to provide a total pain score ranging from 0 to 10. The FLACC tool has been extensively tested and determined to have good interrater reliability and excellent validity based on changes in pain scores from before to after analgesic administration and excellent correlation with the Objective Pain Scale (OPS), the CHEOPS, the Toddler Preschool Preoperative Pain Scale (TPPPS), and good correlation with self-reported pain scores using faces pain scales.[59,61–63] The FLACC scale has been translated into several languages, including Spanish, Chinese, Swedish, French, Italian, Portuguese, Norwegian, and Thai.

Comfort Scale

The Comfort scale (Table 44.5), developed for use in an intensive care setting, consists of six behavioral and two physiologic measures, each of which has five response categories, thereby allowing detection of subtle changes in the child's distress.[64] Initial evaluation of the Comfort scale found acceptable interrater reliability and good correlations with VAS scores in 37 mechanically ventilated infants.[64] Another study evaluated the reliability and validity of the Comfort scale as a postoperative pain instrument in children after thoracic or abdominal surgery.[65] This study found good to excellent interrater agreement for all categories except respiratory response, for which there was moderate agreement. Additionally,

TABLE 44.4 The FLACC Behavioral Pain Scale

	SCORING		
Categories	**0**	**1**	**2**
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent to constant frown, clenched jaw, quivering chin
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to, distractible	Difficult to console or comfort

Each of the five categories, (F) Face; (L) Legs; (A) Activity; (C) Cry; (C) Consolability, is scored from 0 to 2, which results in a total score between 0 and 10.

TABLE 44.5 Comfort Scale

	1	2	3	4	5
Alertness	Deeply asleep	Lightly asleep	Drowsy	Fully awake and alert	Hyper-alert
Calmness or Agitation	Calm	Slightly anxious	Anxious	Very anxious	Panicky
Respiratory Response	No coughing and no spontaneous respirations	Spontaneous respiration with little or no response to ventilation	Occasional cough or resistance to ventilator	Actively breathes against ventilator or coughs regularly	Fights ventilator; coughing or choking
Physical Movement	No movement	Occasional, slight movement	Frequent slight movement	Vigorous movement limited to extremities	Vigorous movement including torso and head
Blood Pressure	Less than baseline	Consistently at baseline	Infrequent increases of 15% or more (1–3 episodes during observation period)	Frequent increases of 15% or more (>3 episodes)	Sustained increase >15%
Muscle Tone	Muscles totally relaxed; no muscle tone	Reduced muscle tone	Normal muscle tone	Increased muscle tone and flexion of fingers and toes	Extreme muscle rigidity and flexion of fingers and toes
Facial Tension	Facial muscles totally relaxed	Facial muscle tone normal; no facial muscle tension evident	Tension evident in some facial muscles	Tension evident throughout facial muscles	Facial muscles contorted and grimacing
Heart Rate	Below baseline	Consistently at baseline	Infrequent elevations of 15% or more above baseline	Frequent elevations of 15% or more above baseline	Sustained elevation of 15% or more above baseline

strong correlations between Comfort and VAS pain scores support the use of the Comfort scale as a postoperative pain assessment instrument in children.

After a systematic review of observational pain measures, the FLACC and the CHEOPS[60] scales were recommended for assessment of pain associated with medical procedures, the FLACC for postoperative pain, and the Comfort scale for pain in children in critical care.[30] Despite the extensive science supporting the use of behavioral tools, it may be difficult to separate behaviors caused by pain from those caused by other sources of distress in some children.[66] Accurate pain assessment therefore requires careful consideration of the context of the behaviors. Input from the parents or caregivers may be valuable as proxy measures, although some parents may lose objectivity in such a situation. Similarly, a regular caregiver may best assess older children with significant developmental delay. When in doubt regarding the source of distress, a trial of analgesics is appropriate and may be both diagnostic and therapeutic.

Parents' Postoperative Pain Measure

The Parents' Postoperative Pain Measure (PPPM) is a 15-item yes/no questionnaire that is completed by a parent/caregiver and designed specifically for use at home without involvement of a health professional (E-Table 44.1). A score of 6 or greater correlates with clinically significant pain. This tool has been validated for children 2 to 12 years old[58,67] and is useful for research and quality improvement projects, especially as more operations are done on an outpatient basis.[68]

LIMITATIONS OF PAIN ASSESSMENT

It remains unclear whether integration of routine pain assessment into clinical practice improves patient outcomes. A critical review of the studies that addressed this question determined that in two of six studies, children experienced a reduction in pain intensity when a standardized pain assessment tool was used; in two studies there was no change in pain intensity; and in two studies pain intensity decreased when pain assessment was combined with pain management interventions.[69] Studies that examined sustainability of the benefits over time reported conflicting results, and most studies were identified as having major methodologic problems.[70,71] Additional investigation is required to determine whether routine pain assessment has any effect on pain outcomes.

Despite the large body of evidence supporting the psychometric properties of numerous structured pain assessment tools, there remains considerable variability in the interpretation of the clinical relevance of pain scores.[33] Attempts have been made to define what range of pain scores is associated with a perceived need for medicine or what magnitude of change in pain score is associated with a perception of better or worse pain.[50,72,73] A survey of 6- to 16-year-old hospitalized children found that a median pain score of 3 on a 0-to-6 Faces Pain Scale was associated with the child's perceived need for medicine.[72] Others have reported that a 10-mm change in a 0-to-100-mm VAS score was the minimum difference whereby children in the emergency department perceived their pain to be slightly better or slightly worse.[73] In the postoperative period, children with a median pain score of 6 on a 0-to-10 NRS scale perceived the need for an analgesic, whereas those with a score of 3 felt there was "no need" for treatment.[50] In addition, children felt "a little better" or "worse" if the NRS scale changed by at least 1. Despite these findings, there was large variability and overlap in scores associated with these outcomes.

Evaluations of the effectiveness of pain treatment algorithms based on numerical pain scores have yielded conflicting results. One study reported increased prescription of opioid and nonopioid analgesics, an increased administration of nonopioids, and reduced pain scores in children who received postoperative pain treatment based on a pain score–based algorithm.[74] Children whose pain management was algorithm-based experienced more nausea, but no other adverse effects. In contrast, hospitalized adults whose pain management was based on a numerical pain treatment algorithm experienced a 2-fold increase in episodes of oversedation and a 49% increase in opioid-related adverse drug events.[75] This latter study highlights the potential for harm when numeric pain scores alone are used to guide decisions regarding pain treatment. A comprehensive approach to pain assessment that includes consideration of the child's self-reporting (when available), combined with behavioral observation and the overall clinical context, is required to direct treatment decisions.[76]

It has been suggested that the widespread adoption of a pain score as the fifth vital sign contributes to the overprescribing of analgesics and sedatives.[77] National survey data demonstrate that approximately 276,000 adolescents in the United States abused prescription pain relievers in 2015, second only to marijuana. Unfortunately, even prescription use of opioids in the teenage years has been identified as an independent risk factor for nonmedical use of opioids in early adulthood.[78] Adult data show that many patients use only a fraction of their prescribed opioid after common outpatient procedures.[79] At one author's institution (BW), quality improvement data showed that children used only 10% to 20% of the opioid prescribed to them after tonsillectomy, and data from other institutions demonstrate that significant amounts of opioid are prescribed regardless of patient age or weight.[80] These data highlight the need for procedure-specific opioid prescribing guidelines for children, as well as the importance of patient and family education regarding proper use, storage, and disposal of prescription opioids.

SPECIAL CONSIDERATIONS FOR THE COGNITIVELY IMPAIRED CHILD

Children who are cognitively impaired experience pain more frequently than cognitively intact children because of many inherent conditions, such as spasticity, muscle spasms, the need for assistive devices for positioning and mobility, and the need for invasive surgical procedures. Indeed, as many as 60% of children with cerebral palsy undergo orthopedic surgery by 8 years of age, and many of them require repeated procedures.[81] Yet both children and adults who are cognitively impaired receive fewer analgesics than those who are cognitively intact with similar painful conditions.[82,83] Barriers to effective pain management in the cognitively impaired include the complexity of pain assessment in those who cannot verbalize their pain, outdated beliefs that these children have altered or blunted pain perception, limited evidence for the safety and efficacy of analgesic regimens, and an exaggerated concern regarding opioid adverse effects, particularly respiratory depression. Although there is also evidence of cognitive impairment as an independent risk factor for needing a rescue intervention when patient-controlled analgesia (PCA) by proxy is used,[84] this may reflect challenges in thorough assessment of these patients rather than inherent differences in pain tolerance or opioid metabolism. Difficulties with pain assessment have led to the virtual exclusion of these children from clinical drug trials, leading to deficits in our knowledge of how to effectively manage their pain. A survey of clinicians who treat children who are cognitively

Does your child...[a]

- Whine or complain more than usual?
- Cry more easily than usual?
- Play less than usual?
- Not do the things she or he normally does?
- Act more worried than usual?
- Act more quiet than usual?
- Have less energy than usual?
- Refuse to eat?
- Eat less than usual?
- Hold the sore part of his or her body?
- Try not to bump the sore part?
- Groan or moan more than usual?
- Look more flushed than usual?
- Want to be close to you more?
- Take medicines when normally refuses?

[a]Answering "yes" to 6 or more questions indicates clinically significant pain.

TABLE 44.6 Revised FLACC for Pain Assessment in the Cognitively Impaired[a]

	0	1	2
Face	No particular expression or smile	Occasional grimace/frown; withdrawn or disinterested (Appears sad or worried)	Consistent grimace or frown; frequent/constant quivering chin, clenched jaw (Distressed-looking face; expression of fright or panic)
Legs	Normal position or relaxed	Uneasy, restless, tense (Occasional tremors)	Kicking, or legs drawn up (Marked increase in spasticity, constant tremors or jerking)
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense (Mildly agitated [e.g., head back and forth, aggression]; shallow, splinting respirations, intermittent sighs)	Arched, rigid, or jerking (Severe agitation head banging; shivering [not rigors]; breath-holding, gasping or sharp intake of breath; severe splinting)
Cry	No cry (awake or asleep)	Moans or whimpers, occasional complaint (Occasional verbal outburst or grunt)	Crying steadily, screams, or sobs; frequent complaints (Repeated outbursts, constant grunting)
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or "talking to"; distractible	Difficult to console or comfort (Pushing away caregiver, resisting care or comfort measures)

[a]Revised descriptors for children with disabilities shown in parentheses.

impaired identified inadequate pain assessment tools and inadequate training and knowledge of providers as significant barriers to effective pain management, despite respondents' beliefs that children who are cognitively impaired perceive pain to a similar extent as cognitively intact children.[85]

Revised Face, Legs, Activity, Cry, Consolability (r-FLACC) Observational Tool

Initial evaluation of the FLACC tool in children with cognitive impairment found a good correlation between scores assigned independently by different observers and by parent global ratings of pain.[86] Although measures of exact agreement between observers were acceptable for the face, cry, and consolability categories, measure of agreement for the legs and activity categories were less acceptable, likely because of coexisting motor impairments such as spasticity. The FLACC tool was therefore revised to incorporate additional descriptors of behaviors most consistently associated with pain in children with cognitive impairment (Table 44.6).[87] Interrater reliability for the total FLACC scores, as well as for each of the categories, improved when the evaluation included the revised FLACC (r-FLACC) in 52 cognitively impaired children. Also, good correlation among r-FLACC, parent, and child scores supported its criterion validity. r-FLACC scores were noted to decrease after an opioid was administered, supporting the construct validity of the tool. The pragmatic attributes of the r-FLACC were compared with those of the Nurses' Assessment of Pain Intensity (NAPI) and the Non-Communicating Children's Pain Checklist (NCCPC-PV) (E-Tables 44.2 and 44.3).[88] Clinicians using these tools to score pain rated the complexity as less and the relative advantage and overall clinical utility of the FLACC and the NAPI to be greater compared with the NCCPC-PV, suggesting that these tools may be more readily adopted into clinical practice.

Strategies for Pain Management

Pain is a complex phenomenon that occurs because of the transmission of nociceptive stimuli from the peripheral nervous system through the spinal cord to the cerebral cortex. Pain perception is further influenced by emotions, behavior, and previous pain experiences via multiple synapses in the limbic system, frontal cortex, and thalamus. Given the complexity of the pain mechanism, effective treatment of pain requires the use of multimodal therapies that target multiple sites along the pain pathways, as illustrated in Fig. 44.4. Multimodal treatment includes many nonpharmacologic techniques that are used more commonly for brief procedures (e.g., comfort position, cold/vibration, distraction) in addition to pharmacologic interventions (see further). *The primary goal of this approach is to minimize opioid needs and opioid-related side effects.*

Analgesics with additive or synergistic activity and different adverse effect profiles should be selected so that adequate analgesia can be provided with fewer adverse consequences. Thus pain can be treated at the peripheral level using local anesthetics, peripheral nerve blockade, NSAIDs, antihistamines, or opioids. At the spinal cord level, pain can be treated with local anesthetics, neuraxial opioids, α_2-adrenoceptor agonists, and *N*-methyl-D-aspartate (NMDA) receptor antagonists. Finally, at the cortical level systemic opioids, α_2-agonists, and voltage-gated calcium channel $\alpha_2\delta$ proteins (targets for anticonvulsants) can be used.[89] Most cases of moderate to severe pain are best treated with a multimodal approach.

The strategy for postoperative pain management is an integral part of the preanesthetic plan, so that informed consent for procedures, such as placement of peripheral or regional blocks, can be obtained (see Chapters 42 and 43). Additionally, appropriate teaching of techniques such as PCA should begin in the preoperative period. An honest discussion with the child that, although some discomfort is inevitable, every effort will be made to minimize pain after surgery, decreases the anxiety related to the perioperative experience. This, together with the use of nonpharmacologic techniques, may even reduce the need for opioids and other analgesics. Selection of an analgesic regimen requires careful consideration of many factors, including scope and requirements of the surgical procedure, age and cognitive abilities of the child, the child's previous pain experience and response to treatment, underlying medical conditions that might alter the response to pain medications, and child and family preferences. The goal should be for the child to emerge from anesthesia in reasonable comfort, because it is generally easier to maintain analgesia in a pain-free child than to achieve analgesia in a child with severe pain. Fig. 44.5 presents a flowchart describing strategies for assessment and management of acute postoperative pain in a child.

E-TABLE 44.2 Noncommunicating Children's Pain Checklist: Postoperative Version

Vocal	Social
Moaning, whining, whimpering (fairly soft)	Not cooperating; cranky, irritable, unhappy
Crying (moderately loud)	Less interaction, withdrawn
Screaming or yelling (very loud)	Seeks comfort or physical closeness
A specific sound or vocalization for pain	Difficult to distract; not able to satisfy or pacify
Facial	**Activity**
Furrowed brow	Not moving, less active, quiet; jumping around, agitated, fidgety
Change in eyes, including squinting, eyes opened wide, eyes frown	
Turn down of mouth, not smiling	
Lips pucker up, tight, pout, or quiver	
Clenches or grinds teeth, chews, thrusts tongue out	
Body and Limbs	**Physiologic Signs**
Floppy	
Stiff, spastic, tense, rigid; gestures to or touches part of body that hurts; protects, favors, or guards part of body that hurts; flinches or moves away part of body that hurts; moves in specific way to show pain	Shivering
	Change in color, pallor; sweating, perspiring; tears
	Sharp intake of breath, gasping; breath-holding

SURGICAL CONSIDERATIONS

The scope and requirements of the surgical procedure, as well as specific postoperative issues, should be discussed with the surgical team before choosing an analgesic regimen, particularly if a regional technique is planned. For example, the site of placement of an epidural catheter and choice of epidural solution will differ in a child with a vertical midline incision from a child with a transverse suprapubic incision. With certain procedures, an epidural catheter may intrude into the surgical field or access to the catheter site in the postoperative period may be obscured by a cast or dressing. In such cases, the catheter may be tunneled subcutaneously away from the surgical field. Alternatively, one or more epidural catheters may be placed under direct vision by the surgeon at the end of the procedure (e.g., spinal fusion or selective dorsal rhizotomy).[90] Postoperative pain is managed using an infusion of local anesthetic and/or opioid solutions through the catheter.[91] Painful muscle spasms after certain procedures are often ameliorated by continuous regional analgesia.[91–93] This effect is partly related to the density of blockade and may also require supplemental oral or parenteral benzodiazepines if the block alone is inadequate. Refractory spasms of the bladder, which can be quite problematic after some surgeries (e.g., ureteral reimplantation), can also be effectively treated with NSAIDs (e.g., ketorolac) or anticholinergics.[94] Intravesical bupivacaine has also been used to manage bladder spasm, although close attention must be paid to dosing to avoid toxicity.[95,96] Epidural blockade may favorably alter diaphragmatic mechanics after thoracotomy and upper abdominal surgery. This effect is likely a result of the motor blockade of the intercostal muscles and alteration in the resting length of the diaphragm and is not solely a result of reversal of diaphragmatic inhibition.[97–100] However, it remains uncertain whether analgesia alone, achieved by systemic opioids or central neuraxial blockade, diminishes postoperative diaphragmatic inhibition or significantly improves postoperative pulmonary function.[101,102] Effective analgesia, however, does improve child compliance with measures such as deep breathing and early mobilization, thereby reducing the incidence of postoperative complications.[103]

Child-Related Considerations

Age and Cognitive Abilities

Analgesic techniques, such as infiltration of the wound with local anesthetics, peripheral nerve blocks, or regional blockade that minimize the use of opioids and central respiratory depressants, may be ideal for preterm or very young infants with impaired central respiratory drive.[104,105] Acetaminophen can be a useful adjunct, because when used within its recommended dose range, it has a large therapeutic window with few untoward effects. Although the judicious use of opioids is not contraindicated,

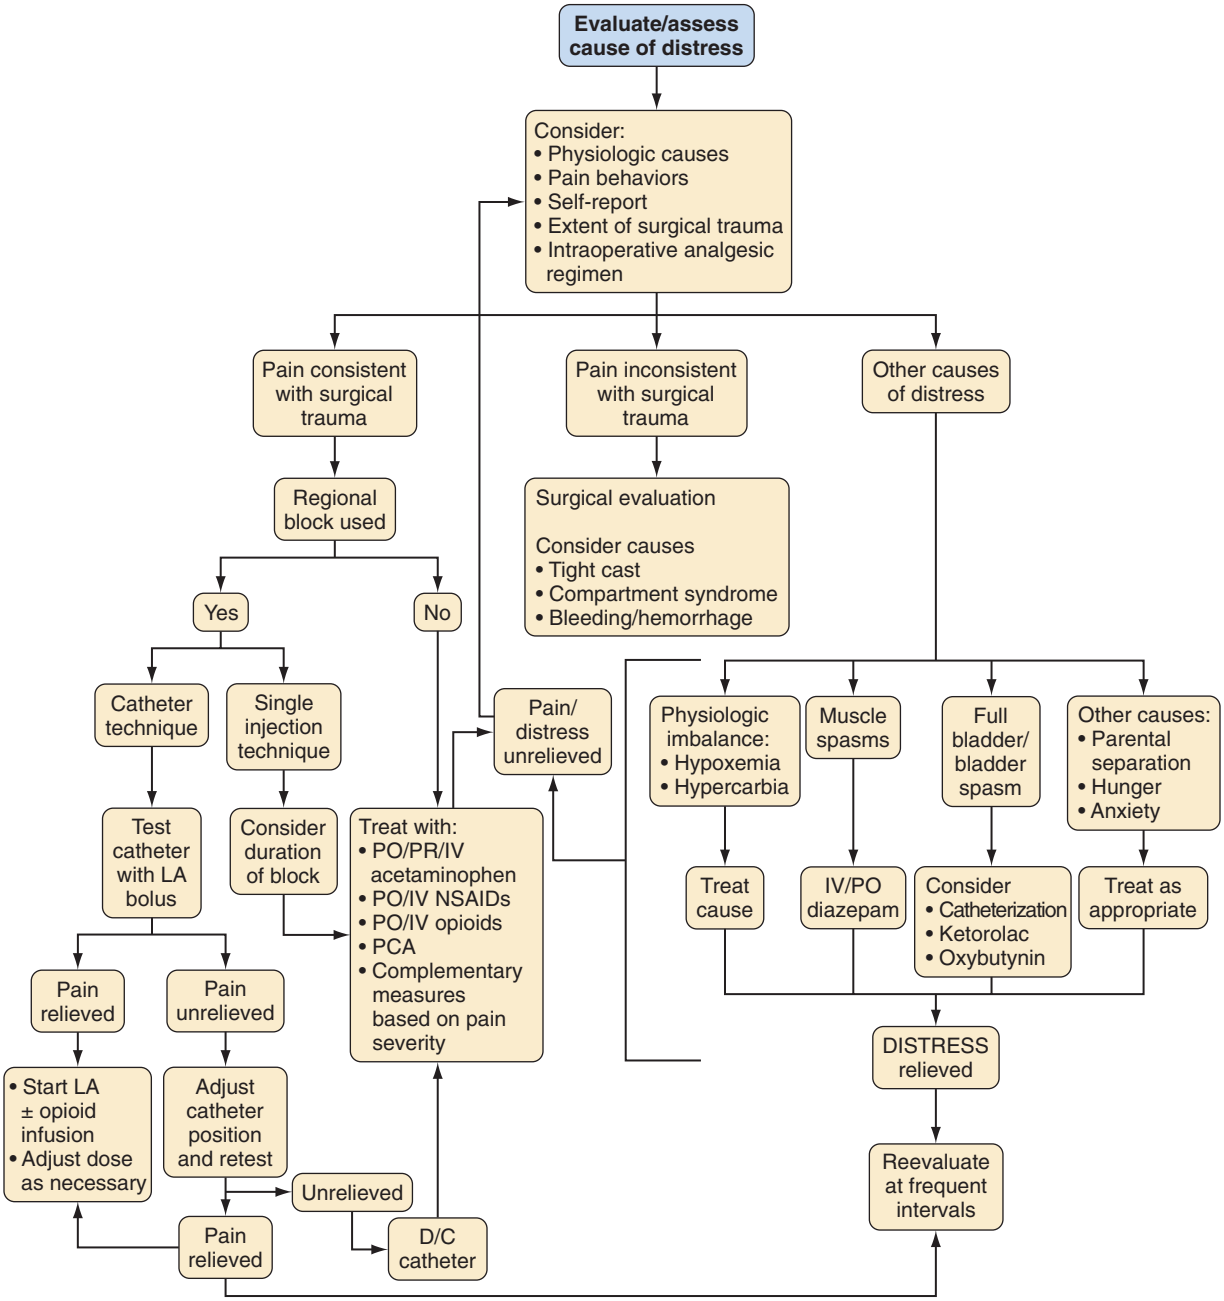

FIGURE 44.5 Flowchart for assessment and management of acute postoperative pain in a child. *D/C*, discontinue; *IV*, intravenous; *LA*, local anesthetic; *NSAIDs*, nonsteroidal antiinflammatory drugs; *PCA*, patient-controlled analgesia; *PO*, orally; *PR*, per rectum.

preterm or term infants younger than 1 month of age who receive these medications require careful observation and monitoring to detect respiratory depression.[106] The use of local anesthetics in infants younger than 6 months of age also requires more careful attention to dose because decreased protein binding of local anesthetics puts them at increased risk for toxicity.[107]

Older infants and toddlers who are expected to experience moderate to severe pain may be adequately treated with oral opioids when oral intake resumes. Alternatively, low-dose continuous opioid infusions, nurse-controlled analgesia (NCA),[108] or regional blockade may be required in those undergoing extensive surgery. Nonpharmacologic techniques that focus on distraction, such as child-life therapy and the presence of a comforting parent, can augment the analgesic therapy.

Preschool- and school-aged children have greater fears and better understanding of the postoperative experience than do their younger counterparts. Most cognitively intact children 7 years of age or older are able to understand the concept of PCA, which may help to give a sense of control back to the child during a period in which all other aspects of control are removed.[109] Such issues of control and dependency assume even greater importance in adolescents; allowing them to participate in decision making will contribute to the success of any analgesic technique.[109] Regional techniques are excellent for providing analgesia in all age groups

and are associated with a reduced incidence of adverse effects compared with systemic opioids (e.g., nausea, vomiting, excessive sedation, dysphoria, and respiratory depression). Children with significant developmental delay require special consideration of their physical disability, as well as cognitive abilities, although in most cases the pharmacologic actions of the drugs are not altered.

Regardless of the child's age, a detailed history regarding the child's previous pain experience, analgesic history, response to treatment, and adverse effects from previous analgesic regimens should be carefully considered when selecting a pain management technique. An opioid-naive child undergoing surgery for the first time requires smaller doses of opioids for a shorter duration compared with a child with chronic pain who has developed opioid tolerance because of long-term or repeated opioid use. Analgesic selection should also be modified based on the effectiveness of analgesics for that particular child in the past. As the use of genomic testing becomes more available and clinically feasible, identification of target polymorphisms, particularly in the cytochrome P450 enzyme system, may be used to tailor drug selection and dosing.

Pharmacologic Treatment of Pain

NONOPIOID ANALGESICS

Nonopioid analgesics are used as sole agents for mild pain and as important adjuncts for multimodal treatment of moderate to severe pain. Although most nonopioid analgesics produce dose-dependent responses, they are limited by a ceiling effect in the analgesia achieved—that is, larger doses of the medication provide no additional analgesia. Hence, more severe pain is resistant to therapy from these medications alone.[110] Ideally, nonopioid medications (Table 44.7) are delivered on a scheduled basis for at least the first few days postoperatively, while opioids are available pro re nata (PRN) for breakthrough pain.

Acetaminophen

Acetaminophen is the most common antipyretic and nonopioid analgesic used in children. Despite years of study, the predominant mechanism of its analgesic action remains unclear. It may exert its analgesic effects by blocking central and peripheral prostaglandin synthesis, reducing substance P–induced hyperalgesia, and modulating the production of hyperalgesic nitric oxide in the spinal cord.[111–113] In addition, acetaminophen might produce analgesia via activation of descending serotonergic pathways.[114–116] One putative site of action may be inhibition of prostaglandin H_2 synthetase at the peroxidase site.[115] Effective analgesia and antipyresis have been described with plasma concentrations of 5 to 20 μg/mL[117–121]; a target effect-site (similar to cerebrospinal fluid) concentration of 10 μg/mL reduces pain after tonsillectomy by 3.6/10 pain units.[122] The total daily dose of acetaminophen via any route is age- and weight-based, but should not exceed 75 mg/kg for children, 60 mg/kg for neonates 32–44 weeks postconceptual age, and 40 mg/kg for preterm neonates 28–32 weeks.

The recommended dose for oral administration is 10 mg/kg every 4 hours or 15 mg/kg every 6 hours, or a total daily dose of 60 mg/kg per day, which is less than the upper daily limit of 75 mg/kg. Acetaminophen has a wide margin of safety when administered in the recommended therapeutic dose range. However, hepatotoxicity has been reported with doses only slightly above the recommended dose, suggesting that acetaminophen may have a narrow therapeutic index in some children.[123,124] Because of these reports and on the advice of a U.S. Food and Drug Administration panel, the manufacturers have reduced the maximum daily dose to 3 g. Acetaminophen is available in a wide variety of formulations, alone or in combination with decongestants, for oral use in a variety of cold remedies, and with opioids for the treatment of moderate to severe pain. There are currently more than 600 over-the-counter acetaminophen-containing products, increasing the risk of an overdose because children may take more than one formulation that contains the drug. Frequent review of medications and parental education is needed to minimize the risk of overdose. In the past, pediatric liquid formulations of acetaminophen as in infant drops were commonly supplied in larger concentrations than that in elixirs, resulting in dosing errors. As a result, the 80-mg/mL concentration has been removed from the U.S. market by the manufacturer, and liquid formulations have been standardized to 32 mg/mL. This concentration equals approximately 0.5 mL/kg of acetaminophen if given as a 15-mg/kg dose. Since both gastric fluid volume and pH are unchanged after liquid acetaminophen (40 mg/kg of a 50 mg/mL elixir, 0.8 mL/kg) administered orally 90 minutes before induction of anesthesia, it is feasible to use this preoperatively. Whether these results are applicable to acetaminophen that is administered closer to the time of induction is not known.[125]

Intravenous (IV) formulations of paracetamol (acetaminophen) have been used in Europe and Australia for many years and are now available in the United States. IV acetaminophen is available as a 10-mg/mL solution and should be infused over ~15 minutes in a dose of 12.5 mg/kg every 4 hours or 15 mg/kg every 6 hours, with a total daily limit of 75 mg/kg (although at the time of writing, the IV manufacturer continues to recommend a 4 grams per day

TABLE 44.7 Oral Dosing Guidelines for Commonly Used Nonopioid Analgesics

Medication	Individual Dose for Children <60 kg (mg/kg)	Individual Dose for Children ≥60 kg (mg)	Dosing Interval (hours)	Maximum Daily Dose for Children <60 kg (mg/kg)	Maximum Daily Dose for Children ≥60 kg (mg)
Acetaminophen	10–15	650–1000	4–6	75[a]	3000
Ibuprofen	5–10	400–600	6	40	2400
Naproxen	5–6	250–375	12	10	1000
Diclofenac	1	50	8	3	150
Ketorolac[b]	0.5	30	6–8	2	120
Tramadol	1–2	50	6	8	400

[a]See text for new age-related dosing.
[b]Ketorolac should be administered for a maximum of 5 days or 20 doses up to 15 mg per dose for children <60 kg or 30 mg per dose for children >60 kg.
Modified from Berde CB, Sethna NF. Analgesics for the treatment of pain in children. *N Engl J Med.* 2002;347(14):1094–1103; and World Health Organization. *World Health Organization Guidelines on the Pharmacological Treatment of Persisting Pain in Children with Medical Illnesses.* WHO: Geneva, Switzerland; 2012.

limit, unlike the recommendations for oral acetaminophen). In neonates between 32 and 44 weeks postconception age, a loading dose of 20 mg/kg should be followed by 10 mg/kg every 6 hours (every 12 hours in 28–31 weeks postconception age).[126] Each dose of IV acetaminophen must be documented in a timely manner to avoid overdoses from multiple dosing; several cases of frank overdoses have occurred in young infants who received excessive doses of IV acetaminophen on the ward.[124,127–129] Dosing recommendations for premature and full-term neonates continues to be an active area of research, and one study has shown weight to be a better predictor of individual pharmacokinetics than either postconception or gestational age.[130]

After IV administration of acetaminophen, analgesic onset occurs within 15 minutes and antipyresis within 30 minutes.[131,132] IV acetaminophen rapidly penetrates the blood-brain barrier, yielding detectable concentrations in the cerebrospinal fluid (CSF) within 5 minutes of administration, and peak CSF concentrations within 57 minutes after injection (compared with 2 to 3 hours after rectal or oral administration). This explains the fast onset of its analgesic and antipyretic effects.[133] A large multicenter trial reported that 1 gram of IV paracetamol and 2 grams of IV propacetamol (equivalent to 1 gram acetaminophen) provided superior analgesia with a reduced need for morphine compared with placebo in adults after lower extremity joint replacement.[134] The propacetamol group experienced a greater incidence of local skin reactions and pain on injection compared with the IV paracetamol group. A controlled randomized trial reported that both rectal acetaminophen, 40 mg/kg, and IV acetaminophen, 15 mg/kg, administered after induction of anesthesia in children undergoing adenotonsillectomy provided good analgesia for the first 6 hours after surgery.[135] However, children who received acetaminophen rectally had a greater duration of analgesia and did not require rescue analgesia as early as those in the IV group.[135] This is attributable to the slow absorption of rectal acetaminophen, causing sustained effective concentrations (see also Fig. 4.2).[136] When compared with oral acetaminophen, there was evidence of lower intraoperative opioid requirements (again attributable to differing time to peak effect-site concentration), but no difference in postoperative opioid consumption in young children undergoing cleft palate repair when children received scheduled acetaminophen via the oral or IV route.[137]

Slow and unpredictable absorption of acetaminophen after rectal administration, however, results in variable blood concentrations, with peak concentrations reached between 60 and 180 minutes after administration (Fig. 4.2).[120,138,139] This unpredictability was illustrated in a series of studies from the same group of investigators examining opioid-sparing with rectal and IV acetaminophen in infants undergoing major abdominal and thoracic surgery. In the rectal study, no opioid-sparing effect was detected, and plasma concentrations of acetaminophen varied 50-fold among patients.[140] In a follow-up study in the same population using IV acetaminophen, opioid consumption was reduced by 60% and the frequency of apnea was also reduced.[141] In children undergoing orthopedic surgery, a loading dose of 40 mg/kg rectal acetaminophen followed by 20 mg/kg every 6 hours yielded serum concentrations of 10 to 20 μg/mL in half of the patients, with no evidence of accumulation over a 24-hour period.[138] This dosing scheme is now the one most commonly recommended when the rectal route is used, but it should be noted that scheduled dosing with this scheme would result in a dose of 80 mg/kg per day (or 100 mg/kg on the first day with the loading dose). Contrary to previous assumptions, acetaminophen is relatively evenly distributed in most suppositories, allowing them to be split to achieve a desired dose, although accuracy of dosing is problematic.[142]

In conclusion, acetaminophen has opioid-sparing potential with very few adverse effects and a low risk of toxicity with appropriate dosing. The oral and IV routes produce equivalent analgesia when differences in onset time are considered. The rectal route should be considered a "last resort" because of unpredictable absorption and limited dosing options. Financial considerations have limited the routine use of IV acetaminophen at many centers in the United States.[143]

Nonsteroidal Antiinflammatory Drugs

NSAIDs provide excellent analgesia for mild to moderate pain resulting from surgery, injury, and disease. Their principal mechanism of action is via inhibition of the enzyme prostaglandin H_2 synthetase at the COX site, causing a reduction in the production of prostaglandins at the site of tissue injury and attenuation of the inflammatory cascade. In addition to their peripheral effects, the NSAIDs have also been shown to exert a direct spinal action by blocking the hyperalgesic response induced by activation of spinal glutamate and substance P receptors.[144] Decreased production of leukotrienes, activation of serotonin pathways, and inhibition of excitatory amino acids, NMDA-mediated hyperalgesia, and central inhibition of prostaglandin biosynthesis have been proposed as additional mechanisms of action.[145,146] The COX-1 enzyme is present in the brain, gastrointestinal tract, kidneys, and platelets and is expressed constitutively. It preserves gastric mucosal integrity and function, platelet aggregation, and renal perfusion. COX-2 expression is induced by inflammation or tissue injury. Selective COX-2 inhibitors reduce inflammation but have less effect on gastric mucosal function and have fewer effects on platelet aggregation, thereby resulting in fewer adverse effects. Their deleterious effects on renal perfusion, however, are no different than the nonselective COX drugs, because COX-2 is constitutively expressed in renal tissues and may be involved in prostaglandin-dependent renal homeostatic processes.[147] The risks of renal toxicity increase in the presence of hypovolemia, cardiac failure, preexisting renal dysfunction, or with the concurrent use of other nephrotoxic drugs. Reports of thrombotic cardiovascular and CNS events after both long-term and short-term use in adults led to withdrawal of two of the COX-2 inhibitors, rofecoxib and valdecoxib, from the market[148,149]; the risk of these agents causing thrombotic complications in children remains unknown. Most pediatric studies have evaluated the use of nonselective COX medications. In adult studies, COX-2 inhibitors have generally, but not always, produced analgesia roughly equivalent to that of traditional NSAIDs.

Ibuprofen, one of the oldest orally administered NSAIDs, has been used extensively for treatment of fever and pain related to surgery, trauma, arthritis, menstrual cramps, and sickle cell disease. A large, controlled, randomized, double-blind study reported a greater decrease in VAS pain scores with ibuprofen than with acetaminophen or codeine in children presenting to the emergency department with acute pain after musculoskeletal trauma.[150] Additionally, more children who received ibuprofen had VAS scores less than 30 on a 0-to-100-mm VAS scale than in the other two groups. The recommended dose of ibuprofen is 5 to 10 mg/kg every 6 hours. Like acetaminophen, ibuprofen is available in a variety of formulations and concentrations, placing children at risk for an overdose. For pediatric use, ibuprofen is available as follows:

- Concentrated drops containing 50 mg ibuprofen in 1.25 mL
- Oral suspension containing 100 mg of ibuprofen in 5 mL

- Junior Strength chewable tablets or caplets containing 100 mg of ibuprofen in each

Diclofenac provides effective analgesia after minor surgical procedures in children. It is available only as an oral tablet in the United States, but it is available as a suppository and in the injectable form in several countries. The pediatric dose of diclofenac is 1 mg/kg every 8 hours orally, 0.5 mg/kg rectally, and 0.3 mg/kg IV.[151] The oral and rectal doses reflect bioavailabilities of 0.36, 0.35, and 0.6 for suspension, dispersible tablets, and suppository forms, respectively. When diclofenac was administered rectally, the relative bioavailability was greater and the peak concentration was reached earlier than after enteric-coated tablets administered orally.[152] Children who received diclofenac experienced analgesia comparable to those who received caudal bupivacaine or IV ketorolac for inguinal hernia repair.[153–155] In children undergoing tonsillectomy and/or adenoidectomy, diclofenac yielded superior analgesia with less supplemental opioid dosing, less nausea and vomiting, and earlier resumption of oral intake compared with acetaminophen.[156,157] Although there are occasional reports of increased bleeding and restlessness in the recovery room in children who received diclofenac compared with those who had received papaveretum during tonsillectomy,[158] a Cochrane review established that NSAIDs did not cause any increase in bleeding that required a return to the operating room (OR) for children. However, when examining the bleeding risk with different types of NSAIDS, ketorolac (but not other NSAIDS) was associated with a statistically significant increase in bleeding after tonsillectomy.[159,160] Overall, there was less nausea and vomiting with NSAIDs compared with alternative analgesics, suggesting their benefits outweigh their negative aspects. A prospective, randomized trial assigned 91 children with sleep-disordered breathing to acetaminophen with ibuprofen or morphine for analgesia after tonsillectomy. There was an almost 4-fold increase in the number of desaturation events (from preoperative levels) during the first postoperative night in the morphine group, and a decrease in the number of desaturation events during the same period in the ibuprofen group. Overall, the pain scores in the morphine group were less, but there was no statistically significant difference. The study was terminated early as a result of preliminary results and an incident of respiratory depression at home, resulting in admission to the pediatric intensive care unit (ICU) in the morphine group.[161]

Ketorolac, indomethacin, and ibuprofen are the only injectable NSAIDs available in the United States. Indomethacin is the most commonly used NSAID used for closure of patent ductus arteriosus in preterm neonates. The IV formulation of ibuprofen is labeled for children and adults in the United States. Ketoprofen, parecoxib, and diclofenac are other injectable NSAIDs that are available outside the United States. A large multicenter study compared the risks of serious adverse events from IV ketorolac, ketoprofen, and diclofenac in more than 11,000 adults undergoing major surgery.[162] The results indicated that 1.4% of adults experienced a serious adverse outcome, including surgical site bleeding (1%), death (0.17%), severe allergic reactions (0.12%), renal failure (0.09%), and gastrointestinal bleeding (0.04%), with no differences in outcomes among the groups. Similar large-scale studies are not available for children, but one placebo-controlled study of 161 children undergoing tonsillectomy who received IV ibuprofen (10 mg/kg IV) (n = 82) demonstrated an opioid-sparing effect without an increase in bleeding,[163] consistent with the findings of larger reviews.[160]

Ketorolac has been shown to provide postoperative analgesia similar to opioids in children of all ages.[164–167] Its benefits include lack of opioid adverse effects (respiratory depression, sedation, nausea, and pruritus), making it an attractive choice for the treatment of postoperative pain. However, in common with all NSAIDs, it carries risks of platelet dysfunction, gastrointestinal bleeding, and renal dysfunction. Ketorolac (1 mg/kg) given to 18 preterm and term neonates undergoing painful procedures in the OR or the neonatal ICU,[165] revealed reduced pain scores (Neonatal Infant Pain Scale) with no incidents of systemic or local bleeding and no hematologic, hepatic, or renal complications (note that this dose is twice the usually recommended dose of 0.5 mg/kg). Similarly, no adverse effects on surgical drain output, renal or hepatic function tests, or oxygen saturation after major surgery were noted in 37 infants and toddlers between 6 and 18 months of age.[168] Children in that study received continuous morphine infusions postoperatively, confounding the evaluation of the analgesic efficacy of ketorolac. In single dose studies, the pharmacokinetics (PK) of ketorolac in infants and small children (2–18 months of age) appear to be homogeneous and show a relatively rapid elimination of the analgesic S enantiomer, with slower clearance of the R enantiomer.[168,169] Finally, ketorolac has been used to supplement opioid analgesia, with no increase in renal or bleeding complications in infants and children after open heart surgery.[170–172] Nevertheless, because ketorolac can reduce renal blood flow, many recommend that its course be limited to 48 to 72 hours, and that renal function be checked if a course of administration greater than 72 hours is required.[168,169]

Another contentious issue regarding NSAIDs relates to their effects on bone healing and their use in children undergoing spinal fusion. Prostaglandins play an integral role in bone metabolism and significantly influence bone resorption and formation; however, their effects on bone formation predominate. NSAIDs inhibit the formation of prostaglandins, thereby raising the concern that they could promote nonunion after spinal fusion. Studies in rabbits and some studies in adults have reported a greater incidence of nonunion or pseudarthrosis, particularly with the use of large doses of ketorolac.[173,174] However, no differences in curve progression, hardware failure, pseudarthrosis, or need for reoperation have been found in children and adolescents who received ketorolac in the immediate postoperative period compared with those who did not.[175–177] Of note, the majority of the pediatric data are from otherwise healthy children with idiopathic scoliosis, making it problematic to extrapolate these data to children with comorbidities or those with neuromuscular scoliosis. There is no unique advantage of the IV route with NSAIDs. There is also no evidence that IV ketorolac is a more potent analgesic than comparable (i.e., equipotent) doses of a number of other NSAIDs administered by oral or rectal routes.[178]

A meta-analysis of the use of NSAIDs for postoperative pain that included 27 studies compared 567 children who received NSAIDs with 418 children who did not.[179] The coadministration of NSAIDs and opioids during the perioperative period decreased opioid requirement in the postanesthesia care unit (PACU) and the first 24 hours after surgery, decreased pain intensity in the PACU, and reduced postoperative nausea and vomiting (PONV) during the first 24 hours postoperatively. Although NSAIDS appear to be more effective than acetaminophen for acute pain,[180] modeling studies show that combination therapy prolongs the duration of analgesia of both drugs.[181] Many studies have also demonstrated the benefits of scheduled combination therapy in children, often performing better than either drug alone.[182,183] Therefore these two medications are part of the World Health Organization global

guidelines on treating pain in children[184] and should serve as the foundation of a safe, effective, and opioid-sparing analgesic regimen.

Tramadol

Tramadol is a synthetic analog of codeine that exerts its analgesic properties by two complementary mechanisms. One of its metabolites has a weak affinity for the μ opioid receptor with no affinity for the δ or the κ receptors. In addition to its mild opioid effects, it also inhibits serotonin and norepinephrine uptake. Its main advantages over opioids include reduced incidences of respiratory depression, sedation, nausea, and vomiting. However, tramadol undergoes metabolism via the CYP2D6 pathway, and there are concerns that "ultrametabolizers" could produce excessive amounts of the potent *O*-desmethyltramadol metabolite, a metabolite with 200-fold greater affinity for μ receptors than tramadol.[185,186] A common formulation of oral tramadol is an elixir in a concentration of 100 mg/mL, a formulation that is easily inadvertently overdosed. This concentrated dose should be administered as "drops," but some have mistakenly administered this concentration in milliliters, resulting in an overdose. To preclude such overdoses, many jurisdictions have limited the concentration of oral tramadol to 5 to 10 mg/mL. Toxicity occurs after administration of 7 to 10 mg/kg of tramadol.[187] Other adverse effects associated with its use include nausea and vomiting (9%–10% of cases), pruritus (7%), and rash (4%).[188] It is reported to cause dizziness, and its use has been associated with seizures. Tramadol is available only in tablet form alone or in combination with acetaminophen in the United States. However, it is available in a liquid formulation (see earlier text), as a suppository, and as an injectable solution in other countries, allowing for greater flexibility of dosing. Therefore it has been used to provide analgesia by many routes, including oral, rectal, IV (including PCA devices), epidural, and by local infiltration.

Tramadol is used for postoperative pain treatment in children undergoing ambulatory surgery and has also been used when transitioning from IV opioids to oral analgesics. Two doses of tramadol (1 mg/kg and 2 mg/kg orally) were compared in children who were being transitioned from morphine PCA. Children who received 2 mg/kg required fewer supplemental analgesics with no difference in adverse effects compared with those who had received 1 mg/kg.[188] Tramadol, 2 mg/kg IV, produced similar analgesia and sedation, with fewer episodes of oxygen desaturation compared with morphine 0.1 mg/kg IV, in children with obstructive sleep apnea undergoing adenotonsillectomy.[189] Tramadol has also been found to produce a similar analgesic effect as that of ilioinguinal and iliohypogastric nerve blocks in children undergoing herniorrhaphy.[190] The tramadol group, however, experienced a greater incidence of nausea and vomiting. The incidence of PONV can be reduced by using a slow-release oral formulation; this reduces early peak concentrations and allows sustained plasma concentrations. Tramadol PCA has also been found to provide adequate analgesia with less sedation, earlier awakening, and earlier extubation in children undergoing atrial or ventricular septal defect repair compared with those who received morphine via PCA.[191]

Tramadol has also been effective when administered via the neuraxial route. Caudal tramadol (2 mg/kg) produced reliable postoperative analgesia comparable with that produced by caudal morphine (30 μg/kg) in children undergoing inguinal hernia repair.[192] No additional pain medications were required in the first 24 hours in more than 90% of children in each group. Rigorous drug-specific neurotoxicity studies, however, are lacking, and therefore this route of administration is not recommended until such data are available and confirmed. Another study compared the analgesic efficacy of 2 mg/kg tramadol administered IV or by peritonsillar infiltration in children undergoing adenotonsillectomy.[193] Both groups experienced excellent analgesia in the first hour. However, the local infiltration group experienced more prolonged analgesia and required fewer rescue doses of acetaminophen compared with the IV group. Overall, tramadol appears to be an analgesic of medium potency with a low incidence of adverse effects that may be used alone for mild to moderate pain and for its opioid-sparing effect in children with severe pain.

Ketamine

There has been increasing interest in the use of ketamine, an NMDA-receptor antagonist, in the treatment of both chronic and acute pain. Its professed benefits include an opioid-sparing effect, avoidance of opioid tolerance, prevention of central sensitization and wind-up, mitigation of opioid-induced hyperalgesia, and provision of synergistic analgesia in multimodal regimens by virtue of its own antinociceptive properties. Case series in children with intractable pain resulting from advanced stages of cancer have reported reduction in opioid requirement, decreased opioid adverse effects, improvement in pain control and function, and increased ability to interact with their families.[194–196] Ketamine is also very popular as a single agent for both analgesia and sedation for burn care.[197]

Studies evaluating the use of ketamine alone or in combination with opioids for acute postoperative pain in children have yielded equivocal results. In one study, children undergoing tonsillectomy who received IV ketamine 0.5 mg/kg after induction or at the end of surgery experienced reduced pain scores and required fewer rescue analgesics compared with those who received placebo.[198] All children in this study received a standardized analgesic regimen, including rectal diclofenac before the start of surgery and oral acetaminophen at scheduled intervals postoperatively. Another study reported reduced pain scores and reduced requirement for rescue analgesics in children who received ketamine as a bolus dose and by infusion that began before the start of a tonsillectomy, compared with those who received a single bolus dose of ketamine at the end of surgery.[199] Intramuscular (IM) ketamine 0.5 mg/kg has also produced equivalent analgesia in terms of similar pain scores and need for rescue analgesics compared with IM morphine 0.1 mg/kg as sole analgesics for tonsillectomy.[200] Other studies have found no such benefits when ketamine was compared with placebo for tonsillectomy, urologic, and orthopedic surgery.[201–204]

A meta-analysis of 35 randomized controlled trials compared 567 children who received ketamine as an adjuvant analgesic by a variety of routes for a variety of surgical procedures with 418 who did not receive ketamine.[205] Although the use of ketamine was associated with reduced pain intensity in the PACU and there was a reduced need for nonopioids, there was no opioid-sparing effect. A systematic review of 37 studies included 4 in children, 2 of which demonstrated beneficial effects of ketamine administered as an adjuvant analgesic and 2 of which found no benefits.[206] The investigators could draw no conclusions regarding the use of ketamine as an adjuvant analgesic. The use of ketamine in all the previous studies was associated with only a few mild and self-limiting adverse effects. Further investigation is needed to evaluate the benefits of low-dose ketamine for acute postoperative pain before its routine use can be recommended.

Gabapentin

Gabapentin is an anticonvulsant that exhibits an analgesic effect through binding to presynaptic calcium-channels and modulating the release of glutamate and other excitatory neurotransmitters. It is available in 100-, 300-, 600-, and 900-mg tablets as well as a 50-mg/mL oral solution. Although it has been studied most extensively for chronic neuropathic pain, there is substantial evidence in adults for its analgesic effects on acute pain,[207] and it is also useful in preventing PONV.[208] There is comparatively less evidence for its benefit in pediatric acute pain, but a prospective, randomized study of children undergoing posterior spinal fusion demonstrated a significant reduction in morphine consumption in the early postoperative period when given as a preoperative loading dose of 15 mg/kg followed by 5 mg/kg three times daily.[209] Another study using only a single preoperative dose did not show an opioid-sparing effect.[210] Gabapentin does not cause respiratory depression, but sedation is a common adverse effect, which may confound patient assessment when coadministered with opioids.

OPIOID ANALGESICS

Opioids are indicated for moderate to severe pain after surgery or trauma, for acute painful crises such as in sickle cell disease, as well as for chronic painful conditions such as cancer. Opioids mimic the effects of endogenous ligands known as endorphins, exerting their effects by binding to specific opioid receptors located at presynaptic and postsynaptic sites in the brain, spinal cord, and peripheral nerve cells. There are four opioid receptors in the CNS: μ, κ, δ, and σ.[211–213] When these receptors are activated, they inhibit neurons by decreasing the release of excitatory neurotransmitters from presynaptic terminals. The μ receptors are further subdivided into μ_1 receptors, responsible for supraspinal analgesia and physical dependence; and μ_2 receptors, responsible for respiratory depression, bradycardia, physical dependence, and gastrointestinal dysmotility.[214] Activation of the κ receptors causes analgesia without significant respiratory depression, whereas activation of the σ receptors causes dysphoria, tachycardia, tachypnea, hypertonia, and mydriasis. The δ receptors modulate the activity of the μ receptors.

Drugs that exert their effects on opioid receptors are classified as agonists, antagonists, partial agonists, and mixed agonist-antagonists. Agonists are neurotransmitters that bind to a receptor and exert their pharmacologic effects. Antagonists, on the other hand, bind to the receptor but do not initiate any effects; yet by occupying the receptor they block the effects of agonists. Partial agonists have reduced intrinsic activity and produce less than a maximal response. They act as antagonists as well because they block the agonists from access to the receptor. The mixed agonist-antagonist drugs act as agonists at certain opioid receptors and antagonists at others. E-Table 44.4 depicts the various opioid receptors, their effects, as well as the drugs that exert activity on each of them. The opioids that are used most commonly in the management of pain are μ-receptor agonists, including morphine, hydromorphone, the fentanyls, methadone, hydrocodone, and oxycodone. Of these, morphine is the opioid that is most commonly used as first-line therapy for moderate to severe pain in children and, consequently, is the agent with which clinicians have the greatest experience. Table 44.8 lists the relative potencies and suggested initial doses of the opioids in common clinical use. Developmental pharmacology, PK, and side effects of opioids are discussed in depth in Chapter 7.

Delivery Techniques

The blood concentration of opioids must be maintained within a therapeutic range to provide effective analgesia and avoid undesirable adverse effects, such as excessive sedation and respiratory depression. Both the dose and the route by which the opioid is delivered determine how well one is able to maintain the blood concentration within this therapeutic window and minimize adverse effects.

TABLE 44.8 Opioid Analgesics: Relative Potency and Initial Dosing Guidelines[a]

Drug	Potency Relative to Morphine	Oral Dose	Intravenous Dose	IV/PO Dose Ratio
Morphine	1	0.3 mg/kg every 3–4 hours Sustained release: 20–35 kg: 10–15 mg every 8–12 hours 35–50 kg: 15–30 mg every 8–12 hours	Bolus: 0.1 mg/kg every 2–4 hours Infusion: 0.01–0.03 mg/kg per hour	1:3
Hydromorphone	5–7	0.04–0.08 mg/kg every 3–4 hours	Bolus: 0.02 mg/kg every 2–4 hours Infusion: 0.002–0.006 mg/kg per hour	1:4
Fentanyl	80–100	NA	Bolus: 0.5–1 μg/kg every 30 minutes to 2 hours Infusion: 0.5–2 μg/kg per hour	NA
Codeine	0.1	0.5–1 mg/kg every 4–6 hours	NR	NA
Oxycodone	1–1.5	0.1–0.2 mg/kg every 4–6 hours	NA	NA
Hydrocodone	1–1.5	0.1–0.2 mg/kg every 4–6 hours	NA	NA
Methadone[b]	1	0.1–0.2 mg/kg every 6–12 hours	0.1 mg/kg every 6–12 hours	1:2
Nalbuphine	0.8–1	NA	50–100 μg/kg every 3–6 hours	1:4–5

IV, intravenous; *NA*, not applicable; *NR*, not recommended; *PO*, oral.

[a]Recommended doses are for infants >6 months of age. For younger infants, reduce initial doses to 25% of these doses and increase as needed.

[b]Methadone has a long half-life and can accumulate, causing delayed sedation or respiratory depression. If sedation or respiratory depression occurs, doses should be withheld until sedation resolves. Then the drug is restarted at a smaller dose and extended dosing interval.

E-TABLE 44.4 Classification of Opioid Receptors

Receptor	Effect	Agonist	Antagonist
mu (μ)	μ_1; Supraspinal analgesia, physical dependence μ_2; Hypoventilation, bradycardia, physical dependence, euphoria, ileus	Morphine, codeine, hydromorphone, fentanyl, sufentanil, alfentanil, meperidine, methadone, remifentanil	Naloxone, pentazocine, nalbuphine
delta (δ)	Modulate μ receptor activity, weak analgesia, euphoria	Enkephalins	Naloxone, metenkephalin
kappa (κ)	Analgesia, sedation, hypoventilation, miosis	Dynorphin, pentazocine, butorphanol, nalbuphine, buprenorphine, nalorphine	Naloxone
sigma (σ)	Dysphoria, hypertonia, tachycardia, tachypnea, mydriasis	Pentazocine, ketamine	Naloxone

Modified from Stoelting RK. Opioid agonists and antagonists. In: Stoelting RK, ed. *Pharmacology and Physiology in Anesthetic Practice*. Philadelphia: JB Lippincott; 1991.

Oral Administration

Oral opioids are well tolerated and suited for children with mild to moderate pain, for those who undergo outpatient surgery, or as adjuncts to regional anesthetics. For those with regional anesthetics, oral administration of an opioid just before the block is expected to wear off may provide a smooth transition and more stable and satisfactory analgesia. In most cases, oral opioids are better tolerated after resumption of oral intake.

Hydrocodone and oxycodone are two of the most commonly prescribed oral opioids. Both are available in a variety of formulations either alone or in combination with acetaminophen. Both hydrocodone and oxycodone are available in liquid form, making them easy to prescribe for infants and young children. Oxycodone is available in 1-mg/mL and 20-mg/mL strengths. The 1-mg/mL strength is easy to dose and administer to infants, whereas the 20-mg/mL strength is reserved for older children with chronic pain and should rarely be used to treat acute postoperative pain. Although the different formulations allow flexibility in dosing, extreme caution is required in prescribing and dispensing the correct concentration to avoid a potentially lethal overdose.

There are many combination products containing oral opioids and a nonopioid adjuvant, such as acetaminophen. Although the primary advantage of these combinations is to reduce the number of tablets needed, this is outweighed by the disadvantage of a potential overdose of acetaminophen, and also results in suboptimal dosing (i.e., PRN) when scheduled dosing of adjuvant medications results in the greatest amount of opioid sparing. Therefore we discourage the use of combination products and encourage the practice of scheduled dosing of nonopioids complemented by as-needed dosing of opioids for breakthrough pain. *Indeed, this strategy is an important trend in the contemporary use of opioids for acute pain that can ameliorate the problems of opioid adverse effects and overuse. A multimodal analgesic approach, which leverages the synergistic interactions between nonopioid and opioid analgesics, can result in enhanced analgesia with fewer untoward effects and reduced opioid requirements.*[215–217] Although randomized controlled trials are still limited in infants and children, we believe that the preponderance of evidence and clinical experience support a multimodal strategy as logical and clinically beneficial to children and should be used as the principal approach to treating most acute pain.

It should be noted that many oral opioids (oxycodone, hydrocodone, codeine) undergo metabolism via the CYP2D6 pathway (see Chapters 6 and 7). Hydrocodone and oxycodone have intrinsic analgesic properties, but codeine is a prodrug that requires conversion to morphine via demethylation. There are significant genetic polymorphisms that affect the relative production of active metabolites of these drugs (oxymorphone, hydromorphone, and morphine, respectively). These differences result in individuals who are poor-, rapid-, or ultra-metabolizers, depending on the number of functional copies of the CYP2D6 allele present, and they account for significant variability in the response to these drugs. Ineffective conversion of codeine to morphine may be present in up to 7% to 10% of Caucasian children. On the other hand, another polymorphism, present in about 0.5% of children, results in rapid demethylation of codeine to morphine, producing exaggerated conversion to morphine and excessive sedation and respiratory depression when codeine is administered to children with this polymorphism.[186,218] These incidences differ with ethnicity, with a significantly greater incidence of polymorphisms in North African descendants.[219–223] Numerous case reports have described severe and sometimes fatal respiratory depression in ultra-metabolizers who were prescribed codeine, most often in children with obstructive sleep apnea.[186] These reports have prompted the U.S. Food and Drug Administration to issue a black box warning for codeine and tramadol in children undergoing tonsillectomy (http://www.fda.gov/downloads/Drugs/DrugSafety/UCM339116.pdf) and has further contraindicated use in children <18 years (https://www.fda.gov/Drugs/DrugSafety/ucm549679.htm). To minimize the risk of complications from codeine, one institution identified those children with polymorphisms to CYP2D6 and restricted the codeine use to those without a polymorphism, eliminating complications from codeine.

Therefore, because of both its lack of effect in some children (poor-metabolizers) and an exaggerated effect in others (ultra-metabolizers), we strongly discourage the use of codeine unless their polymorphisms have been characterized. It is also important to note that with active metabolites of codeine excreted in breast milk, there has been a report of an opioid overdose in a neonate who was breastfed by a mother who was an ultra-metabolizer,[224] and mothers taking oxycodone while breastfeeding reported similar rates of infant sedation as those taking codeine.[225] Other oral opioids metabolized by CYP2D6 have also resulted in serious and fatal complications as a result of polymorphisms.[185,226,227] Thus all opioids, including oxycodone, hydrocodone, and tramadol, are at risk for similar complications associated with polymorphisms as codeine. Alternatively, if pain is of moderate or lower intensity, another class of analgesics (e.g., NSAIDs, ketamine, or dexmedetomidine) may be substituted.

Methadone is a synthetic opioid with a very prolonged elimination half-life (mean of 19 hours) in children between 1 and 18 years of age, and a large bioavailability (approximately 80%) after oral administration. Oral or IV methadone has been considered a good alternative to the use of continuous opioid infusions because repeated dosing at intervals of every 6 to 12 hours can achieve relatively stable plasma drug concentrations.[228] Although it is used most frequently to facilitate weaning of opioid-tolerant children, it has also been recommended for postoperative analgesia and for transitioning children from parenteral to oral opioid therapy.[229–231] Methadone is especially useful for children with cancer, burns, or other serious illnesses who require a long-acting oral opioid, because it is available in an elixir formulation. Unlike some sustained-release formulations of other opioids, oral methadone is also relatively inexpensive. Note that crushing tablets of most sustained-release formulations of other opioids renders them into immediate-release, relatively short-acting medications. Methadone should be thought of as virtually a combination analgesic. It is supplied as a racemic mixture. The *l*-isomer acts as a μ opioid, whereas the *d*-isomer acts as an antagonist at the NMDA subclass of excitatory amino acid receptors. Action at NMDA receptors makes methadone uniquely effective in the treatment of neuropathic pain. This NMDA-blocking action, and a differential activation of receptor-mediated endocytosis versus protein kinase activation,[232,233] may lead to a relatively slower rate of development of tolerance for methadone compared with some other opioids. Despite these advantages of methadone, it requires careful titration and repeated reassessment to avoid delayed oversedation. This challenge in methadone dosing is due, in part, to its slow and widely variable clearance, as well as to its effects on NMDA antagonism, generating incomplete cross tolerance on conversion to methadone from other opioids. In opioid-naive subjects, a single dose of IV morphine is roughly equipotent to a single dose of methadone. Although morphine has active metabolites, the slower clearance of methadone compared with morphine translates, in opioid-naive subjects, into daily IV methadone requirements that are roughly one-third those of morphine. *However, in the setting of marked opioid tolerance, such as in the case of children with*

advanced cancer or in the setting of intensive care, the equipotent daily dose of IV methadone may be as small as one-tenth the preceding daily dose of IV morphine.[121,228,234–236] A convenient web-based calculation tool (http://www.globalrph.com/narcoticonv.htm) has synthesized the information from these and other studies to aid in opioid conversions in both opioid-naive and opioid-tolerant subjects. In our practice, this calculation tool appears quite useful, although it must be noted that it has not received independent assessment for use in children. Smartphone applications for multiple platforms are also available.

Intravenous Administration

Intermittent IV injections with opioids of short or moderate duration administered on an as-needed basis (PRN) do not achieve stable blood concentrations and predispose to periods of excessive sedation alternating with periods of inadequate analgesia. Yet this technique remains the most common method of treating postoperative pain in many centers. A partial solution to this problem is to prescribe the opioid at closer intervals (such as 2 hourly) and then use a "reverse-PRN" schedule, in which the medication is offered at the prescribed interval but the child can choose to take it or refuse it. Children should be assessed frequently, with the goal of administering the next dose before moderate to severe pain recurs. The use of a long-acting opioid, such as methadone, has been recommended to provide more prolonged and stable periods of analgesia than could be achieved with shorter-acting opioids, approaching the efficacy of continuous infusions.[237] However, careful titration of dosing and frequent assessment of the child are required because of methadone's slow and variable clearance. Alternatively, administration of shorter-acting opioids via continuous infusion or a PCA device should be considered.

Continuous IV opioid infusions are an excellent means of providing analgesia to children with moderate to severe pain who are unable to use PCA, such as infants, young children, and those who are cognitively impaired or physically disabled.[238] Once a therapeutic blood concentration of the opioid is achieved by administering an initial loading dose, an infusion rate can be selected to maintain that concentration without excessive fluctuations. Additionally, rescue doses of IV opioids may be required for breakthrough pain. Opioids, however, cause a dose-dependent respiratory depression by shifting the CO_2 response curve, reducing its slope, and decreasing the hypoxic ventilatory response. Residual and synergistic effects of sedatives and hypnotics in the early postoperative period further increase the risk of opioid-induced respiratory depression. This is particularly true in preterm and term infants because of age-related differences in elimination and clearance of opioids and other sedating medications (see also Chapter 7). This is of particular concern with the use of continuous opioid infusions because inappropriate dosing or prolonged elimination may lead to drug accumulation, placing children at risk for side effects. In a recent prospective audit of 10,726 opioid infusions in the United Kingdom and Ireland, the overall risk of permanent harm was found to be 1 in 10,000 cases, and serious events without permanent harm 1 in 383, with half of the serious events being respiratory depression.[239] Therefore the rate of the infusion should be carefully selected, based on the child's age, comorbidities, and clinical condition. Additionally, children who receive opioid infusions should be monitored and assessed frequently for depth of sedation and respiratory rate. *The onset of sedation and bradypnea is an important clinical index of incipient respiratory depression* and should alert the nursing staff and physicians to decrease the infusion rate and observe the child more closely. Use of pulse oximetry is widely recommended during continuous opioid infusions, especially in opioid-naive children and other children at increased risk for respiratory depression. Another method of IV opioid delivery is via PCA (see further). With any infusion technique, scrupulous attention must be paid to protocols for checking pump settings to avoid errors. Pump programming errors, none of which caused serious harm, but which had the potential to do so, occurred in 17 instances in the U.K. audit, all from a single center, highlighting the critical importance of system safeguards to prevent patient harm.[239]

Intramuscular and Subcutaneous Routes

Intermittent IM and subcutaneous (SC) injections of opioids are obsolete because they are frightening and unpleasant for children and are often perceived as worse than the pain for which they are administered.[240] Additionally, they have the PK disadvantage of unpredictable and erratic uptake if regional blood flow is impaired, and they produce pronounced wide swings in blood concentrations. The goal of maintaining an even level of analgesia is thus nearly impossible to achieve with these routes of administration. An important exception is the use of indwelling SC catheters for continuous infusions and PCA as in palliative care.

Selection of Opioids for Parenteral Use

Morphine is the opioid most commonly used for postoperative analgesia and has been extensively studied in all pediatric age groups. After major abdominal, thoracic, and orthopedic surgery, children who received continuous morphine infusions had reduced pain scores compared with those who received intermittent IM or IV injections.[241–243] However, other investigators were only able to demonstrate reduced pain scores with continuous morphine infusions compared with intermittent IV injections of morphine in children between 1 and 3 years of age, and not in infants in the first year of life.[244,245] Similarly, evidence of the beneficial effects of opioid analgesia in ameliorating the postoperative response to surgical stress are conflicting. A significant reduction in serum β-endorphin concentrations has been reported in neonates after the initiation of a continuous infusion of postoperative morphine.[246] In neonates whose lungs were mechanically ventilated, both epinephrine and norepinephrine concentrations decreased after the initiation of morphine or fentanyl infusions.[247] However, β-endorphin concentrations decreased only in the children who received fentanyl. When the effects of continuous infusions of morphine were compared with those of intermittent IV injections of morphine on the stress response in children between 1 and 3 years of age, reduced glucose concentrations in the continuous infusion group suggested only a modest ablation of the stress response in this age group.[244]

Several studies have described the PK of morphine administered as a continuous infusion and evaluated the pharmacodynamic effects of morphine on respiratory indexes in neonates, infants, and children after various surgical procedures. In children 14 months to 17 years of age who underwent cardiac surgery,[248] morphine infusions were adjusted between 10 and 50 μg/kg per hour to minimize discomfort and avoid excessive sedation. Supplemental boluses of 100 μg/kg morphine were administered for breakthrough pain. Steady-state morphine concentrations were achieved in 4 hours. Those children who could self-report their pain reported good analgesia with morphine concentrations in excess of 12 ng/mL. Morphine infusions of 10 to 30 μg/kg per hour yielded mean serum concentrations between 10 and 22 ng/mL with less than 2% experiencing evidence of respiratory depression (partial pressure of carbon dioxide [$PaCO_2$] > 50 mm Hg).

Furthermore, children who received morphine infusions of 10 to 30 μg/kg per hour breathed spontaneously after extubation of the trachea, and those who were weaned from assisted to spontaneous ventilation maintained a normal $PaCO_2$. On the other hand, 60% (3 of 5 children) who received a greater infusion rate of morphine, 40 to 50 μg/kg per hour, experienced hypercarbia ($PaCO_2$ 48-66 mm Hg). A subsequent study by the same investigators evaluated the severity of respiratory depression in infants and children aged 2 days to 18 months treated with morphine. Of those whose morphine concentrations exceeded 20 ng/mL, approximately 70% experienced respiratory depression ($PaCO_2$ > 55 mm Hg and/or a depressed slope of the CO_2 response curve) compared with 15% to 28% of those whose concentrations were less than 20 ng/mL.[249] The investigators suggested a steady-state morphine concentration of 20 ng/mL as a threshold concentration for respiratory depression in this age group.

Previous studies determined that the clearance of morphine is impaired in preterm infants and that clearance increases with postmenstrual age (see Fig. 7.11).[250] Additionally, morphine clearance is impaired in full-term infants up to 1 to 2 months of age, at which time it is comparable with that in older children and adults.[106,251] Preterm and full-term neonates, therefore, have a narrower therapeutic window for morphine analgesia compared with older children. Indeed, these groups have reduced morphine requirements postoperatively, requiring fewer rescue doses of morphine when receiving continuous infusions or intermittent bolus doses.[252] Therefore opioids should be carefully titrated in infants in a monitored environment with significantly reduced continuous infusion rates. Based on PK modeling and morphine clearance predictions, a target morphine concentration of 10 ng/mL can be achieved with morphine infusions ranging from 5 μg/kg per hour in term neonates to 16 μg/kg per hour in 1- to 3-year-old children (see Chapter 7).[253] In addition, reduced clearance in patients with renal insufficiency can result in accumulation of the potent morphine-6-glucuronide metabolite, which can cause delayed respiratory depression, so morphine should be avoided in these patients.[254]

Pharmacodynamic differences between infants and children have been postulated as the mechanism responsible for the greater sensitivity of infants (compared with older children) to the respiratory depressant effects of opioids. However, this may not be the case. Although rodent data suggest that the brain concentrations of opioids in neonates are greater than those in older children at similar serum concentrations,[255] these findings may not be applicable to humans. Neonatal rats have a relatively immature brain and a far more permeable blood-brain barrier than that in human infants. Consequently, the rodent may not be an appropriate model to depict the human condition.[256] It appears that the "increased sensitivity" is related, at least in part, to PK variables, perhaps in some measure as a result of a neonate's decreased conjugating ability.

Regardless of the mechanism, respiratory depression remains the most feared adverse effect of opioids administered by any route. Current monitoring technologies have numerous advantages and disadvantages (see the "Monitoring the Child Using PCA" section). Neonates and infants younger than 6 months of age are at greater risk for opioid-induced respiratory depression because the ventilatory responses to airway obstruction, hypoxemia, and hypercapnia are immature at birth and mature over the first several months of life in preterm as well as full-term infants (see also Figs. 4.8 and 4.9). Indeed, there was a 4.5% incidence of failure to wean from the ventilator and a 13.5% incidence of apnea (30 seconds or more that required intervention) or severe respiratory depression in spontaneously breathing neonates who received opioids for postoperative pain.[257] Another report of a 3-year surveillance period for adverse drug reactions described 15 children aged 2 days to 17 years who experienced opioid-induced respiratory depression.[258] Respiratory depression in the latter study was defined as apnea, hypoxemia, cyanosis, a marked decrease in respiratory rate, or a need for naloxone. Although this study was unable to define the incidence of respiratory depression because the denominator was unknown, it did identify several predisposing factors, including age younger than 1 year (7 of 15 children), drug errors (including prescription and administration errors; 6 of 15 children), concurrent medical problems (diminished respiratory reserve, hepatic, and/or renal impairment), and concurrent sedative drugs. A prospective U.K. audit found 14 cases of respiratory depression (out of 10,726 total infusions, or 0.13%), 10 with NCA, 2 with continuous infusions, and 2 with PCA.[239] Potentially contributing risk factors in half of the cases included very young age and neurodevelopmental, respiratory, or cardiac disease. In contrast to the earlier studies, no case of respiratory depression was reported in 110 children older than 3 months of age who received opioid infusions postoperatively.[259] Interpretation of this literature is confounded by different monitoring techniques and different definitions of respiratory depression. For instance, in the latter study, a 4.5% incidence of clinically significant hypoxemia was reported but was not included in their definition of respiratory depression. Additionally, children in that study were monitored with hourly documentation of respiratory rate, but oxygen saturation was not monitored after discharge from the PACU, thereby reducing the ability to detect more subtle episodes of respiratory depression. In summary, the results of these studies suggest that children who receive opioids require careful monitoring for respiratory depression, with appropriate age-based reduction of dosage, particularly for neonates and infants younger than 6 months of age.

The most common adverse effect of opioid therapy is nausea and vomiting. One study reported nausea and vomiting in 34 of 80 children (42.5%) who received postoperative morphine infusions. These were well managed with antiemetic therapy in all but two children who required discontinuation of the opioids.[259] In the same study, the incidence of pruritus and urinary retention was 13% for both and that of dysphoria was 7%. Seizures have been reported in two neonates who received bolus doses of morphine followed by infusions of 32 and 40 μg/kg per hour and whose serum morphine concentrations were 61 and 90 ng/mL, respectively.[260] Irregular jerking movements, as well as one case of a generalized seizure, have been reported in children 1 to 15 years of age receiving postoperative morphine infusions.[241] Metoclopramide, 0.10 to 0.15 mg/kg (100–150 μg/kg) given IV, is an effective antiemetic but may also cause sedation and dystonia. The serotonin-receptor antagonist antiemetics, such as ondansetron and dolasetron, have the advantage of virtually eliminating the risk of dystonic or oculogyric reactions that occur with phenothiazines, butyrophenones, and metoclopramide. However, headaches occur in a small number of those who receive serotonin-receptor antagonists. A "microdose" naloxone infusion (0.25–1.0 μg/kg per hour) reverses the incidence of both nausea and pruritus after opioids without affecting the analgesia or opioid consumption.[261,262] A more recent dose-escalation study demonstrated that doses of 1 to 1.65 μg/kg per hour resulted in greater efficacy in reducing adverse effects, particularly pruritus, without degrading analgesia.[262] It is likely that these results may be generalized to other routes of opioid administration.

Opioid-induced bowel dysfunction, reported in more than 90% of patients receiving opioid therapy, occurs by blocking propulsive peristalsis, inhibiting secretion and increasing reabsorption of intestinal fluids, and decreasing the activity of excitatory and inhibitory neurons in the myenteric plexus. Bowel dysfunction manifests as abdominal distention and bloating, delayed gastric emptying, and constipation. Aggressive prophylactic measures, including osmotic, lubricant, or stimulant laxatives, should be prescribed early in the course of treatment. A newer selective gastrointestinal peripheral μ-opioid receptor antagonist, methylnaltrexone, was approved for use in adults in 2008. Although adult studies have shown promising results with the use of this agent,[263,264] its pediatric use has been described in only a few case series.[265,266]

Fentanyl may be a useful substitute for morphine in children with hemodynamic instability, in whom a decrease in peripheral vascular tone is undesirable, and in whom histamine release caused by morphine is not well tolerated. Additionally, its rapid onset of analgesia makes it ideal for children with severe escalating pain who require urgent pain relief. Fentanyl is metabolized by the liver into an inactive metabolite, norfentanyl, which is excreted via the kidneys. It is 80 to 100 times more potent than morphine. Although its elimination half-life is significantly less than that for morphine, its context-sensitive half-life during chronic infusion increases exponentially as a result of growing tissue storage (see Chapter 7). Like morphine, the elimination half-life of fentanyl in neonates is nearly twice that in adults, predisposing them to a greater risk for accumulation compared with older infants.[267,268] As with morphine, a reduction in hepatic blood flow in very young infants further decreases fentanyl clearance. For a given bolus of fentanyl, plasma concentrations in infants between 3 months and 1 year of age are less than those in older children and adults.[269] This finding is consistent with the almost 2-fold greater clearance of fentanyl in children compared with neonates. In children 18 days to 14 years of age who were mechanically ventilated, the clearance of fentanyl was age related yet quite variable, with the slowest clearance occurring in infants younger than 6 months of age and the most rapid in those between 6 months and 6 years of age.[270] The clearance of fentanyl is slow in preterm infants, with the clearance correlating with the postnatal age.[271]

Fentanyl is known to cause all the adverse effects reported with opioids, including pruritus, nausea, vomiting, constipation, and sedation. Respiratory depression and chest wall and glottic rigidity, however, are its most feared adverse effects. One study compared the incidence of respiratory depression in full-term and former preterm infants and young infants receiving 2-μg/kg bolus doses of fentanyl every 2 hours or a continuous infusion of 1 μg/kg per hour after abdominal or thoracic surgery.[272] Randomization was terminated prematurely because of a 6-fold greater incidence of apnea that required intervention in the bolus dose group compared with the continuous infusion group (89% vs. 14%). The continuous infusion arm was continued for another 20 children, resulting in a 25% incidence of apnea in this group. In contrast, the incidence of respiratory depression (based on transcutaneous $PaCO_2$ measurements and the incidence of apnea) for a given plasma fentanyl concentration in infants 1 to 12 months of age and children 1 to 5 years of age was less than that in adults undergoing hernia repair or other peripheral surgery.[273] Differences in surgical procedures and the inclusion of preterm infants in the former study may account for the significant difference in the incidence of apnea found in these two studies.

Although chest wall rigidity usually occurs after the rapid bolus administration of high-dose fentanyl, it has also been reported in an infant after a low-dose continuous infusion of fentanyl. Chest wall rigidity was reported in 9% of preterm and full-term neonates who received an average of 4.9 μg/kg over a 2- to 3-minute period for a procedure or for perioperative analgesia.[274] In every case, naloxone reversed the chest wall rigidity. Additionally, a case of chest wall rigidity has been reported in a preterm neonate after high-dose fentanyl was administered to the parturient before a cesarean section.[275] Although administration of naloxone has been used successfully to treat cases of chest wall rigidity, severe cases associated with rapid oxygen desaturation may require the use of neuromuscular blocking drugs and mechanical ventilation.

The use of continuous fentanyl infusions in infants and children has been associated with a rapid development of tolerance, as indicated by a steady increase in infusion rate to maintain the desired effect[276,277] and a large incidence of opioid withdrawal syndrome after termination of the infusion.[277,278] The incidence of opioid withdrawal is directly related to the total dose administered and the duration of infusion.[277,278] Iatrogenic opioid withdrawal was reported in 21 of 37 neonates (57%) after continuous fentanyl infusions during extracorporeal membrane oxygenation.[277] Both a cumulative fentanyl dose greater than 1.6 mg/kg and extracorporeal membrane oxygenation that lasted more than 5 days were predictors of opioid withdrawal. A similar incidence has been reported in 23 children 1 week to 22 months of age who received continuous fentanyl infusions during mechanical ventilation.[278] This study also found that a cumulative dose of 1.5 mg/kg of fentanyl over 5 days was associated with a greater than 50% incidence of withdrawal symptoms. Furthermore, a cumulative dose of 2.5 mg/kg as a continuous infusion over 9 days was 100% predictive of the occurrence of withdrawal. Finally, movement disorder and irritability have been reported after withdrawal of fentanyl infusion in five infants who were mechanically ventilated.[279] None of the infants who developed the movement disorder had received another opioid after withdrawal of fentanyl, whereas five of eight controls who did not develop withdrawal during the same period had received a substitute opioid. These data suggest that opioid withdrawal occurs earlier and with greater frequency after fentanyl infusions compared with other opioids. Therefore it seems prudent to use fentanyl infusions for pain relief during periods of hemodynamic instability, such as in the early postoperative period, and to transition to another opioid, such as morphine, as soon as the child is stabilized. Children who require fentanyl infusions for 5 days or more should undergo a slow taper (e.g., 10% decrease every 12 hours) or be transitioned to another parenteral or oral opioid regimen.

Hydromorphone has a spectrum of action similar to that of morphine. Adult opioid equipotency data suggest that it is 3.5 to 7 times as potent as morphine.[280–283] A study performed in children with mucositis pain after bone marrow transplant reported that a 7:1 conversion ratio of morphine to hydromorphone underestimated hydromorphone requirements by 27%.[284] These data suggest that a 5:1 conversion ratio may be more appropriate, particularly in children with chronic pain. Despite its widespread use, there are very few studies that evaluated the use of hydromorphone in children. One small pediatric study randomized patients to morphine or hydromorphone PCA (5:1 ratio) and showed no difference in analgesia or side effects.[285] A meta-analysis of adult studies showed very similar analgesia and side effect profiles.[286] Overall, morphine and hydromorphone are very similar for most outcomes. Because side effect profiles for each drug may differ within an individual patient, it remains common practice to prescribe a trial of hydromorphone in children who experience

unacceptable adverse effects with morphine (or vice versa). Hydromorphone does have more rapid effect-site equilibration compared with morphine,[286] so there is a theoretical risk of dose stacking and subsequent respiratory depression with morphine compared with hydromorphone, but the requisite large studies needed to examine the clinical significance of this risk have not been done. It should be noted that the analogous hydromorphone-3-glucuronide has been associated with dose-dependent neuroexcitatory effects in hospice patients with renal insufficiency, but no significant cases have been reported in children. Therefore hydromorphone (or fentanyl or methadone) is a preferential choice in patients with kidney disease.[287] Although hydromorphone has an active glucuronide metabolite that is cleared by the kidney, it is considered intermediate in risk, better than morphine, but worse than fentanyl and methadone, for patients with renal failure.

Meperidine, used clinically for many years,[288,289] is approximately one-tenth as potent as morphine. Accumulation of normeperidine, its active metabolite (which has CNS stimulant properties), after repeated doses places children at risk for seizures.[290] Therefore its use has been restricted to the treatment of postoperative shivering[291,292] or rigors after amphotericin. A single dose of dexmedetomidine (0.5 μg/kg) has been used successfully for the treatment of postoperative shivering and may replace meperidine for this indication.[293] Although its short-term use continues by a small number of clinicians for procedural sedation and analgesia, other analgesics are preferable choices. Meperidine is not recommended for PCA or as a continuous infusion and has been removed from the formulary of many children's hospitals.

Patient-Controlled Analgesia

PCA was first studied in adults in 1965. The initial interest with this technique was as a research tool for the study of pain. By the early 1970s, it was identified as an excellent strategy for treating pain in the clinical setting, with studies demonstrating that pain relief was achieved by PCA with relatively smaller doses of opioids and with greater patient satisfaction than with conventional methods.[294] However, it was not until the late 1980s that PCA was studied in children.[295] Since that time, it has become the preferred method for opioid delivery in children older than 6 to 7 years of age (depending on their level of understanding) for acute pain, as well as chronic pain associated with cancer or sickle cell disease.[284,295–298] The primary benefit of PCA is that it allows children to titrate the analgesic to the extent of their pain. The goal is for the child to self-regulate a blood opioid concentration within the therapeutic range. Most children strike a balance between adequate pain relief on the one hand and adverse effects of the drug on the other. This approach, which grants the child some degree of autonomy, is the rationale given since pain is an entirely subjective and individual experience and that opioid metabolism and pain perception varies among individuals. It also reduces the apprehension of older children and adolescents regarding pain relief because they can control it and they can tailor the opioid delivery to the extent of pain they have at a given time–for example, before physical therapy, removal of tubes or drains, dressing changes, or getting out of bed. Additionally, the use of PCA avoids delays in administration of analgesics associated with standard "as-needed" orders of IV opioids and allows smaller doses of opioids to be delivered more frequently without increasing nursing workload. Therefore PCA is thought to provide more consistent pain relief with less total opioid dosing, resulting in fewer adverse effects, such as sedation, nausea, and vomiting. Purportedly, children using PCA report better analgesia and reduced pain scores compared with children who must rely on the nursing staff to administer analgesics when they are in pain. These and other benefits of PCA have been extensively touted in the medical literature,[298–300] as well as in the lay press.[301] Recently, however, risks associated with PCA use have also been highlighted and are discussed later.[302–304] Recognition of these risks has led to recommendations for careful dosing and monitoring of all children who are receiving opioids, particularly those receiving continuous infusions and those with specific risk factors.[305]

Child training is a necessary part of PCA, because successful use of PCA requires that both the child and family understand how it works.[306] The instructions should be clear that the pump should be activated whenever the child feels pain, that children cannot give themselves "too much medication" because of the computer lockout interval, that the child should not wait for severe pain to activate the pump, and that a dose can also be given in anticipation of painful stimuli, such as ambulation or chest physiotherapy. Most importantly, PCA does not mean *parent*-controlled analgesia, and parents should never activate the pump unless specifically authorized to do so by the primary care or pain service physician (see the "Nurse-/Caregiver-Controlled Analgesia" section later in this chapter).[305]

PCA Equipment

PCA devices are microprocessor-driven pumps connected to the child's IV line via Y tubing. For safety reasons, the IV tubing should incorporate a one-way valve to prevent backflow of the PCA drug up the tubing and an unintended delivery of a large bolus of opioid. Alternatively, PCA may be delivered through a separate IV line. These pumps allow programming of the individual dose to be administered, the minimal interval between doses (lockout interval), and the maximal cumulative allowable dose over a 4-hour period. Some pumps allow programming of a maximum number of doses per hour. Most pumps allow delivery of a continuous basal infusion (CBI) in addition to the demand dose. All PCA pumps should have a locking mechanism, so that neither the settings nor the medication cartridge can be changed without using a key, making the device virtually tamper-proof. The child is able to self-administer the preprogrammed doses by pushing a button. A liquid crystal display on the pump displays the programmed settings, the cumulative dosage, the number of doses administered, and the number of times that the button was pushed but no dose was given either because it was during the lockout interval or the 4-hour limit had been reached. This information allows clinicians to track opioid usage and make appropriate changes to the PCA prescription based on the usage pattern. Most children older than 6 to 7 years are able to push the button themselves. In general, a child who can play video games has the cognitive skills required to push a button to achieve a desired response and use PCA effectively.

Choice of Drug and Drug Dosages

Morphine remains the most common opioid administered via PCA, although hydromorphone is a valid first-line option, especially for patients with renal disease or a history of intolerance to morphine. Fentanyl is also used, but the disadvantage is a more rapid development of tolerance. Suggested initial dosages for opioids via PCA for opioid-naive children are presented in Table 44.9. Children with opioid tolerance require adjustments to these settings, considering the previous opioid history and the opioid doses that the child was receiving before the acute painful stimulus. Indeed, one study reported that children with sickle cell disease

TABLE 44.9 Patient-Controlled Analgesia Dosing Guidelines

Drug	Demand Dose (μg/kg)	Lockout Interval (minutes)	Continuous Basal Infusion (μg/kg per hour)	4-Hour Limit (μg/kg)
Morphine	10–30	8–15	0–20	250–400
Hydromorphone	2–6	8–15	0–4	50–80
Fentanyl	0.5	5–10	0–0.5	7–10

self-administered more than double the dose of morphine via PCA, required more nonopioid adjuvant analgesics, reported greater pain scores, and stayed in the hospital for twice the duration compared with non–sickle cell disease–affected children after laparoscopic cholecystectomy.[307]

Fentanyl PCA has been used with success as a first-line and a secondary drug in children with cancer pain, as well as acute postoperative pain.[300,308] Most of the adverse effects, including nausea and pruritus, were mild and easily managed. However, some reported an overall incidence of apnea and hypoxemia of 3.5% in 212 children receiving PCA, of whom 144 had received fentanyl.[300] Finally, children who received tramadol PCA after heart surgery were extubated earlier and had less sedation, comparable pain scores, and a similar incidence of emesis as those who received morphine PCA.[191] The IV formulation of tramadol is not yet available in the United States, but some studies from Europe and China support its use in the postoperative period.[191,309] The benefits that hydromorphone PCA offers over morphine PCA in the chronic and acute pain settings require further investigation.

Pump Settings

Most PCA pumps have five settings to adjust:

- A *loading dose* of opioid ranging from 0.025 to 0.1 mg/kg of morphine divided into incremental doses is usually given to establish adequate analgesia before therapy is turned over to the child, because self-administered doses with this technique are generally small. A sufficient interval between incremental doses must be allowed, so that the morphine achieves its peak effect before the next dose, thereby avoiding an overdose. If PCA is started in the PACU, opioid doses administered during surgery must be considered before prescribing a loading dose. Additionally, it may be desirable to administer the loading dose via the PCA pump so that it is included in the initial 4-hour or hourly limit of the PCA since children who receive IV-PRN doses of opioids in the PACU, followed by initiation of PCA, may be at risk for oversedation and respiratory depression from opioid stacking. Children who have received opioids toward the end of surgery, those who awaken in comfort, or those who receive nerve blocks may not need a loading dose and may start to use the demand doses as needed on awakening.
- A *patient bolus dose*–that is, the dose that will be administered with each child's activation of the pump–must be prescribed. These small boluses are usually in the range of 0.01 to 0.02 mg/kg of morphine in opioid-naive subjects.
- A *lockout interval* of usually 5 to 15 minutes prevents a child from activating the pump until the full effect from the previous bolus is achieved, and it should correspond to the time from IV injection to the peak effect of the drug.
- A *continuous basal infusion* ranging from 0.00 to 0.02 mg/kg per hour of morphine (or more, in opioid-tolerant subjects) may be used in selective cases (see later text).
- A *maximum hourly dose or a 4-hour limit* may be chosen to limit the cumulative amount of drug a child can administer. Once this limit is reached, the child cannot activate the pump until the 4-hour limit has passed. Four-hour limits allow for increased flexibility in dosing over greater periods of time and pain intensity. Typically, the maximum hourly dose ranges from 0.05 to 0.1 mg/kg and 4-hour limits from 0.25 to 0.4 mg/kg of morphine in opioid-naive subjects. This amount may be chosen based on the average hourly use of morphine during the past 24 hours or, in children started on PCA immediately after surgery, at the reduced range of the dosage scale. Fig. 44.6 presents sample PCA orders, including choice of drugs, dosing, and suggested monitoring.

Continuous Basal Infusions

The use of a CBI of the opioid to supplement child-administered doses remains a subject of controversy. The primary benefit of CBI is improved quality of sleep[310] as near-therapeutic plasma opioid concentrations are maintained, as illustrated in Fig. 44.7A. On the other hand, as depicted in Fig. 44.7B, a child who receives only PCA bolus dosing with no CBI is likely to awaken with unrelieved pain that may require multiple doses to again achieve adequate pain relief. Decreased nocturnal awakenings secondary to pain, improved restfulness or sleep patterns, reduced total opioid consumption, fewer adverse effects, and improved analgesic effectiveness are all potential reasons for using CBI. However, the use of CBI commits the child to receiving a fixed dose of opioid regardless of the level of sedation, and has the theoretical potential for overriding one of the inherent safety features of PCA–that is, an excessively sedated or somnolent child is unlikely to push the button and therefore receives no additional opioid but, with a fixed infusion, drug may accumulate (Fig. 44.7C), with the potential for hypoventilation.[311] Furthermore, it has also been argued that programming errors with CBI can lead to more serious adverse events because the opioid medication is delivered regardless of the child's level of sedation.[309,312]

Some studies in adults have suggested that the use of CBI has limited benefit in terms of efficacy and is associated with a greater incidence of opioid adverse effects, including respiratory depression.[313–315] Studies in children, however, have yielded conflicting results.[297,298,316–320] Children 7 to 19 years of age who received PCA with CBI after orthopedic surgery reported significantly reduced pain scores compared with those who received PCA boluses alone or IM morphine.[298] There were no differences in morphine consumption or in opioid adverse effects among the three groups, with no incidents of respiratory depression. Notably, child satisfaction was greatest in the PCA with CBI group. Similar pain scores with improved sleeping patterns have also been reported with the use of PCA with CBI, compared with those who received PCA alone, on the first two postoperative nights in children after abdominal surgery. No incidents of respiratory depression or excessive sedation were reported in either group.[297] Children who received CBI with PCA or NCA in one study reported slightly reduced pain scores without differences in morphine use or adverse effects after spine fusion surgery compared with those who received

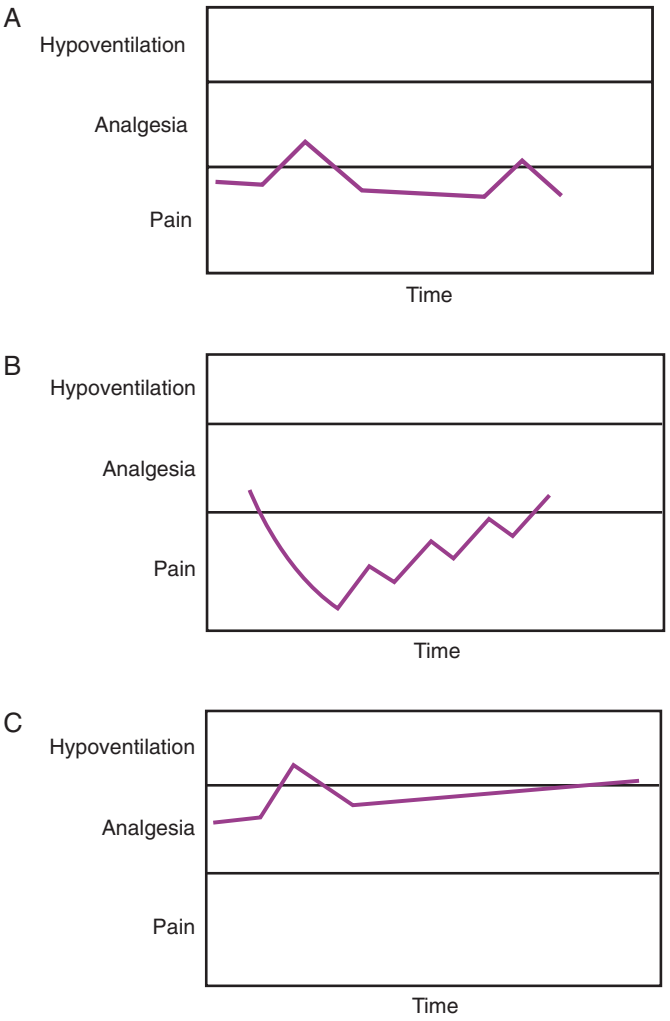

FIGURE 44.7 Patient-controlled analgesia (PCA) with an appropriate dose of continuous basal infusion. **A,** Use of an appropriate dose of continuous basal infusion (CBI) maintains near-therapeutic plasma opioid concentrations during sleep with rapid increase to analgesic concentrations as soon as the child awakens and activates the PCA button. **B,** Chart depicts plasma opioid concentrations in a child who is receiving PCA bolus doses only, with no CBI. Plasma concentrations decrease significantly when the child is asleep, necessitating multiple doses to achieve analgesic concentrations. **C,** An excessive dose of CBI results in opioid accumulation with delayed hypoventilation even when the PCA button is not activated. (Reproduced with permission from Berde CB, Solodiuk J. Multidisciplinary programs for management of acute and chronic pain in children. In: Schecter NL, Berde CB, Yaster M, eds. *Pain in Infants, Children and Adolescents.* 2nd ed. Philadelphia: Lippincott Williams and Wilkins; 2003:476.)

PCA or NCA alone.[320] In contrast, others have reported greater morphine use and a greater incidence of hypoxemia with similar pain scores in children who received PCA plus CBI after surgery compared with those who received PCA alone.[318,319] A subsequent study found that children who received PCA with a CBI of morphine (4 µg/kg per hour) experienced fewer adverse effects and less hypoxemia than children who received PCA with 10 to 20 µg/kg per hour) CBI or those who received PCA bolus doses alone, noting similar pain scores in all three groups.[317] Both of the PCA with CBI groups reported better sleep at night than did the PCA alone group.

A meta-analysis of data from the previously mentioned studies found no difference in pain scores or opioid consumption between children who received a CBI and those who received a bolus-only PCA. Improved sleep quality was reported in three of the four studies that examined this outcome. Although there was a 4.6% incidence of excessive sedation (a marker of respiratory depression risk) in the CBI groups as opposed to none in the bolus-only group, this difference was not statistically significant. Overall, the pooled studies had significant heterogeneity and small sample sizes (and thus lower-quality evidence). Therefore the authors concluded that further large-scale randomized trials are necessary.[310]

Based on these studies and our own experience, we hold the view that the use of CBI may benefit some children, although it requires careful selection of dose, based on the surgical severity and the child's comorbid conditions and vigilant monitoring to ensure safety. CBI should be used as a routine for most children with pain resulting from cancer, for most children with mucositis resulting from cancer treatment or bone marrow transplantation, and for a large number of children with sickle cell vasoocclusive episodes. A sensible compromise may be to (1) use CBI at night with the goal of improved sleep quality and (2) allow patients to self-regulate during daytime hours. At our institutions, the standard practice is to use CBI, unless limited by somnolence or hypoventilation, for the first night in most children after selected major painful surgeries, such as scoliosis surgery, pelvic osteotomies, and thoracotomies, unless concomitant regional analgesia techniques are used.

Nurse-/Caregiver-Controlled Analgesia

Activation of the PCA pump by the bedside nurse, a parent, or a caregiver (such as a grandparent) has been used with success in children who are unable to push the button because of young age or because of physical or cognitive impairments.[84,299,300,320,321] In much of the literature, and in some policy statements by the Joint Commission and other organizations, there is, in our view, too little distinction between activation of PCA pumps by nurses and activation by nonclinician surrogates. The term *caregiver* is used variably in this literature; here it is used to mean nonclinician surrogates. In pediatrics, this means primarily parents and other family members. A small study of 12 children who received NCA after spine fusion surgery reported adequate analgesia, parent and nurse satisfaction, and no complications.[320] Children who received NCA received smaller total morphine doses compared with those who could use the PCA device themselves, likely because of the tendency for nurses to underestimate their patients' pain. A larger observational study of 212 children who received parent- or nurse-controlled analgesia with morphine, fentanyl, or hydromorphone reported effective analgesia (pain scores 3/10 or 2/5 or below) in more than 80% of children.[300] Pruritus occurred in 8% and vomiting in 15% of the children on the first day of treatment. Nine children (4.2%) required naloxone for the following: apnea (n = 4), hypoxemia (n = 1), excessive sedation (n = 3), or to facilitate extubation (n = 1). Six of these children had significant comorbid conditions, and five received additional sedatives. These investigators emphasized the importance of close monitoring to minimize risk and permit early intervention when using nurse-/caregiver-controlled analgesia (NCA/CCA). Another study found that the incidence of overall adverse events in opioid-naive children who received NCA was similar to that in children who received PCA after surgery (22% and 24%, respectively).[84] However, children who were able to self-administer PCA required

only minor interventions (stimulation, reduction in opioid dosage, or supplemental oxygen), whereas those who received NCA were more likely to require more aggressive interventions, such as opioid reversal, airway management, or escalation of care. They found that cognitive impairment and opioid dose on the first postoperative day independently predicted adverse events. Although the mean time to the occurrence of adverse events was 16 to 27 hours, some events occurred during the third postoperative day, suggesting that monitoring, including continuous pulse oximetry, should be continued as long as the PCA is used. In a study of children with cancer, five respiratory and/or neurologic serious adverse effects were reported, with one child requiring naloxone during the 576 days of treatment with NCA/CCA.[321] In that study, pulse oximetry was used only at the discretion of the provider, perhaps reducing the investigator's ability to recognize hypoxemia in some children. Furthermore, the reduced incidence of adverse events may be explained by the fact that most children in that study were not opioid naive and may have developed some degree of opioid tolerance. A study of 10,000 pediatric patients receiving NCA further confirms the safety and tolerability of this delivery method.[108] For infants younger than 1 year of age, few studies have examined the role of NCA. One study of almost 800 infants, NCA fentanyl, morphine, or hydromorphone all provided similar analgesia, although rapid response team calls (total of 39) were significantly more frequently associated with morphine than with fentanyl use.[322] Only one rapid response call was for apnea.

For safety reasons, however, it is important to distinguish between authorized and unauthorized use of the PCA button by an individual other than the child. Several reports describe serious adverse events, including excessive sedation, severe respiratory depression, respiratory arrest, and death, attributed to unauthorized activation of the PCA device by parents, spouses, other family members, and health care providers.[84,323–326] The practice of PCA by proxy has therefore come under scrutiny and its safety questioned by the Joint Commission and the Institute for Safe Medication Practices (ISMP).[327–329] In 2004, the Joint Commission issued a sentinel event alert based on PCA errors reported to the U.S. Pharmacopeia. Of 460 errors that resulted in death or some level of harm to the patient, 15 resulted from PCA by proxy, including 12 attributed to family members, 2 to a nurse, and 1 to a pharmacist.[327] In interpreting this report and some other reports, it should be emphasized that many do not cite denominator data (total numbers of patients receiving PCA vs. NCA/CCA), so it is difficult to assign numbers for relative or absolute risks of these techniques. Recognition of these risks has led the Joint Commission and ISMP to strongly recommend that specific policies and procedures be developed and implemented related to the use of PCA by individuals other than the child. Such policies must address the following issues:

- Appropriate selection of children. Many pediatric centers restrict parent-controlled analgesia to children with chronic pain, those who require palliative care, and in special circumstances for children who undergo repeated and extensive surgery. In pediatric centers worldwide, NCA is increasingly being used, with appropriate observation, for both opioid-naive and opioid-tolerant children.
- The specific process of identifying suitable caregivers who will be allowed to activate the PCA button.
- Communication among clinicians, including the primary service physician, the pain service team, and the primary bedside nurse, regarding the suitability of CCA.
- An educational plan for health care providers involved in the decision making.
- Education of caregivers, including pain assessment, recognition of opioid adverse effects, and scenarios when not to activate the PCA button (e.g., when the child is asleep or somnolent). The caregiver should be encouraged to call the nursing staff when in doubt.
- Monitoring protocols, including assessment of sedation depth, respiratory status, and pain assessment at regular intervals. It must be emphasized that the primary responsibility for monitoring the safety and effectiveness of analgesia remains with the nursing staff. Electronic monitoring, including pulse oximetry, is widely used in this setting.

With carefully defined policies and procedures, adequate education of clinicians and caregivers, prevention of unauthorized dosing, and vigilant monitoring, it may be possible to reduce the frequency of adverse events from PCA, NCA, and, especially, CCA. However, large outcomes studies are needed after implementation of such policies to confirm the safety and efficacy of practice based on these recommendations. Our view is that NCA is a well-established practice and should be encouraged as a generally safe and effective means for delivering opioids to children who are unable to self-administer.

Risks and Adverse Events With PCA

Despite its numerous benefits, the use of PCA has been associated with a wide range of adverse effects, adverse events, and unfavorable outcomes in adults.[302,303,324,330–333] Although some adverse effects from PCA therapy may be attributed to the opioid drugs themselves or to patient comorbidities, a significant number of harmful effects occur as a result of human error, with incorrect prescribing, dispensing, administration, or equipment failure. E-Table 44.5 describes the causes of PCA medication errors as identified by the ISMP.[328–330,334] Increasing awareness of preventable adverse events from PCA has led to improved pump technology directed at minimizing the likelihood of programming errors, including the development of smart PCA pumps that use bar-coded syringes and an integral bar-code reader to prevent incorrect programming of drug concentration. Potential PCA pump errors have been reduced with "smart pumps."[335] Children are at greater risk for medication-related adverse events resulting from calculation errors in drug doses (because all doses are based on body weight or body surface area) and to developmental differences in PK. However, data for PCA-related adverse events in children are limited.[304,336–338] The reported incidence of respiratory depression in children receiving PCA ranges from 0% to 25%.[84,336,337,339,340] Risk factors for respiratory depression identified by these studies include cumulative opioid dose, use of basal infusions, concomitant administration of sedatives, and comorbid conditions, including renal failure and cognitive impairment. Recognition of the risks from PCA[341,342] has led organizations, such as the ISMP, to emphasize the importance of monitoring children who use PCA and of the need for detailed child and staff education regarding its use.[343]

Monitoring the Child Using PCA

Despite the recommendation from the ISMP that practitioners should identify children at risk for opioid-related respiratory depression and define the appropriate level of monitoring, there remains no consensus regarding the risk/benefit ratio and effectiveness of any specific forms of monitoring for children receiving PCA, NCA, or CCA. No monitor in widespread use today detects respiratory depression in all circumstances, so nursing staff are

E-TABLE 44.5 Causes of Patient-Controlled Analgesia Errors

Improper child selection	Extremes of age: preterm infant, neonate
	Significant airway, neurologic, or respiratory compromise
Inadequate child education	Inability to identify PCA button
	Mix-up with nurse call button
Unauthorized activation of PCA device	Individuals not authorized by medical team, such as parents and other caregivers, pushing PCA button
Inadequate staff training	Inadequate knowledge of programming of PCA pump
	Inability to recognize excessive sedation and/or respiratory depression
Prescription errors	Inappropriate opioid selection
	Incorrect conversion
	Dosing error: units µg vs. mg, decimal point
Dispensing errors	Wrong drug or concentration
	Incorrect labeling
	Incorrect transcription of prescriptions
Pump programming errors	Wrong drug, concentration, settings
	Failure to double-check settings against prescription and with second practitioner
Inadequate monitoring	Frequency of monitoring
	Pulse oximetry, capnography as indicated
	Prompt recognition of adverse effects and timely intervention
Flaws in equipment design	Default opioid concentrations
	Dosing units: mL vs. mg
	Activation button resembles nurse call button
	No audible signal when child receives PCA dose
	Pumps that do not require review of all settings before infusion starts

PCA, patient-controlled analgesia.

the frontline personnel for detection. Extensive nursing education and standard monitoring protocols are essential to the safe use of PCA (especially with CBI) in children.

The Anesthesia Patient Safety Foundation (APSF) recommended the use of continuous respiratory monitoring (minimally pulse oximetry and a continuous measure of respiratory rate) for children receiving PCA, neuraxial, or serial doses of parenteral opioids.[344] Additionally, the APSF recommended that reliable alerting methods, such as audible alarms, central stations, or pagers, be implemented to ensure timely and appropriate clinician response to deteriorating respiratory status of those receiving opioid therapy. The impact of implementing such technology on the incidence of PCA-related adverse events requires investigation. *It must be emphasized that pulse oximetry can detect hypoventilation only if the child is breathing room air.*[345] Oximetry is *not* a measure of ventilation but rather of oxygenation. The use of supplemental oxygen interferes with the ability of pulse oximetry to detect respiratory depression by delaying the onset of desaturation.[345,346] Any patient requiring supplemental oxygen while using a PCA should have additional measures in place to detect hypoventilation. Additionally, respiratory monitoring that uses impedance changes across electrocardiogram leads to detect chest wall movement will not detect partial upper airway obstruction and does not ensure that ventilation is adequate.

Sidestream sampling of end-tidal carbon dioxide ($ETCO_2$) via a nasal cannula or noninvasive capnography detects respiratory depression earlier and more frequently than does pulse oximetry or periodic checks of respiratory rate in adults who are receiving opioids via PCA, or for procedural sedation/analgesia.[347,348] Although similar data for children receiving PCA therapy are not available, studies in children undergoing procedural sedation in the emergency department and ICU have reported that capnography detected respiratory events that would have been unrecognized by pulse oximetry, periodic respiratory rate monitoring, and/or clinical examination.[349–352] Additionally, these studies identified instances of respiratory depression that were recognized by abnormal capnography before oxygen desaturation was detected. Thus capnography may provide the earliest warning of impending respiratory compromise and may alert clinicians to carefully evaluate the children under their care and adjust opioid doses accordingly. Conversely, in real-world practice, capnography cannulas can be difficult to maintain in proper position in children on a busy postoperative ward, readings can be influenced by mouth breathing, and this technology also has the potential for false-positive and false-negative conclusions.[353] Acoustic impedance (usually on the neck) is better tolerated than nasal capnography by children,[354] and has the advantage over chest wall impedance of detecting upper airway obstruction. However, it is not 100% sensitive, and episodes of oxygen desaturation are not always correlated to a low respiratory rate.[355]

Newer technology incorporates a fully integrated PCA system with modules for continuous monitoring of oxygen saturation and $ETCO_2$.[356] Some of these pumps also have a feature that shuts off PCA delivery if preset threshold parameters for oxygen saturation and $ETCO_2$ are reached. Studies evaluating the benefits of such technology in reducing PCA-related adverse events in children are needed. Although electronic monitoring has an important role in patient safety, all currently available methods are imperfect. Moreover, they generate frequent false alarms that annoy children and families, disturb the restorative sleep of both children and parents, and contribute to desensitization of nurses' vigilance. Despite these limitations of electronic monitoring, it has been reported that the use of computerized physician order entry and involvement of dedicated pediatric pain teams improved compliance with routine monitoring and increased the likelihood of early identification of adverse events.[357]

REGIONAL BLOCKADE AND ANALGESIA

The use of local anesthetics, both with and without the addition of central neuraxial opioids and other adjuncts, offers many advantages in the postoperative setting. Blockade with long-acting local anesthetic or continuous peripheral nerve blockade with infusion of local anesthetic via catheters and elastomeric infusion pumps can provide postoperative analgesia for outpatient surgery so that a child can be discharged home in comfort. Reducing or eliminating the need for systemic analgesics diminishes the potential for adverse effects associated with their use (see Chapters 42 and 43). Regional blockade affords the ability to provide excellent analgesia to children who might otherwise not tolerate larger doses of opioids. This group includes some neonates, especially preterm and former preterm infants who are at risk for apnea; children with problems of central ventilatory control, respiratory disease, or precarious airways; or those who risk obstruction with sedation (e.g., children with obstructive sleep apnea). Epidural analgesia that covers thoracic dermatomes improves resolution of ileus and return to normal feeding after major abdominal surgery.[358,359]

There are few absolute contraindications to regional blockade. Anatomic anomalies, such as myelodysplasia, sacral dysgenesis, and other abnormalities, either disrupting the epidural space or making access to it impossible, may prevent the performance of a caudal or epidural block. A report of epidural analgesia in children with myelodysplasia, however, suggests that catheters may be used safely in these children when placed at a level above the anatomic neural abnormality.[360] In cases involving these types of anatomic anomalies, we encourage consultation with experts in pediatric regional anesthesia, prior review of imaging studies, and consideration of fluoroscopic guidance. A needle and block should never be placed through infected tissue or near it. Children with burn injuries may be candidates for continuous regional techniques, provided the burned area is distant from the catheter insertion site (see Chapter 36). We do not believe that the benefits of regional analgesia outweigh the potential risks inherent in inserting catheters through burned tissue or close to it.

Sepsis presents a similar problem. In general, it is not advisable to place caudal or epidural catheters in children with sepsis for fear of seeding the epidural space during a period of bacteremia. Peripheral nerve, plexus, or intrapleural catheters may pose less of a problem in this regard, but there are no data to provide guidance regarding this issue. Coagulopathy and thrombocytopenia are relative contraindications to regional anesthesia, with mild abnormalities in hemostasis not necessarily precluding a regional block. When considering the risk of hematoma, it is safer to place a catheter in a site that can be compressed (e.g., femoral) as opposed to a site that cannot (e.g., epidural, paravertebral). In unusual cases, and with proper consideration of risk/benefit issues, fresh frozen plasma or platelets can be infused at the time of a regional procedure to provide temporary correction of coagulopathy. The considerations regarding regional anesthesia, coagulopathy, and anticoagulation are complex and have been reviewed extensively for adults by consensus groups from the American and European Societies of Regional Anesthesia.[539] In the absence of additional pediatric data, we recommend that

clinicians review these adult publications as provisional guides for pediatric regional anesthesia as well. When placing a catheter for continuous blockade, consideration of the state of coagulation must include the time of catheter withdrawal as well as placement. If a child is to receive postoperative anticoagulation, for example, a continuous block should not be considered unless anticoagulation therapy can be held temporarily around the time of catheter removal.

When a nerve repair or revision is planned for an extremity, some surgeons may wish to assess motor or sensory function postoperatively. In these cases, consultation with the surgeon should precede a plan for postoperative regional analgesia. If the surgery involves the legs, a caudal or lumbar epidural catheter can be used with opioids or adjunctive drugs such as clonidine without local anesthetics. Very dilute concentrations of local anesthetics (e.g., 0.05%–0.075% bupivacaine or ropivacaine) often can provide additive analgesia if needed without significantly impairing motor function.

There is no consensus on the timing of a regional block (at the beginning or end of the surgical procedure). Placing a single-injection caudal block before incision confers a similar duration of postoperative analgesia, after a surgical procedure of 1 hour or less, as placing it at the end of surgery. For example, the times from recovery until the first request for analgesics after caudal blocks placed before incision or after surgery for inguinal herniorrhaphy were similar.[361] For more prolonged procedures, the block may be renewed with a second caudal injection before emergence or a catheter placed and redosed at appropriate intervals (usually approximately 1.5 hours). A volume of half of the original dose is usually sufficient if less than 2 hours have elapsed. A reduced concentration of local anesthetic is usually effective for postoperative analgesia. Adjunctive additives, such as clonidine, have also been shown in some studies to prolong the action of "single-shot" central neuraxis and some peripheral blocks (see later discussion) permitting a single-injection block placed before the incision to augment both intraoperative and postoperative analgesia for longer operations. In cases of major surgery on the extremities and shoulders, there is a growing trend toward placement of indwelling plexus or peripheral nerve catheters for local anesthetic infusions for several days, both for adults and children, as detailed subsequently in the section on catheter techniques.[362,363]

Evidence suggests that placing a block at the beginning of surgery offers several potential advantages.[364] Although preemptive or preventive analgesia is a reproducible phenomenon in laboratory studies, the results in humans have been conflicting. For example, initial studies in adults demonstrated a dramatic decrease in the incidence of phantom limb pain when an epidural block was administered before an amputation, although subsequent studies did not consistently reaffirm the initial observations.[365–367] Similarly, children who receive intraoperative neural blockade may experience less postoperative pain than those managed with general anesthesia alone, with the duration of analgesia in some cases lasting beyond the pharmacologic action of the block. On the other hand, a blinded study of caudal anesthesia administered either before or after inguinal surgery failed to show a difference in postoperative analgesia.[368]

It is theorized that interruption of nociceptive impulses at the spinal cord level attenuates imprinting of painful stimuli on the sensory cortex or forestalls the development of spinal cord hyperexcitability and "wind-up," thereby reducing the neural input and persistent postoperative pain.[367,369–372] It has also become increasingly evident, however, that if preemptive or preventative analgesia is to have a beneficial effect, other conditions must be met: the block must be of sufficient duration in relation to the nociceptive stimulus, it must extend into the postoperative period, and it must be effective at preventing central transmission of the nociceptive signals.[364] This third requirement suggests that a multimodal analgesic approach may offer the greatest benefit. The presence of poorly controlled preoperative pain may sensitize the CNS, rendering pain difficult to control via intraoperative or postoperative interventions.[373] Additionally, epidural opioids have been shown to reduce the inflammatory response after surgery in adults, as indicated by interleukin-2 concentrations, suggesting that attenuating the stress response to surgery may improve postoperative analgesia.[374]

Further evidence suggests that local anesthetic infiltration of the incision site, especially when performed in conjunction with a regional anesthetic technique, may be an effective means of providing prolonged analgesia after surgery.[375,376] This simple and effective approach can be used before or at the end of virtually any surgical procedure. A major limitation of wound infiltration with currently available local anesthetics is that the duration of analgesia is usually only 4 to 6 hours. Because postoperative pain commonly persists for several days, it would be more useful to administer local anesthetics for 2 to 4 days. To achieve this, the surgeon must place a multi-orifice catheter in the tissue planes of the wound during closure, through which local anesthetics can be infused.[377] Several commercially available kits using these "soaker hoses" have been shown to be effective. A disposable elastomeric pump, filled with local anesthetic that infuses local anesthetic continuously into the surgical tissues, can be placed at the end of surgery and the child sent home with it infusing for several days. Although this is an effective supplemental strategy to achieve postoperative analgesia, practitioners should be aware of complications that have been reported in adults.[378] *A note of caution: the concentration of local anesthetics, such as bupivacaine, and the infusion rate must be carefully prepared to avoid a local anesthetic overdose if such an approach is planned, particularly after chest surgery and in neonates and small infants.*[379]

A suspension of biodegradable polymer microspheres or lipospheres that contain bupivacaine has been used in experimental preparations and a commercially available liposomal foam. After injection, these microspheres release bupivacaine in a controlled manner to provide blockade of peripheral nerves for periods of 2 to 6 days, depending on dose, formulation, and site of injection.[380–383] Despite considerable initial enthusiasm in adults, the clinical utility of this formula has not proven to provide significantly extended analgesia in adults compared with conventional bupivacaine.[384,385] An alternative experimental approach to providing prolonged analgesia is the use of modified neurotoxins. Site 1 sodium channel blockers, such as tetrodotoxin and neosaxitoxin, have very strong affinity for sodium channels in vitro. Tetrodotoxin and neosaxitoxin are nonneurotoxic and do not significantly block sodium channels in the myocardium.[386] In animals, the combination of these toxins with bupivacaine, epinephrine, or clonidine markedly prolongs the nerve block and reduces systemic toxicity. Neosaxitoxin shows no cardiotoxicity in animals[387] and has shown promise for wound infiltration in clinical trials.[388,389]

Peripheral nerve and plexus blocks tend to provide blocks of greater duration than do central neuraxial blocks, the former lasting 8 to 12 hours, and on occasion exceeding 24 hours. Depending on the nature of the surgery, this may permit the child to transition to nonopioid analgesics at the time the block wears off, thereby

eliminating or reducing the use of opioids and their potential untoward effects. Children undergoing outpatient surgery may be discharged after a single-injection regional block, but follow-up the next day with the family is necessary to ensure that the block has receded and no complications have developed. This is especially the case after peripheral nerve blocks. Parents must further be cautioned that there may be some degree of motor blockade present, and that the blocked limb must be protected from injury. If a lower extremity is blocked, assistance with ambulation is mandatory. Techniques for regional anesthesia and analgesia are discussed in detail in Chapters 42 and 43.

Choice of Local Anesthetics, Additives, and Dosing

Dilute long-acting local anesthetics, such as bupivacaine 0.125% to 0.25% or ropivacaine 0.1% to 0.2%, are the most commonly used local anesthetics for regional blockade. In Europe and Canada, levobupivacaine is available and has the advantage of smaller risk of toxicity than bupivacaine (see Chapter 42). Ropivacaine and levobupivacaine have the dual advantages when compared with bupivacaine of a relatively prolonged duration of action and decreased motor blockade. Epinephrine (1 : 200,000–1 : 400,000) is often added to bupivacaine to decrease systemic absorption and increase duration of action, although *caution is advised when a digital or penile block is performed, because of the risk of inducing ischemia by direct vasoconstriction.* (Note that the avoidance of epinephrine for digital blocks is based on limited and historical evidence [concentrations of epinephrine of 1 : 80,000 in the past, not 1 : 200,000 as is currently used], and current proponents of the practice have used epinephrine without complications).[390–393] There is probably little advantage to adding epinephrine to the local anesthetic in continuous infusions, since prolonging the block effect is not a consideration.

Initial studies concluded that the optimal concentration of bupivacaine that provides maximum sensory blockade without motor blockade for caudal analgesia was 0.125%,[394] although subsequent studies demonstrated that the optimal concentration was actually 0.175% (7 mL of 0.25% bupivacaine combined with 3 mL of saline solution).[395,396] More concentrated solutions of bupivacaine (0.2%–0.25%) may be used for blocks that do not significantly affect motor function, such as for an ilioinguinal-iliohypogastric nerve block after herniorrhaphy.

Block duration correlates most closely with total local anesthetic dose. The use of a higher concentration such as 0.5%, as is common in adult practice, will produce a block that is 40% longer in duration than an equal volume of 0.25%.[397] This will, of course, increase the incidence of motor blockade. The clinical significance of motor blockade (e.g., site of blockade, need for early ambulation) versus the benefit of prolonged duration (i.e., a block lasting until the following morning instead of wearing off in the middle of the night) must be weighed for each patient. Because most peripheral single-injection blocks can be accomplished with 0.2 to 0.3 mL/kg, it is feasible to stay well under the maximum allowable dose of 2.5 mg/kg (i.e., 0.5 mL/kg of a 0.5% solution). Supraclavicular brachial plexus block using a combination of perineural 0.5% ropivacaine and dexamethasone or IV dexamethasone produces a block with an average duration of 25 hours, ensuring a first postoperative night with an excellent analgesia.[398] Pediatric peripheral nerve blockade can be extended with the addition of α_2-adrenoreceptor agonists (9.75 vs. 3.75 hours).[399] Another example is that thoracic epidural analgesia after Nuss bar placement may be enhanced with a denser blockade. For these blocks, motor block is of less significance because most lung expansion is produced by the diaphragm.[100] For thoracic epidural blocks, we use ropivacaine 0.2% with an opioid and clonidine.

Ropivacaine, an *l*-enantiomer amide local anesthetic, is widely used in children, particularly in neonates and infants.[400–403] In both pediatric and adult studies, the duration of analgesia after ropivacaine is similar to that after bupivacaine, although motor block occurs more frequently with bupivacaine. In a review of 16 pediatric studies of caudal blockade, ropivacaine and bupivacaine were both effective. Ropivacaine caused less motor block than bupivacaine in 6 studies and similar motor block in 8 studies. For caudal block, the duration of motor block with either local anesthetic was short-lived.[404] Ropivacaine is less cardiotoxic than bupivacaine, but it is also less potent in adult studies than bupivacaine,[405] although similar results are obtained with larger doses of ropivacaine.[406] In terms of developing terminal apnea, infant rats tolerate 1.5 times the dose of ropivacaine compared with bupivacaine. The doses for the onset of respiratory distress and seizures are similarly increased with ropivacaine.[402] These differences are more pronounced in infant rats than in adult rats. Animal data suggest that the toxic thresholds for both CNS and cardiovascular toxicity are increased 20% to 30% with this agent in both adults and infants, although seizures can still occur with ropivacaine if the dose exceeds the toxic threshold. Although recommended dose limits are similar for bupivacaine and ropivacaine (2.5 mg/kg bolus, 0.4–0.5 mg/kg per hour infusion), pharmacokinetic modeling suggests that larger doses of ropivacaine are likely safe.[407] Based on these data, some institutions have increased the allowable infusion limits for ropivacaine to 0.6 mg/kg per hour.

The authors recommend using a levorotatory enantiomer (levo-enantiomer), such as ropivacaine, in preference to the racemic mixture, bupivacaine, in infants younger than 6 months of age because of the potential increased margin of safety.[403,408] Another option for continuous infusion is chloroprocaine, which undergoes rapid ester metabolism in the bloodstream, and thus has a low risk of toxicity. Because of chloroprocaine's favorable therapeutic margin in infants, larger volumes can be infused to achieve adequate spread of blockade, an important consideration with epidural analgesia following extensive intraabdominal or intrathoracic operations. Another option with a similar decreased toxicity is levobupivacaine (the levorotatory isomer of bupivacaine). This drug possesses properties similar to bupivacaine with a moderate reduction in the toxicity risks inherent with bupivacaine.[409–411] However, levobupivacaine has become difficult to obtain in the United States, although it is commonly used in place of bupivacaine elsewhere.[412]

Opioids have been injected in the epidural and intrathecal spaces for analgesia in children, both with and without local anesthetics. Central neuraxial opioids have been used for more than two decades to produce effective analgesia in children. However, opioids administered into the central neuraxis have the potential to cause delayed respiratory depression and are generally avoided in the outpatient setting to ensure the safety of children after discharge (see further).[413]

Adjuvant drugs have been added to the local anesthetic administered for caudal blockade to prolong the duration of the sensory block, an obviously desirable attribute for a single-injection block. However, their use is not without controversy. Many drugs have been injected into the epidural space with only limited laboratory evidence for safety and lack of neurotoxicity; therefore some caution is necessary.[414] Clonidine, 0.5 to 2 μg/kg, has been shown to lack evidence of neurotoxicity. It increases the duration

of analgesia after bupivacaine in caudal blocks by approximately 3 hours, with insignificant hemodynamic effects, mild sedation, and no delay in recovery times.[415–421] Despite these reported beneficial effects of clonidine, one double-blind investigation found no difference between IV and caudally administered clonidine in a dose of 2 μg/kg as an adjunct to caudal blocks using bupivacaine, and another found no difference in duration or quality of analgesia when compared with caudal bupivacaine alone.[422,423] Conversely, when clonidine was used in conjunction with levobupivacaine, children who received clonidine in the caudal space demonstrated a significant delay in the need for rescue analgesia and reduced pain scores compared with those who received IV clonidine, suggesting that the prolonged analgesia occurs at a spinal cord site of action.[420,421,424] Caudal clonidine produces less nausea, itching, ileus, and urinary retention than opioid additives, although it may increase postoperative somnolence or respiratory depression at doses in excess of 1 μg/kg, particularly in the neonate.[423,425–427] The clearance of clonidine in infants is approximately one-third that of older children.[428] The preponderance of evidence, as shown in a meta-analysis,[429] supports the use of clonidine to prolong the analgesic effect of central neuraxial blocks, but we caution against the use of more than 1 μg/kg for outpatient procedures, especially in younger infants, because of an increased risk of respiratory depression. The use of adjuvant caudal dexmedetomidine 1 μg/kg, another α_2-adrenoreceptor agonist, is increasing. Sensory block duration is reported to increase by 8.21 hour (95% confidence interval 5.02, 11.40 hours).[430]

Dexamethasone has been studied in both perineural and systemic administration with results similar to clonidine. For caudal block, both perineural and IV dexamethasone (0.5 mg/kg) provide improved quality and duration of analgesia.[431,432] Adult data with peripheral blocks show equivalence between perineural and IV dexamethasone as well.[398] There is increased potential for neurotoxicity with any adjuvant compared with local anesthetic alone, so using IV agents to prolong blockade is likely the safest approach.[433]

Preservative-free ketamine has also been used for caudal analgesia, both alone and in combination with bupivacaine. Doses of 0.5 mg/kg appear to provide adequate analgesia, without untoward behavioral effects, such as those reported with IV or oral administration.[434] When combined with bupivacaine, the duration of analgesia approached 24 hours.[206,435,436] In a comparison with IV ketamine, caudal (*S*)-(+)-ketamine significantly prolonged the duration of analgesia, despite similar plasma concentrations.[436] One clinical study suggested a specific spinal site of action. *Only preservative-free ketamine should be used because preservatives have been associated with neurotoxicity.*[437,438] In the United States, preservative-free ketamine is currently unavailable.[417,439]

When performing a regional block, the total safe dose of local anesthetic should be calculated first and the volume and concentration of the solution adjusted if necessary to avoid administering a toxic dose. Most peripheral blocks can be performed with 0.2 to 0.3 mL/kg of local anesthetic, but single-injection caudal blocks require 0.75 to 1.25 mL/kg. Since a larger volume equates to a greater risk of administering a toxic dose, more dilute concentrations should be used. This is particularly important when performing blocks in infants. For example, a 7-kg infant has a maximal allowable dose of 17.5 mg of bupivacaine (or 2.5 mg/kg). If a 0.25% solution (2.5 mg/mL) were administered, the total volume would be limited to 7 mL. The maximum dose should probably be slightly more restrictive in infants younger than 6 months of age. At this age, a cautious approach is to further reduce the allowable dose by 25% to 30%, particularly if an infusion is to be used following the initial bolus. For example, a 4-kg 2-month-old infant would be permitted to receive 2.7 mL (6.6 mg) of the same solution. A simple rule of thumb for calculating the maximum bolus dose of bupivacaine and ropivacaine in children older than 6 months is 1 mL/kg of 0.25% or 0.5 mL/kg of 0.5% solution. For most circumstances, there is little benefit in using 0.5% concentration. Use of different concentrations increases the odds of a dose calculation error. To prevent this type of error, some hospitals have standardized dosing for infiltration and boluses to a single concentration, namely, 0.2% for ropivacaine or 0.25% for bupivacaine.

Choice of Block and Techniques

Single-Injection Techniques

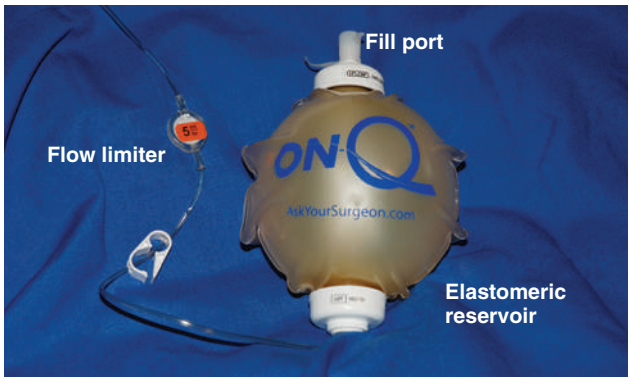
There are many circumstances in which the simplicity and duration of action of a single-injection block is desirable. Both neuraxial blocks and peripheral plexus and nerve blocks can be effective as single-injection techniques. The caudal block remains the most commonly used technique in pediatric regional anesthesia. It provides analgesia of the lower extremity and lower abdomen, and is easily and quickly performed in most infants and children (see Chapter 42). When an operation is performed on both legs, it is often preferable to bilateral lower extremity blocks.

The use of ultrasound makes the identification of plexuses and peripheral nerves much easier in an anesthetized child. Peripheral nerve stimulation using Teflon-coated needles remains an effective technique, but it is being used less frequently as familiarity with ultrasound and its benefits increases.[440] To precisely position the needle in the target area and avoid piercing adjacent structures, one must develop skill in coordinating its trajectory with the ultrasound image so that the needle tip does not pass out of the plane of view. Although it remains unknown whether ultrasound and more precise needle placement will reduce nerve injury, there is evidence that it reduces the volume of local anesthetic needed to produce an effective block.[441,442] Ultrasound visualization of the local anesthetic surrounding a nerve or plexus provides reliable confirmation that a block will be successful. Nerve blocks of the lower extremity can often be used instead of caudal blockade (see Chapters 42 and 43). The primary disadvantage is that multiple blocks (i.e., femoral and sciatic) are needed to cover the entire extremity. They provide a field of analgesia limited to the operative site, but they have a prolonged duration of analgesia (usually at least twice that of caudal block) and eliminate some of the potential undesirable effects of central neuraxis blockade, such as urinary retention (and need for a urinary catheter) or unintentional unilateral blockade (of the nonoperative leg). Blockade of the femoral nerve, the sciatic nerve, and the nerves of the ankle is easily performed in children by using similar techniques to those in adults (see Chapters 42 and 43). Regional blockade of the upper extremity may involve an interscalene, supraclavicular, infraclavicular, or axillary block, or less commonly, blockade of the individual nerves at the level of the arm or wrist. Unlike the lower extremity, a single block of the brachial plexus can provide anesthesia to the entire extremity. Paravertebral blocks may be used in lieu of an epidural after thoracic or upper abdominal surgery. This block may be considered for procedures of limited scope, such as open-lung biopsy or thoracostomy for drainage, but the duration of blockade is limited to several hours. An emerging approach is ultrasound-guided placement of paravertebral catheters for continuous infusion for thoracic

and upper abdominal surgery.[443,444] For open-chest procedures, intercostal blocks by the surgeon pose a low risk and may be indicated, although their effectiveness is limited by their short duration. Epinephrine is commonly included in the local anesthetic for these blocks to limit the rate of uptake. More extensive surgery anticipated to cause postoperative pain of longer duration may be best managed with a catheter (continuous infusion) technique.

An ilioinguinal-iliohypogastric nerve block provides excellent postoperative analgesia for inguinal herniorrhaphy, a common outpatient procedure in children (see Chapters 42 and 43). It appears similar in efficacy to a caudal block, with a duration of analgesia of at least 4 hours when bupivacaine with epinephrine is used. For orchiopexy, ilioinguinal nerve block has been found to be as effective as caudal blockade to the T10 level in a randomized and blinded investigation.[445] In our experience, however, postoperative analgesia for procedures that involve considerable manipulation and traction on the spermatic cord and testis may be better managed with caudal blockade in younger children. Penile block is effective for both circumcision and distal, simple hypospadias repair. More extensive procedures on the penis, especially repair of penile-scrotal hypospadias, require a caudal or pudendal block, rather than a penile block, to produce effective analgesia.[446]

The use of single-injection neuraxial opioids is an additional technique that can provide longer-lasting analgesia, but must be used in inpatients only because of the need for respiratory monitoring. Intrathecal morphine has been administered to infants and children for several decades and provides long-acting analgesia (up to 24 hours) after a single injection.[447,448] It is absolutely essential that only preservative-free preparations of the drug be used because preservative-containing solutions may result in injury to the central neuraxis. Intrathecal doses ranging from 4 to 10 μg/kg are usually chosen. Because of the hydrophilicity of this agent, respiratory monitoring is mandated. Respiratory depression, as well as pruritus, nausea, and urinary retention, are reported after intrathecal morphine. We most commonly use this modality for analgesia after posterior spinal fusion. The drug can be administered by the surgeon under direct vision of the dura, but if administered at the beginning of the case, it has been reported to reduce intraoperative blood loss.[449,450] This route of administration has also been used before cardiac surgery.[451] The effective intrathecal dose of opioid is roughly one-fifth to one-tenth that of the epidural dose, and the duration of action, especially with morphine, is significantly prolonged. Therefore observation in a monitored setting must be continued for 24 hours or until no further evidence of respiratory compromise exists (without the use of naloxone).



Catheter Techniques

A catheter placed in the epidural space or adjacent to a nerve or plexus can be used to provide continuous uninterrupted analgesia for prolonged periods after surgery. These catheters are commonly used for about 3 days but may be used for more prolonged periods in selected situations. However, the risk of infection does increase when catheters are left in place for more than 3 days.[452] If necessary, catheters tunneled under the skin may be left in situ for more than 7 days,[453,454] and they have been left in place for longer periods without infectious complications in palliative care patients.[455] Catheters can also be placed in intrapleural or extrapleural and/or retropleural locations to provide analgesia after thoracic surgery.[456] In our experience, intrapleural analgesia reduces but does not eliminate the need for systemic opioids, especially if thoracostomy drains are present. We rarely use this technique because toxic concentrations of local anesthetic and seizures have been reported.[457] Continuous extrapleural, intercostal, and paravertebral catheters can be placed either through the operative field or percutaneously. In adult studies, and in a smaller series of pediatric studies, these techniques appear to provide excellent analgesia at rest, but with movement they provide only partial opioid sparing. Some clinicians regard these techniques as providing many of the advantages of thoracic epidural analgesia, with the potential for reducing the risks and adverse effects of thoracic epidural analgesia.

Continuous regional blockade is remarkably effective and safe, although as with any technique, monitoring for untoward effects is necessary to prevent complications. New technology for the delivery of drugs to peripheral nerves and plexuses has made it possible for children to receive the benefits of continuous neural blockade after discharge from the hospital or day surgery unit.[362] Catheters may deliver local anesthetics and other medications via controlled infusion devices that use a pressurized elastomer-bulb reservoir that controls the infusion rate with a flow limiter (ON-Q pump, I-Flow LLC, Lake Forest, CA; Infusor, Baxter Healthcare Corporation, Deerfield, IL; Accufuser, Moog Medical Devices, Salt Lake City, UT; Easypump, B Braun Melsungen AG, Melsungen, Germany; and others) (E-Fig. 44.3). These devices can be used at home after discharge, for infusion of medication into a tissue plane to provide a continuous field blockade or a continuous peripheral nerve block. As the use of peripheral nerve blocks continue to increase, we believe that these techniques may eventually become more common than neuraxial analgesia for suitable indications.

Infusion of local anesthetics in the subcutaneous (SC) tissues at the incision site or into the surgical plane using these devices provides prolonged analgesia in both adults and children. Several types of these infusion systems are available, including ones that have options for fixed, variable, or continuous infusion rates with a bolus option. The latter two must be used with caution in smaller children in whom local anesthetic toxicity from excessive dosage may be a risk; we generally use the fixed-rate devices. When continuous peripheral nerve or plexus blocks are used for outpatients, a carefully designed system must be in place to follow up with these children to avoid complications and achieve early detection of potentially adverse events. Patient and family education to recognize potential complications, along with telephone follow-up, are necessary to ensure safe use of catheters at home. Cases have been reported of possible excessive doses of local anesthetic from a continuous infusion pump used at home, although no catastrophic events have been reported.[458]

CAUDAL AND EPIDURAL CATHETERS. With experience and proper equipment, the lumbar or thoracic routes are feasible at any age, but specific expertise is required for infants and toddlers. Regardless of the level of insertion, the goal should be to place the tip of the catheter as close as possible to the dermatome(s) most affected by the operation. Practitioners who have less experience with direct epidural catheterization in children should consider placing the catheter via the caudal route for children younger than 6 years of age. In infants and children up to about 6 years of age, catheters may be advanced freely from the caudal canal cephalad to thoracic levels with excellent success.[459] This is possible in part because young children have a less developed vascular plexus and more compact and globular fat than do older children and adults.[459,460] However, other authors describe less reliability with caudal-to-thoracic advancement of catheters in children larger than 10 kg.[461] This has been attributed to the more mature

E-FIGURE 44.3 ON-Q pump (I-Flow LLC, Lake Forest, CA), an elastomeric infusion device for ambulatory continuous regional blockade. The pump bulb is filled with local anesthetic and pressurized. The flow restrictor is readily set to the desired flow rate, and the system is disposable.

composition of the contents of the epidural space and the lumbar lordosis that occurs with walking. With age, the epidural fat appears to lose the spongy gelatinous character noted in infants and the spaces between the fat globules become less distinct.[459,460] Catheters made of nylon or polyamide may be less likely to kink beneath the skin and seem to thread more easily than those made of Teflon or other materials. The catheter should never be advanced if resistance is felt. Similar difficulties in advancing catheters that resulted in catheters looping backward, kinking, or puncturing the dura have been reported in neonates weighing less than 3.5 kg.[462] If a caudal catheter is threaded to higher lumbar or thoracic levels, the position should be confirmed with imaging or other functional assessment.

Epidurography has been used to confirm the position of the catheter tip. In one series of 20 preterm infants, epidurography revealed misplaced catheters in 3 infants or 15%. New data suggest that misplacement of threaded catheters in all ages may be more common than is generally recognized.[463] In this series of 724 epidurograms, unexpected misplacement was detected in 11 or 1.5%, including 3 intravascular catheters, despite negative test doses; 2 intrathecal without cerebrospinal fluid aspiration; 4 that were intraperitoneal; and 1 each in the rectum and psoas compartments. These authors recommended epidurography in all cases, although this is not the current standard of practice and must be weighed against the risks of radiation exposure in young children. If specific dermatomal placement of a catheter is sought, one should consider obtaining an imaging study to confirm the dermatomal level of the tip of the catheter, and the aforementioned data suggest that imaging might be advisable whenever a catheter is advanced to a level substantially more rostral than its insertion level.

As an alternative to epidurography, ultrasound can be used and is especially useful in infants weighing less than 10 kg. It is readily available in most ORs and does not expose the child to radiation. Ultrasound can be used to estimate the skin–ligamentum flavum distance to aid in placement, as well as imaging proper catheter placement. In general, it is more difficult to image the actual catheter but local anesthetic spread can be easily visualized with anterior depression of the dura on injection.[464,465]

Another alternative is a nerve-stimulating catheter, which allows real-time monitoring of the location of the tip of the catheter as it is advanced cephalad.[466,467] If a stimulating catheter is not available, a saline solution–filled catheter can serve in its stead. The technique requires the use of saline loss-of-resistance and avoiding air bubbles in the epidural space or in the catheter-connector-injection system, because air impedes electrical conduction. With either system, neuromuscular blockade must be avoided because it abolishes the motor response. Used in conjunction with a nerve stimulator set to very low milliamperage (approximately 6 mA), the muscles supplied by a nerve root will twitch as the catheter approaches the segments that supply that dermatome, thereby confirming the catheter tip's location. Specifically, twitches in the feet and ankles occur with catheter tips around L5 to S1, hip flexion occurs with catheter tips around T12 to S1, abdominal muscle twitches without hip flexion imply thoracic positioning above T12, and intercostal muscle twitches imply midthoracic tip positioning. Finger twitches would imply advancement to around T1. This technique can also be used to detect catheter malpositioning. Bilateral twitching at a current less than 0.6 mA generally implies subarachnoid positioning. Unilateral twitches in a narrow motor distribution at a current less than 1 mA may suggest advancement out a root foramen. Unilateral twitches at a current less than 1 mA in a very broad motor distribution may indicate subdural positioning. Absence of twitches as the current is increased to about 15 mA (in the absence of air bubbles or neuromuscular blockade) generally indicates that the epidural catheter is not in the epidural space (Table 44.10). Our experience is that the use of one of these confirmatory techniques when catheters are threaded cephalad can help avoid problems with failed or incomplete blocks in the postoperative period.

TABLE 44.10 Estimated Dermatomal Level With Epidural Catheter Advancement

Amperage (mA)	Estimated Dermatomal Level	Twitch Response Level
6	L5-S1	Feet and ankles
6	T12-S1	Hip flexors

The choice of drugs for epidural infusions depends on several factors, including site of surgery, site of the epidural catheter tip, and child risk factors. Local anesthetics, lipophilic opioids, and, to some extent, clonidine all have more restricted cephalad distribution of action during infusions compared with hydrophilic opioids, such as hydromorphone or morphine. Consequently, optimal positioning of the catheter tip during insertion can improve the analgesic action postoperatively. Experience in adults suggests that when local anesthetics are used, analgesia is optimized when the tip of the epidural catheter is positioned at or slightly above the dermatomal levels involved in the surgery. This effect may be more pronounced when children are moving than when they are at rest. Positioning at levels slightly above the dermatomal levels involved in surgery is more relevant for surgery in lumbosacral dermatomes compared with upper thoracic dermatomes because of the greater distance between root level and dorsal horn level in these two circumstances.[468]

Placement of catheters at thoracic levels requires consideration of risk/benefit trade-offs. Therefore if a catheter tip is at the lumbar or caudal level and the surgery is in thoracic and upper abdominal dermatomes, continuous infusions containing local anesthetics alone or with lipophilic opioids, such as fentanyl or sufentanil, are likely to be ineffective. Increasing the infusion volume is limited by the maximum allowable systemic local anesthetic concentrations. In this circumstance, a reasonable alternative is to administer hydrophilic opioids (e.g., morphine or hydromorphone) through lumbar or caudal catheters. Such a technique, however, precludes the optimal use of local anesthetics and the considerable benefit that may accrue from a multimodal approach to regional analgesia. Overall, we do not endorse the practice of placing lumbar catheters for thoracic dermatomal coverage.

An epidural catheter can be placed in an awake, sedated, or anesthetized child. A prospective analysis of data from the PRAN database found that the risk of inserting an epidural catheter in

an anesthetized child by an experienced clinician is not greater (and may be less) than attempting such placement in an awake adult, nor is it clear that a child can accurately report sensations of paresthesia or differentiate the discomfort of needle passage from more ominous pain.[107,469,470] There is a perception that placing an epidural in the thoracic region is more dangerous than in other spinal levels, but current data do not support this. In the U.K. epidural audit, serious (grade 1) complications were independent of the level of insertion. Overall, there was a greater risk of all types of complications in thoracic epidurals placed in neonates and infants, but half of these complications were the less severe grade 3. Risk is likely more related to the age of the patient rather than level of insertion.[470] In a report of four cases of neurologic complications in children with epidurals, three of four catheters were at T11 or lower.[471] We believe that data and experience support the safety of placement of epidural catheters in anesthetized children by anesthesiologists trained and experienced in this procedure, although the tolerances for error in infants are smaller than in adults and older children.[107,470,472,473]

It is extremely important to secure caudal catheters to the skin with a clear occlusive dressing to avoid contamination or dislodgment and to allow daily inspection of the site. In addition, tincture of benzoin or other adhesive solution reduces the incidence of catheter and dressing displacement. For a caudal catheter, the use of an adhesive-edged plastic drape, covering the area from the gluteal crease over the dressing, also helps prevent fecal soiling of the dressing by children who are in diapers. Another option is to tunnel the caudal catheter in a cephalad-lateral direction, which decreases colonization rates to that seen with epidural catheters.[454] Despite the above precautions, if a dressing becomes detached and the insertion site is contaminated, it is prudent to remove the catheter. The use of lumbar or thoracic catheters removes the insertion site from the diaper area and thereby further reduces the potential for contamination of the catheter and the insertion site.

Successful management of children with an epidural catheter requires carefully coordinated monitoring protocols, nursing management, and medical management of drug selection and dosing. As with PCA or continuous-infusion opioids, the orders should be standardized and written in consultation with the nursing staff, so that misinterpretations are less likely to occur (Fig. 44.8). Because the single most sensitive monitor of children receiving epidural opioids is the nurse, rather than a mechanical or electronic device, education of the nursing staff is of paramount importance to ensure safety. Nursing staff can also assess the adequacy of analgesia and thereby help to titrate the drug dose. Catheter insertion sites should be inspected at least once daily by the pain service, both for the integrity of the dressing and for any evidence of erythema or skin infection (Fig. 44.9). *When continuous infusions are used, the tubing connecting the infusion pump to the catheter should not have any injection ports and it should be clearly labeled as an epidural catheter to preclude unintended epidural administration of drugs intended for IV use.* We use color-coded tubing and a color-coded drug cassette for the continuous administration of regional agents. Although the same pumps are used for IV PCA administration, it is immediately obvious what route the drug is intended for simply by recognizing the tubing and cassette color.

A variation of traditional epidural analgesia and PCA is the technique of patient-controlled epidural analgesia (PCEA).[474] With this variation of traditional PCA, children are generally maintained with an infusion of epidural analgesics (frequently opioid alone or an opioid–local anesthetic mixture) and have the capability of self-administering supplemental doses when needed. When using this technique, the background infusion is used to provide the majority of the analgesia and the child can add to this when needed. It must be emphasized that the time needed for a bolus dose to effect a change with epidural administration is more prolonged than it is with IV agents. Therefore with PCEA lockout intervals are greater (often 15 to 30 minutes) than with PCA.[475,476] The considerations one would use for choosing this technique include the same child-monitoring factors for IV PCA and epidural analgesia, and maximum local anesthetic doses must be carefully calculated to cover the contingency of the greatest possible activation of the PCEA demand doses. Smart pump technology has been demonstrated to improve safety of this technique.[477]

SELECTION OF DRUGS AND DOSES. Local anesthetics, opioids, and adjuvant agents were discussed previously; this section addresses the specifics of drug choices for continuous infusion through indwelling catheters. Many drugs and combinations have been administered via continuous infusion to the epidural space to provide postoperative analgesia.[421] The most common choices involve mixtures of local anesthetics and opioids, such as bupivacaine and fentanyl, although increasingly, clonidine is being added (Table 44.11). Continuous infusions for peripheral nerve and plexus blocks are generally limited to local anesthetics, as evidence for the efficacy of other agents in these blocks is equivocal at best.

The choice of drug is based on several factors: the age and size of the child, the operation, and the underlying medical conditions that may decrease the margin of safety of one of the agents. The volume of solution required to fill the epidural space on a milliliter-per-kilogram basis appears to decrease with age; therefore older children and adolescents may require less volume than infants and young children, based on weight. In children older than 1 year of age, continuous infusions of ropivacaine up to 0.4 mg/kg per hour for up to 72 hours produced stable blood concentrations of unbound ropivacaine without evidence of accumulation or toxicity.[478,479] In very young or preterm infants, however, the risk of accumulation of the amino-amide local anesthetics, and thus the potential for toxicity, is particularly problematic.[480,481] Neonates are at increased risk for potential local anesthetic toxicity because of decreased protein binding (resulting in increased unbound drug) and possibly immature drug metabolism. The manifestations of local anesthetic toxicity in infants and neonates may be more difficult to recognize than in adults. Hence, we recommend a conservative maximum infusion dose for ropivacaine of 0.2 mg/kg per hour for infants younger than 6 months, which produces stable plasma levels for up to 72 hours.[482] Bupivacaine is generally not recommended because of evidence of accumulation in some neonates and small infants, and its lower therapeutic index, especially in this population; however, if ropivacaine is not available, the same reduced maximal dose limits apply (i.e., <0.2 mg/kg per hour).[481,483] Of the five cases of local anesthetic toxicity reported to the PRAN, four were in infants 3 months of age or younger, highlighting the greater risk in this age group.[107] Because safe infusion rates of ropivacaine in the neonate frequently provide insufficient analgesia when wide dermatomal coverage is needed, the amino-ester local anesthetic chloroprocaine may be used in an epidural infusion instead.[484,485] Although the amino-amide local anesthetics are slowly cleared in neonates and young infants, the amino-ester chloroprocaine is cleared extremely rapidly, even in preterm infants, via ester hydrolysis, with an elimination half-life of several minutes.[484] This permits large doses and infusion rates with a reduced risk for

Child's weight: _____ kg
Allergies: _____

Continuous regional analgesia via (check appropriate modality)

☐ Caudal epidural ☐ Lumbar epidural ☐ Thoracic epidural ☐ Plexus or peripheral nerve catheter (specify)

_____

The catheter is _____ cm at the skin. Loss of resistance (for lumbar and thoracic epidurals) was at _____ cm.

Infusion:

(Choose one only) ☐ Bupivacaine ☐ Ropivacaine ☐ Chloroprocaine
(Concentration) ☐ 0.075% ☐ 0.1% ☐ 0.2% ☐ 1% (chloroprocaine only)

Additives (caudal and epidural only):

Opioid *(choose one only)* ☐ Fentanyl ☐ Hydromorphone ☐ Morphine
Concentration (μg/mL): ☐ 1 ☐ 2 ☐ 3 ☐ 5 (hydromorphone and morphine only) ☐ 7 (morphine only) ☐ 10 (morphine only)
☐ Clonidine Concentration (μg/mL): ☐ 0.5 ☐ 1

Infusion rate: Start at _____ mL/h. Range: _____ to _____ mL/h. This is a maximum of _____ mg/kg/h of local anesthetic and _____ μg/kg/h of opioid.

Dosing guidelines for regional anesthesia/analgesia solution

	Local anesthetics		Opioids			
	Bupivacaine or ropivacaine	Chloroprocaine	Fentanyl	Hydromorphone	Morphine	Clonidine
Concentration	0.05%-0.1% (0.5-1 mg/mL) May use up to 0.2% for ropivacaine	1%-1.5% (10-15 mg/mL)	1-3 μg/mL	3-7 μg/mL	5-10 μg/mL	0.5-1 μg/mL
Suggested dose	Less than 6 months of age: 0.2 mg/kg/h; Maximum dose: 0.2 mg/kg/h 6 months of age or older: 0.2-0.4 mg/kg/h Maximum dose: 0.4–0.5 mg/kg/h	0.2-0.8 mL/kg/h (neonates)*	0.3-1 μg/kg/h	1-2.5 μg/kg/h	1-5 μg/kg/h	0.1-0.2 μg/kg/h

*Note that the concentration of additives must be proportionally reduced with chloroprocaine if higher infusion rates are administered to avoid overdose.

Treatment of side effects:

Respiratory depression: For RR < ____ BPM, immediately stop epidural infusion and call acute pain service STAT. Administer O_2, ensure clear airway, and assist ventilation if necessary.

☐ Naloxone (Narcan) 1 μg/kg IV = _____ μg, repeat q1min as needed

Nausea and vomiting: ☐ Ondansetron 0.1 mg/kg (4 mg maximum) = _____ mg IV q6h
☐ Metoclopramide 0.1 mg/kg (10 mg maximum) = _____ mg IV q6h

Pruritus: ☐ Nalbuphine 0.05 mg/kg = _____ mg IV q4h

☐ *For any of above,* begin naloxone infusion at 0.25 μg/kg/h = _____ μg/h

Adjunctive medications: ☐ Acetaminophen 10 mg/kg PO q4h for 24 hours then q4h prn
Inadequate analgesia: ☐ Morphine 0.05-0.1 mg/kg IV = _____ mg q3-4h prn for pain
☐ Ketorolac 0.5 mg/kg IV = _____ mg q6h prn for pain (up to 15 mg ≤ 50 kg; up to 30 mg > 50 kg)
Muscle spasms: ☐ Diazepam 0.05-0.1 mg/kg IV = _____ mg q6h prn

Monitoring and equipment: *must choose for patients receiving epidural opioids*

☐ Continuous pulse oximetry and respiratory monitoring
☐ O_2 and bag/mask delivery system, suction at the bedside

Nursing orders:

VS: ☐ q4h: temp, HR, RR, BP, pain score
☐ Dermatome level for caudal and epidural
☐ Spo_2 and sedation score (required if opioids are used). Call acute pain service for RR < _____ bpm.
☐ Record Bromage score q8hr; call acute pain service if 4 or less (choose for children receiving local anesthetics).

Call acute pain service for any questions or problems: inadequate analgesia despite intervention, loose or contaminated dressing, catheter disconnect, sedation score >3, increased somnolence, confusion, agitation, dizziness, tinnitus, hypotension, bradycardia, fever >38.2°C; inflammation, tenderness, or swelling at catheter site; Bromage score >0.

Maintain IV access.

For epidural or peripheral nerve block of lower extremity: Ambulate with assistance only with order from primary service and Bromage score of 0. Pad block extremities and elevate heels off of bed.

systemic toxicity. Case reports of chloroprocaine toxicity in infants are rare, generally short-lived (<1 minute), and self-limiting owing to its rapid metabolism.[486,487] Previous concerns regarding neurotoxicity after chloroprocaine involved a succession of formulations with preservatives, including metabisulfite, methylparaben, and ethylenediaminetetraacetic acid, although the current formulation is preservative-free. An epidural solution of 1% to 1.5% chloroprocaine can be infused at rates of 0.2 to 0.8 mL/kg per hour.

When a block is not previously established in the OR, it is useful to dose through catheters with local anesthetic (without opioids) at a volume of 0.05 mL/kg per spinal segment or between 0.5 and 1 mL/kg of local anesthetic, not to exceed 5 mg/kg of lidocaine, or 2.5 mg/kg of bupivacaine or ropivacaine. Some clinicians administer a loading dose of opioid as well, such as 1 to 3 µg/kg of hydromorphone. Bupivacaine infusion rates should not exceed 0.4 mg/kg per hour (e.g., 0.4 mL/kg per hour for 0.1% bupivacaine) for children because toxicity may result.[488] If epidural local anesthetic infusions are begun without either opioids or clonidine (e.g., 0.0625%–0.125% bupivacaine) and inadequate analgesia occurs at infusion rates of 0.3 to 0.4 mL/kg per hour (a maximum dosage of 0.4 mg/kg per hour), further increases in the local anesthetic infusion rate or concentration should be avoided. Instead, correct placement of the catheter should be confirmed (e.g., with an epidurogram or chloroprocaine/lidocaine test dose) if dermatomal levels cannot be unequivocally determined. If the catheter is properly located, an epidural opioid or clonidine can be added to the local anesthetic infusion. It is imperative to confirm that an epidural catheter is properly functioning immediately after an infant or child arrives in the PACU or if there is any question of its proper location later. If an amino-amide local anesthetic has been given during or after surgery as an initial bolus followed by a continuous infusion, then use of a repeat bolus dose of these amino amides may result in a "stair casing" of plasma concentrations, with a risk for systemic toxicity. Although administration of epidural or systemic opioids may provide analgesia, they may not clarify the site of the epidural catheter. For this reason, confirmation of the catheter location is imperative whenever the clinical picture is not clear. Several means of accomplishing this are described later.

FIGURE 44.9 Superficial skin infection at the site of an epidural catheter insertion. The catheter was withdrawn, and the problem resolved with local skin care only.

Local anesthetic and opioid combinations (e.g., 0.1% bupivacaine or ropivacaine with fentanyl 2 to 3 µg/mL or hydromorphone 3 to 5 µg/mL at infusion rates of 0.2 to 0.4 mL/kg per hour) via lumbar epidural catheters or caudal catheters advanced to a lumbar position, provide adequate analgesia in most children undergoing lower abdominal or lower extremity surgery. Fentanyl alone (0.3 µg/kg per hour) has been shown to provide 90% effective postoperative analgesia after a levobupivacaine block was established during surgery.[489] However, the blood concentrations achieved with epidural fentanyl are in the therapeutic range, suggesting that much of the therapeutic effect is due to systemic absorption, not entirely surprising with a highly lipophilic agent.[490] We do not recommend the use of epidural fentanyl for this reason. Epidural opioids should be used with great caution, or at considerably reduced doses, in children at risk for apnea or hypoventilation (e.g., former preterm infants, children with chronic respiratory failure or disorders of central control of ventilation, or those with

TABLE 44.11 Commonly Used Medications for Epidural Administration

	Dose Range	Untoward Effects	Comments
Local Anesthetics		Motor block	
Bupivacaine	0.2–0.4 mg/kg per hour		Maximum dose 0.2 mg/kg per hour for infants <6 months
Ropivacaine Levobupivacaine	0.2–0.5 mg/kg per hour 0.2–0.5 mg/kg per hour		Levo-enantiomer; 20%–30% less toxicity than racemic amino amides. Maximum dose 0.2 mg/kg per hour for infants <6 months.
Chloroprocaine	1%–1.5%; 0.2–0.8 mL/kg per hour (neonates)		
Opioids		Respiratory depression, sedation, pruritus, urinary retention	
Fentanyl	0.3–1 µg/kg per hour		Lipophilic; high rate of systemic absorption
Hydromorphone Morphine	1–3 µg/kg per hour 1–5 µg/kg per hour	Delayed respiratory depression from rostral spread	Hydrophilic; use when surgery is more extensive. Hydromorphone recommended over morphine due to less rostral spread.
Adjuncts			
Clonidine	0.1–0.2 µg/kg per hour	Sedation, respiratory depression at greater doses, hypotension (possibly postural) at high doses	Increased risk of apnea with high doses in neonates

TABLE 44.12 Treatment of Untoward Effects of Epidural Opioids

Adverse Effect	Treatment	Infusion Rate
Pruritus	Naloxone, 0.5–1 μg/kg IV or infusion at 0.25–1 μg/kg per hour	No change, or decrease opioid concentration, or remove opioid if pruritis persists
	Nalbuphine, 0.025–0.05 mg/kg IV every 6 hours	
Nausea and vomiting	NPO for 24 hours	Decrease opioid concentration or decrease rate by 10%–20% or remove opioid if nausea persists
	Naloxone, 0.5 μg/kg IV or infusion at 0.25–1 μg/kg per hour	
	Ondansetron 0.1 mg/kg (maximum 4 mg) IV every 6 hours	
	Metoclopramide, 0.1–0.15 mg/kg IV every 6–8 hours	
Urinary retention	Bladder catheterization (one time; some institutions keep urinary catheters in these children routinely)	Decrease opioid concentration
	Naloxone, 0.5 μg/kg IV or infusion at 0.25–1 μg/kg per hour	
	Indwelling urinary catheter	
Respiratory depression[a]; child unarousable, hypoxemic, hypercarbic, or apneic	Oxygen by mask; assisted ventilation if needed Naloxone, 5–10 μg/kg IV Transfer child to monitored setting until episode is fully resolved. Consider naloxone infusion (0.25–1 μg/kg per hour)	Discontinue infusion; consider possibility of intrathecal catheter migration (check by aspirating)
	Consider naloxone infusion (0.25–1 μg/kg per hour)	

IV, intravenous; *NPO*, nothing by mouth.
[a]Stop infusion until the child is alert, if using morphine or hydromorphone.

obstructive sleep apnea). In very young infants, epidural infusions of both local anesthetics and opioids and other adjuvants can be used safely, but they require increased surveillance and reduced initial infusion rates. This is because (1) drug clearance may be reduced; (2) protein binding, which is decreased, may increase the free serum drug concentrations; and (3) titration to clinical end points (e.g., pain scoring) is less precise. A double-blind randomized study demonstrated that the combination of 0.1% bupivacaine with 1 μg/mL of fentanyl provided superior analgesia compared with local anesthetic alone, with no increase in adverse effects, when infused through thoracic catheters after thoracotomy in infants younger than 6 months of age.[491] In contrast, another study found no incremental benefits in children after abdominal surgery from the addition of fentanyl to epidural catheters with greater local anesthetic concentrations (e.g., 0.125% bupivacaine at 0.3 mL/kg per hour).[489,492] The use of fentanyl as an adjunct may increase PONV.[492] In some centers, application of epidural infusions, especially with opioids, for children younger than 3 to 6 months of age is restricted to intensive care areas. Acetaminophen or NSAIDs can also be administered if adjunctive analgesia is needed.

If the catheter tip is positioned at the thoracic dermatomes, bupivacaine or ropivacaine with opioid may be used for thoracic and upper abdominal surgery.[93,103,493–496] Infusion rates may need to be decreased for thoracic catheters compared with lumbar catheters because the capacitance or volume of the epidural space appears to be less than in lumbar regions. The authors have noted that some older children and adolescents require greater than expected infusion rates to achieve adequate dermatome levels for analgesia. Using hydromorphone may be of benefit in these instances, as its greater hydrophilicity results in wider spread. We rarely use epidural morphine and prefer a continuous epidural infusion of hydromorphone when greater spread is desired, as its adverse effect profile appears to be preferable. Studies in adults suggest an epidural potency ratio of between 2:1 and 3:1, compared with 5:1 for systemic morphine.[497] When mixed with a local anesthetic for lumbar epidural infusion, concentrations of 3 to 5 μg/mL of hydromorphone yield a solution that results in an appropriate infusion rate of both drugs. Hydrophilic opioids, especially when administered by infusion, require prolonged careful observation (see later discussion). If somnolence, shallow breathing, or hypopnea occurs, the infusion must be stopped, not simply decreased, until these effects subside and appropriate therapy is instituted (Table 44.12). Common epidural infusions and alternative modalities for pain management of sample cases are provided in Appendix 44.1.

Adjuvant agents, particularly clonidine, can be administered continuously via epidural catheter, most commonly in combination with or in place of local anesthetics and opioids. The primary analgesic effect appears to be via an α-adrenergic mechanism. Although epidural clonidine has been found to be less potent in terms of analgesic efficacy compared with epidural opioids, such as fentanyl, it has occasionally been substituted for neuraxial opioids because it is associated with a smaller incidence of untoward effects, such as respiratory depression, nausea, and pruritus.[498–501] This also suggests that the combination of all three agents, each at smaller concentrations than required individually, might be beneficial at reducing the incidence of adverse effects while optimizing analgesia, but carefully controlled studies have yet to be performed.

Risks and Untoward Effects

Adverse effects associated with regional analgesia can be grouped according to those caused by the technique (e.g., the catheter) and those related to the medications (e.g., local anesthetics, opioids, other adjuvants). Three large prospective studies have confirmed the safety of regional anesthetics in children, detecting very small complication rates.[470,472,502]

Local anesthetics in the dilute concentrations used for postoperative analgesia have a very small incidence of untoward effects. Motor blockade occurs less frequently with dilute concentrations, but can be observed even with small concentrations of bupivacaine,

TABLE 44.13	Bromage Score[a] for Assessment of Motor Function of the Legs
Full motor function: can flex hip, knee, and ankle	0
Can't flex hip (unable to perform straight-leg lift)	1
Can't flex hip or knee	2
Can't flex hip, knee, or ankle	3

[a]Note that alternative scoring schemes for the Bromage scale exist that range from 1 to 4 (sometimes denoted I–IV) that directly correspond to the 0–3 scale depicted here.

such as 0.1%. As discussed earlier, children with neuromuscular disorders causing motor weakness are especially at risk and should be observed carefully for exacerbation of their motor weakness. Motor weakness and blockade can result in several problems. Inability or difficulty in ambulation may impede recovery. The inability of a child to move a limb can result in skin breakdown or peripheral nerve compression injuries, especially if meticulous attention to frequent repositioning does not occur. We are aware of a case of complex regional pain syndrome in the distribution of the peroneal nerve that arose in this manner. Motor blockade should be avoided, and frequent examinations can quantify motor function using the Bromage score (Table 44.13). At our institutions, motor function is assessed every 8 hours along with the other vital signs pertinent to regional blockade. If motor blockade occurs, the clinician should (1) reduce the dose (volume or concentration) of local anesthetic, (2) pay strict attention to padding and to frequent repositioning of the extremity involved, and (3) consider stopping the infusion until motor function returns. *Rapid onset of more profound motor block during epidural infusion should raise immediate concern about erosion of the catheter into the subarachnoid space.* Motor blockade may occur more frequently with peripheral nerve or plexus analgesia than with epidural blocks, and is subject to the same precautions. When children are discharged home with a peripheral nerve catheter, it is particularly important to teach the parents how to deal with motor blockade and to protect the extremity from unintended injury.

The PK of bupivacaine have been studied in infants and children after both single-injection doses[503] and continuous infusions. Reduced protein binding increases the free fraction of circulating bupivacaine, which increases the risk of bupivacaine toxicity.[504] Neonates and infants with immature clearance may be at particular risk for bupivacaine accumulation.[483] Seizures and cardiac arrest have been reported when large doses of bupivacaine have been administered, usually after excessive infusion rates or unintended intravascular injection. Limited information is available regarding extended administration over days, although low concentration solutions (and therefore low total doses) reduce the risk for toxicity. *l*-Enantiomers of amino amides (ropivacaine and levobupivacaine) have toxic thresholds that are greater than that of bupivacaine by as much as 30%, and such drugs should be considered in smaller children and for blocks that require greater infusion rates and for greater durations. A particular "hidden" risk occurs when a block is functioning less than optimally and bolus doses are administered in an attempt to broaden the dermatome level. Even though the infusion rate is kept within the recommended range, the bolus doses can raise the blood concentration above the toxic threshold. *Whenever a local anesthetic is administered by continuous infusion, nursing and medical staff must be aware of the signs and symptoms of local-anesthetic toxicity, be vigilant in monitoring for the early detection of those signs, and be familiar with the use of lipid rescue protocols to treat toxicity if it occurs.* The use of lipid emulsion for treating local anesthetic toxicity is discussed in detail in Chapter 42.

Tachyphylaxis during prolonged administration of local anesthetics is a theoretic consideration, although no systematic studies have addressed this phenomenon in children. In animal models, tachyphylaxis is accelerated by hyperalgesia and prevented by agents that prevent hyperalgesia at spinal sites. One rationale for coadministration of opioids or clonidine in epidural infusions may be to reduce the incidence or severity of tachyphylaxis. As discussed in Chapter 42, hemodynamic stability is maintained in children younger than 6 years of age during spinal or epidural blockade, even with extensive sympathetic blockade. As children approach school age, however, rapid position changes may produce hemodynamic responses after extensive sympathetic blockade, and this must be considered in children who receive continuous epidural blockade. Orthostatic changes may be exacerbated when epidural clonidine is infused, and extra caution should be taken.

Neuraxial opioids confer several potential adverse effects, including respiratory depression, nausea, urinary retention, and pruritus. Indeed, despite their proven analgesic efficacy, not all practitioners are proponents of their use because of these effects, preferring other adjuvants instead.[505] The most effective means of treating or preventing the adverse effects is the use of opioid antagonists or mixed agonist-antagonists. This approach directly targets the etiology of the signs rather than simply treating their manifestations. Low-dose naloxone infusions, which have been shown to be effective in children receiving parenteral opioids, are also effective for treating the adverse effects of neuraxial opioids, although pediatric data are lacking.[506–510] We have used rates similar to those shown effective in the PCA studies, beginning at 0.25 μg/kg per hour.[261] This infusion rate can be titrated upward as needed to 1 μg/kg per hour without adversely affecting analgesic efficacy.[262]

The most worrisome and dangerous complication is respiratory depression. The lipophilic agents (fentanyl and sufentanil) have the widest therapeutic indexes. This results from greater receptor binding in the substantia gelatinosa of the spinal cord adjacent to the area of drug administration, thus limiting the rostral spread of the drug, but systemic absorption is considerably greater, resulting in risk of respiratory depression owing to greater blood concentrations. Even though the hydrophilic opioids, hydromorphone and morphine, pose a risk for respiratory depression, the incidence remains small when prudent dosing is followed. Nevertheless, reports in the pediatric literature of respiratory depression after epidural administration of morphine demonstrate that vigilance in monitoring is mandatory.[413,511,512] *The hallmark of impending overdose of central neuraxial opioids is increasing sedation and decreasing DEPTH AND RATE of respiration. It is important to recognize that the depth of respiration must be assessed, not just the rate, because children frequently develop decreased tidal volume before the respiratory rate decreases, leading to alveolar hypoventilation and the potential for hypercarbia and hypoxemia.*[513] Monitoring patients receiving neuraxial opioids entails considerations similar to those with systemic opioids as discussed earlier. As previously noted, pulse oximetry becomes a poorly sensitive monitor for hypoventilation if the child is using supplemental oxygen, and capnographic techniques are plagued by a high rate of false alarms and not well tolerated by children. Again, it is emphasized that no monitor can replace vigilance and frequent clinical assessment.

Oversedation, diminished respiratory depth, and slowing of the respiratory rate are treated by decreasing the rate of opioid

administration and, if necessary, administering small incremental doses of naloxone (0.5–1 μg/kg) every few minutes until the adverse effects are reversed (see earlier discussion). A continuous low-dose infusion of naloxone, as described earlier (0.25–1 μg/kg per hour) may need to be started. More profound respiratory depression, including inability to arouse the child and apnea, must be treated more aggressively. *The new development of respiratory depression in a child receiving what appears to be an appropriate opioid dose should always raise the question of catheter migration into the subarachnoid space. Whenever central neuraxial opioids are administered, facilities must be immediately available at the child's bedside for resuscitation, in the unlikely event of respiratory depression.* It is recommended that emergency equipment, including a bag-valve device, appropriate sizes of masks and airways, and suction, be at the child's bedside or in a "code cart" that is accessible within seconds, should the need arise. Naloxone should similarly be immediately available, without the need to obtain the drug from the pharmacy. All children receiving continuous regional analgesia should also have an IV line (a heparin lock is adequate in those children not requiring IV fluids).

Pruritus is a common adverse effect associated with epidural or intrathecal opioid use, occurring in as many as 30% to 70% of children. Antihistamines are less effective antipruritics in this situation, because the primary mechanism is a central opioid, not a histamine effect. Thus opioid antagonists, used in small doses, are most effective. Again, low-dose infusions of naloxone can be administered with good results.[262,506,507,509,510] Some practitioners have found low-dose nalbuphine to be effective to antagonize pruritus (25 to 50 μg/kg every 6 hours PRN).[507,508] In the only pediatric study of nalbuphine, it was no better than placebo. However, the placebo arm in this study had a remarkable efficacy of 58% (nalbuphine 57%).[514]

Nausea and vomiting can also occur in association with opioids (both systemic and neuraxial) and may be more common with morphine than with fentanyl. Children who are fasted during the first 24 hours after surgery do not vomit excessively, even when given caudal morphine.[515] As with all other opioid adverse effects, nausea and vomiting respond to the previously mentioned doses of naloxone or mixed agonist-antagonists, such as nalbuphine. Some antiemetics, such as antihistamines and butyrophenones (e.g., droperidol), may cause sedation and should be used with caution. Serotonin receptor antagonists, such as ondansetron (0.1–0.15 mg/kg, maximum 4 mg) or dolasetron (0.35 mg/kg, maximum 12.5 mg), may be effective and not cause sedation.[516] Metoclopramide in doses of 0.1 to 0.15 mg/kg IV every 6 to 8 hours may provide adequate relief, with less sedation than other drugs of its class. It is sometimes prudent to decrease the infusion rate of the epidural (if the block level permits) or the opioid concentration in the infusate when untoward effects require treatment. Untoward effects of epidural opioids and their treatment are summarized in Table 44.12.

Urinary retention is a relatively common complication of neuraxial opioids. Studies of single-injection caudal blocks have found that this complication does not occur when epidural local anesthetics are used, only when neuraxial opioids are added.[517] Neuraxial opioids depress detrusor contractility in a dose-dependent manner, and this effect may actually outlast the analgesic effect of the drug by hours.[518,519] Different approaches have been used for this problem, including indwelling urinary catheterization and the use of opioid antagonists.[520]

Concerns have been raised that regional analgesia could mask or delay the detection of compartment syndrome of an extremity because of the intensity or quality of analgesia produced by neural blockade.[521] Despite the theoretical worries, this has not been demonstrated in numerous studies, and indeed, the opposite has been observed, that the onset of pain in a patient with previously adequate analgesia from an epidural or nerve block is an early warning sign that may herald the onset of compartment syndrome.[522,523] The concentration of local anesthetics used for postoperative analgesia appears to be inadequate to mask the intensity of ischemic pain caused by compartment syndrome.[524] In addition, epidural blockade is not effective in controlling the discomfort from intense pressure (as demonstrated by the parturient's ability to perceive pressure during labor contractions despite being pain-free). The loss of effective analgesia in a child at risk of compartment syndrome should raise suspicion and prompt urgent investigation before any changes are made to the analgesic regimen (see also Chapter 30).

Catheter-Related Complications

Catheter-related complications are common, with an incidence of around 5% in most studies.[452,502] Although they are generally minor, a nonfunctioning catheter usually results in premature discontinuation of the infusion and a reliance on opioids for analgesia. Inadequate analgesia must prompt an examination of the child and a review of the operative procedure and the analgesic technique. The dermatome level should be determined using differentiation between cold and warm sensation in children who are cognitively and developmentally able to cooperate. Presence of a dermatome level suggests a successful block of inadequate height. No demonstrable blockade suggests a primary malfunction, although low concentrations of local anesthetic may make differentiation of the level difficult in some children. If there were difficulties during catheter placement coupled with a lack of effective analgesia when the child emerges from general anesthesia, the catheter is likely malpositioned. We often use epidurography in this situation to determine whether the catheter is in the epidural space. Misplacement in various locations has been reported, including the subdural space, paravertebral space, tissue planes adjacent to the spine, and even in an epidural blood vessel after a negative test dose.[463,525–527] The catheter's location can be easily visualized on a plain radiograph (or with fluoroscopy in the OR) after the injection of a small volume of nonionic contrast agent. Contrast agent in the epidural space has a characteristic "bubbly" appearance, with the contrast agent centrally located over the spinal column (Fig. 44.10). The existence of a median raphe in the epidural space has been postulated and may be the cause of unilateral multi-dermatome blockade.[528] This has been demonstrated on epidurography when unilateral blockade has occurred (Fig. 44.11). A single unilateral dermatomal band of analgesia or temperature-sensation change may indicate that the catheter has passed through a spinal foramen. In some cases, simply withdrawing the catheter 1 or 2 cm may allow proper repositioning within the epidural space. A functional, rather than anatomic, method of confirming epidural placement is the "chloroprocaine test," which has the advantage of both providing rapid analgesia (with a properly located catheter) and confirming the site of placement. A chloroprocaine test is presented in Fig. 44.12.

On occasion, a collection of fluid may be found at the skin insertion site and pooling under the dressing. Experience suggests that in most cases this is not, as one may fear, cerebrospinal fluid, but rather edema fluid, or occasionally local anesthetic solution, tracking along the catheter's course and leaking through a hole in the skin from the subcutaneous tissues. Local anesthetic solutions

FIGURE 44.10 An epidurogram shows the appearance of the contrast agent centered in the spinal column and also the bubbly appearance of the contrast agent, presumably produced by the epidural fat and plexus.

FIGURE 44.11 Epidurogram taken with fluoroscopy demonstrating unilateral spread of contrast agent. The contrast agent appears to have a very sharp edge precisely in the center of the spinal column, demarcating one side of the epidural space from the other.

would test negative for glucose and protein, whereas cerebrospinal fluid and edema fluid would test positive for glucose and protein. It usually requires no special treatment except reinforcing the dressing. It subsides as the edema and third-space fluids are mobilized in the first days after surgery. Application of collodion or cyanoacrylate skin bonding over the insertion site can reduce leakage around the catheter.[529]

The catheter site should be inspected daily to ensure that the dressing is intact and to assess for the presence of infection. Infections are exceedingly rare, perhaps in part because of the bactericidal properties of the local anesthetics themselves.[530] Although colonization of catheters, usually with *Staphylococcus epidermidis* and other gram-positive organisms, appears common, adult and pediatric studies have shown that this is not associated with neuraxial infection.[531,532] In the U.K. epidural audit, there were three cases of deep tissue infection and 25 local infections reported out of 10,660 epidural catheters, and longitudinal data from a single institution showed similar rates of infection.[470,533] Tunneling a catheter subcutaneously may reduce the risk of bacteriologic contamination and permit the use of a catheter for a greater period of time.[454] A study of the microbiology of the infusion fluids and delivery systems has demonstrated that catheter-related infections of the deep tissues, including epidural abscess, appear to have their origin in local skin infections that track along the catheter's path or via a bacteremia.[534] *Any sign of local infection is cause for immediate catheter removal.* Epidural abscess is a catastrophic complication that can be generally avoided if the catheter is removed early, when only a localized cutaneous infection is present.[535] Clinical signs include fever, malaise, and back pain. Specific neurologic signs, paresthesias, and motor symptoms (e.g., flaccid paralysis as cord compression develops, eventually progressing to spasticity) may occur late in the course if early warning signs are not heeded, but may progress rapidly once established. Children who develop fever or sepsis need to be evaluated on an individual basis. If a clear source for the fever is found, it is acceptable to leave the catheter in place with regular and frequent observation and reassessment, although we remove it if a child is overtly septic or if the situation is unclear.

Plexus Catheters

Catheters may be placed adjacent to upper and lower extremity plexuses. The prolonged duration of analgesia after a single-injection plexus blocks reduces the need for an indwelling catheter in many instances, and duration of action can be further prolonged by the adjunctive use of dexamethasone.[398,536] Specialized kits for peripheral nerve and plexus cannulation are commercially available. These catheters are inserted using the same landmarks and techniques as for placing a single-injection block. After initial dosing, 0.125% bupivacaine or 0.2% ropivacaine at 0.1 to 0.2 mL/kg per hour may be infused. Potential complications of continuous brachial plexus blockade include infection and nerve injury, although these are quite rare, and no persistent neurologic deficits have been reported in major pediatric databases.[452,458]

Infusions can be delivered with conventional infusion pumps or disposable elastomeric controlled infusion devices described earlier. We often use conventional infusion pumps for inpatients owing to reduced cost and to the increased safety that may be inherent in the familiarity of the inpatient nurses with such systems. The disposable devices permit the child to be discharged home and still receive long-lasting analgesia with a regional anesthetic. Most commonly, 0.2% ropivacaine is used at rates of 0.1 to 0.2 mL/kg per hour.[452] An organized system of daily follow-up by telephone or visiting nurses is essential for safety and efficacy of such a service, but both limited published and anecdotal experience suggests that ambulatory analgesia with peripheral neural blockade can be an effective modality in pediatric outpatients.[458] Catheters with multiple side holes can be placed in a fascial plane or wound bed by the surgeon at the time of closure and local anesthetics are infused over several days for postoperative analgesia. There

PROCEDURE FOR THE CHLOROPROCAINE TEST

An anesthesiologist is present for the procedure with use of standard monitors and supplies for providing respiratory or hemodynamic support.

1. A loading dose of chloroprocaine 3% is divided in five equal increments, each given at 1- to 2-minute intervals (over 5-10 minutes total) according to weight approximately as follows: (doses may be adjusted according to clinical circumstances)

Weight Group	Increment Volume	Total Volume
0-10 kg	0.125 mL/kg	0.6 mL/kg
10-20 kg	0.1 mL/kg	0.5 mL/kg
20-35 kg	2.5 mL (fixed volume)	12.5 mL (fixed volume)
35-60 kg	3 mL (fixed volume)	15 mL (fixed volume)
≥60 kg	3.5 mL (fixed volume)	17.5 mL (fixed volume)

2. Incremental dosing is stopped before giving the full dose if there are clear signs of bilateral lower extremity sensory or motor block, or a very definite reduction in heart rate (e.g., 30 beats/min) and blood pressure (e.g., 25-mm Hg drop in systolic pressure). In most cases, because you are performing this test because of signs of pain, there is some tachycardia and hypertension relative to baseline values at the start of the test. Transient cessation of crying in an infant or toddler is not a sufficiently specific positive response to warrant interruption of the test.

3. A catheter positioned in the **thoracic** epidural space will generally not show lower extremity sensory or motor block with the chloroprocaine test, but should give a very clear drop in heart rate and blood pressure, as well as a clear and persistent reduction in pain reports or pain behaviors.

4. If the chloroprocaine test is positive (i.e., confirms epidural placement), this implies that a stronger or different epidural solution is needed for steady-state pain relief. Because hydromorphone is sufficiently hydrophilic to spread from lumbar to thoracic spinal levels, **switching the solution from bupivacaine-fentanyl to bupivacaine-hydromorphone will provide good steady-state pain relief in >90% of these cases**. A typical loading dose of hydromorphone of 2 μg/kg (0.002 mg/kg) will provide analgesia within 30 minutes in most cases.

If the chloroprocaine test fails to confirm epidural placement, the catheter is repositioned, removed, or replaced according to clinical circumstances.

FIGURE 44.12 Chloroprocaine test to determine regional catheter function as performed at Children's Hospital, Boston. (Personal communication, C. Berde.)

are very limited data in children, but such techniques have been reported to be effective.[377,537,538] There are no studies to date comparing infusion rates; volumes of 2 to 5 mL/hour of 0.2% ropivacaine have most commonly been used, infused via the elastomeric pumps previously described.

Removal of Catheters and Transition to Oral Analgesics

The transition from continuous regional blockade to oral analgesics should ideally be achieved without a significant decrement in the quality of pain relief for the child and should permit the clinician to revert to more aggressive modalities, should the decision prove to be premature. The duration of continuous blockade is, of course, in large part dependent on the type of operation and the underlying medical and/or surgical problems of the child. Some children do well with transition to oral analgesics on the morning after surgery. This is often the case for the child who has undergone an uncomplicated ureteral reimplantation. For more painful procedures, such as Nuss bar placement for pectus excavatum in an adolescent, strong analgesics will be required for a greater duration. The norm in this situation is up to 3 days. We find it most effective to begin the transition from regional analgesia to oral therapy early in the morning. As soon as the regional infusion is discontinued, a dose of oral analgesic, usually an oral opioid such as oxycodone, is administered. In addition, by this time the child should already be receiving scheduled nonopioid oral adjuvants (i.e., NSAID, acetaminophen). This ensures that the oral agents have provided their full effect before the block recedes. The catheter is not removed until the child has demonstrated that the oral agents provide adequate comfort without any residual analgesia from the block, so that blockade can be reestablished if transition fails.

Children who are anticoagulated require special consideration before removing epidural catheters. Although there are no specific pediatric data, the recommendations of the consensus panel of the American Society of Regional Anesthesia and Pain Medicine, last published in 2010, are generally accepted.[539] The report notes *"the initiation of systemic therapeutic heparin therapy for medical or surgical indications in the presence of a neuraxial catheter potentially increases the risk of hematoma formation during catheter removal"* (https://www.asra.com/advisory-guidelines/article/1/anticoagulation-3rd-edition). Recommendations regarding how long to withhold heparin therapy before removing the catheter and how long to wait before restarting heparin vary based on whether the patient is receiving subcutaneous prophylactic doses (withhold 4–6 hours before removing the catheter, and restart immediately after removing it) or a therapeutic IV infusion (withhold 2–4 hours before removing

the catheter, restart the infusion 1 hour after removal). Fractionated or low–molecular-weight heparins pose a risk as well, compounded by several different regimens in common clinical use (once-a-day vs. twice-a-day dosing), differences between different agents, and the inability to assess the degree of anticoagulation with commonly available tests of coagulation (prothrombin time and partial thromboplastin time). The consensus panel recommends that catheters should be removed no sooner than 10 to 12 hours after the last dose of low–molecular-weight heparin with once-a-day administration, and dosing should resume no sooner than 4 hours after the catheter's removal. The use of continuous regional techniques is not recommended when twice-a-day administration is used. Many national societies have also published evidence-based guidelines that can assist in decision making, and the American Society of Regional Anesthesia and Pain Medicine has developed a smartphone app on this subject.

Pain Management in the Cognitively Impaired Child

The goals of pain management in the child with cognitive impairment are to minimize discomfort, maximize function, and improve the quality of life. With these goals in mind, the child's pain management plans should include multimodal pharmacologic and nonpharmacologic strategies tailored to the severity and etiology of pain. The World Health Organization's analgesic guideline[184] provides a framework for decision making related to analgesic use based on severity and persistence of pain.

OPIOID ANALGESICS

The use of opioids in children with cognitive impairment has been limited by concerns regarding potential adverse effects and a perceived reduced margin of safety because of diminished cardiorespiratory reserve and neurologic impairment. Indeed, one study identified that cognitive impairment was an independent predictor of adverse events from PCA/NCA.[84] It is, therefore, necessary to carefully balance the goals of providing adequate analgesia while minimizing adverse events related to analgesic treatments. For moderate to severe pain, scheduled nonopioid analgesics combined with judicious use of opioids titrated to effect is a suitable option. Children with cognitive impairment may lack the cognitive and motor skills to use PCA devices successfully. In these children, NCA or CCA will permit titration of small amounts of opioids to effect, without significantly increasing nursing workload.[540] A study of children whose postoperative pain was managed by parent- or nurse-controlled analgesia reported low pain scores and modest opioid requirements, with the use of basal infusions in addition to bolus dosing, in the majority of children.[541] Adverse effects included nausea and vomiting, and pruritus requiring treatment in 14% and 32% of children, respectively. Supplemental oxygen was required in 79% of the children, and respiratory depression requiring naloxone was noted in 2.8%. The management of two children was remarkable, in that one had received an average morphine dose of 0.045 mg/kg per hour and four concomitant sedatives, including diphenhydramine, diazepam, droperidol, and chloral hydrate, and the second had received only a small dose of morphine and no other sedatives, but the basal infusion of morphine was implicated as the cause of respiratory depression. Both recovered without sequelae. The studies noted previously highlight the importance of frequent and careful assessment of pain, depth of sedation, and respiratory status (using continuous pulse oximetry and/or noninvasive capnography) to ensure the safety and the comfort of children with cognitive impairment receiving opioid therapy

NONOPIOID ANALGESICS

Nonopioid adjuvants, such as acetaminophen, NSAIDs, or tramadol, should be added to provide synergistic analgesia and to reduce opioid requirements. They may be administered orally or via gastrostomy tubes. IV ketorolac provides excellent analgesia in children who have not initiated oral intake after surgery, although the risks of platelet dysfunction must be considered if ongoing bleeding is an issue. The α_2-agonist clonidine has also been used for its synergistic analgesic effects in these patients. However, it has the potential to cause sedation and hypotension.

Muscle spasms and clonus are an ongoing source of pain that may be difficult to differentiate in children who are cognitively impaired, and may be exacerbated after surgical procedures, particularly orthopedic and neurosurgical procedures. Diazepam, baclofen, and tizanidine all effectively treat acute painful muscle spasms after surgery in children with spasticity, but all of these medications have sedative effects, which can confound patient assessment when used with opioids. Benzodiazepines in particular have synergistic respiratory depressant effects when used in conjunction with opioids, so judicious use is essential.

EPIDURAL AND REGIONAL ANALGESIA

Epidural analgesia has been used with success in children who are cognitively impaired who are undergoing lower extremity orthopedic procedures, selective dorsal rhizotomy, and Nissen fundoplication.[91,542] Epidural catheters may be technically difficult to place in some of these children because of contractures and spine deformities. However, when feasible, this technique provides excellent analgesia, reduces muscle spasms, and promotes overall child comfort, with a small incidence of sedation and respiratory depression. Some children will still experience muscle spasms and will require intermittent benzodiazepines. Epidurals have been compared with systemic opioids in children with cerebral palsy undergoing selective dorsal rhizotomy.[91,543] Epidural catheters were placed under direct visualization by the neurosurgeon at the end of surgery. Both studies showed improved analgesia in the epidural groups, and one study demonstrated a lower incidence of desaturation in the epidural group, which allowed patients in this group to go directly to the general ward (instead of the pediatric ICU).[543] In summary, these studies support the attributes and safety of epidural analgesia in children with cognitive impairment.

Children with cerebral palsy who received continuous infusion of local anesthetics via catheters tunneled into the incision site following orthopedic surgery experienced significantly lower pain scores and required less oral analgesics on the first two postoperative days, compared with controls who received oral analgesics alone.[537] Although data related to peripheral and plexus blocks in cognitively impaired children are limited, our experience suggests that these, too, are safe and effective in this population and can contribute to reducing the reliance on systemic analgesics and, thereby, their adverse effects.

Emerging data must be used to guide treatment plans and protocols that incorporate frequent evaluation and careful monitoring of children with cognitive impairment. Involving a multidisciplinary pain team that includes the primary care provider, pain specialist, psychologist, nurse, physical therapist, and occupational therapist is required to provide the level of expertise to care for these children with special needs.

Summary

Postoperative analgesia is an integral and essential component of any pediatric anesthetic plan. Contemporary knowledge of anatomy, physiology, pharmacokinetics, and pharmacodynamics in infancy and childhood permits the anesthesiologist to apply advanced anesthetic and analgesic techniques with excellent efficacy and safety to all children. Analgesic plans should use a balanced approach, including nonopioid analgesics and regional anesthetic techniques, with the goal of minimizing opioid consumption and side effects. Clinical examples of postoperative management strategies are presented in Appendix 44.1. The optimal use of these modalities requires an understanding of the techniques outlined in this chapter, as well as the integration of multiple medical and nursing disciplines in the assessment and care of these children. A well-organized pediatric pain service and an educated nursing staff are the keys to the successful management of acute pain, which, in turn, can be expected to result in improved care for infants and children.[544]

ACKNOWLEDGMENT

We wish to thank Charles J. Coté, Maurice Zwass, and Shobha Malviya for their prior contributions to this chapter.

This authoritative reference provides a succinct yet complete review of the pharmacology of effective analgesic regimens in children.

Llewellyn N, Moriarty A. The national pediatric epidural audit. *Paediatr Anaesth*. 2007;17(6):520-533.

The largest prospective study on epidural anesthesia to date followed patients into the postoperative period and highlights the incidence and nature of complications and adverse events, which were rare. This should be read in conjunction with the French study and the PRAN studies.

Lynn AM, Nespeca MK, Opheim KE, Slattery JT. Respiratory effects of intravenous morphine infusions in neonates, infants, and children after cardiac surgery. *Anesth Analg*. 1993;77(4):695-701.

This old but important study identified the threshold serum morphine concentration for respiratory depression in neonates, infants, and children receiving continuous morphine infusions following heart surgery to be 20 ng/mL and, as such, provides a framework to guide appropriate dosing of morphine in these populations. The authors recommended careful observation of all children receiving morphine because of the wide variability in the CO_2 response slope seen in their subjects.

Malviya S, Voepel-Lewis T, Burke C, et al. The revised FLACC observational pain tool: improved reliability and validity for pain assessment in children with cognitive impairment. *Pediatr Anesth*. 2006;16:258-265.

The FLACC tool was revised to incorporate behavioral descriptors consistently associated with pain in cognitively impaired children. This paper describes the development of the Revised Face, Legs, Activity, Cry, Consolability (r-FLACC) scale and demonstrates its reliability and validity in assessing pain in this vulnerable population.

Maxwell LG, Kaufmann SC, Bitzer S, et al. The effects of a small-dose naloxone infusion on opioid-induced side effects and analgesia in children and adolescents treated with intravenous patient-controlled analgesia: a double-blind, prospective, randomized, controlled study. *Anesth Analg*. 2005;100(4):953-958.

This study demonstrated that a low-dose naloxone infusion significantly reduced the incidence and severity of opioid-induced adverse effects, including pruritus and nausea, without affecting opioid-induced analgesia. These data address the important clinical problem of opioid-induced adverse effects that frequently limits the utility of opioids in the treatment of pain.

Michelet D, Andreu-Gallien J, Bensalah T, et al. A meta-analysis of the use of nonsteroidal anti-inflammatory drugs for pediatric postoperative pain. *Anesth Analg*. 2012;114(2):393-406.

This meta-analysis shows that perioperative NSAID administration reduces opioid consumption and PONV during the postoperative period in children. In 27 randomized controlled trials, perioperative administration of NSAIDs reduced opioid requirement in the postanesthesia care unit (PACU) and for the first 24 hours after surgery, decreased pain intensity in the PACU and PONV during the first 24 hours postoperatively. Results from this study suggest that multimodal analgesia should be used in an effort to reduce opioid consumption and adverse effects in children undergoing surgery.

Morton NS, Errera A. APA national audit of pediatric opioid infusions. *Paediatr Anaesth*. 2010;20(2):119-125.

This very large prospective audit of opioid infusions of all types (continuous, PCA, NCA) confirmed the safety of these techniques, but highlights the potential complications and pitfalls that are always present. Respiratory depression and pump programming errors each occurred in about 1 of 766 cases and 1 of 631 cases, respectively, and there was one permanent injury (1 of 10,000 cases).

Polaner DM, Taenzer AH, Walker BJ, et al. Pediatric regional anesthesia network: a multi-institutional study of the use and incidence of complications of pediatric regional anesthesia. *Anesth Analg*. 2012;115(6):1353-1364.

This is the first report from this network in the United States that prospectively examined the incidence of adverse events and complications in nearly 15,000 regional blocks in children. There were no permanent complications detected. PRAN now has over 140,000 cases accrued. These data provided similar results to those reported in the French study.[472]

Voepel-Lewis T, Burke CN, Jeffreys N, et al. Do 0-10 numeric rating scores translate into clinically meaningful pain measures for children? *Anesth Analg*. 2011;112(2):415-421.

This study provides important information regarding the clinical interpretation of NRS pain scores in children. Ten NRS scores were found to be reliably associated with the child's perceived need for medicine, perceived pain relief, and satisfaction with pain treatment. However, a significant overlap in scores associated with these outcomes suggests that the use of specific cutoff scores to guide treatment decisions would be inappropriate in children.

von Baeyer CL, Spagrud LJ. Systematic review of observational (behavioral) measures of pain for children and adolescents aged 3 to 18 years. *Pain*. 2007;127(1-2):140-150.

This is a comprehensive review of the numerous behavioral observational measures of pain for children and identifies the most appropriate tools for assessing pain in various settings, including the postoperative period and in critical care.

Appendix 44.1 Clinical Examples of Postoperative Analgesic Management Strategy

Case 1

A 2-year-old child, ASA 1 (American Society of Anesthesiologists physical status classification system, category 1) presented for inguinal hernia repair, weight 15 kg.

CONSIDERATIONS

- Mildly painful surgery
- Outpatient setting–avoidance of nausea and oversedation is helpful

ALTERNATIVES

1. Ilioinguinal nerve block: bupivacaine 0.25% with epinephrine 1:200,000, 0.2–0.3 mL/kg × 15 kg = 3–5 mL (3.75 mL on each side)
2. Wound infiltration with bupivacaine 0.25% with epinephrine 1:200,000, 0.5 mL/kg × 15 kg = 7.5 mL (3.75 mL on each side)
3. Caudal block using bupivacaine 0.125% to 0.25% with epinephrine 1:200,000, 0.5 to 0.75 mL/kg × 15 kg = 7 to 11 mL
4. Add acetaminophen, 10 to 15 mg/kg every 4 to 6 hours (oral), or ibuprofen, 5 to 10 mg/kg every 6 hours.
5. Consider adding IV ketorolac 0.5 mg/kg to intraoperative management at conclusion of surgery and consultation with surgeon.

Case 2

A 6-month-old, 6-kg child, ASA 1, presented for ureteral reimplantation.

CONSIDERATIONS

- Moderately painful surgery, bladder spasms
- Urinary retention is not an issue
- Pain assessment using behavioral tools such as the *Face, Legs, Activity, Cry, Consolability (FLACC) scale*

ALTERNATIVES

1. Epidural analgesia
   - For caudal approach, need to cover approximately 10 dermatomes (5 sacral, 5 lumbar); initial bolus, 10 × 0.05 mL/kg per dermatome × 6 kg = 3.0 mL. May reduce bolus dose to 0.3–0.5 mL/kg for direct lumbar placement.
   - Bupivacaine 0.1% with hydromorphone, 3 µg/mL, starting at 0.2 mL/kg per hour × 6 kg = 1.2 mL/hr
   - Apnea monitoring, pulse oximetry, and frequent observation
   - Add scheduled acetaminophen, 10 to 15 mg/kg every 4 to 6 hours (oral) or 15 mg/kg every 6 hours (IV), or 35 to 40 mg/kg initial dose (rectal) followed by 20 mg/kg every 6 hours (rectal) not to exceed 100 mg/kg per day (rectal).
   - Add ketorolac 0.5 mg/kg every 6 hours for 48 hours for bladder spasms.
2. Continuous IV morphine infusion
   - Loading dose of up to 0.075 to 0.1 mg/kg × 6 kg = 0.45 to 0.6 mg in incremental doses if needed
   - Infusion starting at 0.02 mg/kg per hour (20 µg/kg per hour) × 6 kg = 0.12 mg/hour
   - Apnea monitoring, continuous pulse oximetry, and frequent observation
   - Add scheduled acetaminophen and NSAID if possible.
3. Nurse-controlled analgesia (NCA) with morphine
   - Loading dose 0.05 to 0.1 mg/kg × 6 kg = 0.3 to 0.6 mg administered via patient-controlled anesthesia (PCA) pump in the postanesthesia care unit (PACU)
   - Continuous basal infusion of 0.01 to 0.02 mg/kg per hour
   - Bolus dose of 0.02 to 0.03 mg/kg
   - Lockout interval: 8 to 15 minutes
   - Four-hour limit of 0.25 to 0.3 mg/kg
   - Apnea monitoring, continuous pulse oximetry, and frequent observation
   - Add scheduled acetaminophen and NSAID if possible.

Case 3

A 6-week-old, 3-kg child, ASA 3, presented for thoracoabdominal incision for excision of a Wilms tumor.

CONSIDERATIONS

- Painful surgery
- Pain assessment using behavioral tools such as FLACC
- Impairment of respiration
- Many dermatomes involved
- Bladder catheter warranted

ALTERNATIVES

1. A continuous epidural infusion (direct placement at T8-9 or inserted through the caudal approach and threaded to the mid-portion of the surgical incision)
   - For caudal approach, need to cover approximately 16 dermatomes (5 sacral, 5 lumbar, 6 thoracic): Initial bolus 16 × 0.05 mL/kg per dermatome × 3 kg = 2.4 mL loading dose. May reduce bolus dose to 0.3–0.5 mL/kg for direct thoracic placement. The infusion could be chloroprocaine 1.5% at 0.2 to 0.3 mL/kg per hour or ropivacaine 0.1% to 0.2% at a dose not exceeding 0.2 mg/kg per hour
   - Add scheduled acetaminophen if possible.
   - PRN IV opioid should be available.
   - Apnea monitoring, continuous pulse oximetry, and frequent observation
2. NCA with morphine
   - Loading dose of 0.05 to 0.1 mg/kg × 6 kg = 0.3 to 0.6 mg administered via PCA pump in the PACU
   - Continuous basal infusion of 0.01 to 0.02 mg/kg per hour
   - Bolus dose of 0.02 to 0.03 mg/kg
   - Lockout interval: 8 to 15 minutes
   - Four-hour limit of 0.25 to 0.3 mg/kg
   - Apnea monitoring, continuous pulse oximetry, and frequent observation
   - Add acetaminophen 10 to 15 mg/kg every 4 hours (oral) or 35 to 40 mg/kg initial dose (rectal) followed by 20 mg/kg every 6 hours (rectal) not to exceed 100 mg/kg per day. IV acetaminophen 15 mg/kg every 6 hours may be used instead.

Case 4

An 8-year-old, 18-kg girl with cerebral palsy, severe cognitive impairment, ASA 3, presented for femoral osteotomy.

CONSIDERATIONS

- Painful surgery
- Altered/individual pain behaviors: use specific tools for pain assessment such as r-FLACC
- Potential for altered pain perception
- Increased risk of opioid-induced respiratory depression
- May need benzodiazepines for muscle spasms

ALTERNATIVES

1. Continuous epidural analgesia
   - For caudal approach, need to cover approximately 10 dermatomes (5 sacral, 5 lumbar); initial bolus, 10 × 0.05 mL/kg per dermatome × 18 kg = 9 mL. May reduce bolus to 0.3–0.5 mL/kg for direct lumbar placement.
   - Bupivacaine 0.1% with hydromorphone 3 μg/mL, starting at 0.2 mL/kg per hour × 18 kg = 3.6 mL/hour
   - Apnea monitoring, pulse oximetry, and frequent observation
   - Add acetaminophen scheduled, 10 to 15 mg/kg every 4 hours (oral) or 35 to 40 mg/kg initial dose (rectal) followed by 20 mg/kg every 6 hours (rectal), not to exceed 100 mg/kg per day (rectal). IV acetaminophen 15 mg/kg every 6 hours may also be added.
   - Add scheduled NSAID if possible.
2. Femoral nerve, fascia iliaca, or lumbar plexus block
   - There is the need to block the distribution of the femoral, lateral femoral cutaneous, and obturator nerves.
   - Single-injection block of the peripheral nerves will provide analgesia for 8 to 16 hours; a continuous catheter technique will provide greater duration of analgesia.
   - Blockade of just the upper leg is provided without risks of urinary retention or motor block of the contralateral leg.
   - 0.2% ropivacaine or 0.125% to 0.25% bupivacaine; initial dose of 0.3 mL/kg = 5.4 mL, followed by infusion of 0.2 mL/kg per hour = 3.6 mL/hr.
   - Add scheduled acetaminophen and NSAID if possible, and diazepam as needed for muscle spasms.
3. Continuous IV morphine infusion
   - Loading dose of up to 0.05 to 0.1 mg/kg × 18 kg = 0.9 to 1.8 mg in incremental doses if needed
   - infusion starting at 0.02 mg/kg per hour (20 μg/kg per hour) × 18 kg = 0.36 mg/hour
   - Apnea monitoring, continuous pulse oximetry, and frequent observation
   - Add scheduled acetaminophen and NSAID if possible.
   - Consider IV/PO diazepam, 0.05–0.1 mg/kg, for muscle spasms.
4. NCA analgesia with morphine
   - Loading dose 0.05 to 0.1 mg/kg × 18 kg = 0.9 to 1.8 mg administered via PCA pump in PACU
   - Continuous basal infusion of 0.01 to 0.02 mg/kg per hour
   - Bolus dose of 0.02 to 0.03 mg/kg
   - Lockout interval: 8 to 15 minutes
   - Four-hour limit of 0.25 to 0.3 mg/kg
   - Apnea monitoring, continuous pulse oximetry, and frequent observation
   - Add scheduled acetaminophen and NSAID if possible.
   - Consider IV/oral diazepam, 0.05–0.1 mg/kg, for muscle spasms.

Summary

THE PRACTICING PEDIATRIC ANESTHESIOLOGIST is involved in chronic pain in one of three main venues: a child who is scheduled for a procedure, in consultation, or during acute pain management rounds. In this chapter, we focus on the essential approaches to children with chronic pain and provide guidelines to help the children and colleagues who request anesthesiology assistance.

Chronic Pain in Children

Chronic pain affects a large number of children.[1] Back pain has been reported in up to 50% of children by the mid-teens,[2] and abdominal pain occurs weekly in up to 17%.[3] Other conditions, such as headaches, complex regional pain syndrome (CRPS), fibromyalgia, limb pain, chest pain, and joint pain, are also common and may substantively affect their quality of life.[4–7]

Several chronic medical conditions are strongly associated with pain and blur the boundaries between acute and chronic pain treatment, including sickle cell disease, cystic fibrosis,[8] epidermolysis bullosa,[9] and cancer. These children require frequent hospitalizations, and their pain can be severe. Because these children present with pain in the hospital, treatment often follows the model for acute pain management based on medication use. However, psychosocial factors heavily influence the child's ability to cope with the pain and have a variable effect on the child's suffering, depending on personal and family factors.[10,11] It is appropriate to include psychology, child-life, and physical therapy consultations as part of the comprehensive team approach to developing a therapeutic plan for these children. The ultimate goal for each of these medical conditions is to stabilize the child's condition and return her or him home. For many, the painful disease and dysfunction are persistent, thus necessitating a long-term plan that is integrated with acute management.

Multidisciplinary Approach

The model of care that appears to work optimally for children with chronic pain is one in which multiple disciplines are involved in developing a coordinated care plan.[4,12] In the outpatient setting, there is a pain physician, a psychologist, nurses, and a physical therapist. Sometimes, a neurologist or physiatrist may be involved. Anesthesiologists managing children with chronic pain should make use of these disciplines when recommending a plan of care. Advocating for the involvement of other therapeutic specialties can advance the child's care beyond suggesting a regional block or medication.

THE PAIN PHYSICIAN

The consulting anesthesiologist in an inpatient setting may be called on to provide care for one of three reasons. First, the child may need a regional nerve block, such as an epidural steroid injection for magnetic resonance imaging–confirmed discogenic pain or epidural catheter placement to assist physical therapy. This consultation is fairly straightforward and is an extension of basic regional anesthesia principles. Second, the child who has been prescribed long-term use of opioids or other medications that interact with anesthetic or postoperative pain drugs may present for consultation. The anesthesiologist must investigate which chronic medications have been prescribed and determine whether drug interactions may exist. Opioid requirements of patients who take opioids chronically may have different requirements during and after surgery that may differ from those who are opioid naïve. This approach is an extension of basic perioperative anesthesia management. Third, a consultation may be requested to assess and diagnose the source of pain. This scenario is the most complex and requires a detailed history and thorough physical

examination. These children often require multidisciplinary care beginning with the initial evaluation and extending through treatment.

THE PSYCHOLOGIST

Pain is more than just a physical phenomenon. It can cause and be exacerbated by stress, suffering, family dysfunction, social tension, anxiety, and depression.[7,13] Pain can disrupt almost any aspect of the life of the child and family. Family and school problems can worsen a painful condition and dramatically reduce a child's level of function. The family is invariably involved in the child's suffering and should be included in the process of evaluating the pain.

Families are often wary about seeing a psychologist and are afraid of being stigmatized. It is important to emphasize that pain is what the child says it is, regardless of whether an organic cause can be identified. The child should be treated as a person, not just as the painful body part. Such an approach should be emphasized to the child's family to begin to address the pain.

Psychology-based therapy includes relaxation training, biofeedback, hypnotherapy, coping skills training, and psychotherapy. Together, these therapies are referred to as cognitive behavioral therapy, which is a cornerstone of chronic pain treatment. Therapies aimed at parental and familial aspects of the child's pain include teaching strategies for behavioral interventions (e.g., distraction), activity pacing, consistent discipline, coaching skills training, stress management, and occasionally, family therapy.

THE PHYSICAL THERAPIST

Physical therapy is a crucial component of evaluating and treating chronic pain. The painful condition can cause loss of muscle strength and range of motion, which may affect the biomechanics and daily function of the body. Children can become deconditioned and require a conditioning program to regain lost strength and stamina. These changes affect the original pain site and generate secondary pain problems that need to be addressed.

Physical therapy can benefit many painful conditions (e.g., myofascial pain improves with stretching and range-of-motion exercises) and is the foundation of treatment for others (e.g., CRPS).[14] Emphasizing self-reliance and responsibility for their own care is an important aspect of caring for adolescents. However, young and older children in pain cannot be expected to work aggressively at home without the support of a structured program. Parental involvement is especially important for younger children, but the caretakers must be taught techniques to encourage and support the child, while not making them the child's taskmasters.

Therapies provided by physical therapy include stretching, strengthening, and reconditioning programs. Range-of-motion exercises and endurance training are also important. Aquatic therapy is very useful for children who cannot bear weight on their lower limbs or have limited range of motion or strength. Massage, heat, and cold therapies are also helpful adjuncts to increase function and enhance other physical therapy modalities.

Transcutaneous electrical nerve stimulation (TENS) is an effective,[15] low-risk, analgesic therapy that is usually provided under the guidance of a physical therapist. TENS is excellent for localized pain. The fact that it is portable, can be used discreetly, and has few adverse effects makes it attractive for use at school. Because tolerance to TENS can develop with prolonged use, children need to limit use to no longer than 2 hours at a time. They can take a break for an amount of time equal to the TENS use and then restart it.

THE NURSE

Pain nurses play a major role in hospital-wide education of floor nurses regarding assessment and treatment of pain, including the use of epidural and patient-controlled analgesia (PCA) pumps. When beginning a chronic pain program, the first personnel to recruit should be an advanced practice nurse who can be trained to triage, perform the initial evaluation and intake assessment, and assist with all subsequent pain-related issues that do not require the direct input of a physician.

THE CONSULTANT

Anesthesiologists should be cognizant of their limitations and judiciously use consultants to help diagnose conditions and fashion the optimal treatment plan. Neurologists typically are well versed in headache management and familiar with the medications used for neuropathic pain. Physical medicine and rehabilitation specialists can assist in structuring a treatment plan for a variety of musculoskeletal pains and are accomplished in the treatment of spasticity.

General Approach to Management

Most children with chronic, non-cancer pain are adolescents who require special considerations in terms of their history and physical examination. Because they are between childhood and adulthood, their behavior can fluctuate broadly and frequently. It is important to address them directly but also involve the parents to the extent needed to obtain the relevant and complete history. The clinician should not try to be "cool" with the adolescent patient, because teenagers tend to find that approach condescending and may respond negatively. The examiner should instead find a point of common interest and use it to establish rapport.

Adolescents tend to be image conscious. They may or may not want to discuss body functions such as defecation or menstruation, even when these functions are directly relevant to the problem. If a child appears to be uneasy with the questions being asked, the physician should proceed in a straightforward manner, acknowledge their feelings, and reassure them that the information is needed to ensure that appropriate care is delivered. When discussing these children with their parents, clinicians should refer to them as "children and young adults" rather than just "children" because even 12- and 13-year-olds like to think they are no longer children.

HISTORY

The basic history focuses on the pain: location, duration, quality, intensity, aggravating and alleviating factors, associated symptoms, past therapies, and the tests that have been performed and by whom. Pain intensity is often assessed using a 0 to 10 numeric rating scale for children older than approximately 8 years of age. The child must be asked about the current pain level and about the best and worst pain levels to obtain an idea of the pattern of pain and when it peaks. Quality descriptors include *burning*, *sharp*, *aching*, *throbbing*, *tingling*, *numb*, *weird*, and others; each may give a clue about the type of pain the child is experiencing. Odd descriptors, burning, and tingling suggest neuropathic pain; sharp, tight, and aching may indicate bony or muscular causes; throbbing suggests a vascular component; cramping or pain that comes in waves often suggests spasms of a muscle or hollow viscus.

A vital part of the chronic pain evaluation process is to look for *red flags*, which are signs or symptoms that may indicate a serious illness. Some of the red flag signs and symptoms for major pain

TABLE 45.1	Red Flag Signs and Symptoms for Abdominal Pain
Persistent right upper or right lower quadrant pain	
Dysphagia	
Persistent or cyclic vomiting	
Gastrointestinal blood loss	
Family history of inflammatory bowel disease, celiac disease, or peptic ulcer disease	
Pain that awakens the child from sleep	
Arthritis	
Nocturnal diarrhea	
Involuntary weight loss	
Deceleration of linear growth	
Delayed puberty	
Unexplained fever	
Hepatosplenomegaly, masses, or perianal lesions	
Bilious emesis	
Costovertebral angle tenderness	

TABLE 45.2	Red Flag Signs and Symptoms for Secondary Headache
Persistent vomiting	
Focal neurologic signs	
Meningeal signs	
Unexplained fever	
Increased intracranial pressure	
Changes in behavior or mental status	
Sudden onset of severe headache	
Morning headaches	
Headaches that awaken the child from sleep	

TABLE 45.3	Red Flag Signs and Symptoms for Back Pain
Unexplained fever	
Night sweats	
Weight loss	
Night pain	
Constant pain	
Bowel function changes	
Urinary retention	
Neurologic changes in legs: trouble walking, foot drop, weakness, loss of reflexes, sensory changes	

types can be found in Tables 45.1, 45.2, and 45.3. For example, a child with back pain who also has weak legs and incontinence may have a tethered spinal cord. Headache that is worse in the morning and associated with vomiting suggests increased intracranial pressure. Back pain with pain running down the posterior leg and loss of ankle jerk suggests compression of the S1 nerve root.

A complete pain evaluation comprises further history regarding medications, allergies, family history, and a thorough review of systems. Certain painful conditions, such as migraine headaches,[16] fibromyalgia,[17] irritable bowel syndrome (IBS),[18] and sickle cell disease, have a genetic basis. Knowing the family history can assist in making the correct diagnosis. The child sometimes may model his or her behavior after a family member. For example, if a parent has a "bad back" and is functionally compromised, the child also may complain of back pain. This does not mean the child is faking the complaints but simply patterning the behavioral response to pain after a model that he or she understands. Treatment can include reassurance, cognitive behavioral therapy, and gentle physical therapy to restore the child's functional ability and help him or her with any underlying issues. Family and social histories can be useful in fashioning a treatment plan in conjunction with the general history, physical examination, and relevant testing.

PHYSICAL EXAMINATION

The physical examination should focus on the area of interest, but a brief general examination is also important. A full screening examination, including a neurologic examination, takes only a few minutes and can be combined with the social history. A systemic illness may manifest as a localized complaint–for example, diabetes can manifest as abdominal pain or leukemia as focal bone pain.

When examining a child of the opposite sex, the physician should have a nonfamily observer of the same gender as the child present. Some children are very conscious of their bodies and may consider routine examination maneuvers as invasions of their privacy. The occasional child has a history of being abused and can be further traumatized by even a standard examination. Physicians can demonstrate examination techniques that may make the child feel uneasy. For example, a pinprick examination requires a needle or sharp object (a fractured tongue depressor creates a sharp end to test pinprick, but does not look like a needle); the examiner should touch his or her own skin with the object first to demonstrate that blood is not being drawn. Children are often fascinated by the deep tendon reflexes and usually have fun with that examination. Children with chronic pain often have had many examinations, and doing something a little different or fun can help them accept the current evaluation and enhance rapport.

ANCILLARY DATA

By the time patients with chronic pain have reached a pain clinic, they usually have undergone several investigative tests, and those data should be reviewed. After it becomes clear that there is no life-threatening illness, the focus should shift away from further testing. This is often a hard transition for families and children to accept, especially if no concrete diagnosis has been made to explain the pain. It is a challenge for them to embrace the thought that the pain itself is the disease rather than something that is still undiagnosed. Any study that may help to explain the pain or make a diagnosis that had not been entertained should be recommended. However, pursuing tests and imaging in an unfocused manner wastes resources and causes families to postpone treatment while waiting for a diagnosis. Until the patient wholeheartedly endorses the treatment plan and becomes active in it, the child or adolescent's pain will continue unabated.

Chronic Pain Conditions

Any part of the body can hurt, but in practical terms, several diagnostic clusters represent most pediatric pain conditions. The frequency and intensity of the pain can be striking. One study on the 3-month prevalence, characteristics, consequences, and provoking factors of chronic pain described the experience of 749 children and adolescents in one elementary and two secondary schools[19]: 83% experienced pain during the preceding 3 months. The leading sources of pain were headaches (60.5%, also perceived

as most bothersome), abdominal pain (43.3%), extremity pain (33.6%), and back pain (30.2%). Many subjects reported associated sleep problems, restriction in hobbies, and eating problems. School absenteeism reached 48.8% in the population with pain. The use of health care resources by children and adolescents with pain was extensive: 50.9% visited the physician's office, and 51.5% reported use of pain medication.

ABDOMINAL PAIN

Abdominal pain is a major source of distress in children that causes anxiety and invites a large amount of testing. This painful condition, formerly referred to as *recurrent abdominal pain*, is now described as *functional gastrointestinal disorders* (FGIDs).[20] Specific criteria exist for the major categories so that FGIDs are no longer considered diagnoses of exclusion. The pain is thought to be caused by abnormal interactions between the enteric nervous system and central nervous system.[21] Research suggests that peripheral sensitization and abnormal central processing of afferent signals at the level of the central nervous system play roles in the pathophysiology of visceral hyperalgesia—a decreased threshold for pain in response to changes in intraluminal pressure.[22] Mast cells are increased in number in the ileum and colon of adults with IBS, and treatment with mast cell stabilizers can improve visceral hypersensitivity in these patients.[23] The history and physical examination focus on excluding warning signs and symptoms of underlying disease (see Table 45.1).[20,24] The role for testing, endoscopy, and radiographic evaluation is limited.

Multidisciplinary treatment of FGIDs includes medication, psychological interventions, and education, which often need to be ongoing. The most important aspect of the treatment plan is to establish realistic goals, which frequently means return of function rather than complete elimination of pain. Although the literature for treatment is sparse, tricyclic antidepressants (TCAs) such as amitriptyline, nortriptyline, or doxepin have been used effectively for FGID-related pain. Anticonvulsants also are useful because they modify nerve conductivity and transmission. Antacids, antispasmodic agents, smooth muscle relaxants, laxatives, and antidiarrheal agents can be added to address symptoms. Data support the use of peppermint oil capsules in managing IBS, although gastroesophageal reflux can be a limiting adverse effect.[25] Probiotics may also be helpful to control IBS symptoms, including abdominal pain.[26] Children with functional bowel disorders can have abnormal bowel reactions to physiologic stimuli, noxious stressful stimuli, or psychological stimuli (e.g., parental separation, anxiety). Children benefit from cognitive behavioral therapy, coping skill development, biofeedback, hypnosis, and relaxation techniques (Table 45.4).[27,28]

TABLE 45.4 Care Pathway for Abdominal Pain

Evaluation
Medical examination
Behavioral medicine assessment
Review of records, treatments, history, and physical findings
Consultations with pediatrics, surgery, and gastroenterology specialists as indicated by presence of red flags; assessment may include laboratory testing, ultrasound, computed tomography or magnetic resonance imaging, endoscopy, lactose testing
Treatment of Functional Gastrointestinal Disorders
Medications: tricyclic antidepressants; consider gabapentin; peppermint oil
Behavioral medicine: important and effective to de-medicalize therapy; de-emphasize testing and search for organic diagnoses; redirect focus to treatment and improved function
Physical therapy: not usually involved; trial of transcutaneous electrical nerve stimulation (TENS) if abdominal wall origin found
Other therapy:
Blocks are rare, except in palliative situation; celiac plexus with local anesthetic and steroid; epidural
Trigger point injections if abdominal wall trigger points found
Acupuncture
Hypnosis
Meditation
Dietary management

HEADACHE

Headaches can be categorized as primary or secondary. Primary headaches include migraine, tension, cluster, and trigeminal neuralgia headaches. Secondary headaches are those attributable to head and neck traumas; muscle spasms; vascular disorders; nonvascular intracranial disorders; infection; eye, ear, cranium, nose, sinus, and teeth or mouth diseases; homeostatic disturbances; and psychiatric disorders. Headaches represent one of the more poorly tolerated types of chronic pain, with greater medication use than for other types. Of 77 children with long-term headaches who were followed up to 20 years after the initial diagnosis, 27% were headache free, and 66% had improved.[29]

Migraines (especially migraine without aura) and tension-type headaches are the most common types of pediatric headaches. Prevalence estimates of migraine vary 1% to 3% in children 3 to 7 years of age and 8% to 23% in adolescents.[30] It occurs more frequently in boys than girls between 4 and 7 years of age, and then the prevalence equalizes between 7 and 11 years of age. After 11 years of age, three times as many girls as boys have migraines.[31] Studies are not routinely recommended in the absence of focal neurologic findings. However, the practitioner must be alert to red flag signs and symptoms that warrant imaging and laboratory studies to rule out an underlying condition as a cause of the headaches (see Table 45.2).

There is a genetic component to migraine and chronic tension headaches; 50% to 77% of children with migraines have a positive family history for migraine headaches, especially on the maternal side. The clearest genetic link has been established for familial hemiplegic migraine.[16]

Children with frequent headaches often suffer from medication overuse headaches related to chronic or repeated use of over-the-counter analgesics. Ideally, abortive headache medications should be used no more than two to three times per week to prevent medication overuse headaches from developing. If possible, children should be gradually weaned off analgesics.

Treatments for migraine and tension-type headaches overlap greatly. Pharmacologic interventions can be divided in two types. First, abortive treatment focuses on stopping the acute headache. Second, prophylactic therapy is indicated for those patients with more than two headaches per month, for children with severe attacks, and for those with frequent headaches unresponsive to medication (Table 45.5).[32] The importance of lifestyle modifications when necessary cannot be overstated. These may include improved sleep, increased aerobic exercise, limitation of caffeine intake, stress management, attention to hydration, and avoidance of skipping meals.

Attempts to abort headaches typically begin with nonsteroidal antiinflammatory drugs (NSAIDs). If these are not effective, triptans

may be considered. Only two are approved for use in children by the U.S. Food and Drug Administration (FDA): rizatriptan for children 6 to 17 years old and almotriptan for ages 12 to 17. Opioids are not appropriate in most circumstances. Overall, the lack of randomized, controlled pediatric trials precludes an evidence-based recommendation.[33] However, the anticonvulsant topiramate is a promising medication for the prevention of migraine headaches.[34–36] Tricyclic antidepressants such as amitriptyline may be beneficial, especially when combined with cognitive behavioral therapy.[37]

Coenzyme Q10 is deficient in approximately one-third of children and adolescents who report frequent headaches.[38] A significant number of those experienced both decreased headache frequency and severity after beginning supplementation with coenzyme Q10.

COMPLEX REGIONAL PAIN SYNDROME

Type I and type II CRPS differ only in the presence of a documented nerve injury in type II (formerly called *causalgia*). Pain is an obligatory feature, often occurring alongside allodynia or hyperalgesia. There must be evidence at some time (not necessarily at the time of diagnosis) of edema, changes in skin blood flow, or abnormal sudomotor activity in the region of pain. There are often features of a motor disorder such as tremor, dystonia, and weakness that sometimes lead to a loss of joint mobility. Nail and hair growth can also be affected. In the past, three distinct stages were described. However, it may be that there are phenotypic subtypes instead of stages.[39]

From a clinical standpoint, the typical pediatric CRPS patient is older than 10 years of age, Caucasian, female, and very active or a high achiever from an active family, and the child or adolescent presents with lower extremity pain.[40] A genetic predisposition is suggested by the clinical observation that CRPS is rare in the African American population. The rarity of CRPS in preadolescent children suggests a developmental aspect to its origin.

It is important to obtain a detailed history of the mechanism of trauma and the signs and symptoms. The examiner should specifically look for pain, allodynia, hyperalgesia, and hyperpathia. Edema and color changes do not have to be present at the time of diagnosis, but there should be a history of such changes in the recent past (Fig. 45.1). A complete neurologic examination includes

FIGURE 45.1 Complex regional pain syndrome involves the patient's left foot and ankle. Notice the cyanosis and mottling. The affected foot was cool, and allodynia was prominent. Left foot toenails had not been trimmed in 3 months.

testing muscle strength, reflexes, sensory responses (e.g., cold, touch, pinprick), capillary refill, temperature, and color differences. The physician should also look for deep tissue hyperalgesia. Occasionally, noninvasive or invasive testing may be helpful, but it is not sensitive or specific. These evaluations may include an electromyogram with nerve conduction velocity (EMG/NCV), quantitative sensory testing (QST), and quantitative sudomotor axon reflex testing (QSART) to detect small fiber dysfunction; thermography; and bone scans. Sympathetic ganglion blocks are not considered necessary for diagnosis, but they can be part of the therapeutic approach.

The therapeutic goal for CRPS is restoration of function. It may seem simple, but in daily practice, this may represent the biggest challenge for the physician and the child. The therapeutic approach to the child with CRPS is multidisciplinary, with a focus on the psychosocial and physical aspects of the disease (Table 45.6). Education is important, and the information available on the Internet is ubiquitous, although it is often discouraging and not applicable to children with CRPS. No isolated treatment technique has been helpful for this condition. Children and physicians should follow an algorithm and adjust the therapeutic strategy every 4 weeks if the child does not respond satisfactorily to chosen measures.

The mainstay of CRPS treatment is physical therapy. However, the pain can be severe and disabling enough to prevent active participation by the child in the physical therapy program. Pharmacologic therapy is often initiated to facilitate physical therapy. Medications prescribed for neuropathic pain such as TCAs and anticonvulsants have been used frequently, although the evidence for this in the pediatric population is limited. It must be emphasized to the patient and family that no medication is curative and that the role of medications is to allow full participation in physical therapy. It is reasonable to use NSAIDs and opioids for a short time until the primary medications take effect. The psychology team must play an active role in the overall treatment program. Psychosocial issues must be aggressively addressed. With physical therapy, psychology, and medications,

most children achieve good results and disease resolution. In unusually refractory cases, for which interdisciplinary outpatient programs are insufficient, inpatient pain rehabilitation programs are recommended.

The role of interventional therapy in the treatment of CRPS is to alleviate the pain and provide the child with the opportunity to tolerate and advance in physical therapy. Sympathetic nerve blocks are widely used in adults, although a systematic review revealed a lack of randomized, controlled trials to confirm the effectiveness of this approach in short-term and long-term pain relief.[41] Interventional therapies can be a double-edged sword, representing an easy solution that can demotivate the child from taking an active role in his or her physical therapy. However, pain may be too severe to allow physical therapy and thereby accelerate loss of function.

TABLE 45.6 Care Pathway for Complex Regional Pain Syndromes

Evaluation
Medical examination
Behavioral medicine assessment
Physical therapy assessment
Review of records, treatments, history, physical findings, and radiographic studies
Treatment
Medications: tricyclic antidepressants, gabapentin, oxcarbazepine
Behavioral medicine: very important, especially in refractory cases
Physical therapy: activate, range of motion, desensitization, strength training. Structured home program extremely important; may use transcutaneous electrical nerve stimulation (TENS) unit
Other therapy: Consider intravenous regional block for hand or foot Consider lumbar sympathetic block catheter and admission for structured program for lower extremity complex regional pain syndrome (CRPS) that is refractory despite best efforts of patient and family Consider high thoracic epidural or continuous brachial plexus catheter for upper extremity CRPS

Several techniques enjoy popularity among pediatric pain specialists. Least invasive is TENS, which is usually provided by a physical therapist. For isolated limb CRPS, intravenous (IV) regional blockade with local anesthetic and adjuncts such as clonidine, ketamine, or ketorolac can be performed, though interventional treatment is not without controversy.[42] General anesthesia or deep sedation is frequently required because placement of IV catheters in the affected limb and inflation of the tourniquet are poorly tolerated. More invasive alternatives include placement of a lumbar sympathetic plexus catheter (Fig. 45.2) and a tunneled epidural catheter at the relevant dermatomal level. The duration of infusion ranges from 3 to 5 days to as long as 4 to 6 weeks, and the procedures require extensive logistical support. An alternative approach is to place a peripheral nerve catheter for a continuous block.[43] Spinal cord stimulation and intrathecal drug delivery are rarely used for pediatric CRPS because of the overall good prognosis with more conservative treatment and the continued growth of the skeleton, which can change the area of paresthesias in the case of spinal cord stimulators. Ketamine infusions are increasingly being used for CRPS, but this treatment is poorly supported by limited quality evidence.[44]

Graded motor imagery (GMI) is an emerging technique that consists of a stepwise approach that includes left-right limb discrimination exercises, limb activity imagery, and mirror therapy[45] that has some early evidence for use in adults.[46]

MUSCULOSKELETAL AND RHEUMATOLOGIC PAIN

Musculoskeletal pain is a recognized problem in children and adolescents, and back pain commonly affects adolescents.[47–50] The most commonly encountered causes of chronic pediatric musculoskeletal pain are diffuse idiopathic musculoskeletal pain (juvenile fibromyalgia), chronic back pain, juvenile idiopathic arthritis, CRPS (discussed previously), and pain secondary to joint hypermobility. Although many factors are blamed for musculoskeletal pain (e.g., heavy backpacks, participation in sports,

Consultation with specialists in orthopedics; magnetic resonance imaging or computed tomography, as indicated by history and examination findings
Treatment
Medications: Tricyclic antidepressants Muscle relaxants (e.g., baclofen, cyclobenzaprine) Anticonvulsant (if radicular component) Nonsteroidal antiinflammatory drug of choice Cyclooxgenase-2 inhibitor for gastrointestinal or bleeding issues If disk disease with radicular pain is documented, up to three epidural steroid injections may be helpful
Behavioral medicine: biofeedback, coping skills, and relaxation techniques
Physical therapy: Stretching, postural rehabilitation, general reconditioning, and lifting techniques Limit bed rest; reactivate Transcutaneous electrical nerve stimulation (TENS) Exercise program
Other therapy: Acupuncture Yoga Chiropractic (older patients, lumbar only) Massage Trigger-point injections Additional modalities for specific indications include back bracing, surgery, bisphosphonate therapy

sedentary lifestyle, scoliosis, increased body mass index), only a few have been proven to contribute to musculoskeletal pain. In more than half of cases in one study, the cause could not be identified, and only a minority of children had an underlying disease process (e.g., spondylolysis, infection, tumor, disk problem). Radiologic findings correlated poorly with the pain and failed to distinguish between those with and without pain.[47] Selected red flags for back pain are provided in Table 45.3. A care pathway for the evaluation and treatment of back pain in children and adolescents is presented in Table 45.7.

A special group of children with musculoskeletal pain are those with rheumatologic diseases. Most children referred to the rheumatologist's office report musculoskeletal pain. Only some are diagnosed with a true rheumatologic disease; juvenile idiopathic arthritis is the most common diagnosis. Besides pain, the diseases often manifest as morning stiffness, fatigue, and sleep problems. The process may progress and cause joint deformities and destruction owing to osteoporosis, with resulting growth abnormalities and functional disability. Management combines pharmacologic and nonpharmacologic interventions. The mainstay of therapy includes NSAIDs, acetaminophen, and rarely, opioids for severe breakthrough pain. The rheumatologist may prescribe agents such as methotrexate, cyclophosphamide, or systemic corticosteroids for severe flare-ups. Splints, physical therapy, and psychological interventions such as cognitive-behavioral therapy are often used.[51]

Children with Ehlers-Danlos syndrome (benign joint hypermobility syndrome) and other connective tissue disorders suffer from unstable joints that become very painful from repeated dislocations and mechanical stress. The mainstay of therapy for hypermobility pain is physical therapy that focuses on joint protective strategies. Specific guidelines to assist physical therapists who are unfamiliar with this approach are available.[52] Additionally, low-impact aerobic activity (aquatic physical therapy, elliptical machine, stationary bike) should be encouraged.

Some young women present with fatigue, poor sleep, and pain or unusual tenderness in multiple sites. Fibromyalgia is more common in adolescents than expected, and it can be a significant problem. Although still commonly tested, the presence of tender points is no longer considered diagnostic for fibromyalgia by the American College of Rheumatology. Instead, the newer (2010) criteria focus on the number of body parts that are described as painful, the severity of symptoms, and the chronicity of the pain complaints.[53] Therapy includes education, medications, and general restorative therapy, with a focus on aerobic reconditioning. Traditionally, TCAs and cyclobenzaprine have been prescribed; duloxetine and milnacipran have been shown to be helpful in adults.[54,55] As with many chronic pain conditions, cognitive-behavioral approaches are valuable components of treatment.[56]

Musculoskeletal pain is a particularly difficult problem in children with cerebral palsy.[57] Spasticity itself can be painful, and daily stretching exercises are reported to be painful by many children. Some children with cerebral palsy are nonverbal, making assessment even more difficult. The parents or guardians can provide information about how the child expresses pain and how the pain manifests during daily life. If diaper changes seem to hurt, the practitioner should suspect hip or perineal pain. Pain after eating or a history of hard stools may point to constipation-based abdominal pain. A careful and sometimes staged examination is required. A thoughtful, empirical approach to therapy and judicious use of radiologic and laboratory evaluations can often lead to the diagnosis (Table 45.8).

PAIN IN SICKLE CELL DISEASE, TRAIT, AND VARIANTS

Sickle cell disease is a hereditary disorder characterized by abnormal hemoglobin S (see Chapter 10). About 8% of African Americans carry the sickle cell gene. The homozygous form (sickle cell disease [HbSS]) manifests as a hemolytic anemia with unique vasoocclusive features. The heterozygous form (sickle cell trait [HbAS]) is milder and manifests as a borderline anemia and rarely with vasoocclusive features. Sickle cell/hemoglobin C disease (HbSC) has a clinical presentation similar to that of HbSS, but its vasoocclusive episodes are fewer and usually less intense.

From a pain management perspective, the homozygous HbSS genotype manifests as acute pain attacks (e.g., pain crisis, vasoocclusive episodes, acute chest syndrome) or as underlying chronic pain with acute exacerbations (e.g., avascular necrosis, vertebral collapse, joint involvement). Treatment frequently requires a multidisciplinary approach with close cooperation among the hematologist, psychologist, and pain physician.[58] Most of the episodes can be managed at home with NSAIDs or acetaminophen, supplemented with opioids or with tramadol.[59] In severe cases, children often are hospitalized and treated with IV opioids, although they should be gradually weaned off the opioids as the primary process improves. For episodes of localized, hard-to-control pain or if acute chest syndrome develops, epidural analgesia can provide excellent relief.[60] Rarely, children require opioid maintenance with long-acting preparations of morphine or oxycodone

TABLE 45.8 Care Pathway for Nonverbal Patients

Evaluation
Medical examination Often tricky; go slowly May need more than one visit to complete the examination Try to isolate body part during examination, to avoid generalized effect Watch facial or vocal and parent reaction to each examination maneuver
Behavioral medicine assessment: often not possible
Physical therapy assessment: often already engaged in therapy
Review of records, treatments, history, and physical findings
Video documentation: parent may be able to capture pain behaviors for examiner to view
Treatment
Medications: often taking multiple agents at baseline and coordination with other practitioners is important; apply general principles in choosing medications; long-acting opioid is sometimes beneficial for refractory musculoskeletal pain; watch for worsening of constipation.
Behavioral medicine: often not possible if patient's cognitive ability is too low, but the family sometimes can benefit because they carry a large burden when caring for children with multiple medical problems
Physical therapy: often already engaged; if not, engage for musculoskeletal pain or help therapist focus efforts of a particular region of the body
Other therapy: Nerve blocks can be used to identify painful areas, if more than one seems active. Rarely, a patient must be brought to the operating suite for an infusion of remifentanil to differentiate opioid responsiveness from potentially centralized or behavioral pain phenomena; the latter may respond to anticonvulsant therapy. Intrathecal baclofen (and occasionally morphine) Surgical therapy for selected conditions
Cautions
Site of pain is often unclear.
Do not forget to look in the ears.
If patient is spastic, strongly consider hip pathology (e.g., subluxation, bursitis, infection).
Constipation, gallbladder pain, and gastroesophageal reflux are possible.
These patients often require more testing than verbal patients.
Be careful with use of nonsteroidal antiinflammatory drugs because gastroesophageal reflux can be a problem and reporting abdominal pain as a signal of gastrointestinal side effects may not be possible.

TABLE 45.9 Care Pathway for Sickle Cell Disease

Evaluation
Medical examination
Behavioral medicine assessment: may be limited to social support in acute setting
Review of records, treatments (need opioid exposure history for dosing), and history
Hematology almost always directly involved, with focused evaluation
Treatment of Vaso-occlusive Episodes
Medications: opioid (often requires basal infusion for several days); nonsteroidal antiinflammatory drug; consider neuropathic medication for hyperalgesia
Behavioral medicine: can be helpful, although learning techniques in the acute setting may be difficult; introducing this modality early in life may be more helpful
Physical therapy: transcutaneous electrical nerve stimulation (TENS) for localized pain
Other therapy: Regional anesthesia may be helpful. Strongly consider thoracic epidural for acute chest crisis.
Treatment of Chronic Problems
Medications: may involve chronic opioids; otherwise follows treatment of particular pain condition
Behavioral medicine: per particular pain condition; early involvement may reduce need for hospitalizations
Physical therapy: per particular pain condition; may have joint, bone, and deconditioning issues from recurrent vasoocclusive episodes

(Table 45.9). Hyperalgesia over the affected area suggests peripheral or central sensitization, although the role for neuropathic medications is undefined. Fortunately, the use of hydroxyurea by hematologists (to increase hemoglobin F levels and decrease the proportion of HbSS) has had a positive effect on the number and intensity of vasoocclusive episodes.[61]

Pain Pharmacotherapy

Pain treatment has received less study in children than adults; this is also true for much pediatric pharmacologic therapy. In the absence of U.S. FDA–approved indications and experimental data, off-label use of many medications used to treat chronic pain is common. In this situation, the decision to select a particular medication is most often based on extrapolation from adult literature, expert consensus, applied theory, and clinical judgment. Three categories of medications are available for consideration: nonopioid analgesics (i.e., NSAIDs and acetaminophen), opioid analgesics, and a broad spectrum of adjuvant analgesics, including anticonvulsants, antidepressants, muscle relaxants, local anesthetics, *N*-methyl-D-aspartate (NMDA) receptor antagonists, α_2-agonists, and corticosteroids.

NONSTEROIDAL ANTIINFLAMMATORY DRUGS

NSAIDs are a heterogeneous group of mild analgesics (salicylates, propionic acid derivatives, oxicams, napthylalkanones, and fenamates). Their mechanism of action is to inhibit cyclooxygenases (COXs) at the sites of prostaglandin H_2-synthetase enzymes. There are two subtypes of COXs: COX-1 is constitutive and always present; COX-2 is inducible and produced in the body under proper conditions. NSAIDs have different selectivity for COX-1 or COX-2; selective COX-2 inhibitors have predominant action on inducible COX-2. The benefit of selective blockade is decreased risk of gastrointestinal bleeding. Celecoxib is the only selective COX-2 inhibitor available in the United States. NSAIDs are effective in musculoskeletal pain and as an abortive treatment of migraine headaches.[62,63]

The analgesic and antiinflammatory actions of NSAIDs are dose dependent, reaching a ceiling beyond which there is no additional benefit from increasing the dose. Unlike opioids, NSAIDs do not induce any physical dependence or tolerance.

The choice of NSAID is empirical, based on clinical judgment. If the child provides a history of good response to a particular NSAID, we tend to continue it or to adjust the dose. If the response is inadequate, we select a different medication until we

find one that is effective. In children with a history of gastrointestinal side effects, we prescribe combination preparations with protective agents (e.g., misoprostol), add a histamine 2 (H_2)-receptor or proton pump inhibitor, or switch to a selective COX-2 inhibitor. Preexisting renal disease and disorders that reduce actual or effective intravascular volume significantly increase the risk for renal toxicity. In such children, NSAIDs must be used cautiously. Recent research has highlighted an increased risk of cardiovascular events related to use of NSAIDs. We recommend limited, short, intermittent use.[64,65]

OPIOIDS

The current literature does not support the long-term use of opioids for chronic nonmalignant pain. Opioid prescription practices have undergone increased scrutiny by medical, state, and federal authorities as opioid consumption, abuse, and deaths from opioids reached alarming proportions. Regulatory requirements are set by medical or pharmacy boards and vary from state to state. Clinical practice differs among practitioners and institutions. In an attempt to unify the field, several professional societies and governmental organizations have stepped in and published evidence-based guidelines for safe opioid prescribing in nonmalignant pain (e.g., American Pain Society, American Academy of Pain Management [AAPM],[66] and the Centers for Disease Control [CDC][67]). In pediatric pain practice, drug abuse by teens and diversion by proxy are the main concerns. In general, to ensure compliance with regulations and safe opioid prescription practices, several tools have been recommended as parts of clinical routine. Our group uses a controlled substances agreement, which delineates the rules of engagement (e.g., we are the only office prescribing opioids for the patient, lost prescriptions will not be reissued, we will drug screen for compliance, and so on). We obtain informed consent (during which we discuss the risks of long-term opioid use and the potential for drug interactions) and a standard risk of abuse assessment tool.[68] A history of substance abuse (mainly in adolescent and young adult populations) and a family member with substance abuse and a dysfunctional social situation are red flags for opioid prescribing. In these cases, close monitoring (weekly or biweekly visits as opposed to monthly or bimonthly visits) and limited medication quantities are warranted, but not always practical for patients living at a distance. Under those circumstances, we make every effort to collaborate with their local family physician and defer prescribing of medications to them. Additionally, we document side effects, management, and treatment goals in our electronic medical record. These tools are used to provide standardized care for all patients by all providers. State laws vary and providers need to become aware of their particular state's laws. More guidance can be found in the CDC guidelines for safe opioid prescribing,[67] though they are directed at adult practice.

The use of opioids for treatment of pain in children is almost entirely reserved for acute and cancer-related pain. However, there are selected pediatric chronic pain conditions for which opioids can improve the quality of life and the functional capacity without putting patients at significant risk of addiction, tolerance, and toxicity. Opioid agonists are used almost exclusively; agonist-antagonists have less popularity because of a ceiling effect and the potential to precipitate withdrawal when administered alongside a pure agonist. We typically use opioids in two scenarios. The first features opioids as a bridge while titrating other classes of medications to effect or while awaiting physical therapy or an intervention to exert its effect. In the second scenario, we use opioids as maintenance analgesics in carefully selected children (e.g., chronic musculoskeletal pain in a child with cerebral palsy, severe deformities in patients with neuromuscular disorder, children with juvenile rheumatoid arthritis or Ehlers-Danlos syndrome, epidermolysis bullosa). Medication is titrated in increments toward the main goals of optimal (although rarely complete) pain relief, improved function, and minimal adverse effects. Escalations are usually seen with exacerbations of the primary disease process. Common opioid adverse effects that occur with long-term use can be found in Table 45.10. Morphine, oxycodone, and hydromorphone offer equal flexibility in route of administration (tablets, syrup) and availability of immediate and controlled-release formulations. Active metabolites of morphine (morphine-3-glucuronide and morphine-6-glucuronide) are renally excreted, which is relevant in patients with renal insufficiency. Codeine has been removed from the formularies of many children's hospitals, following the 2013 FDA warning.[69] Codeine is a prodrug of morphine with variable metabolism and efficacy depending on patient's genetic makeup (see Chapters 6 and 7). Without pharmacogenetic screening, drug concentrations can be unpredictable and can range from undetectable to lethal after administration of a single dose. More studies in pharmacogenetics and genomics are becoming available and we are getting closer to personalized analgesia for opioid selection,[59] where effectiveness is maximized and adverse effects are minimized.[70,71]

Immunosuppression

Alternate Opioids

Several groups of children are at increased risk of developing significant complications related to analgesics. For example, those with inflammatory bowel disease (IBD) face the possibility of toxic megacolon with opioids; children with bleeding disorders and IBD are at increased risk for ulcerations and bleeding with NSAIDs, and those with gastrointestinal dysmotility disorders may develop ileus secondary to opioid agonists. In these situations, tramadol and butorphanol are alternate analgesic treatments. Tramadol provides analgesia for moderate pain without the additional risk of gastrointestinal bleeding or inducing an ileus. Tramadol effects analgesia via several pathways, including a weak μ-receptor opioid agonist action and by blocking monoamine reuptake in the central nervous system (similar to antidepressants). On the basis of its latter action, tramadol is a popular analgesic for neuropathic pain, especially for controlling paresthesias,

allodynia, and touch-evoked pain. The likelihood of developing either tolerance or dependence is small, although both have been reported with tramadol. Despite its weak opioid properties, sudden discontinuation of tramadol can cause withdrawal symptoms. The usual dose of tramadol is 1 mg/kg, up to 100 mg every 6 hours (400 mg/d maximum). The dose in children with renal impairment (creatinine clearance <30 mL/minute) should be reduced by 50% and in those with liver impairment by 25%. Pharmacogenetic variability in CYP450 2D6 affects the clearance of tramadol in a manner similar to that of codeine, which has led the FDA to investigate safety issues in children, especially in the post-tonsillectomy population.[72] Common adverse effects include nausea, vomiting, sedation, constipation, diarrhea, dizziness, headache, seizures, and hallucinations. Rare side effects include orthostatic hypotension, syncope, tachyarrhythmia, serotonin syndrome, lowered seizure threshold, and long QT interval.

Butorphanol is a partial opioid agonist-antagonist, approximately 7 to 10 times more potent than morphine. It affects motility to lesser degree than opioid agonists. Butorphanol can be administered via the IV and intranasal routes but may cause dysphoria. Because of its partial agonist nature, its dosing exhibits a ceiling effect. However, butorphanol can be supplemented by opioid agonists if needed for severe breakthrough pain without leading to (theoretical) withdrawal. The advantage of nasal butorphanol is that it bypasses the gastrointestinal system if absorption is a concern. The usual dose is 0.01 mg/kg, up to 1 mg IV, usually 0.5 mg every 3 to 4 hours as needed. The nasal preparation delivers 0.5 mg per spray, which limits its use in smaller children.

Tapentadol is a new μ-opioid receptor agonist and norepinephrine reuptake inhibitor. Tapentadol is 18 times less potent than morphine in binding to human μ-opioid receptor and is 2 to 3 times less potent than analgesics in animal models. Its opioid effect can be reversed using naloxone. Tapentadol has no active metabolites. It has been approved for chronic pain associated with diabetic neuropathy, which makes it a good option treatment for other neuropathic pain states. In children, tapentadol has been used when other opioids failed, although this indication is not evidence-based. Respiratory and gastrointestinal side effects mimic those of standard opioids. In addition, tapentadol decreases the seizure threshold similar to tramadol and may cause a serotonin syndrome if administered in conjunction with other serotonergic drugs. Its use is not recommended in conjunction with monoamine oxidase inhibitors. Dosing is 25 to 50 mg orally q4-6h, maximum 600 mg/day for immediate forms, and 500 mg/day for extended-release forms.

Special consideration should be given to methadone. In addition to being an opioid agonist, methadone is also reasonably effective in controlling neuropathic elements of pain. However, there are a few important caveats for its use. Its prolonged half-life increases the risk of accumulation, sedation, and respiratory depression. The 1:1 methadone/morphine equianalgesic ratio often cited in standard tables is unintentionally misleading. The greater the dose of opioid being converted, the more skewed the conversion ratio; the methadone/morphine ratio ranges from 1:2.5 to 1:14.3 in one study.[73] Because of the prolonged half-life, dose adjustments should be made no more frequently than every 5 days. A unique side effect of methadone is its potential to prolong the QT interval and increase the dispersion of repolarization on the electrocardiogram.[74] Because the dispersion of repolarization is less than 100 msec, it remains unlikely that methadone can trigger torsade de pointes unless used with other medications that prolong the QTc.

Chronic Opioid Exposure and Surgery

When a child receiving long-term opioid therapy presents to the operating room, several simple rules need to be followed to ensure successful perioperative care. We begin with a thorough medication history, including drug dose and frequency. If the patient has not taken a morning dose of opioid, that dose should be replaced by the IV route to avoid withdrawal. It is essential to convert the home medication into morphine equivalents. The daily dose of home opioids should be provided as a baseline, orally or IV (if on non per os status), with all further dosing in addition to the baseline. Because of tolerance to opioids, larger than usual doses may be required. It is advisable to titrate the dose of opioids to achieve an adequate level of analgesia. Opioid consumption during the perioperative period may be more than three times that observed in patients not treated with long-term opioids. Underusing opioids in the perioperative period results in poor pain management and withdrawal phenomena.[75,76]

ADJUVANT DRUGS

Anticonvulsants

Anticonvulsants have been widely used in the pharmacologic treatment of chronic pain since the 1960s. However, pediatric studies are lacking. The clinical practice with anticonvulsants is extrapolated from adult studies and best practice, rather than randomized clinical trials. Often referred to as membrane stabilizers, anticonvulsants exert their effects on neural receptors, ion channels, and nerve conductivity. They modify the level of excitatory and inhibitory neurotransmitters and activation of nerve cells. They are most effective in controlling neuropathic pain. First-generation agents (e.g., carbamazepine) have been largely replaced by second-generation drugs (e.g., oxcarbazepine) with more favorable adverse effect profiles.

Therapeutic effect is achieved with all membrane stabilizers by gradual titrating the dose. The purpose of this approach is twofold: first, to avoid developing adverse effects by allowing the child to develop tolerance (mainly to sedation) and second, to determine the minimal effective dose. The initial treatment course often lasts 3 to 6 months, after which time the child's condition is reassessed. At the completion of the treatment, the child is gradually weaned off the medication in reverse order of its titration. Although weaning is not necessary to prevent seizures, rapid discontinuation may result in pain, sleep, or mood disturbances. Gradual weaning allows rapid re-escalation in case the pain returns, but rarely does it require a full dose. We stop at the minimal effective dose controlling the symptoms and maintain the child on the medication for an additional 3 to 6 months. Although the use of anticonvulsants for pain in children represents an off-label use, this class of agents is a mainstay of therapy for selected pain conditions. The choice of drug is based on thoughtful consideration and expert consensus, as randomized, controlled trials are lacking (even for adults).[77]

Gabapentin and Pregabalin

Gabapentin is an anticonvulsant with a complex mechanism of action. Its name is deceiving; gabapentin does not interact with the γ-aminobutyric (GABA)-ergic system. It binds to the α_2-delta subunit of the voltage-dependent calcium channel and reduces the release of glutamate in the dorsal horn of the spinal cord. This leads to decreased production of substance P, less activation of α-amino-3-hydroxy-5-methylisoxazole-4-propionate (AMPA) receptors on noradrenergic synapses, decreased transmitter release, and decreased neuronal activity. This mechanism is shared by both gabapentin and pregabalin.[76,78]

Gabapentin is usually the drug of choice for neuropathic pain such as CRPS because of its good tolerability, minimal adverse effects, and positive clinical experiences. In addition to causing sedation, its use in children can lead to retention of sodium and water, development of peripheral edema, and weight gain. In adolescents, gabapentin can cause mood swings, irritability, and suicidality. Despite these concerns, gabapentin is used frequently after providing a detailed explanation of its effectiveness and side effects with the child and parents. The target dose is up to 35 mg/kg per day in three divided doses orally, although, doses up to 70 mg/kg per day are possible. The dose of gabapentin does not have to be adjusted in liver failure because it is not metabolized by the liver. However, it is excreted via the kidney, so the dosing interval should be increased in children with renal impairment. Pregabalin is chemically related to gabapentin but has fewer adverse effects and a significantly faster titration schedule. It is approved for postherpetic neuralgia, diabetic neuropathy, and fibromyalgia in adults; experience in children is growing.

Topiramate

Best studied for the treatment of migraine headaches, topiramate can be applied to the full spectrum of neuropathic pain states.[35] It suppresses the appetite as a unique side effect, which makes it a good choice for children with neuropathic pain who are concerned about gaining weight. Topiramate has carbonic anhydrase–inhibiting properties that can cause a metabolic acidosis and renal stones in children with a medical or family history of nephrolithiasis.

Oxcarbazepine

Oxcarbazepine is the second-generation relative of carbamazepine for the treatment of neuropathic pain. Although rare, Stevens-Johnson syndrome can occur with oxcarbazepine and with several other anticonvulsants. Hyponatremia may also occur, as well as adverse effects in common with other anticonvulsants such as sedation, difficulty concentrating, ataxia, and mood instability.

Carbamazepine, Valproic Acid, and Phenytoin

The effectiveness of carbamazepine, valproic acid, and phenytoin for chronic pain has been discussed elsewhere.[79] Carbamazepine has proven effective in the treatment of trigeminal neuralgia, spasticity in multiple sclerosis, and spinal cord injury (compared with tizanidine). Phenytoin has been used alone or in combination with buprenorphine for cancer pain, providing good pain relief in more than 60% of patients. Despite their effectiveness, the use of phenytoin and carbamazepine is limited by liver and renal toxicity (serial laboratory testing is necessary), aplastic anemia, Steven-Johnson syndrome, and syndrome of inappropriate secretion of antidiuretic hormone–like symptoms. Valproate lacks renal side effects but can cause pancreatitis.

Antidepressants

Two major groups of antidepressants are used in the treatment of chronic pain**:** TCAs (e.g., amitriptyline, nortriptyline, desipramine, doxepin, imipramine) and serotonin reuptake inhibitors. Serotonin reuptake inhibitors are further divided in selective serotonin inhibitors (SSRIs; e.g., fluoxetine, paroxetine) and serotonin-norepinephrine reuptake inhibitors (SNRIs; e.g., venlafaxine, duloxetine, milnacipran).[80] When prescribing antidepressants to adolescents and young adults, we recommend vigilance for the potential increase in suicidal ideation and attempts. Patients and families should be informed in detail about this possibility to ensure that they communicate with the provider should these occur. It is prudent to refer patients at greater risk for psychiatric comorbidities to a psychologist for evaluation before prescribing this class of medications.

Tricyclic Antidepressants

The efficacy of TCAs in the treatment of neuropathic pain has been confirmed in meta-analyses.[80,81] The doses required to control chronic pain are usually less than those used in the treatment of depression. The adverse effects of TCAs are the major limiting factor in prescribing them. The onset of adverse effects can be reduced by slow dose escalation, as is done with anticonvulsants. The most frequent side effect is sedation, which often benefits patients with disrupted sleep. We prescribe the drug to be taken one hour before bedtime and monitor the child in the morning. If carryover sedation is present, it is reasonable to decrease the dose or encourage the patient to take the medication earlier in the evening. Because of the anticholinergic effects of TCAs, patients may experience a dry mouth, constipation, urinary retention, or weight gain.

TCAs prolong the QT interval, which may lead to lethal arrhythmias. Before initiating therapy, it is prudent to obtain a careful past medical and family history of cardiac symptoms and conduction abnormalities. In addition, a baseline electrocardiogram to rule out congenital long QT syndrome is warranted. Because concomitant use of SSRIs, SNRIs, or tramadol can prolong the QT interval, decrease the seizure threshold in children with a seizure disorder, and cause serotonin syndrome, simultaneous use of these agents should proceed with great caution. Amitriptyline and nortriptyline are the most commonly prescribed TCAs. A starting dose for both drugs is 0.25 mg/kg orally at night, which can be increased as indicated and tolerated to 0.75 to 1 mg/kg over a few weeks. Analgesic effects first appear by 1 to 3 weeks, as with antidepressants effects. Nortriptyline is a metabolite of amitriptyline, with similar utility for pain but less sedation. If top-range dosing is required, periodic electrocardiographic monitoring for QTc changes is recommended.

Selective Serotonin and Norepinephrine Reuptake Inhibitors

The effectiveness of SSRIs and SNRIs in treating neuropathic and nonneuropathic pain such as fibromyalgia and low back pain is poor. SSRIs do not appear to play a role as analgesics.[82] SNRIs have modest support for use in adult fibromyalgia[54,55,83,84] but are not first-line treatments. Minor adverse effects are common, and there is a boxed warning regarding the potential for suicidal ideation in older teens and young adults.[85] Prescribing of both medications in children is best left to those who prescribe them frequently as dosing has not been well established and psychological monitoring is important.

Muscle Relaxants

Muscle relaxants are frequently used as an adjunct to other medications (mostly NSAIDs) in patients with myofascial pain. Data are limited, even in adults, but suggest a role for musculoskeletal conditions and neurologic conditions associated with spasticity,[86] as well as for nonspecific back pain in adults.[87] A caveat for patients with hypermobile joints: muscle relaxants may promote joint subluxations by lowering muscle tone. Therefore they should be used judiciously in this population.

Cyclobenzaprine

Cyclobenzaprine is a centrally acting muscle relaxant. Its major adverse effects are somnolence, dizziness, and asthenia. The usual

starting dose is 5 mg orally at night and can be increased to 10 mg after 5 to 7 days, unless the child has difficulties awakening in the morning. The dose can be escalated up to 10 mg three times per day, limited by sedative effects.

Baclofen

Baclofen is one of the most powerful centrally acting muscle relaxants. It interacts with the GABA-B receptor subtype. It is usually indicated in patients with spasticity (cerebral palsy or multiple sclerosis) but can be used for myofascial pain. Patients report fewer sedative effects compared with cyclobenzaprine or tizanidine. The starting daily dose is 10 to 15 mg orally, divided into two or three doses. The dose can be escalated every 3 days by 5 mg. In children 7 years or younger, the maximum daily dose is 40 mg/day and for those older than 8 years, the maximum dose is 60 mg/day. Baclofen is one of a few medications approved for intrathecal administration by implanted pumps, which is usually reserved for children with severe spasticity (e.g., cerebral palsy, spinal cord injury).

Methocarbamol

Methocarbamol is a centrally acting relaxant of skeletal muscle. Its mechanism of action is not fully understood. Methocarbamol gained its popularity because of its minimal sedative adverse effects, which made it a safe adjunct to opioids, enteral or parenteral, in the setting of severe acute postoperative pain after major orthopedic surgeries. Methocarbamol is suitable for daytime administration in patients with chronic musculoskeletal pain and spasms on a short-term scheduled or intermittent basis. The dose of oral and IV forms is 15 mg/kg q6-8h acutely and 10 mg/kg for longer-term use. Methocarbamol should be avoided in patients with renal and liver dysfunction.

Tizanidine

Tizanidine is a centrally acting α_2-adrenergic agonist known to reduce spasticity by presynaptic inhibition of motor neurons. Structurally, tizanidine is similar to clonidine, but only $\frac{1}{10}$ to $\frac{1}{50}$ as potent for lowering blood pressure. Similar to clonidine, tizanidine causes dose-related sedation, more so compared with methocarbamol and baclofen. Predominantly used in patients with spasticity related to multiple sclerosis and spinal cord injury, tizanidine has found its applications in chronic musculoskeletal pain conditions associated with muscle tightness. The usual dosage is 2 to 4 mg orally, usually at night to facilitate sleep.

Local Anesthetics, α^2-Adrenergic Receptor Agonists, Topical Agents, and *N*-Methyl-D-Aspartate Receptor Antagonists

Many drugs are used in the treatment of pediatric chronic pain,[88] and they have a wide array of mechanisms of action. Oral medications with local anesthetic properties such as mexiletine and clonidine have been used in the treatment of neuropathic pain in patients with CRPS. Mexiletine and others are used orally, as a transdermal patch, or added to local anesthetic solutions in IV regional techniques. The major limiting factor in the use of these drugs is their adverse effect profile, which includes hypotension, sedation, bradycardia, and nausea (particularly mexiletine). The α_2-adrenergic agonist properties are also part of the mechanism of action of the muscle relaxant tizanidine.

The topical agent capsaicin, derived from hot chili peppers, can be helpful in managing neuropathic pain, but its application can cause a burning sensation where it is applied. As a result, it is often poorly tolerated. The topical lidocaine patch has been effective in the controlling symptoms of postherpetic neuralgia and has been used for localized myofascial pain, hyperpathia, and allodynia in other neuropathic conditions.[89] Pharmacokinetic studies in adults have found minimal blood concentrations of lidocaine, suggesting a large margin of safety,[90] although similar studies in children have not been forthcoming.

NMDA receptor antagonists such as ketamine, amantadine, and dextromethorphan have anecdotal evidence supporting their utility in the treatment of neuropathic pain. NMDA receptor antagonists may also exert an opioid-sparing effect. An important limiting factor of the broader use of ketamine in the treatment of chronic pain symptoms is the potential for psychotropic side effects (see reference 88 for a detailed review).

Complementary Therapies

Alternative therapies have appealed to patients for a long time. Because traditional medical therapies have a high failure rate, patients continue to search for better treatments. Many types of therapies have been used to treat chronic pain, including massage, yoga, herbal preparations, tai chi, meditation, chiropractic, and acupuncture. As a consultant, the anesthesiologist should consider suggesting some of these therapies when they seem appropriate. TENS and biofeedback have been discussed earlier. Of note, evidence supporting effectiveness for most of these interventions is minimal,[91] although they have a minimal risk of side effects, except in certain situations.

Acupuncture and its derivative, acupressure, originated in China and constitute an important part of traditional Chinese medicine (Fig. 45.3). In acupuncture, the body energy or qi (pronounced *chi*) circulates in body meridians and collaterals. Meridians and collaterals are pathways that represent body organ systems called the zang-fu organs. In Chinese medicine, pain is caused by alterations in the circulation of qi in these channels owing to multiple causes. Acupuncture has been used in many acute and chronic pain conditions. The data from randomized, controlled trials are insufficient to support or refute the effectiveness of acupuncture.[92]

Summary

The pediatric anesthesiologist may be called on to assist with the care of a child or adolescent with chronic pain.[93,94] The basic tenets of care apply, and a careful history and focused physical

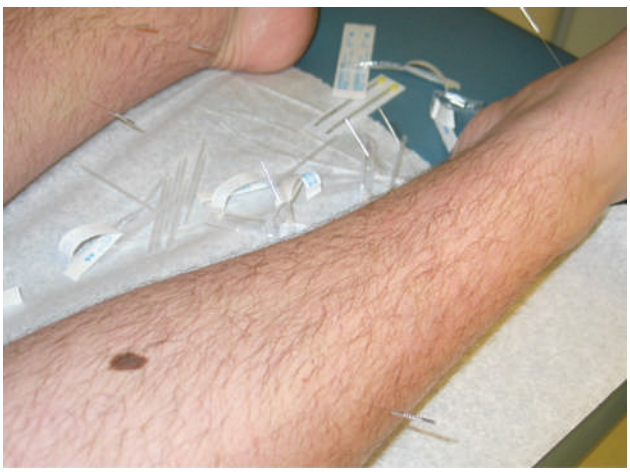

FIGURE 45.3 Acupuncture needles in situ.

examination remain key components of the evaluation. The first step is to ensure that the child is not being physically harmed by the painful condition (i.e., ensuring safety). The second step is to undertake a focused diagnostic evaluation and design of a therapeutic regimen. Treatment for all but the simplest painful conditions uses multiple disciplines in a coordinated attack on the pain. The input of psychologists is a prominent part of chronic pain management, and psychological treatment is not a sign of psychiatric disease or malingering, but a tool that is powerful and effective. Physical therapy and judicious use of medications round out the approach to most chronic pain problems in children. The occasional use of interventional modalities and opioids is warranted, but success will be limited if the problem is viewed in a unidimensional manner. Many patients benefit from alternative approaches to therapy, and these disciplines can be used in a prudent fashion to expand the range of therapies that can be recommended.

Summary

THE APPROACH TO PROVIDING ANESTHESIA outside the operating room (OR) for children (also known as "non–operating room anesthesia" [NORA] or "Off-site Anesthesia") varies greatly among health care organizations and even from one anesthesia provider to another. Because of its very nature, NORA practice is neither as standardized as anesthesia delivered in the OR nor is it as well studied or reported. As such, it is a difficult topic to review using an evidence-based approach. For instance, although most anesthesiologists would agree on the general approach for delivering anesthesia to a 2-year-old child undergoing an inguinal hernia repair, much more variability (in terms of drugs used, airway management techniques, and general organization of care) exists in providing anesthesia for a magnetic resonance imaging (MRI) scan. This issue is made even more confusing by the fact that NORA procedures that are performed with deep sedation in one institution may be accomplished with general anesthesia and tracheal intubation in another. Furthermore, a procedure that is performed using deep sedation provided by an *anesthesiologist* in one institution may have sedation provided by a specialist *other* than an anesthesiologist at another institution.[1]

The discussion of anesthesia services outside the OR must also include the recognition that the level of sedation/anesthesia for a given child at any moment during a procedure is often a matter of some conjecture. Almost any procedure that involves pain, or absolute movement control in a child, necessitates deep sedation or general anesthesia. The distinction between these two states (defined by the presence or absence of movement in reaction to painful stimuli) is often not completely clear.[2] For anesthesiologists, the difference is more of semantic interest than practical importance. Anesthesia services are often requested outside the OR when deep sedation is what is delivered, and vice versa. Finally, anesthesia is often provided outside the OR for patients with significant comorbidities undergoing routine procedures. Many of these children would be managed with moderate/deep sedation by other specialists were it not for the complexity of the child's underlying illnesses(s). Comorbid conditions that require referral to an anesthesiologist vary among institutions but common (generally accepted) examples include the following[3]:

1. Extremely young age, including healthy children younger than 2 months of age
2. History of prematurity (<32 weeks gestational age at birth) and postmenstrual age less than 60 weeks
3. History of ongoing apnea and bradycardia episodes
4. Craniofacial anomalies or any known difficult functional or anatomic airway problem
5. Cyanotic congenital heart disease or cardiomyopathy
6. Any serious coexisting disease such as sickle cell disease or muscular dystrophy that would qualify a patient as American Society of Anesthesiologists (ASA) status III–IV.
7. Procedures that require elective airway control (intubation) or respiratory control such as breath-holding

With these considerations in mind, this chapter focuses on issues specifically related to the delivery of anesthesia and deep sedation outside the OR *provided by anesthesiologists*. Issues concerning

minimal, moderate, and deep sedation, as well as issues involving care by specialists other than anesthesiologists, are covered in Chapter 48.

Standards and Guidelines

Anesthesia outside the OR must meet the same standards as anesthesia given in the OR. Specifically, Medicare's *Conditions for Participation* for hospitals are enforced by The Joint Commission (TJC) regardless of location of care. The *Conditions for Participation* are principles that are articulated to surveyors as instructions in the Interpretive Guidelines published in January 2011, and available at http://www.cms.gov. These guidelines describe appropriate training, credentialing, and oversight of sedation and anesthesia providers and some of the specific requirements for care documentation. The ASA has developed templates for the required policies that help institutions meet the standards of the Interpretive Guidelines. These resources can be downloaded (or links are provided) from the ASA website at http://www.asahq.org. With particular reference to NORA, there are several notable templates, as follows:

1. Preanesthesia Evaluation Policy, Form, and Note

   Within 48 hours immediately before the delivery of the first dose of medication for the purpose of inducing anesthesia, a qualified practitioner must perform a preanesthesia evaluation of the patient that includes, at a minimum: (1) a review of the medical history including anesthesia, drug and allergy history, and (2) an interview if possible, given the patient's condition, and examination of the patient. In addition, the following must be reviewed and updated within 48 hours prior to anesthesia:
   - a. Notation of the anesthesia risk.
   - b. Identification of potential anesthesia problems.
   - c. Additional preanesthesia data or information, if applicable and as required in accordance with standard practice prior to administration of anesthesia (i.e., stress tests).
   - d. Development of the plan for the patient's anesthesia care, including the type of medications for induction, maintenance and postoperative care and discussion with the patient (parents) of the risks and benefits of the delivery of anesthesia.
2. Intraoperative record policy. Standard data elements and timing must be included in the intraoperative record–just as in the OR. In other words, the intraoperative electronic record should be accessible from all NORA locations within an institution.
3. Postanesthesia Evaluation Policy, Note, and Form (template). A postanesthesia note must be completed within 48 hours after surgery. The person completing the evaluation does not have to be the person who delivered the anesthetic. The elements of the postanesthesia note include assessment of the following:
   - a. Respiratory function
   - b. Cardiovascular function
   - c. Mental status
   - d. Temperature
   - e. Pain
   - f. Nausea and vomiting
   - g. Postoperative hydration

NORA services must be organized in such a way as to meet the *Conditions for Participation* (and thus TJC) standards mentioned earlier, just as they are met in the OR. Depending on how NORA is organized in a particular institution, this can be challenging. The departments that require anesthesia services must appreciate the need to meet these standards and allow for the infrastructure to meet or exceed them, particularly in preanesthesia assessment and postanesthesia follow-up requirements.

Off-Site Anesthesia: Structure

There is little literature on the organization of pediatric anesthesia services outside the OR. Based on information available from the Pediatric Sedation Research Consortium, we know *some* institutions organize these services through an off-site anesthesia unit that can also be used for general anesthesia or sedation cases.[4] These units have the advantage of providing all anesthesia-related care through one location that contains the personnel and equipment required for anesthesia. Ideally, these units provide a location for preanesthesia assessment, induction, procedure location, and recovery. Children may be transported to remote locations when equipment (such as MRI scanners) cannot be brought to the sedation unit. The advantages of this organizational scheme are many. The uniform environment leads to maximum consistency in the equipment and personnel who interact with children and their families and thus adds to safety, efficiency, parent satisfaction, and effectiveness of care. Specialty teams or microsystems for provision NORA are coordinated groups of professionals who deliver a specific service that achieve the best possible outcomes by developing reliable, efficient, and responsive processes. They are able to meet the individual needs of one child, continually improving care for the next child, and create a user-friendly work environment. The NORA microsystem should be made up of pediatric anesthesiologists, nursing, technical, and administrative personnel who are familiar with the off-site service and dedicated to this care.[5,6] As members gain expertise and comfort with the off-site environment, their care is consistent and reproducible, leading to less confusion with other services. Such systems of care lead to improved effectiveness (decreasing failed anesthesia and sedation cases) and improve patient, family, and staff satisfaction.[7–9]

Another option for NORA organization is the use of standard OR same-day unit admission services and postanesthesia care unit recovery capability while providing induction and procedural anesthesia at the site of the procedure (e.g., endoscopy suite or hematology and oncology unit). This organizational paradigm makes use of existing anesthesia ancillary services but almost always requires patient transport before and after the procedure itself.

Finally, anesthesia services outside the OR may be primarily organized at the site of procedural care (e.g., in radiology departments or gastrointestinal [GI] procedure suites). For this organizational setup, the procedure unit itself may be outfitted for admission and preanesthesia assessment and recovery of children is accomplished in a space contiguous with the procedural location. This kind of organization is most common in children's hospitals, where high volumes of procedures are performed in a given location such as the MRI scanner.[10]

PERSONNEL REQUIREMENTS

Inadequate experience or familiarity with equipment/monitoring devices, poor communications with team members, production pressure, inattention/carelessness, and fatigue have been shown to be critical contributors to anesthesia-related adverse events.[11] The environment and the demands of providing anesthesia outside the OR are unique regardless of the specific organizing strategy. To create a functional and efficient anesthesia microsystem,

several common themes lead to optimal safety and effectiveness of care:

1. Anesthesia providers should rotate on this service with a frequency that allows the development of a working relationship among the anesthesiologists, anesthesia extenders, respiratory therapists, registered nurses, patient care technicians, biomedical engineers, and child-life specialists. This familiarity should be based on a common understanding of the routines and protocols for standard procedures and a common agreement on the goals of the service.
2. Effective and efficient communication among personnel is critical to optimize outcomes. Logically, help from all members of the care team, including the supervising anesthesiologist, should be available to provide definitive care for urgent situations within time frames that would allow optimal outcomes for children with critical events–specifically within 3 to 4 minutes. An explicit chain of communication must be established such that in the event of an emergency there is no confusion about how outside resources (additional anesthesia assistance from main OR, hospital code team) will be activated when necessary. The use of cell phones, Internet phones, "stat buttons,"[12] or other devices to optimize communication in NORA locations is often helpful.
3. The ancillary personnel in each location must be familiar with the needs and processes of providing anesthesia to children.
4. Equipment and monitoring standards should mimic that of the OR. Anesthesia carts, machine preparation, and setup should mirror the OR environment as much as possible to maximize the similarity to the most common workspace. It is critical to have a system that allows appropriate restocking and security of anesthesia carts in all off-site locations with the same frequency and organization as the OR. All off-site carts should include a full range of drugs, intravenous (IV) equipment, fluids, and airway equipment such as tracheal tubes, laryngeal mask airways (LMAs), laryngoscopes, oral and nasal airways, masks, and suction equipment in sizes that would fit all possible pediatric age groups.
5. Scheduling off-site anesthesia resources is complex and time-consuming. Timing for some procedures is inexact. In addition, anesthesia time requirements can vary with the child and the associated pathology. Success is enhanced by focusing the task of scheduling NORA procedures with one individual (or a small group) who intimately understands the process involved in anesthesia. This type of organization allows the NORA service to have one focal point for communication between the individuals who perform procedures and the anesthesia service, thus maximizing communication and minimizing incorrect assumptions of staffing or timing for procedures.
6. Successful off-site anesthesia is maximized when arrangements are made for anesthesiologists to be integrated with other sedation/anesthesia providers in a way that allows them to transfer care for those who are *not* successfully sedated–and convert to anesthesia care as needed.[7,13]

SPECIFIC ENVIRONMENTAL REQUIREMENTS

Equipment and monitoring standards must meet those of the main OR environment. The ASA requires that remote locations must have two sources of oxygen (O_2) (preferably a central source of piped O_2 and a backup E cylinder), suction, an anesthesia machine if administering inhalational anesthetics, a scavenging system for waste anesthetic gases, suction, a self-inflating hand resuscitator bag able to deliver 90% O_2 and positive-pressure ventilation, standard of care monitors and equipment,[10,14] and sufficient electrical outlets, illumination, and space. The ASA Standards for Basic Anesthetic Monitoring include the following:

- Pulse oximetry with audible pulse tone and low-threshold alarm
- Adequate illumination and exposure of the patient to assess color
- Anesthesia machine with O_2 analyzer
- Continuous end-tidal carbon dioxide ($ETCO_2$) analysis with an audible alarm
- Continuous electrocardiogram (ECG)
- Arterial blood pressure and heart rate every 5 minutes or more frequently as indicated
- Temperature monitor, if there is potential for clinically significant changes in body temperature

In addition, it is important to make further adaptations (e.g., duplicates of critical equipment, such as laryngoscope handles and blades). In the MRI unit, it is essential to have MRI-compatible laryngoscope blades and handles, compatible monitoring devices, and MRI-compatible portable oxygen tanks. Each site should be carefully evaluated for important items such as wall-delivered gases (O_2, nitrous oxide [N_2O], and air), the location of suction equipment, and an Ambu bag (Ambu, Copenhagen, Denmark). Every site must have backup gas supplies. If pipeline O_2 is not available, O_2 should be drawn from H cylinders (6600 L) rather than the smaller E tanks (659 L) (oxygen reserves should be checked prior to each use). All equipment for monitoring and resuscitation should be up to date and standardized to that used in the ORs.

Many off-site areas do not have wall suction, especially in the MRI environment. MRI-compatible wall suction is not widely available. An alternative method for providing suction in the MRI suite is to mount a suction canister with 30 feet of suction tubing outside the scanner room.[15] The suction tubing can then be threaded through a hole in the console wall to access for use in the MRI unit.

Scavenging systems should be carefully evaluated in NORA locations. When passive scavenging is not possible, active scavenging may be developed by using the wall-source vacuum or wall suction canisters. A scavenging system dedicated solely to waste gases should be present.[16]

Electrical circuitry in off-site locations must be upgraded to meet OR standards. Specifically, although the outlets tend to be grounded and hospital grade, plug and outlet incompatibility may be a problem. Adapters and conversion plugs must be available. Although off-site locations tend not to have as great a risk of electrical shock or electrocution to the child as in the OR, it is important to remember that these sites do not have line-isolation monitors. In the event of excessive leakage of current, the anesthesiologist would not be warned. Although the National Electrical Code no longer requires line-isolation monitors in nonflammable anesthetizing locations, it is strongly recommended in areas with multiple power sources. To ensure child and health care personnel safety, biomedical engineers must be attentive to the safe maintenance of all electrical equipment.

It is in the nature of NORA that the physical environment and practice patterns are typically that of another medical specialty. It should also be noted that these other specialties practice under standards developed by their own professional organizations that apply to the procedures within their locations reflecting the different procedure goals. The varying specialties involved include (but are not limited to) gastroenterology, dentistry, cardiology, oncology, intensive care, emergency medicine, and radiology.[8] Anesthesia

providers who work in these environments are well served by familiarizing themselves with the standards for the given specialty area they are working in, as published on the individual websites for the various professional organizations.

Quality Assurance of Anesthesia Services and Outcome in the Off-Site Areas

It is important to develop a strategy to track all clinically important complications associated with NORA, as we do in the OR. Each department can set its own thresholds for review; however, certain incidents require a full inquiry for example[17]:

- Aspiration events
- Unscheduled admissions to the hospital as a direct result of the sedation (i.e., because of protracted emesis, prolonged sedation, respiratory or cardiac complication)
- Medication errors that lead to patient harm–or that could potentially lead to patient harm
- Failed procedures resulting from inadequate or problematic anesthesia or sedation
- Cardiovascular or respiratory compromise that requires assistance from an outside rescue team or leads to a "call for help"
- Cardiac arrest
- Respiratory arrest or need for airway rescue

Many institutions choose to follow outcomes such as prolonged nausea and vomiting after anesthesia or O_2 desaturation events.[18] Regardless of the data that the quality improvement (QI) committee chooses to review, the process should include anesthesiologists and anesthesia extenders, nurses, and other technical personnel who are routinely involved in anesthesia care and support. It is particularly important to note that in the case of off-site anesthesia, it is critical to include members of the departments (other than anesthesiology) who were involved with the case being reviewed. The timing of QI meetings depends on the number and acuity of the non-OR anesthesia cases provided at a given institution. Review committee meetings should be considered not just an opportunity to evaluate complications but also a forum for exchange of ideas, expertise, and information that can lead to improvements in the systems of patient care.

Anesthesia Versus Sedation for Non–Operating Room Procedures and Tests in Children

Anesthesiologists always have the option to deliver either deep sedation or anesthesia for procedures outside the OR. The choice of whether to deliver general anesthesia with a secured airway (tracheal tube or LMA) using potent inhalational anesthetics versus deep sedation with face mask O_2 and propofol infusion depends on many factors, including the child's comorbid conditions, the procedure, and the experience and comfort level of the anesthesia provider. Several reviews are available on this topic. For MRI scans, propofol deep sedation has been suggested as a safe and effective option in children with airway pathologic conditions or who are premature or very young.[19] For generally healthy children undergoing MRI scans, adverse events were reportedly less common when deep sedation/anesthesia with propofol and a natural airway were used compared with inhaled anesthesia through an LMA.[20] The same report noted that recovery was faster after propofol (alone) compared with inhalational anesthesia. Similarly, multiple reports have recommended successful outcomes with propofol sedation and general anesthesia with tracheal intubation (GETA) techniques for endoscopies.[21,22] In another study where a direct comparison was made between the techniques for GI procedures, recovery was more rapid and agitation less common after a propofol-based sedation technique rather than an inhaled anesthesia-based anesthetic technique.[23]

No clear evidence exists that one technique is better than another for procedures since both techniques have been reported as effective and safe outside the OR. Recognizing this fact, it is appropriate to carefully evaluate the nature of the sedation/anesthesia provided in the NORA setting and consider all of the possible implications of a given technique for each patient group. For instance, how efficient and effective is the care that is provided? How well does the care provided meet the requirements of the procedure in terms of pain and movement control? How rapid is the emergence from sedation or anesthesia with a given technique? Do the short-term or long-term complications differ? Only after careful analysis can guidelines be established for the optimal technique for a given procedure.[24]

When delivering general anesthesia to children outside the OR, the risk benefit of instrumenting the airway must be carefully evaluated. The LMA has been found to be useful in the MRI or computed tomography (CT) setting because it can be used with spontaneous ventilation, enables the anesthesiologist to monitor $ETCO_2$ continuously, and provides a clear airway for a child who may otherwise have an airway obstruction or who is in a position where the airway is not readily accessible. With the LMA in place, the child can be maintained with a relatively small inspired concentration of anesthesia, allowed to breathe spontaneously, and then rapidly awakened at the conclusion of the scan. After the LMA is placed, anesthesia can be provided with either a continuous infusion of propofol or with a low-dose inhalation agent (e.g., sevoflurane 1.5% in 50% N_2O/O_2). In some circumstances, the LMA may provide a suitable airway in children with bronchopulmonary dysplasia, cystic fibrosis, severe asthma, or active respiratory issues. In children with upper respiratory tract infections, the incidence of mild bronchospasm, laryngospasm, breath-holding, and O_2 desaturation (<90%) in those whose airway was managed with an LMA was reduced compared with those whose airway was managed with a tracheal tube.[25,26] Similarly, the use of LMAs in former preterm infants with bronchopulmonary dysplasia resulted in less coughing and wheezing and greater hemodynamic stability than in those managed with tracheal tubes. In children who underwent a vitrectomy for retinopathy of prematurity, the time to discharge after an LMA was less than that after a tracheal tube.[27] LMAs provide more hemodynamic stability during their removal than during tracheal extubation and may offer a specific advantage in some children.[28]

In healthy children, deep sedation is appropriate (e.g., for an MRI scan); it usually includes a propofol infusion, an optimally positioned upper airway (with a roll under the cervical spine and the neck extended), and noninvasive monitoring (nasal capnometry supplemented with oximetry, an ECG, and noninvasive blood pressure monitoring).[29] The majority of children do not require an airway during deep sedation for medical tests. However, in some (e.g., those with excess secretions or obstructive sleep apnea), the following algorithm of airway intervention may be followed to relieve the obstruction: (1) reposition the head and shoulders, (2) insert an oral or nasal airway,[30,31] (3) if partial obstruction persists, place an LMA, and (4) if the LMA fails to provide adequate gas exchange and oxygenation, place a tracheal tube.

Logistics of Managing Acute Emergencies and Cardiopulmonary Arrest Outside the Operating Room

Although the actual management of a cardiopulmonary arrest should not vary between the OR setting and the non-OR setting, the logistics of performing a resuscitation may be challenged by unanticipated factors, such as personnel who may not be familiar with code situations, an environment that makes performing a resuscitation difficult, or equipment that may be unsafe if used in the particular location (e.g., the MRI environment). It is important that all personnel in the off-site location be familiar with the location and operation of the code cart. The anesthesia cart and the code cart in the off-site location should be stocked in the same precise configuration as all others throughout the hospital and ORs. Standardizing the code carts throughout the hospital ensures that all ancillary personnel can be helpful in locating critical items. If the code cart is kept locked, the key or access code must be readily accessible and in a location that is known to all essential personnel. A hard board on which chest compressions may be performed should be readily available. Each off-site location should have an identified and rehearsed routine for announcing a code situation and summoning aid. Responders to a code must be assured of access to the location to which they are called; in the current age of card-key access, this should be simple but needs to be established in advance of need. The use of patient simulation can be very helpful in testing the team response to critical events. Simulators can be used in place in off-site locations to replicate critical events and evaluate the ability of the care team and backup systems to resuscitate a patient. This methodology has documented significant variation in the ability of rescuers to resuscitate children from sedation or anesthesia critical events in locations outside the OR.[32]

MRI SCANNER

Of all the non-OR environments in which anesthesiologists are asked to provide care, the MRI scanner poses a unique challenge for cardiopulmonary resuscitation. The MRI environment is divided into four zones that correlate with the intensity of the magnetic field and the risk to children and health care providers. These zones are delineated in Table 46.1.

The ASA published a Practice Advisory report in 2009.[33,34] This document advises that in the case of a medical emergency within the scanner, the anesthesia providers should (1) initiate cardiopulmonary resuscitation while immediately removing the patient from zone IV, (2) call for help, and (3) transport the patient to a previously designated safe location in proximity to the MRI suite. This designated location should contain a defibrillator, vital signs monitors, and a code cart with all resuscitation drugs, airway equipment, O_2, and suction. Other acute emergencies that are unique to the MRI environment include a "quench" in the scanner.[33,34] Quenching occurs when the liquid that cools the magnet boils off rapidly and results in helium escaping from the cryogen bath. The magnetic field of the magnet is rapidly decreased because the coils in the magnet cease to be superconducting and become resistive. In addition to performing the institution's protocol in reaction to either of these events, the ASA consultants involved in writing the advisory agree that in the event of a quench (1) the child should be removed from zone IV immediately, (2) O_2 should be administered immediately, and (3) emergency response personnel should be restricted from entering zone IV because of the powerful magnetic field that can exist even after a quench.

TABLE 46.1 Descriptions of the American College of Radiology's Four Zones in the Magnetic Resonance Imaging Suite

ACR Zones	Occupants	Hazards
Zone I	General public	Negligible
Zone II	Unscreened MRI patients	Immediately outside area of hazard
Zone III	Screened MRI patients and personnel	Potential biostimulation interference, access to magnet room
Zone IV	Screened MRI patients under constant direct supervision of trained MRI personnel	Biostimulation interference, radiofrequency heating, missile effect, cryogens

ACR, American College of Radiology; *MRI*, magnetic resonance imaging.

Difficult Airway Management in the Non–Operating Room (Off-Site) Environment

Two potential difficult airway scenarios may occur in non-OR locations: the child with a known difficult airway and the child with an unrecognized difficult airway. There is little peer-reviewed literature that addresses these scenarios, but logic would dictate that children who are identified as having potentially difficult airways should have their airways secured in the controlled environment of the OR. Regardless of an anesthesiologist's comfort level and familiarity with the intended off-site environment, the critical backup personnel and the full array of airway equipment are not generally available in remote locations. It is important to note that a fiberoptic bronchoscope and light source and most video laryngoscopes are not MRI compatible (Tru-MR [Truphatek International Ltd., Netanya, Israel] is an MRI-compatible video laryngoscope. It is easier to secure the airway with these alternative devices in an OR. In this environment, both the nursing and anesthesia support staff (technicians, other anesthesiologists, and otolaryngologists) are readily available and prepared to provide assistance. More recently, the advent of advanced video laryngoscopes has made the requirement for flexible fiberoptic intubations less common.[35] This equipment should be readily available in NORA locations for any child with a proven or suspected difficult laryngoscopy (before and during the procedure). With the trachea intubated, the child may be safely transported to the off-site location for subsequent care. The ASA task force on care in the MRI recommends complex airway management should be performed in a controlled environment outside zone IV.[34]

The more difficult scenario is that of the unrecognized difficult airway[36]; this scenario may best be handled by establishing a local management protocol that can be activated when the situation arises. Each institution has particular equipment, space, and personnel resources. NORA leaders should establish a local protocol for management of the unanticipated difficult airway in an off-site location. In some cases this might involve bringing advanced

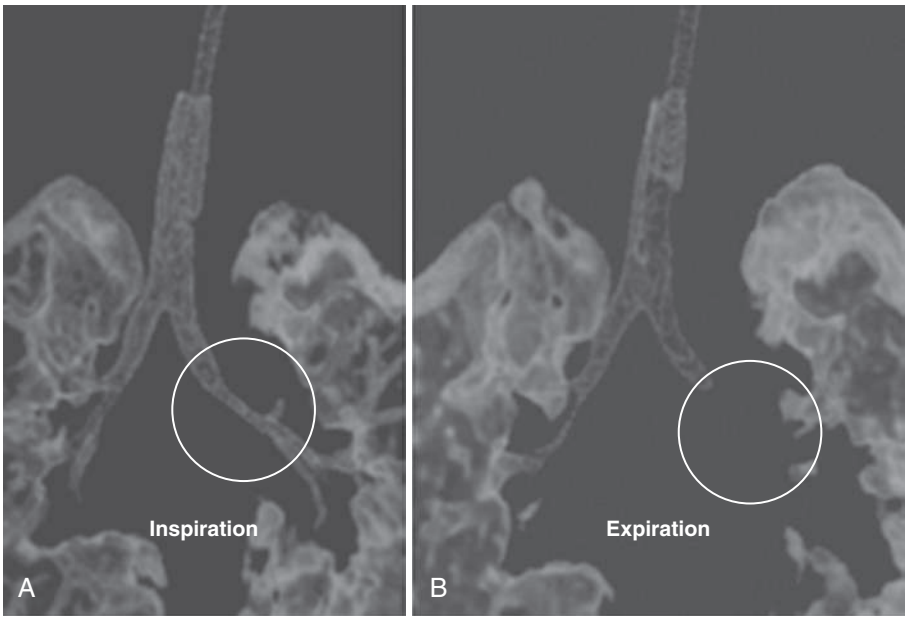

FIGURE 46.1 Three-dimensional dynamic computed tomography scan demonstrating change in caliber of left main-stem bronchus (*circle*) in an intubated child at end-inspiration (pressure held at 15–18 mm Hg) **(A)** versus end-expiration **(B)**.

airway management equipment to the location in a rapid, organized manner. In other cases the best option would include "temporizing" management with alternative airway devices and transporting the child to a location where a definitive airway can be placed in a controlled manner. For this reason, it is important to have alternative airway devices such as LMAs stocked in all anesthesia carts that are designated for off-site locations. In the event that the lungs cannot be ventilated or the trachea intubated, the LMA has a proven track record for providing a lifesaving temporary airway until more definitive action can be taken.[37,38]

Specific Locations for Non–Operating Room Anesthesia

COMPUTED TOMOGRAPHY

CT involves ionizing radiation and can provide a good modality for differentiating between high-density (calcium, iron, bone, contrast-enhanced vascular and cerebrospinal fluid [CSF] spaces) and low-density (O_2, nitrogen, carbon in air, fat, CSF, muscle, white matter, gray matter, and water-containing lesions) structures. Generally, the scan time with the current 64-bit scanners is brief; with actual imaging time ranging from 5 to 50 seconds for image acquisition, many children are able to tolerate CT without sedation or anesthesia. A new generation of high-speed CT scanners obtains images in as little as 0.3 seconds, which should allow even more images to be acquired without sedation and with exposure to less radiation.[39] Children who require anesthesia often have a fragile or unstable respiratory or cardiovascular status. Anesthesia or sedation is often required for children who are unable to cooperate (cognitively impaired children and those younger than 2–3 years of age) or require CT emergently. Emergent indications for CT include head trauma, unstable respiratory status in need of a pulmonary diagnosis, unexplained changes in mental status, neoplasm workup, or radiation therapy planning. Anesthesia management is also necessary with a potentially unstable airway (peritonsillar abscess, anterior mediastinal mass, craniofacial anomaly, tracheoesophageal fistula, uncontrolled vomiting, or gastroesophageal reflux) or the need for breath-holding during acquisition of images (three-dimensional dynamic airway studies) (Figs. 46.1 and 46.2). Some CT units are particularly concerned about children moving when contrast is injected (because of dose restrictions the contrast injection cannot be repeated) and therefore request anesthesia services for any child they cannot confidently predict will stay motionless for the study.

Children with Down syndrome present a particular risk for atlantoaxial instability and may require a head or neck CT to evaluate cervical and temporomandibular anatomy, recurrent sinusitis, or choanal atresia. The reported incidence of atlantoaxial instability varies from 12% to 32%,[40] although anesthesia-related neck complications are almost nonexistent in children with Down syndrome.[37] These children often require cervical spine radiographs before entering grade school or participating in the Special Olympics. Usually, the parents know the outcome of these tests and can convey the results to the anesthesiologist. These studies alone do *not* indicate to the practitioner whether the child is at risk of dislocation.[37] Rather, it is the presence of neurologic signs or symptoms that would herald a spine that is "at risk": abnormal wide-based gait, incontinence, increased clumsiness, fatigue with ambulation, complaints of numbness, tingling in an extremity, weakness of an extremity, or a new preference for sitting games. In infants, these clinical signs may be difficult to assess. In younger children, developmental milestones (e.g., crawling, sitting up, reaching for objects) should be evaluated. Physical signs may include clonus, hyperreflexia, quadriparesis, neurogenic bladder, hemiparesis, ataxia, and sensory loss. Children with atlantoaxial instability on a radiograph are at less risk for dislocation if they do not exhibit any signs or symptoms of instability. Children who are capable of following commands may be asked to perform full neck flexion and extension maneuvers to determine whether

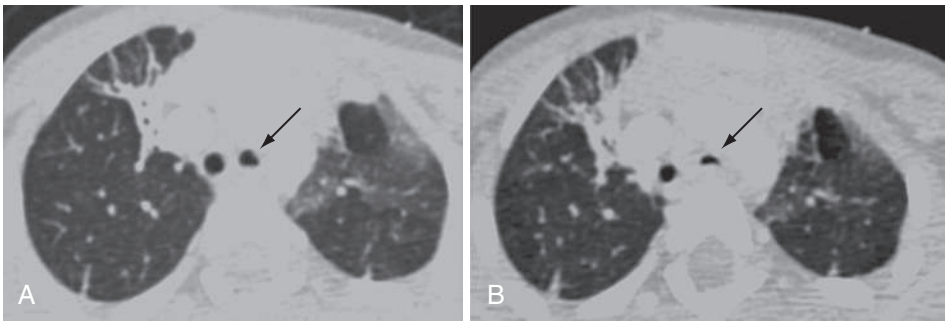

FIGURE 46.2 Three-dimensional CT scan demonstrating change in caliber of left main-stem bronchus *(arrows)* on inspiration **(A)** versus expiration **(B)**.

pain, sensory, or motor manifestations of cord compression develop. When the child is young, unable to cooperate with an examination, or has an uncertain history of atlanto-axial instability, it is wisest to avoid extremes of neck positioning during CT scans and communicate with radiology colleagues about the clinical concerns.

Perhaps the most controversial issue facing anesthesiologists with regard to CT scans is the issue of oral contrast for CT. Because children lack abundant retroperitoneal fat, they do not have the natural contrast needed to elucidate abdominal images. For this reason, children are often required to ingest (orally or via nasogastric tube) diatrizoic acid (Gastrografin) to opacify the stomach and bowel. Oral contrast is useful in the identification of an intraabdominal abscess, mass, fluid collection, bowel injury, pancreatic injury, or other traumatic injury. The oral contrast comes as Gastrografin 3% concentration and may be diluted to a 1:1.5% concentration. Since Gastrografin 3% is hypertonic (2200 mOsm/L) it can cause pulmonary edema, pneumonitis, osmotic effusions, and death if aspirated. Thus the more dilute concentration is recommended for CT, which is thought to be much less dangerous if aspirated. The volume of oral contrast that is administered can be quite large. Neonates typically receive 60 to 90 mL. Infants between 1 month and 1 year of age may receive up to 240 mL. Children between the ages of 1 and 5 years receive between 240 to 360 mL of contrast medium. Risk is introduced when these children require anesthesia within an optimal window after ingestion (usually 30 minutes to 1 hour after receiving the contrast agent) to enhance visualization. By most fasting guidelines (nil per os [NPO]), Gastrografin consumption within 1 to 2 hours of an anesthetic or sedation does not fall within the usual NPO guidelines. On the other hand, the scan must be completed while the Gastrografin is present in the GI tract. Despite the large volume of Gastrografin that may be ingested, there does not appear to be a significant aspiration risk in this population, and many anesthesiologists do not secure the airway with a tracheal tube (Fig. 46.3). A review of the pediatric and adult literature confirms that over the past 35 years (and hundreds of thousands of contrast GI CT scans) only a few case reports have been published of aspiration syndrome attributed to Gastrografin, all in extremely high-risk patients with issues such as bowel obstruction or acute abdomen.[38,41,42]

Several investigators have evaluated the issue of aspiration from different perspectives. In one study, a cohort of 50 children who received oral contrast after blunt abdominal trauma were evaluated for radiologic evidence of aspiration pneumonia or clinical complications of aspiration.[43] Some received general anesthesia and some were neurologically impaired (including several

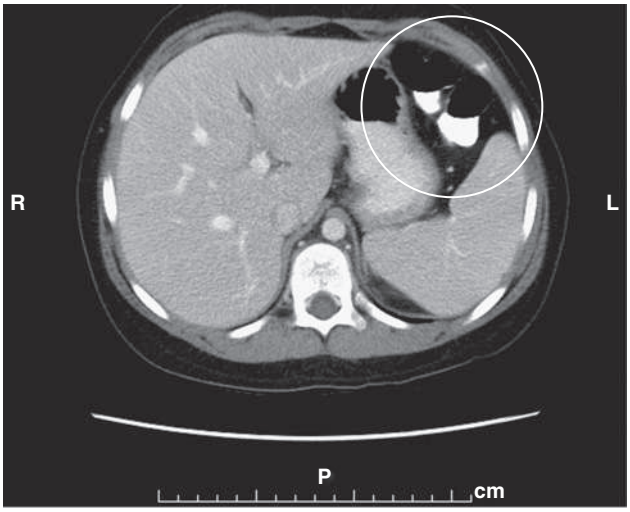

FIGURE 46.3 Four hours after ingestion of Gastrografin, oral contrast is still present in the stomach and small intestine. Although dilute Gastrografin is still frequently present in the stomach at the time of computed tomography, there are as yet no case reports validating an increase in risk of pulmonary aspiration.

with increased intracranial pressure). In this very high-risk group, only one child was thought to have possibly aspirated based on a chest radiograph after the CT scan, although that patient did not develop pulmonary symptoms. Another study evaluated the volume of gastric contents of 365 children undergoing deep sedation or general anesthesia for abdominal CT scans. Omnipaque 3 mL was diluted 50-fold to a volume of 150 mL and given to children younger than 1 year and a volume of 600 mL was given to teenagers–starting 2 hours before the scheduled scan and ending 1 hour before general anesthesia ($N = 207$) or sedation ($N = 158$); all were elective scans with standard fasting times. The authors note that gastric contents exceeded 0.4 mL/kg in 49% of those who received gastric contrast[43] (the actual threshold volume for aspiration is likely closer to 0.8 mL/kg as documented in primates[44]). Two cases of vomiting were recorded. None of the children in the study developed clinical evidence of aspiration. When dilute Gastrografin is used, the risks associated with pulmonary aspiration appear to be small, even in children who are moderately to deeply sedated.[45] Despite this evidence, cohort studies with sufficient power to determine the actual incidence of aspiration in this

setting have not been performed. Therefore, *no* accepted standard of care for the airway management of these children has been determined. Some anesthesiologists induce anesthesia with an IV or inhalational technique and maintain the anesthetic without securing the airway with a tracheal tube. Others perform rapid-sequence induction and tracheal intubation. The lack of consensus among anesthesiologists and the absence of evidence preclude a clear and consistent recommendation for managing the airway in these children. Common sense would lead one to conclude that a rapid sequence induction with tracheal intubation/general anesthesia would be most appropriate for children with bowel pathology that interfered with gastric emptying.

CT scans that involve imaging the airway are also an area of concern for anesthesiologists.[46] Traditionally, although these scans are brief, they have required breath-holding to allow the capture of images with sufficient clarity to be of diagnostic quality. Appropriate apnea intervals can be obtained under anesthesia with tracheal intubation with or without neuromuscular blockade, or by placing an LMA and providing moderate hyperventilation and a bolus of propofol (which results in apnea when ventilation is discontinued). The current generation of "flash" CT technology with ultra-fast image capture is largely eliminating the need for breath-holding with these studies and may further eliminate the need for sedation or anesthesia for many CT studies in children of any age.[39]

NUCLEAR MEDICINE

Nuclear medicine is one of the oldest functional imaging disciplines; these scans are useful for identification of the extent of disease for many neoplasms.[47] They can also be used to detect epileptic foci in refractory epilepsy, evaluate cerebrovascular disease (e.g., Moyamoya disease) and cognitive and behavior disorders, and detect and delineate renal function and disease, including detection of reflux and acute pyelonephritis.[37] Improvements in the hardware for nuclear imaging have greatly decreased the scan time, although even with the advent of two-level emission and transmission scans and combined CT imaging, some of the scan times can still reach 2 hours or more. The equipment in nuclear medicine imaging emits no ionizing radiation; rather, the radiation is contained within the child and is of very low energy levels. Depending on the nature of the study, the children require IV access for administration of the nuclear tracer well in advance of the scan and therefore usually have IV access for the anesthesia or sedation. Many nuclear scans also require an empty bladder to avoid interference from concentrated tracer in an enlarged bladder. Accordingly, the bladder is often catheterized after anesthesia is induced and the radioactive urine that is collected is disposed of in a radioactive-safe manner.

Two nuclear scans that involve anesthesia and present particular challenges are single-photon emission computed tomography (SPECT) and positron emission tomography (PET) scans. Both of these scans can be combined with a CT scan for optimal imaging. SPECT scans use single-photon gamma-emitting radioisotopes and rotating gamma cameras to produce three-dimensional brain images. SPECT scans involve the use of radiolabeled technetium-99m (half-life of 6 hours), which undergoes extensive first-pass extraction and intracellular trapping in proportion to regional cerebral blood flow. This scan is useful for localizing seizure foci. It appears to be as accurate as invasive direct cortical mapping in this regard.[48] Injection of the radionuclide proximate to the time of a seizure will tag areas of increased cerebral blood flow and localize the seizure foci. The child should be scanned within 1 to 6 hours of the seizure and injection of the tracer. This technique poses some obvious logistical challenges since there is no way to predict (exactly) when a seizure will occur. The anesthesiology service must be flexible in providing anesthetic services within the window of time allowed to complete the test whenever the next seizure occurs.

PET scans use radionuclide tracers of metabolic activity such as O_2 usage and glucose metabolism. Radionuclide tracers of glucose may be useful when seeking seizure foci or tumor recurrence.[47,49,50] Unlike SPECT scans, PET scans require a seizure-free period of at least 2 hours. Tracer is then injected and the scan is performed after 30 to 45 minutes. Outpatient scans may be scheduled but are canceled if a seizure occurs. In-patient scans required for children who have frequent seizures can be extremely difficult to schedule and must be coordinated between the neurology and anesthesiology services.

Both SPECT and PET scan techniques are noninvasive. There is little noise associated with them, and there are no issues related to electromagnetic field as there is in the MRI scanner. The patients have to hold very still in a specific position, however, and the detector unit is very close to their face/head. This obviates the use of digital movies for distraction, although music can be used and parents can be present if the patient will be awake. Anesthesia/sedation is required for those patients who cannot hold still in a nonthreatening environment for the time periods required for the scans, which can range from 10 minutes for a PET/CT of the head to 2 hours for SPECT scanning of the body.[47]

STEREOTACTIC RADIOSURGERY

Stereotactic radiosurgery (gamma knife) is a major advance in the treatment of selected malignant tumors (ependymoma, glioblastomas), vascular malformations, acoustic neuromas, and pituitary adenomas in children.[51,52] Radiosurgery is indicated, especially for those children with a tumor located deep in the brain or in an area that could put the child at significant surgical risk (e.g., speech, motor, cerebellum, brainstem areas) or for the recurrent brain tumor that has failed prior treatment. Radiosurgery involves the use of a single large fraction of radiation that is directed at a specific target with minimal radiation exposure to the surrounding normal tissues. Optimal results are achieved with small tumor volumes ($\leq$14 cm^3).[53]

Stereotactic radiosurgery requires the coordination of the departments of radiology, radiation therapy, and anesthesiology. The procedure averages 9 hours but can take up to 15 hours. The stereotactic portion of the procedure begins in the morning in a CT scanner. A stereotactic head frame is applied after induction of general anesthesia and tracheal intubation. Some older children can tolerate the application of the head frame with local anesthesia alone but then develop anxiety because the pressure sensation produced by the head frame can lead to anxiety, nausea, or vomiting. The vast majority of children require general anesthesia for application of the frame and subsequent imaging and surgery. When the head frame is in place, the key to unlock and remove it should be taped to the frame itself, in the event of a situation necessitating its emergent removal (e.g., vomiting, airway obstruction, or accidental tracheal extubation). For smaller children, nasal intubation may provide better stability during transport from the radiology suite to the OR. After the head frame is in place and the imaging study is completed, the child is transported (trachea intubated, sedated, and appropriately monitored) to the postanesthesia care unit while the radiologists and neurosurgeons review

the images and plan radiosurgery. The postanesthesia care unit stay can range from 3 to 5 hours, during which time these children require continuous physiologic monitoring.

After the images are reviewed and the radiosurgery planning is complete, the child is transported to the stereotactic radiosurgery linear accelerator for treatment. The treatment room is equipped with an anesthesia machine and monitors. To minimize radiation exposure to health care personnel, only the child remains in the scanner area during treatment. The child is observed at a distance with video cameras that are focused on both the child and the physiologic monitors. Treatment usually lasts about 1 hour.

After radiosurgery is completed, the child is returned to the postanesthesia care unit where the trachea is extubated under controlled conditions. Risks are inherent with this prolonged anesthesia, which requires multiple transports between sites. Four potentially serious anesthesia-related events were reported in 68 radiosurgery procedures in 65 children.[54] Serious complications in those children who received general anesthesia included obstruction of the tracheal tube while in the head frame and lobar collapse requiring prolonged mechanical ventilation.

RADIATION THERAPY

Radiation therapy for children uses ionizing photons to destroy lymphomas, acute leukemias, Wilms tumor, retinoblastomas, and tumors of the central nervous system. Improved three-dimensional imaging and enhanced computing power have allowed radiation oncologists to conform radiation dose to the shape of the tumor and minimize radiation to the surrounding tissues.[55] The energy absorbed by the tissues is measured in *grays* (Gy), which has replaced the term *rad*. One gray is equivalent to 100 rad. Although most children receive standard x-ray therapy, specific lesions may respond better to bombardment with electron, proton, or neutron beam therapy. The anesthetic considerations are identical regardless of the type of therapy in this respect.[56] A planning session in a simulator is typically scheduled before the initiation of radiation therapy to map the fields that require irradiation while the child is in a fixed position. For proton beam treatments, a planning session is performed in a CT scanner. A fiberglass immobilization mask of the head is made while the child is sedated/anesthetized with propofol and (most often) with a natural airway (Fig. 46.4).

FIGURE 46.4 Child in fiberglass mask for radiation treatment of a cerebral neoplasm.

This cast allows secure positioning to ensure that the child does not move during treatment, but considerable care is required to configure the mask for optimal airway patency while ensuring proper windows for treatments. Once the mask is completed, the use of an oral airway or LMA is not possible as these maneuvers will alter the head position and thus the direction of the radiation beam.

Radiation therapy involves "fractionated" exposure. Repeat sessions are typical. The child must be motionlessness during therapy to precisely target malignant cells. Radiation therapy is typically administered by dividing the total radiation therapy course among daily or twice-daily sessions. In general, most treatment sessions last between 15 and 30 minutes, and the planning simulation session may take as long as 2 hours, depending on the nature and location of the target lesion or area for therapy. For children who require neuraxial treatments for spinal metastases, as many as four fields may be irradiated with the child in both the supine and prone positions. Dividing the total radiation therapy course into discrete daily sessions allows normal tissue repair between sessions while the tumor burden is lessened or destroyed. These children are optimally managed via central venous access that obviates the need for repeated venipunctures. Unless there is a specific airway anomaly, daily anesthetic management typically consists of deep sedation using a propofol infusion (with or without midazolam pretreatment),[57] blow-by oxygen via nasal cannula or face mask, and spontaneous ventilation monitored with $ETCO_2$. Tachyphylaxis does not appear to be an issue even with multiple, frequent treatments.[58] Given all of the challenges, it is somewhat surprising that these treatments have not been associated with an increased adverse event rate. One retrospective review of 177 patients undergoing 3833 radiation treatments documented a 1.3% complication rate.[59] This rate compares favorably with the rate of complications for children undergoing propofol-based anesthesia without cancer.[60]

Dexmedetomidine sedation has been used for radiation therapy, but its use has not become widespread most likely because of the need for a 10-minute loading dose and relatively frequent need for repeated boluses at the doses that have so far been studied.[61] Single-dose IV ketamine 0.5 to 0.8 mg/kg provides effective sedation, albeit with a greater half-life, more movement, and an increased rate of adverse events on emergence (e.g., vomiting) than propofol.[62]

One exceptional case in radiation therapy is retinoblastoma. In this case, the eye must be completely immobile during the treatment. General anesthesia or deep propofol sedation is required to ensure appropriate irradiating conditions; ketamine (in particular), with its side effect of lateral nystagmus, is not appropriate in these cases (see Video 7.1).[62]

The logistics of radiation therapy anesthesia or sedation are complex, even though the treatments themselves are not challenging; only the child remains in the room during treatment. Thus monitoring must be performed using video observation. For this reason, radiation therapy units are equipped with multiple video monitors adjusted to allow viewing of both the child from several views and the physiologic monitors. Children are often moved to allow different angles of access for the radiation treatment; this must be taken into consideration when positioning monitors and power cords. Many cases of spinal irradiation require the child to be prone with the head at a specific angle with respect to the back. Often several adjustments to head position are required to maintain a patent airway with the tight-fitting mask; monitoring expired carbon dioxide is therefore essential.

Most children undergoing radiation therapy are also receiving chemotherapy. As the treatment progresses, nausea, vomiting, and respiratory illness stemming from local radiation effects and chemotherapy can create deteriorating conditions for spontaneous, natural airway ventilation. It is important to work with the child's oncologist to manage symptoms and complete the treatment series as close to the planned treatment regimen as possible, because this is critical to the child's survival and maximizing quality of life.

MAGNETIC RESONANCE IMAGING

MRI, magnetic resonance spectroscopy (MRS), magnetic resonance angiography (MRA), and magnetic resonance venography (MRV) are used for the evaluation of neoplasms, nonhemorrhagic trauma, vascular, cardiac, orthopedic (including joint disorders, osteomyelitis), central nervous system and spinal cord lesions, craniofacial disorders, detecting the origin of developmental delay, behavioral disorders, seizures, failure to thrive, apnea, cyanosis, hypotonia, and in the workup of mitochondrial and metabolic diseases.[63–66] MRA and MRV are especially helpful in evaluating vascular flow and often can replace invasive angiography in follow-up evaluations of vascular malformations, interventional therapy, or radiotherapy.[67,68] All of these imaging modalities are essentially equivalent in terms of the requirements for the provision of anesthesia or sedation and thus can be considered the same as MRI.

Most MRI systems are superconducting magnets set up in a horizontal configuration within the bore so that the magnetic field is directed lengthwise to the child. The magnet is cooled by liquid helium to a temperature of approximately –268°C. The strength of the magnetic field in these scanners is described in tesla (T) units and range from 0.5 to 3.0 T. To put this into perspective, a 1.5-T magnet is the equivalent of 30,000 times the earth's magnetic field.

A variety of safety issues with respect to MRI are important; a review can be found in an American College of Radiology safety paper.[69] All individuals who work in the MR environment should be familiar with the primary recommendations in this paper.

Foremost is the risk of injury from ferromagnetic objects attracted to the magnetic core of the MRI scanner that can cause significant morbidity and mortality (Fig. 46.5). In the presence of an external magnetic field, a ferromagnetic object can develop its own intrinsic magnetic field. The attractive forces created between the intrinsic and extrinsic magnetic fields propel the ferromagnetic object toward the MRI scanner. Numerous injuries including death have been reported from objects accidentally attracted to the MRI magnet, including: an anesthesia cart, a metal fan, pulse oximeter, shrapnel, wheelchair, cigarette lighter, stethoscope, pager, hearing aid, vacuum cleaner, calculator, hair pin, O_2 tank, prosthetic limb, pencil, insulin infusion pump, keys, watches, clipboards, steel-toe or steel-heeled shoes, ferrous jewelry, and even a concealed police revolver.[70,71] Mortality can result from projectile disasters, as when a ferrous O_2 tank was "pulled" from the hands of the respiratory therapist and crushed the skull of the child being scanned.[71a] It is absolutely essential that all portable O_2 tanks are MRI-compatible and that anesthesia carts are not brought into the MRI. Many MRI scanner units now have screening protocols that include a small handheld magnet to test whether objects are ferromagnetic and thus at risk of being pulled into the magnet.

The other major potential morbidity related to MRI scanning results from implanted devices (i.e., cardiac pacemakers, spinal cord stimulators, programmable ventriculoperitoneal shunts) that may malfunction in the powerful magnetic field of the MRI scanner and can cause injury. These injuries are most often caused by inappropriate patient screening or unfamiliarity with a particular implant's MRI compatibility. The U.S. Food and Drug Administration (FDA) has terminology for designating objects in terms of their safety in the MRI environment. *MRI-safe* is defined as not posing any known hazard in any MR environment. *MRI-conditional* refers to objects that may or may not be safe, depending on the specific conditions that are present. *MRI-unsafe* means the object should never be brought into the MRI environment because it poses a potential or realistic risk or hazard. All objects or medical devices should be referenced and vetted for safety prior to being brought into zone IV. Some devices are compatible with 1.5-T but not with 3.0-T units. Current standards for MRI safety include a magnetic metal detector check of all personnel and patients and/or family each time they enter the scanner.

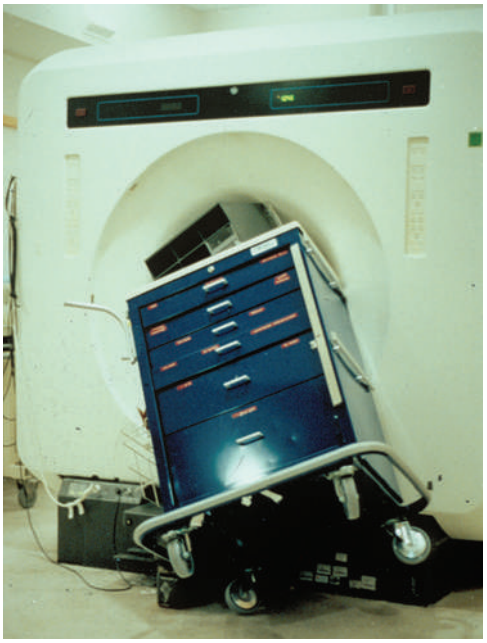

FIGURE 46.5 Magnetic resonance imaging cart that is not compatible inadvertently brought into scanner room. To extricate the cart, the magnet had to be quenched, incurring a cost in excess of $20,000 USD.

All implanted objects should be carefully evaluated before a patient or health care provider enters the MRI suite. The website http://www.MRIsafety.com is a useful resource for identifying MRI-safe objects. Note that stainless steel or surgical stainless objects may interact with the external magnetic field, potentially resulting in translational (attractive) and rotational (torque) forces. Special attention should be paid to intracranial aneurysm clips (may move and potentially dislodge), vascular stents, cochlear and stapedial implants, shrapnel, intraorbital metallic bodies, and prosthetic limbs. In fact, some eye make-up and tattoos may contain metallic dyes and are at risk of causing skin, ocular, periorbital, and cutaneous irritation and burning.[72–74] Among the most important pieces of equipment for vulnerable patients, tracheostomy tubes should be checked before the children enter the MRI scanner. It is generally advised to switch a child's tracheostomy tube to a cuffed tracheal tube for MRI scanning to ensure a secure airway during the scan. Currently small-diameter cuffed tracheostomy tubes (Bivona) from Smiths Medical (Minneapolis, MN) are considered MRI-conditional (at www.MRIsafety.com, search for the MRI-compatible object to determine MRI compatibility).

They are acceptable for use, although the pilot balloon must be taped out of the way for use.

Cardiac pacemaker compatibility is a matter of some debate.[75] Historically, the presence of a pacemaker has been considered a contraindication for the MRI environment. Most pacemakers have a reed relay switch that can be activated when exposed to a strong magnetic field and convert the pacemaker to the asynchronous mode. In at least two known cases, patients with pacemakers died from cardiac arrest while in the MRI scanner.[76] Adverse events associated with pacemakers in the MRI scanner include ventricular fibrillation, rapid atrial pacing, asynchronous pacing, inhibition of pacing output, and movement of the device.[77,78]

Since 1996, however, changes in pacemaker electronics have included decreased ferromagnetic content and increased sophistication of the computer capabilities. In 2004, one study reported no changes in pacemaker capabilities or adverse outcomes after 56 patients with pacemakers underwent 62 MRI procedures.[79] Similar results were reported in 68 patients whose pacemakers were reprogrammed to asynchronous or demand mode before undergoing scans in a 1.5-T MRI scanner. Unfortunately, there is a paucity of data on children with pacemakers or implanted defibrillators who underwent MRI scans, particularly with respect to scanners with 3-T field strength. In one large literature review on this topic (mostly adult data) including almost 1500 patient encounters, 82% were found to have no significant changes in pacemaker function after imaging.[80] No deaths or serious adverse events were reported in this study, and the authors echo the sentiments that MRI scans should only be performed after consultation with experts and (even then) only if benefits are thought to outweigh risks.

Auditory considerations exist with respect to MRI. Specifically, a loud banging sound and vibrations are produced as the forces generated within the gradient coils of the MRI scanner cause the gradient coils to vibrate. The noises generated range from 65 to 95 dB in a 1.5-T magnet. Temporary hearing loss after an MRI scan has been reported.[81] This report suggests that earplugs may prevent the temporary hearing loss associated with MRI. Given these data, earplugs or MRI-compatible headphones are routinely used in children undergoing MRI scans.

Temperature regulation for infants and children during sedation or analgesia is a concern. Cool temperatures and humidity are required for proper magnet function, which are a setup for a child's radiant and convective heat loss, particularly since anesthesia limits intrinsic thermoregulation. On the other hand, the MRI generates radiofrequency radiation that is absorbed by the child and may offset heat lost to the environment. The specific absorption rate (SAR), which is measured in watts per kilogram, is used to follow the effects of RF heating. The FDA allows an SAR of 0.4 W/kg averaged over the whole body.[82] Early data suggested that children can increase their core body temperature by 0.5°C during MRI of less than 1-hour duration in a 1.5-T environment.[83,84] The temperature of infants who underwent MRI scans of the brain increased 0.2°C with a 1.5-T scanner and 0.5°C with a 3-T scanner, with minimal efforts to prevent passive heat loss.[85] More recently a study of almost 200 patients undergoing MRI scans found that 52% of children were hypothermic after their MRI scans,whereas none were hyperthermic.[86] Given the cool environment of the MRI scanner, it appears appropriate to pursue simple interventions to preserve warmth in the scanner, such as covering with warm blankets.

Focal heating remains a concern with respect to monitoring equipment in the MRI scanner. For example, the ECG leads should not have frays or exposed wires; *any coils or loops in a conductor such as ECG wires or a pulse oximeter probe can cause tissue burns* (Fig. 46.6). Cases of first-, second-, and third-degree burns after MRI have been reported.[87] To avoid patient injury, the following precautions should be undertaken: (1) avoid creating a conductive loop between the child and a conductor (ECG monitoring or gating leads, plethysmographic gating wire, and fingertip attachment); (2) do not leave any unconnected imaging coils in the magnet during imaging; and (3) prevent all exposed wires or conductors from touching the child's skin during the scan.

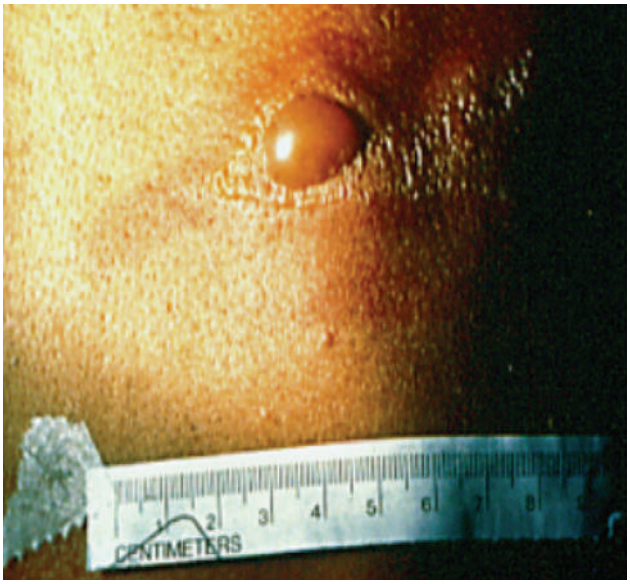

FIGURE 46.6 MRI-induced burn at site of electrocardiogram pad from a frayed lead.

Many MRI scans require contrast administration. Gadolinium (gadopentetate dimeglumine) is an FDA-approved contrast agent that is intravascularly administered for MRI enhancement. Approved for use in 1998, gadolinium provides greater contrast between normal and abnormal tissue throughout the body. Gadolinium forms a complex with chelating agents that facilitates biodistribution to the extracellular compartment and excretion via the kidneys. Unlike iodinated contrast agents, gadolinium complexes do not present a significant osmotic load. Gadolinium agents are considered to be safer than iodine agents with respect to adverse reactions. It is reportedly easily removed with dialysis.[88] On the other hand, recent warnings from the FDA suggest that gadolinium-containing contrast agents may be associated with the development of nephrogenic systemic fibrosis or nephrogenic fibrosing dermopathy in patients with moderate to end-stage kidney disease. The FDA suggests that gadolinium be administered only if necessary in children with advanced kidney failure and that, in those children, prompt dialysis should be considered after gadolinium administration for MRA studies. The incidence of severe anaphylactic or anaphylactoid reactions to gadolinium (0.01%–0.0003%) is less than that of iodine-based contrast media.[89] Another recent concern regarding gadolinium stemmed from evidence that increased uptake and deposition of gadolinium in the dentate nucleus and globus pallidus in normal brain tissue was found at autopsy after repeated scans. Given the lack of long-term follow-up, this has raised safety concerns and prompted some centers to change from using gadolinium to gadoterate meglumine (Dotarem)

or other contrast agents. These latter contrast agents may not accumulate in the brain, although this remains the subject of ongoing investigation.[90–92]

MRI-compatible equipment continues to be developed and improved. Multiple MRI-compatible anesthesia machines (with ventilators), monitors (including wireless models), and infusion pumps are now available. The cost for this equipment is substantial: an MRI-compatible anesthesia machine costs approximately $60,000 to $80,000 U.S. dollars; MRI-compatible monitors range up to $140,000 and compatible infusion pumps cost $12,000 to $18,000 each. This cost may be overwhelming for some institutions, especially in facilities with limited financial resources or limited need for MRI anesthetics. If patient volume is insufficient or financial backing to support such an investment is lacking, then special planning may be instituted to deliver anesthesia without a full complement of MRI-compatible equipment. Specifically, a non–MRI-compatible anesthesia machine could be used in the following manner: the machine must be positioned outside the MRI suite, and 30 feet of airway circuit extension may be threaded through the wall of the scanner to the child within. Alternatively, IV sedation or anesthesia can be delivered using MRI-compatible infusion pumps and O_2 can be delivered using a face mask or nasal cannula. If an MRI-compatible $ETCO_2$ monitor is not available, a conventional carbon dioxide (CO_2) monitor may be situated outside the MRI room in a similar fashion.[85] If GETA or LMA is required without an MRI-compatible anesthesia machine, it is safer to anesthetize the child outside the scanner (anesthesia circuit threaded through the console wall and then back out the entrance door to an induction area), secure the airway, and then move the child into the scanner. Similarly, if propofol sedation is intended, the propofol infusion pump can also be situated outside the scanner and equipped with 30 feet of IV infusion tubing. It is important to determine whether the pump is able to infuse accurately through the resistance of the long tubing and that the caliber of the tubing is sufficiently large that the length of tubing required does not trigger the pump's high-pressure alarm. An Ambu bag or Mapleson circuit (Mercury Medical, Clearwater, FL) must always be situated in the MRI suite and connected directly to an O_2 source within the scanner. This is critical, especially when the anesthesia machine is far from the child.

MRI-safe stethoscopes, stylets, laryngoscope, and flashlights should be available. If they are not available, standard equipment can be used with some modification and testing. The only component of the laryngoscope that is usually *not* MRI-safe is the battery. Replacing the standard battery with a lithium battery may be a simple, safe, and less expensive alternative to purchasing a marketed MRI-compatible and safe laryngoscope. Before introducing any equipment into the MRI environment, a rudimentary safety check should be performed by first passing a handheld magnet over the object to confirm that there is no ferrous material within. As a final safety check, an MRI safety expert should carefully introduce the object into the scanner (before bringing in a child) to confirm safety.

Anesthetic management of children in the MRI suite depends to a large extent on the availability of support personnel and equipment, the anesthesiologist's personal anesthetic practice, and the child's medical history. In clinical practice, the choice of anesthetic varies greatly among anesthesiologists. Airway management may include an LMA, a tracheal tube, or a natural airway (with a roll placed under the shoulders). With an LMA or tracheal tube, either inhalational or IV anesthesia may be used to establish a motionless child. With a natural airway, only IV sedation or anesthesia with propofol or dexmedetomidine is commonly used.[10,93–98] There are few direct comparisons of these two medications in the literature, but investigators have generally found that propofol is more effective and efficient than dexmedetomidine when used alone or in combination with other agents.[29,99] $ETCO_2$ should be monitored; in the case of nasal prongs, a septate design that delivers O_2 (2-4 L/minute) through one nostril while aspirating gas for CO_2 (capnometry) through the other allows for continuous assessment of respirations during spontaneous ventilation. Alternatively, a face mask of oxygen can be used with a sidestream CO_2 monitor placed near the nose or mouth. If respiratory problems occur, immediate access to the airway is not possible while the child is in the bore of the scanner; for this reason, some anesthesiologists may prefer to insert an LMA or tracheal tube in all children. Most LMAs are MRI-compatible, although the pilot balloon should be taped to the circuit tubing when imaging the head or neck because it may create imaging artifacts (Fig. 46.7).

Few studies have directly compared general anesthesia with a controlled airway to IV sedation or anesthesia techniques during MRI. One randomized study of 200 children demonstrated no difference in airway complications between the two groups. However, more pauses occurred during scans (for movement, and so on) with propofol sedation, but much less agitation was experienced on emergence after the scan.[100] To ensure MRI scans without interruption in the majority of children, many begin with infusion rates of propofol 200 to 250 μg/kg per minute in children and either maintain that infusion rate throughout or taper the infusion rate as described previously.[101] For younger children (infants) and children with severe cognitive dysfunction, infusion rates 20% to 50% greater than 250 mg/kg per minute may be required to prevent movement during MRI scans. The addition of remifentanil to propofol using a total intravenous anesthesia technique smooths sedation (see Chapter 8). Other studies documented agitation[102] and prolonged nausea and vomiting[103] after MRI scans performed under general anesthesia with inhalation agents. Some MRI scans (cardiac, thoracic, or abdominal) require breath-holding to obtain adequate images. In such cases, it is necessary to control the airway with an LMA or endotracheal tube and deliver general anesthesia. After reviewing the literature, insufficient evidence exists to recommend a particular anesthetic technique for MRI scans. Anesthesiologists still must consider their own practice environment and expertise, the demands of the scan itself, and the comorbidities of the particular child when selecting an anesthetic technique, particularly for children undergoing a cardiac MRI.

INTERVENTIONAL RADIOLOGY

Interventional radiology (IR) has evolved greatly and the trend is for increased use of IR both as a replacement to and in conjunction with surgical interventions.[104] Many IR procedures are minimally invasive and not particularly painful, although most children require sedation between moderate sedation and general anesthesia to complete their procedure. Procedures vary widely with regard to the level of stimulation, postprocedure pain, and requirements in terms of apnea or positioning. Familiarity with IR procedures and their anesthetic and postoperative requirements are essential for efficient functioning in this area.[105,106] As a large number of cases in IR are scheduled on an urgent or emergent basis, it is vital that anesthesiologists in this area have a well-established habit of mutually respectful communication with the IR team to coordinate patient triage and ensure that cases proceed safely and expeditiously.

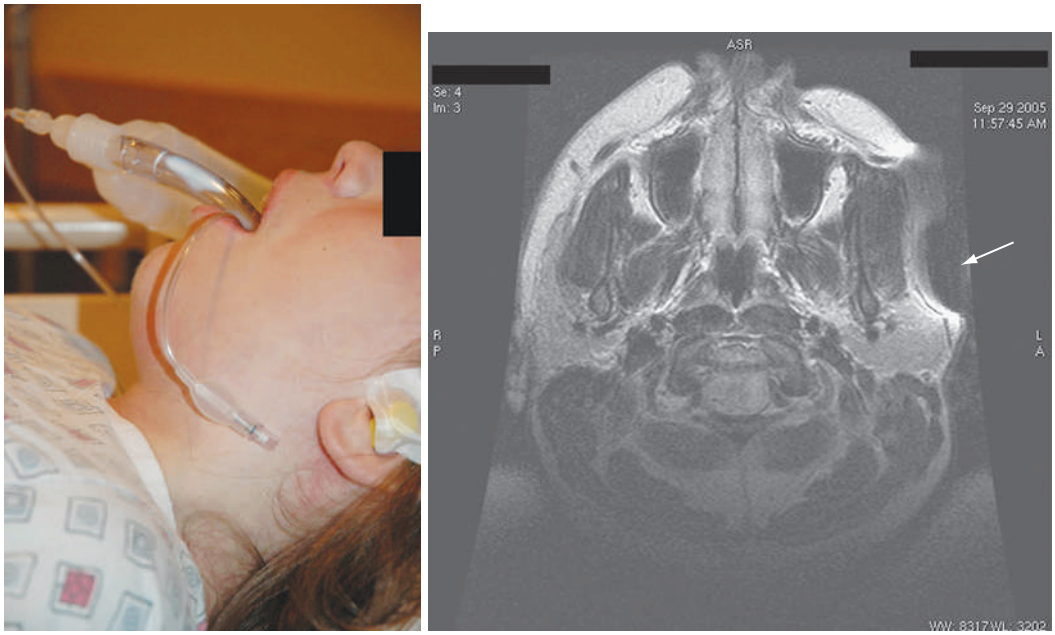

FIGURE 46.7 A, Laryngeal mask airway with pilot balloon left adjacent to face; such positioning could cause MRI artifact. We recommend taping to the Y-piece. **B,** MRI scan of the patient in **A** demonstrating artifact *(arrow)* created by ferrous material in pilot balloon.

Safety Radiation and Contrast Reactions

Radiation safety in IR is of paramount concern and tends to be underappreciated by anesthesiologists.[107] In pediatric settings, we are aided by the "Image Gently" campaign to reduce doses for pediatric patients,[108] but it is ultimately our responsibility to reduce our lifelong exposure to ionizing radiation with its attendant long-term health consequences.[109] Appropriate use of portable lead shields, lead aprons (preferably wraparound), thyroid shields, and lead glasses is crucial, as is increasing when possible one's distance from the radiation source and leaving the room when feasible for angiographic "runs." Portable dosimeters should be worn and monitored in compliance with local regulations.

The use of intravascular contrast media is ubiquitous in interventional radiology and cardiac catheterization. It is important that the anesthesiologist be aware of the risks and potential adverse effects of these agents.[110] Reactions to contrast in patients under anesthesia range from rash to bronchospasm to a diffuse anaphylactoid reaction[111] that can be life-threatening. The incidence of acute reactions, both mild and life-threatening, to contrast media has decreased with the advent of low-osmolality nonionic contrast media. Minor reactions are now estimated to occur in approximately 1% to 3% of patients. The risk of a fatal adverse reaction is estimated to occur 1 : 170,000 times, much improved from the risk in the 1970s of 1 : 30,000. This reduction is due to the use of newer contrast media and improved recognition and treatment of reactions. Anaphylactic shock is the most worrisome of all contrast reactions and may occur as early as 1 minute and as late as several hours after administration of the contrast material. Although adverse reactions to intravascular contrast media are unpredictable, some risk factors are identifiable. Children who suffer from allergies or an atopic disease; children with asthma, significant cardiovascular disease, or paraproteinemia; and children with prior contrast reactions have an increased incidence of adverse reactions.[112] Children who have been identified as being at increased risk of a contrast reaction should be premedicated with corticosteroids and antihistamines.[112,113] Areas where contrast media is routinely given should have protocols in place for the recognition and treatment of a contrast reaction.

The effect of contrast media on renal function must also be considered. The mechanisms underlying renal injury from contrast media are complex and not fully characterized. Direct renal tubular injury as well as renal hypoperfusion seem to play a role.[114] It is important to note that the trend toward low- and iso-osmolar contrast has been helpful in reducing renal damage from contrast. Nonetheless, in patients at high risk for renal injury, such as those with preexisting renal insufficiency (serum creatine ≥1.5 mg/dL), diabetes mellitus, dehydration, cardiovascular disease, hypertension, and hyperuricemia, good hydration must be maintained, along with careful follow-up of renal function.[115] In some institutions, a protocol of prehydration and posthydration with alkalinized IV fluids is used.

Diagnostic Angiography

Diagnostic angiography of the brain or of the periphery requires absolute control of movement, often with intermittent breath-holding to acquire clear images. For pediatric patients, this implies general anesthesia with a tracheal tube. Mature older children who can cooperate with instructions may be able to tolerate a short diagnostic angiogram with nothing more than minimal sedation, but care should be exercised that they do not become disinhibited or so somnolent that they cannot cooperate with breath-holding. Diagnostic angiography usually takes about 1 hour to complete and requires arterial access (usually of the femoral artery). Once access is obtained, the procedure is not stimulating. During these cases, orogastric and nasogastric tubes, esophageal stethoscopes, and esophageal temperature probes should be used with caution because they may cause artifacts on the angiographic images;

consultation with the IR nurses and technologists is recommended to determine where lines and monitors will be least obtrusive. After any femoral arterial access, patients must lie still for a period of time to reduce the risk of complications at the sheath site.[116]

Cerebral angiography may be indicated in the workup or postoperative follow-up of vascular malformation or tumor resections, stroke, hemorrhagic events, vascular disease, and unexplained mental status changes. Hypercarbia to an $ETCO_2$ of ~50 mm Hg may promote vasodilation to allow better access and visualization of cerebral vasculature (E-Fig. 46.1). Although MRA continues to improve, catheter angiography remains the gold standard for delineating vascular structures in the brain.

Any child who requires a study for the potential or confirmed diagnosis of vasculopathies such as Moyamoya disease should be treated with utmost caution. These children should have an anesthetic that minimizes the risk of transient ischemic attacks and stroke during the procedure.[94] Anesthetic care should begin ideally with the preinduction administration of 10 mL/kg of IV fluid to minimize the risk of hypotension (and potential cerebral ischemia) on induction of anesthesia. Sedating the child before starting the IV line decreases crying and hyperventilation that can lead to cerebral ischemia. Gentle mask induction with close attention to blood pressure has also been used in our institution with success. Blood pressure should be carefully maintained, avoiding hypotension with its potential for cerebral hypoperfusion. Vasoactive drugs are rarely necessary but should be available. Intraarterial blood pressure monitoring for these short procedures is rarely necessary. Hypocarbia should be avoided throughout. In the event of vasospasm or difficult access of small, tortuous vessels, locally administered (through the catheter) vasodilators such as nitroglycerin or calcium channel blockers in small doses may facilitate visualization and access. Although often effective for discretely vasodilating specific areas, these will generally not have a clinically important systemic effect on blood pressure. Specific protocols have been suggested for minimizing perioperative strokes in these children.[95] Close attention to postoperative pain control can similarly improve outcomes (see Chapters 24 and 26).

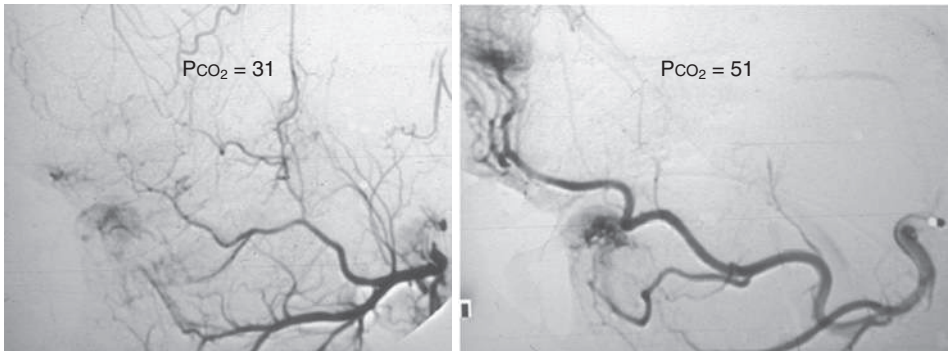
Peripheral diagnostic angiography is less common but may be useful before complex surgical or orthopedic procedures to delineate arterial anatomy. Angiography of the abdomen and pelvis has unique considerations; N_2O can diffuse into the bowel, causing distention and potential distortion of the vasculature of interest; it should be used with caution. In addition, the interventional radiologist may request that the anesthesiologist administer IV glucagon, usually in 0.25-mg increments. Glucagon reduces peristalsis and, as a consequence, reduces motion artifact during image acquisition.[117] However, it may cause nausea, vomiting, hyperglycemia, depression of clotting factors, and electrolyte disturbances[93]; close monitoring is warranted, particularly in neonates and small infants.

Angiography With Embolization

Angiography with interventions can be complex and carry significant risk. Indications for neurointerventional procedures include embolization of intracranial vascular anomalies such as arteriovenous malformations (AVMs), arteriovenous fistulae or aneurysms, targeted injection of intra-arterial chemotherapy for tumors, and presurgical embolization of both AVMs and tumors of the head and neck.[118] These procedures can take up to 10 to 12 hours, and complete immobility is required. Patient padding and positioning must be meticulous for such a long case, as moving the patient once catheters are deployed may be impossible.

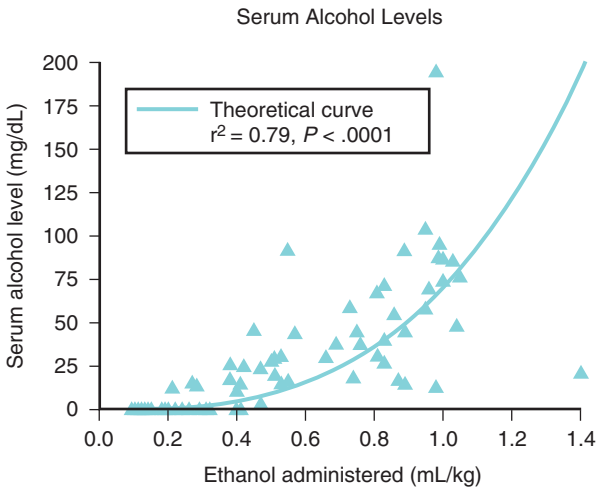
Arterial blood pressure monitoring is usually necessary during the treatment of intracranial AVMs. A maximal acceptable blood pressure should be determined with the radiologist owing to the risk of hemorrhage as flow through the AVM is altered by embolization.[119] For the same reason, close blood pressure control immediately after the procedure is essential. Our group has had some success with low-dose dexmedetomidine infusion overnight after extubation in the IR suite. In infants presenting in heart failure from high-flow AVMs such as vein of Galen malformations,[120] immediate improvements in hemodynamics have been described as high-flow AVMs are closed.[121]

Good IV access is necessary for hydration; the chance of significant blood loss is extremely small. Euvolemia to slight hypervolemia is recommended to offset the osmotic diuretic effect of contrast.[122] Note that a continuous infusion of heparinized saline solution is instilled via the femoral sheath to reduce the risk of microemboli.[123] This can result in a considerable volume of fluid delivered to the patient by the neuroradiologist.



Many agents are used for embolization, including various types of glue, metal coils, or polyvinyl alcohol particles.[124] It should be noted that children can become intoxicated if ethanol is used (E-Fig. 46.2). Embolization of brain AVMs carries the risk that perfusion to surrounding normal brain tissue may be compromised with a concomitant loss of function. While there are descriptions of assessment of adult patients' motor, language, or visual function during test injections of agents such as amobarbital before definitive closure of a feeder vessel, this requires an awake cooperative patient and few descriptions of this technique exist in children.[125,126] The goal in treatment of intracranial AVMs in children is to obliterate the lesion; in our institution we favor surgical resection when possible, usually preceded by embolization for better localization and hemostasis.[127,128]

Injection of intraarterial chemotherapy carries some unique challenges for the anesthesiologist. Accessing the ophthalmic artery for injection of chemotherapeutic drug in retinoblastoma has considerable risk of bronchospasm and bradycardia. Agents such as albuterol or anticholinergics are often administered just before chemotherapy instillation.[129] Nausea and vomiting is reported after the procedure, so aggressive antiemetic prophylaxis is encouraged to prevent a child with a femoral puncture from vomiting.



Embolizations of peripheral AVMs have the potential to be of prolonged duration because in many cases the lesion is quite complex. The natural history of AVMs, like all vascular malformations, is to grow over time, with acceleration of growth during puberty[130]; the end stage is tissue destruction and high-output cardiac failure (E-Fig. 46.3). Blood loss is rarely a risk during these minimally invasive procedures, but excellent hydration is necessary both to offset the diuretic effect of the contrast load and to counteract the hemolyzing effect of sclerosing agents (see later discussion). While complete cure is rare, embolization combined with surgical resection in some cases can keep AVMs symptoms manageable.[131]

Embolization for hemorrhage has a long track record of success in cases of trauma, allowing for less insensible fluid loss and not disrupting tamponade.[132] The greatest predictor of success is the volume of blood resuscitation needed before embolization; a larger requirement presages a worse outcome. Anesthetic management for these children is similar to that of any massive transfusion case (see Chapter 12).

Catheter-based embolization of pulmonary vessels for hemoptysis presents several challenges for the anesthesiologist. Embolization is effective for gaining short-term control of hemoptysis, even

E-FIGURE 46.1 Effect of hypercarbia on caliber of cerebral blood vessels; hypercarbia may assist the interventional radiologist to pass a catheter into small vessels (*right*).

E-FIGURE 46.2 Positive relationship between serum ethanol level and amount of ethanol administered. (From Mason KP, Michna E, Zurakowski D, Koka BV, Burrows PE. Serum ethanol levels in children and adults after ethanol embolization or sclerotherapy for vascular anomalies. *Radiology* 2000;217(1):127–132.)

E-FIGURE 46.3 Arteriovenous malformation of the leg with high-output cardiac failure.

massive hemoptysis, while not affecting the overall disease course in the case of cystic fibrosis.[133] Massive hemoptysis often necessitates single-lung ventilation and transfusion, coupled with the challenge of securing the airway in the face of ongoing oral blood loss. A grey area exists for more stable patients. Some reports have suggested that positive-pressure ventilation may itself be detrimental in cystic fibrosis patients, and that sedation at most is preferable.[134] This must be weighed against a child's ability to lie flat while in a state of respiratory compromise for a potentially prolonged procedure. With any patient undergoing bronchial embolization, clear communication with the patient and family about goals of care in the event of catastrophe is recommended.

Sclerotherapy of Venous and Lymphatic Malformations

Children may present shortly after birth with vascular malformations that arise from *PIK3CA*-associated overgrowth syndromes such as CLOVES (**C**ongenital, **L**ipomatous, **O**vergrowth, **V**ascular malformations, **E**pidermal nevi, and **S**pinal/skeletal anomalies and/or scoliosis [Fig. 46.8]) or Klippel-Trenaunay,[135] or later in life with isolated lesions that, while present at birth, may have not been recognized. The natural history of venous and lymphatic malformations, which are often discrete and not visible at birth, is to grow steadily with the child, expanding rapidly and accelerating in size with puberty.[136,137] One review reported that only 18% of patients with lesions presented before 15 years of age.[96] This rapid proliferative phase may occur in response to hormonal changes (pregnancy, puberty), trauma, or other stimuli. Vascular malformations may be classified as high-flow or low-flow lesions, depending on which vessels are involved.[138] High-flow lesions may include arteriovenous fistulas, some large hemangiomas, and AVMs. Low-flow lesions consist of venous, lymphatic, and capillary malformations (see Fig. 46.9). The mainstay of treatment for many high-flow and low-flow vascular anomalies is chemical sclerotherapy, possibly combined with surgical resection; many lesions are inaccessible surgically or have a poor result from primary surgical resection.[139,140]

FIGURE 46.8 Neonate with severe CLOVES syndrome, a *PIK3CA*-associated overgrowth syndrome.[33]

Sclerotherapy of vascular malformations usually requires a general anesthetic to ensure motionless conditions, especially during complex prolonged procedures that involve injection of potentially painful sclerosants. These procedures require careful planning and discussion between the interventional radiologist and the anesthesiologist for safe airway management, intraprocedural and postprocedural care, and disposition.

The anesthesiologist should be familiar with the mechanism of action and potential risks associated with the various agents used for sclerotherapy (Table 46.2). All sclerosants act by inducing a local tissue reaction that ideally scars closed abnormal vascular channels. Pain and swelling are a result with all sclerosants, to a greater or lesser degree. Ethanol and sodium tetradecyl sulfate produce hemolysis when administered into the vascular bed. They cause hemoglobinuria in a dose-dependent manner, which can result in renal injury necessitating generous hydration and alkalinization of urine to mitigate damage to the kidneys (Fig. 46.10).[141] Hemoglobinuria may not occur until the end of the procedure, sometimes after a large dose of sclerosant has been administered or the tourniquet (if used) has been released. Ethanol in large doses has been associated with serious complications, which has caused its use to fall out of favor as a primary agent in many institutions.[142] The most infrequent but serious risk is cardiovascular collapse, which is generally preceded by hypoxemia and bradycardia. Most reported cases of cardiovascular collapse involved lower extremity malformations,[143] after release of tourniquets in extremities that had been injected with ethanol.

Children with vascular malformations that result in stagnant flow—especially venous malformations—can have preexisting coagulation disturbances that resemble disseminated intravascular coagulation.[144] This is particularly true for patients with *PIK3A*-associated overgrowth syndromes, which have a propensity for huge ectatic veins with slow flow. Children with laboratory indexes

TABLE 46.2 Sclerosants Used for Treatment of Vascular Anomalies[106]

Agent	Indications	Swelling	Pain	Complications
Sodium tetradecyl sulfate	LM, VM	Moderate	Moderate	Hemoglobinuria, skin blistering
Ethanol	LM, VM	Marked	Marked	Nausea, hemoglobinuria, skin blistering, ethanol intoxication, nerve injury, cardiovascular collapse
Doxycycline	LM	Marked	Marked	Minimal
Bleomycin	LM, VM primarily cervicofacial	Moderate	Moderate	Transient fever Concern for pulmonary fibrosis, never described after sclerotherapy
OK-432	LM	Marked	Marked	Not FDA approved for use in the United States

FDA, U.S. Food and Drug Administration; *LM*, lymphatic malformations; *VM*, vascular malformations.

consistent with preexisting consumptive coagulopathy, particularly low fibrinogen, should have a hematology consultation for initiation of anticoagulation before and after the procedure to reduce the chance of a catastrophic periprocedure thromboembolic event.[145]

Vascular malformations that involve the airway are particularly challenging (Fig. 46.9). The anesthesiologist and radiologist should review the imaging studies (preferably MRI) before the procedure. If there is any question of involvement of the oropharynx or nasopharynx, evaluation by a otorhinolaryngologist familiar with vascular anomalies is essential before proceeding with anesthetic induction; nasal fiberoptic endoscopy will provide very useful information and can be performed in the office. Most interventional radiology suites are not situated in the OR. If there is a significant potential for airway compromise, difficulty in attaining a mask airway, or failure to intubate, the airway should be secured in the OR before transport to the radiology suite.

If postsclerotherapy edema and vascular congestion involving the airway structures are anticipated, the child's trachea should be intubated nasally and remain intubated for 48 hours or until the swelling subsides. Nasal intubation is preferred to minimize the risk of dislodging the tracheal tube or premature extubation. The decision to have the child remain intubated after the procedure is usually made after the anesthesiologist and radiologist review the MR images before the procedure. If the trachea remains intubated after the procedure, the trachea is extubated in the intensive care unit after an air leak around the tracheal tube is confirmed or a flexible nasal fiberoptic view of the airway can be performed at the bedside. If there is any doubt about the patency or self-sufficiency of the airway, these children should be transferred to the OR for tracheal extubation in a controlled setting with an otorhinolaryngologist present.

Venous malformations involving the head, neck, or airway structures typically swell with dependency or Valsalva maneuver (e.g., crying). Before extubating the trachea, these children should be positioned head-up to promote venous drainage and reduce swelling. Efforts should be made to minimize coughing before extubation. In the event of respiratory compromise, venous malformations can enlarge when the child coughs, increases intrathoracic pressure, or uses accessory muscles. Attempts at reintubation, cricoid pressure, head extension, and mask ventilation can further enlarge the malformation. Mask ventilation can be challenging, sometimes impossible, if the malformation is swollen and firm. Achieving an occlusive mask seal is particularly difficult when there is swelling of the cheek, tongue, lip, chin, or nares. Venous malformations of the lips and tongue, because of their blue color, can make it difficult to assess the child for hypoxemia in the event of respiratory distress. Reintubation can become impossible in these situations because all of the maneuvers to achieve a mask seal increase venous pressure and swelling. When attempting to reintubate the trachea of a child with intraoral

FIGURE 46.10 Hemoglobinuria after ethanol embolization.

or pharyngeal malformations, special care should be taken to avoid damaging the malformation: even a small nick can create significant bleeding. In the event of oropharyngeal bleeding and inability to mask ventilate and/or intubate, it is critical to have alternative airway devices immediately available. Supraglottic airway (SGA) devices, in particular those with high occluding pressures such as the ProSeal (Teleflex Medical Inc., Research Triangle Park, NC), can be lifesaving. Proper insertion and inflation of the SGA can secure an airway and, more importantly, tamponade bleeding. However, because the SGA rests above the vocal cords, it does not protect the airway from pulmonary aspiration.

ENDOSCOPIC PROCEDURES

GI endoscopy is a common procedure that requires deep sedation or general anesthesia in infants and children. A range of sedation and anesthesia options may be used for both simple[146,147] and more complex procedures, such as foreign body removal, endoscopic retrograde cholangiopancreatography, and percutaneous endoscopic gastrostomy placement.[148] The choice of deep sedation versus general anesthesia (with or without a tracheal tube) depends on the medical condition of the child, the risks associated with the specific procedure, and the anticipated duration. Upper esophagogastroduodenoscopy in infants (<10 kg) generally requires tracheal intubation to prevent airway compression caused by the endoscope pressing the trachealis muscle into the trachea. However, few definitive data exist on this issue (few studies include infants <1 year of age). In some cases, an LMA may be used to secure the airway, deflating the cuff to allow passage of the endoscope, and then reinflating it once the scope has entered the esophagus. It is advised to hold on to either a tracheal tube or an LMA during the procedure to reduce the risk of the endoscopist dislodging it while manipulating the scope.

Many techniques may be used successfully to maintain adequate conditions for upper and lower GI endoscopy. Although all anesthesia-delivery areas must meet ASA standards, scavenging and ventilation in endoscopy suites may not always be up to standard to ensure the safe use of inhalational anesthetics. In these cases, total IV anesthesia can substitute for inhalational anesthetics.[23,149,150] Over the past several years, various combinations of IV agents have been described for the delivery of sedation and anesthesia for GI endoscopy in children. As a general rule, propofol is used either alone,[151] in combination with an opioid (fentanyl or remifentanil),[22,152] or with ketamine.[153] Outcomes after deep sedation or anesthesia with propofol and inhalational anesthesia were similar.[23] However, the time to awakening was more rapid after the inhalational anesthetic, although the incidence of emergence delirium and time to discharge were less after propofol.

Access to the airway is obviously limited once a transoral endoscope is in place. The two most stimulating portions of the esophagogastroduodenoscopy are transoral and transpyloric passage of the endoscope. Once the endoscope has been inserted, the sedation or anesthesia can often be reduced without affecting the procedure conditions. Smooth insertion of the endoscope can be aided by topical spray of local anesthesia to the oropharynx to reduce the discomfort of passing the endoscope and a small bolus of propofol to prevent coughing and gagging. For older children, topicalization of the oropharynx can be accomplished before sedation and the child can position himself or herself for the gastroenterologist (lateral position). Sedation can be subsequently accomplished with the child prepositioned. For cases performed without tracheal intubation, a CO_2 sampling nasal cannula can be placed in the nares or near the mouth (for those who do not breath through the nose) to supplement O_2 and monitor respiration.

Upper endoscopies have the inherent risk of apnea, laryngospasm, bronchospasm, and airway obstruction. Most problems resolve after withdrawal of the endoscope and positive-pressure ventilation with a face mask.[154] In rare situations, tracheal intubation may be required to complete the procedure or resolve an airway issue. Little published evidence exists on which to base age-related practice in endoscopy sedation and analgesia. Experience led several groups to select all infants up to 6 months of age as the age interval for which general anesthesia with tracheal intubation is required because of a greater frequency of respiratory complications.[146,147] When extubating the tracheas in these infants, be wary that residual air in the stomach can impair effective ventilation and contribute to desaturation or O_2 dependence in the recovery room. It is important to remind the endoscopist to suction all air from the stomach before removing the endoscope.

Few large studies have reported outcomes after pediatric GI endoscopy. The Clinical Outcomes Research Initiative (CORI) is a national registry of endoscopic procedures started in 1995. The PEDS-CORI is the pediatric component started in 1999. A 2007 report collected the complications from pediatric upper endoscopy involving 10,236 encounters from 13 different institutions over 4 years.[155] Overall, there was a 2.3% incidence of complications (of any kind). Of these, 79.9% were cardiopulmonary, 18% were GI, and 5.9% were other complications, including prolonged sedation, drug reactions, or rash. Not surprisingly, children who developed complications were younger and had a greater ASA physical status. General anesthesia was associated with a reduced overall complication rate (1.2%) compared with that in the IV sedation group (3.7%). Although these data were not controlled or randomized, they do shed some insight into the complication rates associated with pediatric sedation outside the OR. Data from closed claims analysis confirm the risk associated with endoscopic procedures in children. Half of NORA closed claims involved the GI unit, 25% involved the diagnostic imaging department, and 25% involved cardiac procedures.[156]

Summary

Technological advancements in many areas such as diagnostic imaging, gastroenterology, and interventional radiology continue to increase the need for pediatric NORA. As the need for anesthesia services for children outside the OR continues to expand, anesthesiologists continue to be requested more and more frequently to provide anesthesia services for these venues. It is in our patients' interests and our own professional interest to accept this responsibility and provide the most effective, efficient, and safe anesthesia and sedation outside the OR. More than in any other aspect of pediatric anesthesia care, communication with other specialists and within anesthesia departments is critical to ensure safe and effective care. The anesthetic configuration and equipment demands are unique at each center. Emergency situations should be simulated so that all personnel are familiar with the location of code equipment and emergency airway equipment. Anesthesia delivery in the areas outside the OR is both rewarding and challenging, and should be approached with a commitment to ensure that children will receive a standard of care equal to the care provided in the OR.

ACKNOWLEDGMENT

We wish to thank Charles J. Coté, Babu V. Koka, and Keira Mason for their prior contributions to this chapter.

Beyond PACU: Postoperative Monitoring in the General Care Setting

EMERGENCE FROM ANESTHESIA IN CHILDREN differs substantially compared with adults. The process is multifaceted, dependent on the nature of the surgery, patient characteristics, and the type of anesthesia administered. In young children, emergence from inhalational agents can be quite rapid as a result of increased minute ventilation, increased blood flow to the vessel-rich group (see Chapter 7), and decreased total body muscle and fat stores, whereas emergence from intravenous (IV) agents may be delayed in infants because of decreased clearance because of immature enzyme systems.

One important aspect to appreciate is the rapidity with which serious complications can develop in the postoperative period. For instance, neonates, infants, and young children have decreased cardiopulmonary reserve compared with adults, resulting in a more rapid physiologic deterioration should airway obstruction or bleeding occur. Vigilant and frequent monitoring by pediatric postanesthesia care nurses and anesthesiologists is essential for appropriate postoperative care as well as to prevent and treat adverse events. Parents or primary caregivers should be considered active partners in the postoperative care of the child. Those who routinely provide comfort and care for the child are essential for the child's sense of well-being. In addition, they should be able to alert medical professionals to changes in the child's status that may require urgent medical attention.

Perioperative Environment

A well-designed, safe perioperative environment is essential for the delivery of high-quality pediatric anesthetic and surgical care. This is evidenced by the fact that several prominent national organizations have provided recommendations for the perioperative care of children. The American Academy of Pediatrics (AAP) published a policy statement in 2015 delineating the critical elements of the perioperative environment.[1] These recommendations focus on the patient care facility and medical policies, including staff credentialing and necessary supportive services. This document was developed to complement the Society for Pediatric Anesthesia (SPA) statement on the provision of pediatric anesthesia care.[2] Institutions that desire verification by the American College of Surgeons (ACS) Children's Surgery Verification Program must contain a designated postanesthetic care unit (PACU) with appropriately credentialed staff and supportive resources.[3] These guidelines acknowledge that the perioperative environment can be challenging, and health care facilities must understand these challenges and be prepared to manage children and family members through this difficult process. Policies and procedures based on recommendations from national organizations and developed with input from all stakeholders, including physicians, nurses, family members, and child-life specialists, comprise the foundation for a safe, patient- and family-centered perioperative environment.

The ideal perioperative environment is patient- and family-centered, combining aspects of safety, ergonomics, and comfort for patients, family members, and staff. The family and patient experience starts with the admission process and concludes with the discharge to home or the hospital ward. Familiarity with personnel and surroundings reduces stress for patients and families while fostering trust and comfort. Ideally, a child should be under the care of the same team throughout the perioperative period. For example, the child and family benefit if the admitting nurse

TABLE 47.1	Suggested Essential Bedside Equipment
Oxygen supply with regulated flows	
Oxygen face masks and face tents for spontaneous ventilation (various sizes)	
Oxygen nebulizers for administration of albuterol and racemic epinephrine	
Stethoscope	
Resuscitation bags, self-inflating (Ambu)	
Anesthesia facemasks for positive-pressure ventilation (pediatric sizes: 0, 1, 2, 3; adult sizes: small, medium, large)	
Oral airways (sizes 00, 0, 1–5)	
Nasal airways (sizes 12F–36F)	
Suction and appropriate suction catheters (sizes 6.5F–14F); tonsil-type (Yankauer) attachment	
IV supplies: needles, syringes, saline flushes, alcohol wipes, Betadine solution, gauze pads, Tegaderm dressings (3M, Minneapolis, MN), tourniquets, tape	
Non-latex gloves (various sizes)	
Pulse oximeter and sensors (size appropriate, stick-on type preferred to clip-on type)	
Electrocardiograph, monitor, and pads	
Manual and automated blood pressure device	
All sizes of blood pressure cuffs	

TABLE 47.2	Suggested Emergency Supplies for a Crash Cart or Central Location
Cognitive aids for resuscitation (weight-based pediatric advance life support cards) (e.g., Broselow tapes [see E-Figs. 39.1–39.3])	
Laryngoscopes with blades: Miller 0, 1, 2, 3; Macintosh 2, 3, 4; extra laryngoscope bulbs and batteries	
Endotracheal tubes, sizes 2.0-mm internal diameter (ID) through 8-mm ID; cuffed and uncuffed tubes for all sizes when available	
Stylet appropriate for each endotracheal tube size	
Syringe for endotracheal cuff inflation	
End-tidal carbon dioxide monitor or portable detector	
Tape and liquid adhesive for endotracheal tube fixation	
Intravenous catheter (14-gauge) with 3-mm ID endotracheal tube adapter for emergency cricothyroidotomy (see Fig. 14.25)	
Backup resuscitation bags and masks and oral airways for each bedside	
Nasogastric tubes	
Intravenous infusion solutions, tubing, drip chambers	
Supplies for intravenous cannulation, catheter sizes 24- to 14-gauge	
Cutdown tray, tracheostomy, and suture sets	
Central venous catheter insertion sets (3F–7F, single- and multiple-lumen)	
Tube thoracotomy set and system for suction and underwater seal	
Automated electric defibrillator or defibrillator (adult, child paddles)	
Electrocardiograph	
Pressure transducer system and oscilloscope monitor	
Sterile gowns, gloves, masks, towels, drapes	
Urinary catheters of appropriate pediatric size	
Bed board for cardiopulmonary resuscitation	

later cares for the child and the family in the PACU. This may be achieved by creating an integrated perioperative environment, in which children are admitted, prepared, and allowed to recover in the same space, with the same nurses and child-life specialist.

Privacy and shelter from noise are important aspects of the patient and family experience. The ability to spend time with the child without being disturbed is something that many families appreciate, and this helps the child cope with the stress of a strange environment. Most PACUs contain individual patient rooms or cubicles for preoperative and postoperative care, similar to a typical pediatric intensive care unit (PICU).

Equipment (Table 47.1) and available medications (Tables 47.2 and 47.3) should be standardized throughout the unit and be compatible with transport monitors and other devices used in the medical facility (e.g., PICU). Cognitive aids such as preprinted emergency drug cards should be available for every child.[1] This important safety measure may reduce the risk of drug errors in emergency situations. These rapid reference sheets may be attached to each child's bed or chart on admission so that a quick dose recommendation is readily available. Alternatively, the electronic record should have precalculated emergency drug doses for each child.

Nurses, residents, fellows, attending physicians, and other personnel working in the perioperative area must be competent in the provision of neonatal and pediatric advanced life support. Team training in mock codes and enhanced communication have been shown to improve outcomes.[4–6] Continuous medical education in the provision of pediatric care is often required by hospital credentialing committees as well as institutions requesting ACS verification.[3]

TRANSPORT TO THE CARE UNIT

The PACU should be located near the operating room to decrease the amount of time spent in transport of a sedated and/or critically ill patient. If transporting a sedated patient from a remote location, the patient's vital signs and a metric of respiration should be monitored along the route. Appropriate airway equipment and drugs should be immediately available. Transport from the operating room to the PACU should be carried out under the direct supervision of a trained expert. The security and patency of the airway, IV and arterial lines, drains, and urinary catheters should be checked before transport. Children should be covered during transport to maintain normothermia and appear presentable (e.g., remove garments and sheets that contain blood and secretions).

Unless children are awake, with protective airway reflexes intact, or unless there is a specific contraindication, it is appropriate to transport extubated children in the lateral position (i.e., tonsillectomy recovery position) so that the tongue lies away from the larynx and secretions and vomitus leave the mouth rather than enter the larynx, possibly leading to airway obstruction or pulmonary aspiration. To assess ventilation and maintain a patent airway with the child in the decubitus position, we recommend applying the thumb to the forehead to extend the neck and holding the fingers (the finger tips are the most sensitive part of the hand) over the mouth (or nose) to feel for exhalation. A precordial stethoscope may also be used to auscultate respirations. If the child is breathing room air, a pulse oximeter can serve as a crude metric of ventilation because desaturation will occur quickly if hypopnea develops. However, if oxygen is provided to the child, desaturation may not occur for a considerable time in the setting of apnea, and ventilation should be monitored by close observation, a precordial stethoscope, capnography, or ideally, by a combination of these. We recommend that children in a potentially unstable condition be transported with a pulse oximeter, capnogram, an electrocardiographic (ECG) monitor, and a blood pressure cuff or a transduced arterial line. The monitoring lines, IV drips, infusion

TABLE 47.3 Suggested Recovery Room Medications

Suggested Emergency Medications on Crash Cart[a]
Albuterol (also known as salbutamol outside the United States)
Amiodarone
Atropine
Calcium chloride or gluconate
Dextrose
Diphenhydramine
Dopamine
Epinephrine
Etomidate
Flumazenil
Furosemide
Hydrocortisone, dexamethasone, methylprednisolone
Lidocaine (intravenous and topical)
Naloxone
Neostigmine
Norepinephrine
Physostigmine
Propranolol, atenolol, esmolol, labetalol
Sodium bicarbonate
Sodium nitroprusside
Succinylcholine and rocuronium
Propofol
Verapamil
For inhalation: racemic epinephrine (2.25% at 0.05 mL/kg, common in the United States) *or* epinephrine 1:1000 (0.1%), 0.5 mL/kg, maximum of 5 mL
Medications to Be Kept Under Lock[a]
Diazepam
Fentanyl
Ketamine
Meperidine
Midazolam (intravenous and oral)
Morphine
Potassium chloride
Other Medications for Central Location[a]
Acetaminophen (oral, rectal, and intravenous)
Antibiotics
Antiemetics (e.g., 5-HT_3-antagonist, promethazine, metoclopramide)
Dantrolene
Digoxin
Heparin
Insulin
Mannitol
Potassium chloride
Protamine
Ketoralac
Dexmedetomidine
Sugammadex

[a]Alternative or additional medications may be needed.

pumps, and other equipment should be clearly labeled and simplified before transport. A tackle box containing airway equipment and emergency medications is useful, especially when children are transported to or from remote locations.

A child often appears awake after the stimulation of tracheal extubation and transfer to the stretcher but may subsequently become obtunded and obstruct the airway during transit to the PACU or PICU. Just as frequently, a child may become restless during transit. Although restless behavior has many causes, hypoxia should be ruled out first. The guard rails on the stretcher should always be raised when the child is in it and padding with pillows may prevent injury to the child. Most importantly, the anesthesiologist should remain at the head of the stretcher during transport maintaining vigilance of the child and the monitors throughout the transfer.

ARRIVAL IN THE CARE UNIT

The transfer of care from the operating room personnel to the PACU or PICU is a crucial element of quality patient care that deserves considerable focus and the importance of this process cannot be overemphasized. Ideally, it is a stepwise process following an institutional protocol that begins in the operating room with communication to the receiving unit before the end of the procedure that provides pertinent patient information as well as required nonstandard equipment and medication to the receiving care team. On arrival in the PACU, a rapid assessment of the child should be undertaken to ensure that the child has a patent airway and that the vital signs are stable. Once the child has been properly assessed, an admission heart rate, oxygen saturation, respiratory rate, blood pressure, and temperature should be recorded. Supplemental oxygen is administered as indicated, recognizing the limitations of the monitors to detect hypoventilation in such cases. Many children object to having an oxygen mask fixed to their faces; a funnel-type mask or open hose with large flow rates may be less objectionable (although less optimal). In the healthy child, if the child is awake enough to object to a mask with oxygen, the child does not require supplemental oxygen (although the combative, hypoxic child will require not only oxygen but establishment of a patent airway as well).

Numerous patient safety organizations and health care institutions have devoted considerable time and resources to improve patient transfer processes with the primary objective to improve safety, increase the quality of care, and decrease health care costs. Education of health care personnel about the importance of this endeavor is the first step to implementing effective transfers of care; several methods have been suggested.[4,7–12] Standardized handoffs containing validated checklists and protocols are considered essential components of this process. Institutions with effective and organized handoff systems have reported a decrease in the number of medical errors and improved patient outcomes.[6,13–16]

Surgeons, anesthesia providers, and intensive care physicians involved in the care of the child should be present and actively participate during the transfer of care from the operating room to the PACU or PICU. Specific circumstances such as language barriers, developmental delay, or family concerns should be conveyed to members of the team accepting care of the child. Since cultures vary within and among different institutions, we recommend developing a formalized transfer of care process that focuses of critical aspects of patient care, including pertinent patient information and history, surgical procedures, type of anesthesia administered, airway management, medications (especially antibiotics and analgesics), fluids administered, hemodynamics, estimated blood loss, unexpected events, anticipated patient progress, and information that needs to be relayed to parents or hospital staff in the event the patient is being admitted. Any unanticipated or serious events, such as unanticipated difficult airway, hemodynamic instability, or surgical complications, should be clearly communicated. If continuous infusions of local anesthetics are administered (e.g., epidural catheter infusion), the dose, concentration, rate, and maximum infusion rate should be conveyed. Tasks that need to be completed in the near future should be discussed with the team accepting the care of the patient. All stakeholders should have the opportunity to ask questions and confirm the transfer information at the conclusion of the handoff.

The anesthesia team must remain with the child until he or she has stable vital signs and the PACU or PICU team is comfortable and ready to assume responsibility for the child. Physicians who will be in charge of taking care of the child in the PACU or PICU after the anesthesia team leaves must be clearly identified by name, and methods to contact them (e.g., pager number) must be given to surgeons, anesthesiologists, and regional block and pain services. It is important to understand that barriers may exist at several levels and preclude the effective transfer of care. Such circumstances frequently implicated include external distractions, noisy environments, shift changes, and differences in culture and priorities between individuals providing and accepting care of the child.[12,17–20]

Ideally, the nurses taking care of the child postoperatively are already familiar with the child and family from the preoperative setting. The nurse/patient ratio should be 1 : 1 for sick children and 1 : 2 or 1 : 3 for routine cases. It has been reported that staffing ratios, nursing surveillance techniques, and vigilant monitoring of patients in the PACU by pediatric-trained nursing staff improve patient outcomes.[21–23] Available staffing and resources in the PACU or PICU should be in place before transporting the child from the operating room.

All children should be monitored continuously in the PACU. At the very least, this should include continuous pulse oximetry and intermittent noninvasive blood pressure and temperature monitoring. Most PACUs also monitor the electrocardiogram continuously, although some limit this to children with cardiac disease or complex multiple-organ disease. During emergence, many children are so active that it is impossible to maintain the monitoring devices in place. If the child is not hypoxic and is sufficiently awake to remove the monitors, he or she probably does not require the monitors any longer. If the child falls back to sleep, then a pulse oximeter probe should be reapplied, particularly for at-risk children such as those with obstructive sleep apnea (OSA). For a child who is physically or mentally challenged, it may be necessary to apply light restraints until he or she is oriented and awake.

Central Nervous System

PHARMACODYNAMICS OF EMERGENCE

Emergence from anesthesia is a complex process dependent on the dose and types of medications administered, the age, and the physiologic status of the patient. The age of the child exerts a minimal influence on the wash-out of inhalational anesthetic agents and has little impact on the rapidity of emergence, although age may be a factor for infants younger than 1 year.[24] However, the overall clinical implications of age-related differences in emergence are exceedingly difficult to detect.[25] The speed of emergence correlates more closely with the duration of anesthesia. The greater the duration of anesthesia, the more the tissue compartments become filled with anesthetics and the more time it takes to eliminate the anesthetics for recovery. For example, emergence from 30 minutes of sevoflurane anesthesia is significantly faster than emergence from 2 hours of anesthesia, which is more rapid than from 8 hours of anesthesia.[26] This relationship between emergence time and the duration of anesthesia has less relevance as inhalational anesthetics have become less soluble (e.g., desflurane).[27,28]

Emergence from IV agents can vary significantly from that of inhalational agents. Several studies have evaluated the quality and rapidity of emergence after IV anesthetic agents compared with that after inhalational agents.[29,30] For outpatient surgery, emergence after propofol anesthesia is as rapid as that after sevoflurane but with far less agitation and pain behaviors.[31] The recovery characteristics of propofol with remifentanil (total IV anesthesia [TIVA]; see Chapter 8) have been compared with those after desflurane inhalational anesthesia. Recovery is as rapid as that after desflurane with nitrous oxide, with a similar or reduced incidence of nausea and vomiting but with much less agitation.[32,33]

Although rarely used for maintenance of anesthesia, midazolam is often used as an oral or IV premedication for anxiolysis and amnesia in the preinduction period in children. There is evidence that the addition of midazolam before an inhalational or propofol anesthetic may delay early emergence after brief anesthesia. However, this delay is attenuated as the duration of anesthesia increases and when only late emergence is considered.[34] Midazolam premedication does not affect the incidence of postoperative delirium but has been reported to decrease postoperative nausea and vomiting (PONV).[35–38] IV midazolam at the end of surgery does decrease the incidence of emergence delirium (see later text).

EMERGENCE AGITATION OR DELIRIUM

Emergence agitation refers to an umbrella of signs and symptoms that includes delirium (Videos 47.1 and 47.2), postoperative pain, and behavior disorders. Emergence delirium was first described in a large cohort of postsurgical patients over 50 years ago.[39] From a clinical perspective, it is often impossible to differentiate pure agitation from delirium, although the latter implies a disturbance in attention and represents an acute change from baseline.[40] Despite numerous investigations, differentiating emergence delirium from postoperative pain has proved difficult, although it has been suggested that children who do not make any eye contact or who are unaware of their surroundings are more likely to be experiencing emergence delirium.[41] Emergence delirium typically manifests as thrashing, disorientation, crying, and screaming. The child is unable to recognize parents, familiar objects, or surroundings; is inconsolable; and talks irrationally during early emergence from anesthesia. Emergence delirium occurs more often in children (frequency of 30%–50%) than in adults, particularly in those 2 to 6 years of age.[42,43] The mechanism of emergence delirium in children has not been completely elucidated, but differences in the frontal lobe electroencephalogram[44] and in the locus coeruleus[45] compared with children without delirium may highlight the source of the delirium. Evidence also points to differences in central nervous system (CNS) metabolites in the parietal cortex that may contribute to delirium; lactic acid concentrations and other metabolites after sevoflurane in children correlated with greater Pediatric Anesthesia Emergence Delirium (PAED) scale values than those after propofol.[46]

Several scales have been developed to measure emergence delirium, although only one, the PAED scale, has been validated for this purpose in the postoperative period.[47] Tables 47.4 and 47.5 present two scoring systems that have been used to evaluate emergence behaviors in children. In evaluating emergence delirium with the PAED scale after anesthesia, preliminary evidence suggested that values greater than 10 or possibly greater than 12 were consistent with emergence delirium.[48,49] In the PICU, evidence suggests that a PAED score greater than 8 predicts emergence delirium.[50] The literature regarding postoperative delirium in children is quite confusing in part, because many studies used nonvalidated, unproven scales in children whose pain was not controlled, leaving the cause of the behavior attributable to delirium, pain, or both.

TABLE 47.4 Pediatric Anesthesia Emergence Delirium Scale

	SCORING				
Scored Factor	***0***	***1***	***2***	***3***	***4***
Child makes eye contact with caregiver	Extremely	Very much	Quite a bit	Just a little	Not at all
Child's actions are purposeful	Extremely	Very much	Quite a bit	Just a little	Not at all
Child is aware of surroundings	Extremely	Very much	Quite a bit	Just a little	Not at all
Child is restless	Not at all	Just a little	Quite a bit	Very much	Extremely
Child is inconsolable	Not at all	Just a little	Quite a bit	Very much	Extremely
Total score[a]					

[a]Preliminary evidence suggested that a total pediatric anesthesia emergence delirium score greater than 10 defined emergence delirium, but later evidence suggested that a total score greater than 12 might be more specific.
Modified from Sikich N, Lerman J. Development and psychometric evaluation of the pediatric anesthesia emergence delirium scale. *Anesthesiology* 2004;100:1138–1145.

TABLE 47.5 Postanesthesia Behavior Assessment Scale

Perceptual Disturbances (Maximal Score 3)[a]

0 None evident
1 Feelings of depersonalization (says that situation is not real, comments on "out of body" feelings)
2 Visual illusions or misperceptions (misidentifies objects, such as urinates in trash can)
3 Markedly confused about external reality (misidentifies self or surroundings, such as being at school)

Hallucination Type (Maximal Score 6)[a]

0 None evident
1 Auditory hallucinations only (responds to questions not asked)
2 Visual hallucinations or misperceptions (responds to things only the child can see)
3 Tactile, olfactory (responds to sensations not obvious to others, such as a bug crawling on the leg)

Psychomotor Behavior (Maximal Score 3)[a]

0 No significant agitation
1 Mild restlessness, tremulousness, or anxiety
2 Moderate agitation with pulling at intravenous lines
3 Severe agitation, needs to be restrained, combative

[a]A larger postanesthesia behavior assessment score is associated with a greater degree of postanesthetic distress.
From Przybylo HJ, Martini DR, Mazurek AJ, et al. Assessing behavior in children emerging form anaesthesia: can we apply psychiatric diagnostic techniques? *Pediatr Anesth* 2003;13:609–616.

TABLE 47.6 Prophylactic Measures to Prevent Emergence Delirium

Prophylactic Measure	Timing
Propofol (IV)	TIVA,[31,67] a brief infusion of 3 mg/kg over 3 minutes after sevoflurane,[68] a single dose at the end of anesthesia (1 mg/kg IV)[61,63,65,69,70]
Thiopental (IV)	After induction, 2–3 mg/kg[71]
Opioid (IV)	Meta-analysis[72] of fentanyl, remifentanil, sufentanil, alfentanil; nalbuphine (0.1 mg/kg)[73]
Midazolam (IV)	0.03–0.05 mg/kg at end of anesthesia[74,75]
(PO)	0.2–0.5 mg/kg[76]; 0.5 mg/kg with parental presence[77]
α_2-Agonist (IV) (caudal)	Clonidine 2 µg/kg at induction[76,78,79]; dexmedetomidine 0.3–1 µg/kg at emergence[60,80–83] Meta-analysis of dexmedetomidine demonstrates effectiveness[60,84] Dexmedetomidine 1 µg/kg followed by 1 µg/kg per hour[85] Clonidine 1 µg/kg[86]
Ketamine (IV)	Ketamine 1 mg/kg followed by 1 mg/kg per hour[85] or 0.25 mg/kg[73]
Melatonin (PO)	0.25 or 0.5 mg/kg premedication[87]
Tropisetron (IV)	0.1 mg/kg at induction[88]
Magnesium sulfate (IV)	30 mg/kg followed by 10 mg/kg per hour[89]
Regional anesthesia	Infraorbital block,[28,90] fascia iliaca block[91]
Acupuncture	Heart 7 site bilaterally during surgery[92]

IV, intravenous; *PO*, oral; *TIVA*; total intravenous anesthesia.

Our understanding of emergence delirium continues to evolve. Delirium occurs after surgical procedures and after procedures that are free from pain, such as magnetic resonance imaging.[41,42,51,52] Factors that have been associated with the development of emergence delirium include age 2 to 6 years, the use of less-soluble inhalational anesthetics (e.g., incidence after sevoflurane, desflurane and isoflurane ≫ TIVA > halothane)[30,32,53,54] and the preoperative mental state.[55] Although some claim that there is a greater incidence of emergence delirium after certain painful surgeries, in most of these instances this cannot be proven as pain was not controlled and a nonvalidated metric of delirium was used.[56] A number of other plausible factors that do not predispose to delirium include a rapid emergence from anesthesia,[57] a greater depth of anesthesia,[58] and preoperative anxiety, although the last factor is contentious. Emergence delirium usually lasts less than 15 to 20 minutes, resolves spontaneously if the children are left undisturbed or they are held by their parents, and does not recur.[42]

Several strategies have been used to prevent emergence delirium (Table 47.6). Effective regional analgesia, dexmedetomidine, opioids, ketamine, melatonin, midazolam, magnesium, and propofol have been used with success.[59–63] Fentanyl (2–2.5 µg/kg intranasally or 1–2 µ/kg IV) decreases the duration and intensity of emergence delirium,[64] even in the absence of painful stimuli, most likely because of its sedating effect.[54] Administration of propofol by continuous infusion or by bolus (1–3 mg/kg) at the end of surgery appears to be preventative, although these findings have not been consistent.[49,65] A dose of propofol at induction of anesthesia does not prevent postoperative emergence delirium.[66] Administration of TIVA has been reported to be superior to inhalational agents in the prevention of emergence delirium.[30,32,53] Some clinicians

cannot justify prophylactic treatment to prevent delirium when the local incidence is small.

When emergence delirium does occur, it is important to explain its self-limiting nature to the parents who quickly become frustrated trying to comfort their child. Whether to terminate the delirium pharmacologically or let it take a natural course needs to be discussed with the parents. Many parents prefer to avoid administering additional medications, knowing that the delirium will abate spontaneously after several minutes and that their child will recover to his or her normal disposition soon. Treatment of ongoing delirium has not been widely studied, but current strategies include propofol 1 to 3 mg/kg IV, fentanyl 1 to 2 µg/kg, or dexmedetomidine 0.3 µg/kg. Most use an initial small dose and titrate to effect.

Discharge from the PACU may be delayed while waiting for the delirium to wane or for the effects of the interventional drugs to dissipate. Injury to the child who is delirious, to the site of surgery, or to a parent is a concern, as is pulling out a drain or dressing on a wound or self-extubation. Parental satisfaction decreases when severe emergence delirium occurs. Although the impact of extreme delirium is not fully known, evidence suggests that the incidence of postoperative maladaptive behaviors is greater among children who experience marked emergence delirium.[55]

Respiratory System

CRITERIA FOR EXTUBATION

In most cases, extubation may be safely performed in the operating room. However, a child's condition may necessitate delayed extubation at a more appropriate time in the PACU or PICU. There is widespread agreement that children who have been anesthetized with a full stomach, children at risk for airway obstruction, those with difficult airways, premature infants, and other infants predisposed to apnea should be awake before extubation is attempted. Beyond this, the timing of extubation is a matter of individual judgment. For example, the practice at some institutions is to extubate the trachea when a child is awake and demonstrating eye opening and other purposeful movements, whereas the practice at others is to extubate while the child is deeply anesthetized. Clinicians report only rare problems with either approach.[93,94] Most clinicians agree that either approach is preferable to extubating the trachea during a very light plane of anesthesia (stage 2), when laryngospasm is more likely and vomiting may occur while protective reflexes are impaired.

EXTUBATION IN THE OPERATING ROOM OR POSTANESTHESIA CARE UNIT

Immediately after extubation, oxygen should be administered, and the child should be observed closely to ensure that ventilation, oxygen saturation, and the color of the mucous membranes are adequate and whether airway obstruction, laryngospasm, or vomiting occur. Transport of children out of the anesthetizing location should not begin until the patency of the airway and the adequacy of oxygenation and ventilation have been confirmed.

For children whose tracheas are extubated in the PACU, respiratory insufficiency is the most worrisome and most frequent complication. Respiratory insufficiency represents approximately two-thirds of critical perioperative events when it occurs during emergence from anesthesia.[95] Respiratory insufficiency may manifest in the form of difficulty breathing, or it may present as anxiety, unresponsiveness, tachycardia, bradycardia, hypertension, arrhythmia, or seizures. Cardiac arrest is a late manifestation. When any of these conditions are present, respiratory insufficiency must be considered as the root cause. Hypoxemia, hypoventilation, and upper airway obstruction are the three most common adverse respiratory events that occur in children in the PACU. This is particularly true for children after tonsillectomy complicated by obesity and possible OSA and for those who have undergone diagnostic bronchoscopy.

HYPOXEMIA

Hypoxemia may result from hypoventilation, upper airway obstruction, bronchospasm, aspiration, pulmonary edema, pneumothorax, atelectasis, or rarely from postobstructive pulmonary edema, cardiac shunting, or pulmonary embolism. Hypoxia occurs more rapidly and may be more profound during emergence from general anesthesia because general anesthesia inhibits the hypoxic and hypercapnic ventilatory drive, reduces functional residual capacity, and alters hypoxic pulmonary vasoconstriction. Shivering may further increase oxygen consumption by a factor of two to five[96,97] and exacerbate hemoglobin desaturation.

Postoperative hemoglobin desaturation is more common in children with or recovering from an active upper respiratory tract infection owing to increased airway reactivity, atelectasis, and increased secretions than in children without a history of upper respiratory tract infection.[98,99] In neonates, hypoxia *increases* ventilation for approximately 1 minute but then *depresses* the respiratory drive (i.e., respiratory rate and tidal volume).[100] The normal ventilatory response to hypoxia is delayed for several months in ex-premature nursery graduates with severe bronchopulmonary dysplasia, placing them at particular risk for desaturation in the perioperative period.[101]

HYPOVENTILATION

Severe hypoventilation causes respiratory acidosis, hypoxemia, carbon dioxide narcosis, and apnea. Hypoventilation may result from a decrease in ventilatory drive, muscle weakness, or mechanical effects. Inhalational anesthetics, opioids, benzodiazepines, and other sedating medications (except α_2-agonists) decrease the ventilatory drive in children in a dose-dependent manner. At particular risk for postoperative hypoventilation are children with underlying disturbances in respiration, such as infants with apnea of prematurity (formerly preterm infants of less than 60 weeks postconception age [PCA]); those with CNS injury such as head injury, strokes, and intracranial surgery; obese children; and those with OSA. These children may require prolonged observation in a setting with continuous monitoring capabilities.

Muscular weakness may contribute to respiratory insufficiency. Preexisting muscular disease (e.g., muscular dystrophy) and inadequate reversal of neuromuscular blockade, electrolyte abnormalities, neurologic disorders, drugs, infection, and endocrine disease may impair the respiratory effort sufficiently to cause hypoventilation and respiratory insufficiency. Inadequate analgesia can lead to splinting and hypoventilation, which may in turn increase ventilation-perfusion mismatch and decrease the oxygen saturation.

AIRWAY OBSTRUCTION

Among the most common and serious problems in the PACU is upper airway obstruction. Airway obstruction is a feature in children with known airway problems resulting from congenital anomalies of the face (particularly those with midfacial hypoplasia as in trisomy 21, achondroplasia, and Crouzon disease) and obese children with a history of OSA. Clinical hallmarks of airway

obstruction include hemoglobin desaturation, inspiratory stridor, inspiratory retraction, and paradoxical chest wall motion. Common interventions include stimulating the child, repositioning, suctioning, performing a jaw thrust, insertion of an oral or nasal airway, and application of positive end-expiratory pressure (PEEP) (see Fig. 33.10). If these measures fail, patency of the upper and lower airways should be considered because gas exchange may be compromised by laryngospasm, subglottic narrowing as the result of edema, bronchospasm, atelectasis, or tracheal secretions. Incomplete recovery from general anesthesia or neuromuscular blockade, neck wound hematoma (such as after a thyroidectomy), and vocal cord paralysis may also lead to upper airway obstruction. If the airway is not cleared by any of the previously described maneuvers, oxygen should be administered by mask with continuous positive airway pressure along with the medications necessary to facilitate placement of a tracheal tube.

Postobstructive pulmonary edema is a complication of acute upper airway obstruction and of relief of chronic airway obstruction after tonsillectomy. The mechanism appears to be generation of extreme negative intrathoracic pressure against a closed glottis or obstructed airway and its sudden release, resulting in a dramatic increase in pulmonary blood flow that leads to noncardiogenic or neurogenic pulmonary edema. This complication should be suspected when significant hypoxia, persistent tachypnea, or tachycardia follows a prolonged episode of laryngospasm, airway obstruction, or tonsillectomy and the child has pink, frothy secretions emanating from the airway. Treatment of noncardiogenic pulmonary edema includes tracheal intubation, positive-pressure ventilation with PEEP, 100% oxygen to maintain an adequate oxygen tension, furosemide, and morphine. Furosemide (0.5–1 mg/kg) should be given immediately by IV infusion because it is thought to act by decreasing venous return to the heart by direct venodilatation.[102–105]

Postintubation croup or subglottic edema has been associated with factors such as traumatic intubation, tight-fitting tracheal tubes, multiple intubation attempts, coughing with an in situ tracheal tube, a change in the child's position during surgery, prolonged duration of intubation, surgery of the head and neck, and a history of prematurity (with neonatal intubation), Down syndrome, or croup.[106,107] If the symptoms do not abate, nebulized epinephrine (0.5 mg/kg up to a maximum of 5 mg, or 0.25–0.75 mL of 2.25% racemic epinephrine) should be administered, although its effects are temporary. Repeated use of epinephrine may cause rebound laryngeal edema.[108] If nebulized epinephrine is used, a prolonged period of observation is mandated. Outpatients may require overnight hospital admission or observation in the unit for an extended period. Steroids (e.g., dexamethasone 0.6 mg/kg) are effective for reducing mucosal edema but maximum response is delayed (approximately 6 hours).

RESPIRATORY EFFORT

If the airway is patent, attention turns to the adequacy of ventilatory effort. Residual neuromuscular blockade can be diagnosed by observation (i.e., the patient's ability to lift extremities against gravity or perform a sustained head lift) and quantitatively by assessment with a peripheral nerve stimulator. Depending on the severity and the clinical situation, this condition may be treated with supplemental doses of reversal agents or ventilatory assistance. If the respiratory rate is slow, suggesting opioid-induced respiratory depression, titrated incremental doses of naloxone (0.01–0.1 μg/kg) reverses the respiratory depression without precipitating acute anxiety, pain, or pulmonary edema. If naloxone is effective, continuous monitoring of respiratory status is advised because naloxone has a short half-life of approximately 20 minutes. The same effective total dose may be given intramuscularly to prevent recrudescence of the opioid-induced respiratory depression. Alternately, nalmefene (Revex), a congener of naltrexone, may be used to reverse opioid-induced respiratory depression with a half-life of 10 hours (see Chapter 48). Residual sedation after benzodiazepines may be antagonized with flumazenil but may require an additional 2 hours of observation to ensure that resedation does not occur after reversal.

Children who have an adequate airway and adequate muscular strength may experience difficulty breathing because of pain, restriction from bandages or casts, abdominal distention, pneumothorax, atelectasis, aspiration pneumonitis, or cardiogenic or postobstructive pulmonary edema. In most cases, the history and physical examination focus the differential diagnosis, and when necessary, investigations that include a chest radiograph, blood gas analysis, and possibly invasive hemodynamic monitoring can identify the underlying cause and guide effective treatment.

DISCHARGE OF PRETERM INFANTS FROM THE POSTANESTHESIA CARE UNIT

Preterm infants (<37 weeks gestation) are at risk for apnea after sedation and general anesthesia; however, the risk decreases as infants age.[109–111] Guidelines for monitoring after the administration of sedation or anesthesia have been suggested, but it should be noted that preterm and former preterm children are considered to be a heterogeneous population with various comorbidities and the decision on the length and extent of monitoring should be individualized for each patient.[112–114] However, it is recommended that formerly preterm infants who are 55 to 60 weeks PCA and who are not anemic and not experiencing apnea be observed for an extended period and, if stable, later discharged. Infants younger than 55 weeks PCA, those who are anemic (hematocrit <30%), and those with ongoing apnea should be admitted for monitoring.[109,114–116] Prophylactic administration of caffeine (10 mg/kg IV or orally) may reduce the risk of apnea after general anesthesia for infants at high risk, although it should not supplant postoperative admission and monitoring.[109,112,117,118] Former preterm infants younger than 55 weeks PCA, those with anemia, or those with major cardiorespiratory or neurologic disorders should be admitted and monitored for at least 12 apnea-free hours after general, regional anesthesia, or sedation (see Chapter 4).[112,115,117]

It has been suggested that preterm infants who undergo surgery with spinal anesthesia are at low risk for the development of adverse events compared with those undergoing general anesthesia; however, it should be noted the infants remain at risk for late apnea whereas those receiving general anesthesia are at risk for early apnea.[119–122] Similarly, caudal anesthesia has been reported as an effective alternative to spinal anesthesia in preterm infants undergoing herniotomy.[123–127] Despite evidence of a reduced risk of apnea after regional anesthesia and no postdischarge complications on the day of surgery in some institutions, there is insufficient evidence to make general recommendations regarding this practice. Our recommendation is to admit and monitor these infants regardless of the type of anesthesia administered.

Full-term neonates typically have a reduced risk of apnea and bradycardia after general anesthesia compared with preterm infants. Opinions vary on the minimum PCA for ambulatory surgery in infants 44 to 50 weeks PCA. Many children's hospitals admit all full-term neonates (<28 days of age) for overnight monitoring after general anesthesia, although this is not evidence-based practice.

All full-term infants with a history of apnea and bradycardia or those who have siblings with sudden infant death syndrome should be observed for an extended period or admitted for overnight monitoring after general anesthesia.

Cardiovascular System

BRADYCARDIA

Bradycardia is the most common dysrhythmia in children and requires immediate attention because of its association with decreased cardiac output. *Until proven otherwise, the most common cause of bradycardia in infants and children is hypoxemia.* Other possible causes for bradycardia include vagal responses (e.g., passage of a nasogastric tube, laryngoscopy), medications (e.g., neostigmine, β-adrenergic blockade, α_2-agonists, opioids such as fentanyl), increased intracranial pressure, and high neuraxial anesthetic block. The definition of bradycardia depends on the age of the child; the incidence decreases with increasing age (see Chapter 2).

Treatment is directed at correcting the underlying cause, including the administration of oxygen and ensuring a patent airway. Bradycardia should be immediately treated with oxygen and, if necessary, with ventilation. If these interventions do not immediately restore the heart rate, atropine (0.02 mg/kg) should be administered; if no response is observed within 30 seconds, administration of epinephrine (2–10 μg/kg) is indicated. For symptomatic bradycardia (e.g., hypotension, decreased level of consciousness), immediate administration of epinephrine is indicated. If there is no response to epinephrine, chest compressions should be instituted and standard cardiopulmonary resuscitation algorithms followed (see Chapter 40).

TACHYCARDIA

Tachycardia is an important postoperative sign that is a marker for one of several disorders, such as inadequate cardiac output or oxygen delivery, a response to pain or a direct drug effect (e.g., epinephrine, atropine). Tachycardia may occur in response to hypoxemia, hypercarbia, hypovolemia, hypervolemia, emergence delirium, anxiety, sepsis, fever, a full bladder, a previously unrecognized cardiac conduction abnormality (see Chapters 16 and 18), or heart failure. The threshold for diagnosing tachycardia varies with the age of the child, and decreases with age.

Treatment is directed at correcting the underlying cause. Occasionally, children present with a sustained tachycardia unrelated to the previously described conditions that is refractory to the usual therapy. A cardiac consultation is required to investigate and identify less common causes, such as an aberrant conduction system or ectopic foci, as a source of supraventricular tachycardia (SVT). SVT, which is defined as more than 220 beats/minute in infants and more than 180 beats/minute in children, may be treated with adenosine when there are no other symptoms. However, SVT with accompanied hypotension or decreased level of consciousness may require cardioversion. Children who have had prior cardiac surgery are particularly at risk.

OTHER ARRHYTHMIAS

With the exception of bradycardia and tachycardia, postoperative arrhythmias are rare in children. Isolated premature ventricular or atrial beats may be observed in the PACU and, unless they progress, are not important. Multifocal premature ventricular beats are uncommon in children. They may occur as a result of inadequately treated pain, cardiac conduction defects, or in rare instances, may be a harbinger of malignant hyperthermia (see Chapters 16, 18, and 41), acute rhabdomyolysis with hyperkalemia, inadequately treated pain, a congenital conduction defect, or a structural cardiac defect. Electrolyte and arterial blood gas status should be checked. Children with known congenital heart disease should have continuous ECG monitoring in the PACU (see Chapters 16 and 18); all arrhythmias should be recorded and a cardiologist consulted because this may be the first manifestation of a developing ectopic focus.

BLOOD PRESSURE CONTROL

Hypotension

The anesthesiologist should be familiar with the normal blood pressure ranges of infants and children (see Chapter 2). The measurement should be obtained with an appropriately sized blood pressure cuff; the width of the cuff should be two-thirds of the length of the upper arm. An improperly sized cuff produces spurious readings. Small cuffs may overestimate the blood pressure, whereas large cuffs may underestimate it. Proper placement of the cuff is essential to avoid errors in interpretation.

The most common cause of hypotension in children is hypovolemia from inadequate replacement of blood and fluids lost during the surgical procedure or ongoing blood loss. Clinical hallmarks of hypovolemia are hypotension, tachycardia, urine output of less than 0.5 to 1 mL/kg per hour, slow capillary refill (>3 seconds), and narrowing of the pulse pressure. If the hematocrit is adequate, hypovolemia may be treated with an initial bolus of 10 to 20 mL/kg of isotonic crystalloid solution or albumin. This may be repeated until the blood pressure is normalized. If the hematocrit is inadequate, packed red blood cells (PRBCs) or whole blood should be administered. In this case, a rough guide for the volume of blood required is 4 mL/kg of packed cells or 6 mL/kg of whole blood to raise the hemoglobin 1 g/dL in children and adults (see Chapters 10 and 12). To achieve a desired hematocrit more precisely, the volume of PRBCs may be estimated as follows:

$$\frac{(\text{Desired hematocrit} - \text{present hematocrit}) \times \text{estimated blood volume}}{\text{The hematocrit in the PRBCs}}$$

If the child does not respond to volume expansion, other causes for the hypotension need to be considered, such as occult blood loss (e.g., intraabdominal, retroperitoneal, intrathoracic [blocked chest tube], cardiac tamponade), sepsis, or other disorders. Any factor that interferes with venous return can cause hypotension, including positive-pressure ventilation, auto-PEEP, tension pneumothorax, pericardial tamponade, and compression of the inferior vena cava.

Large end-tidal concentrations of inhalational anesthetics, local anesthetics, or opioids and interactions between benzodiazepines and opioids may produce hypotension through vasodilation (i.e., relative hypovolemia) and direct myocardial depression. However, these factors are rarely important in the PACU. Uncommon causes include anaphylaxis (e.g., latex allergy, antibiotics), transfusion reaction, adrenal insufficiency, systemic inflammation, infection, severe liver failure, and administration of antihypertensive, antidysrhythmic, and anticonvulsant medications. Increased body temperature may cause vasodilation and a relative hypovolemia. The increased metabolic demands of fever may compromise an already stressed myocardium. If a child arrives in the PACU requiring vasopressors and subsequently develops hypotension, consider mechanical causes such as a disconnect or kink in the vasopressor infusion, disruption of the IV access, a disconnect from the pump, or pump failure.

Vasodilation caused by sympathetic blockade associated with regional anesthesia occasionally causes hypotension, especially with a high-level blockade and restricted fluid intake. However, this is quite uncommon in children younger than 6 years of age. Because of the developmental changes in the sympathetic nervous system, most children younger than 6 years of age are normally peripherally vasodilated and therefore have little response to further vasodilation with a regional block.[128,129]

Decreased inotropy, dysrhythmia, cardiomyopathy, calcium channel blockers, sepsis, hypothyroidism, negative inotropic agents, and congestive heart failure are uncommon causes of hypotension in children. Treatment is directed at the underlying cause, such as correcting hypovolemia with volume loading, treating the allergic reaction, or treating the sepsis. Decreased cardiac contractility may be treated by diuresis and the administration of inotropic agents that also decrease the afterload (i.e., inodilators).

Hypertension

Postoperative hypertension in children is less common than hypotension and most often reflects incorrect measurement or pain. A blood pressure cuff that is too small may overestimate the blood pressure and should be one of the first considerations in the differential diagnosis, especially if the child has no other symptoms consistent with pain. Causative factors besides pain include hypervolemia, preexisting hypertension (e.g., renal disease), distended bladder, hypercarbia, hypoxemia, agitation and delirium, increased intracranial pressure, and exogenous vasoactive drugs (e.g., epinephrine).

Renal System

Complications related to the renal system are rare in the postoperative period. The most likely cause of low urine output (<0.5–1 mL/kg per hour) is hypovolemia (e.g., postoperative hypotension). Mechanical obstruction downstream from the kidneys may result from direct surgical interference or a misplaced or dysfunctional urinary catheter (i.e., blood clot or kink). If the child has regional (spinal or epidural) anesthesia that includes an opioid and there is no urinary catheter in place, placement of a Foley or straight catheter may be indicated. Renal failure is a rare possibility in children who have had major operations or have systemic inflammatory disease. If screening tests such as blood urea nitrogen, serum creatinine, and urine analysis suggest renal insufficiency, a pediatric nephrologist should be consulted (see also Chapter 28).

Gastrointestinal System

POSTOPERATIVE NAUSEA AND VOMITING

PONV is one of the most bothersome adverse effects of anesthesia and surgery. Unlike adults, most children are unfamiliar with and have never experienced nausea. It is unlikely that they will warn the PACU personnel that they are nauseated. In children, vomiting and complaining about a "sore tummy" are likely the first and only manifestations of gastrointestinal upset. Among children, PONV is inversely related to age.[130] The incidence of PONV is small in very young children, increases throughout childhood, and reaches a zenith in adolescents, for whom the incidence exceeds that for adults.[130,131]

The type of surgery influences the incidence of PONV. The incidence of PONV in children is greatest after tonsillectomy, strabismus repair, hernia repair, orchiopexy, microtia, and middle ear procedures.[130,132] Before puberty, there are no gender-related differences in PONV; after puberty, girls experience much more PONV than boys.[130] The medical complications of PONV include pulmonary aspiration, dehydration, electrolyte imbalance, fatigue, wound disruption, and esophageal tears. PONV can produce psychological effects that may produce anxiety in the children and parents and lead them to avoid further surgery. The cost implications of PONV can be major because of delayed recovery and discharge, increased medical care, and reoperation. Although these problems are seldom life-threatening, the cumulative costs in terms of prolonged PACU stays, unplanned admissions, and patient dissatisfaction are serious.[133]

EVIDENCE-BASED CONSENSUS MANAGEMENT

Management of PONV is complex, and many treatment strategies have been formulated (Fig. 47.1). Most have been shown to be effective in one study or another. However, the superiority of some treatments over others has not been established, in part because of study design flaws such as inadequate dosing, small sample sizes, or various periods of observations and data collection; some studies monitored PONV only during the first few hours after surgery, whereas others monitored the children for 24 to 48 hours after surgery. To make sense of the conflicting data that exist, consensus-based management strategies for the prevention and management of PONV have been suggested.[131,134,135] These guidelines advise to first identify the children at significant risk for developing PONV as outlined earlier and to then administer prophylaxis in that patient population. Studies frequently focus on postoperative vomiting as the primary outcome because nausea may be difficult to identify in children.

The consensus guidelines recognize that the choice of anesthetic can influence the incidence of PONV in children. Propofol-based anesthesia during operations associated with a large incidence of PONV dramatically reduces the incidence of PONV compared with inhalational anesthesia.[32,136,137] Similarly, multimodal therapy that is a combination of PONV treatment strategies is more effective than a single-treatment strategy.[138–140] Although somewhat controversial, avoidance of nitrous oxide is considered to prevent the development of PONV.[33,138,141,142]

Other strategies recommended to decrease the rate of PONV include the use of the smallest dose of opioids that still provides adequate pain control and the use of regional anesthesia if possible. TIVA is associated with reduced PONV (Chapter 8). The use of nonopioids such as acetaminophen, ketamine, and ketorolac should be considered. Adequate parenteral hydration and avoidance of early postoperative fluid ingestion can reduce the incidence of PONV (see Chapter 4).

PROPHYLACTIC THERAPY

Ondansetron has been studied extensively and shown to decrease early and late PONV at doses of 50 to 100 μg/kg.[134,143] Because the 5-HT_3-receptor antagonists as a group have greater efficacy in the prevention of vomiting than nausea, they are the drugs of first choice for prophylaxis in children. Dexamethasone also is effective in decreasing PONV.[134,140,142,144] Administration of dexamethasone alone or in combination with other antiemetics can extend the period of effective treatment up to 24 hours. Before the black box warning was added for droperidol, it was also recommended for prophylaxis of PONV in the United States[145]; however, for medicolegal reasons alone, it is no longer a first-tier antiemetic. Droperidol is commonly used in low doses, which limit extrapyramidal and sedation side effects. Adequate fluid

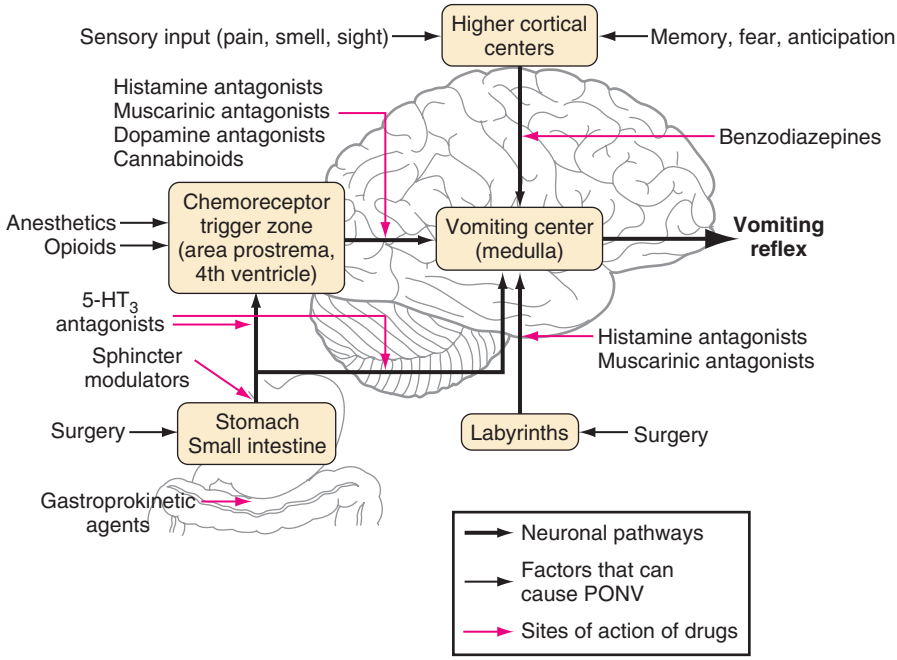

FIGURE 47.1 Treatment strategies for postoperative nausea and vomiting (*PONV*).

resuscitation also plays in important role in PONV prevention. Children given 10 mL/kg of lactated Ringer's solution during strabismus correction had more PONV than those given 30 mL/kg (54% vs. 22%).[138,146]

The most effective prophylaxis strategy in children at moderate or high risk for PONV is to use combination therapy that includes hydration, a 5-HT_3-receptor antagonist, and a second drug such as dexamethasone. Antiemetic rescue therapy should be administered to children who vomit after surgery. An emetic episode more than 6 hours postoperatively can be treated with any of the drugs used for prophylaxis except dexamethasone and transdermal scopolamine.[134,147]

Alternative Treatments

Alternative antiemetic techniques for the prevention and treatment of PONV that have been reported to be successful include acupuncture, electroacupuncture, transcutaneous electrical nerve stimulation, and accupoint stimulation; however, these have not been consistently shown to be effective in children.[148–153]

Postoperative Care and Discharge

PAIN MANAGEMENT IN THE POSTANESTHESIA CARE UNIT

Acute postoperative pain management strategies are discussed in detail in Chapter 44. A child's level of pain (or the perception of pain) changes more rapidly in the PACU than in any other unit of the hospital. Frequent and consistent use of pain scores for children of all ages, including those with developmental disabilities, is essential. Many pain scales have been validated for use in children. More important than the specific scale used, the scale should be used consistently and follow simple principles. For instance, children who are verbal and developmentally appropriate should be encouraged to describe their pain using a self-report scale (e.g., Oucher scale).[154] Young children or those without verbal skills should be assessed using an objective pain behavior scale (e.g., **F**ace, **L**egs, **A**ctivity, **C**ry, **C**onsolability [FLACC] scale).[155,156] Equally as important is the consistent application of protocols to treat pain; treatment of a given pain level should not vary from shift to shift or from one nurse to another.[157]

As with other areas of pediatric pain control, a multimodal approach to postoperative pain is recommended. A plan for pain management should be discussed among the family, surgical team, and anesthesia team before surgery. Depending on the surgery, the plan may include any or all of the following: acetaminophen, nonsteroidal agents, local anesthesia, nerve blocks, regional anesthesia, α_2-agonists, opioids, patient-controlled analgesia, and patient-controlled epidural analgesia.

Acetaminophen and nonsteroidal drugs act through inhibition of prostaglandins and their metabolites. Most of these drugs are given orally and should be given preoperatively or intraoperatively to be effective in the PACU. Occasionally, they may be indicated in the PACU if they were not administered before arrival. Oral acetaminophen (15 mg/kg) or ibuprofen (10 mg/kg) has been shown to decrease opioid requirements by 20% to 30% after a variety of surgical procedures. IV acetaminophen has become available in the United States for children 2 years of age or older, and it is likely to become a popular analgesic for mild to moderate pain in the PACU and as an opioid-sparing drug.[158] The IV dose of 15 mg/kg every 6 hours is recommended for patients weighing less than 50 kg and should be administered over 15 minutes.[159] Studies on IV formulations of propacetamol and paracetamol have mostly been conducted in the European Union since drug approval in 2002; extreme care regarding dosing must be taken when administering these formulations as the recommended doses vary 2-fold. Studies in neonates have suggested the IV formulation is safe and effective in reducing opioid consumption. However, instances of hepatotoxicity have been reported.[160–164] Several randomized, controlled studies and meta-analyses have demonstrated efficacy of IV administration in adults and children for the treatment of mild to moderate pain or fever.[165,166]

Acetaminophen can also be given rectally in doses of 35 to 45 mg/kg; however, because absorption varies and is delayed (i.e., peak concentration at 60–180 minutes after rectal administration), this route is not recommended for use in the PACU.[167] Because of the pharmacokinetics of the rectal route, a greater interval (6 hours) between doses is recommended, and subsequent doses are reduced (20 mg/kg) so that the total dose per 24 hours does not exceed 100 mg/kg.[168] There are no data to provide guidance for rectal acetaminophen beyond 24 hours. If a child has received rectal acetaminophen, the first oral dose should be delayed until 6 hours after the rectal dose.

The nonsteroidal anti-inflammatory drug (NSAID) ketorolac can decrease opioid requirements by approximately 30%. The recommended dosage is 0.2 to 0.5 mg/kg IV (up to 15 mg for children <50 kg and up to 30 mg for children >50 kg) every 6 hours.[169] Caution is warranted in postoperative children with significant bleeding or a history of renal insufficiency. The use of ketorolac is controversial in the pediatric orthopedic surgical literature since the drug has been linked to adverse outcomes including increased bleeding and nonunion of fractures; however, other researchers have suggested it does not negatively impact patient outcomes.[170–173] Similar considerations also apply to parecoxib, another IV antiinflammatory drug.[174]

Opioids are indicated during the immediate postoperative period for any procedure in which moderate or severe pain is not being managed by other means. Morphine, fentanyl, and hydromorphone have a long history of safe use for infants and children in the PACU when vital signs are monitored appropriately. Meperidine is recommended only to treat shivering for children because of the potential for seizures from epileptogenic metabolites (e.g., normeperidine).[175] Opioid dosing should be initiated according to body weight, physiologic development, underlying medical or surgical conditions, coadministered medications, and severity of pain. The goal should be effective and rapid pain relief. Subsequent dosing of the medications should be titrated based on response to the initial dose. Administration of multiple, small, ineffective doses results in prolongation of pain, stress, and anxiety without improving the safety of care provided. With this caveat in mind, patient-controlled analgesia and patient-controlled epidural analgesia (see Chapters 42 and 44) may be used in the PACU environment, but either intervention should be started only after acute pain has been adequately treated. It is essential to reduce opioid dosing by 33% to 50% in those children at risk for OSA due to their known opioid sensitivity. In this population pulse oximetry must be maintained at all times and deaths in PACU have occurred when monitoring was discontinued due to patient upset treated with sedatives or opioids and monitors not reapplied (see also Chapter 33 and Figs. 33.7 and 33.8).[175a]

Regional analgesia is a common mode of intraoperative pain control in the child that extends into the PACU (see Chapters 42 to 44). The PACU personnel should be competent in assessing the adequacy of the block and familiar with the use and programming of the administration pumps.

Evidence that the regional block is effective should first be detected during surgery since the anesthetic requirements for successful surgical completion are reduced. The addition of hydrophilic opioids or clonidine may extend the level and duration of analgesia to some extent over the course of several hours; however, a block many dermatome segments away from the site of the surgical incision is unlikely to remain adequate for very long. The addition of opioids to an epidural or spinal block increases the risk of pruritus, urinary retention, and emesis. Similarly, visceral pain such as bladder spasms (which have thoracic innervation) or sore throat after intubation are not attenuated by a lumbar epidural catheter and must be managed by other measures.

The anesthesiologist must verify that the catheter is properly located in the epidural space. Older children can be questioned about their sensation level using ice or other cold sensation to determine the level of sympathectomy. Preverbal or developmentally disabled children require some other objective form of confirmation. Previous reports have focused on electrical stimulation through the epidural catheter at the time of catheter placement to determine the level of insertion.[176,177] Ultrasound methods for detecting epidural catheter placement have been described.[178–180] Perhaps the most practical method may be radiographic confirmation of the dermatome level of the tip of the catheter, often with the use of an appropriate contrast material (i.e., epidurogram) to ensure appropriate placement in the epidural space. A small amount (<1 mL) of contrast (e.g., Omnipaque 180 or 240) can be infused into the catheter while one radiograph is taken to confirm placement (see Fig. 42.7).[181]

TEMPERATURE MANAGEMENT

The literature documents the detrimental effects of hypothermia and suggests optimal outcomes are achieved when children arrive in the PACU with a normal body temperature. Intraoperative normothermia is key to maintaining a normal temperature postoperatively. Hypothermia is associated with discomfort, bleeding, infections, altered metabolism of drugs, delayed return of cognitive functions, and prolonged recovery.[182–185] Because about 90% of heat loss occurs through the skin, only heat exchange through the skin provides an adequate way of warming children. This method of warming is enhanced by the vasodilation properties of most anesthetic agents. Forced-air warming blankets are effective as the sole method for maintaining normothermia in children.[186–188] Given the vasoconstriction that occurs after anesthesia, attempts at warming are less effective postoperatively than intraoperatively, and most of the detrimental physiologic changes have already taken place.

Infants and children may suffer burns from overly aggressive rewarming measures.[189–191] This is particularly true for nonverbal children, children who are somnolent, and children who have decreased sensation owing to disease or use of regional anesthesia techniques.

DISCHARGE CRITERIA

The recovery process and discharge criteria vary from institution to institution. Some institutions require an assessment by a physician before discharge for all patients, but others require an evaluation only if routine discharge criteria are not met. The modified Aldrete scale is the most common system used to assess discharge readiness, but specific criteria depend on the particular situation or environment to which the child will be discharged.[192–194] For example, a child with a slight degree of postextubation croup or stridor may be discharged for monitoring on a pediatric floor or ICU, but the same child is not discharged to parental care and a 2-hour drive home. The criteria for discharge of children to a general inpatient setting are summarized in Table 47.7. For outpatients, these criteria hold, and the additional criteria outlined in Table 47.8 usually must be met before discharge.

Traditionally, children have been allowed to recover in a first-stage recovery unit until the airway was considered stable, consciousness is regained, baseline motor activity is confirmed, vital signs are stable, and oxygen saturation values are stable in room air (or

TABLE 47.7 Discharge Criteria for Inpatients

1. Recovery of airway and respiratory reflexes adequate to support gas exchange and to protect against aspiration of secretions, vomitus, or blood
2. Stability of circulation and control of any surgical bleeding
3. Absence of anticipated instability in criteria 1 and 2
4. Reasonable control of pain and vomiting
5. Appropriate duration of observation after opioid or naloxone flumazenil administration (minimum of 60 minutes after intravenous naloxone and up to 2 hours after flumazenil)
6. Return to baseline level of consciousness unless transfer is to an intensive care unit environment

TABLE 47.8 Discharge Criteria for Outpatients

All Criteria in Table 47.7, Plus the Following:
1. Cardiovascular function and airway patency are satisfactory and stable.
2. The child is easily rousable, and protective reflexes are intact.
3. The child can talk (if age appropriate).
4. The child can sit up unaided (if age appropriate).
5. For a very young or handicapped child, incapable of the usually expected responses, the preanesthetic level of responsiveness or a level as close as possible to the normal level for that child should be achieved unless the child is to be transferred to another monitored location.
6. The state of hydration is adequate.
7. It may be permissible for parents to carry their children without full recovery of gait (parents must be advised that the child is at risk of injury if improperly supervised).
8. Control of pain should be achieved to permit adequate analgesia by the oral route thereafter.
9. Control of nausea and vomiting should be achieved to allow for oral hydration (see "Discharge Criteria" in text).

at baseline) without respiratory support (unless needed at baseline). Pain should be well controlled. Children then can be transferred to a second-stage recovery unit, where more complete recovery takes place with a reduced nurse/child ratio, until children have met criteria for adequate hydration, minimal emesis, appropriate wound status, stable vital signs, and appropriate ambulation and mental status.

The requirements for children to eat, drink, and void before leaving the secondary recovery area significantly delay discharge. Efforts should be made to reinstate volume homeostasis during surgery, negating any physiologic imperative for oral intake in the immediate postoperative period. Postoperative maintenance fluids should consist of isotonic rather than hypotonic solutions for those expected to remain as inpatients to reduce the risk of hyponatremia (see also Chapter 9).[195–198] Other than children who are at high risk for urinary retention (e.g., history of urinary retention, urethral surgery), there is little evidence that discharge before voiding results in readmission for voiding problems. In fact, this requirement is no longer part of standard discharge criteria.[199] Children who have received a caudal block for surgery are likewise at low risk for urinary retention as long as opioids have not been added to the caudal medication.[194]

Although there are few data on the current status of recovery processes across the country, there appears to be a trend toward one-stage (fast-track) recovery for pediatric outpatients. This process allows selected children to bypass the first-stage recovery and go directly to the second-stage unit based on an appropriate level of consciousness, physical activity, vital signs, respiratory status, and pain control (Table 47.9). This approach has proved successful and quite safe, although appropriate attention to issues such as pain control must be addressed when initiating such a program.

TABLE 47.9 Discharge Criteria for Fast Tracking

Criteria	Score
Level of Consciousness	
Aware and oriented	2
Arousable with minimal stimulation	1
Responsive only to tactile stimulation	0
Physical Activity	
Able to move all extremities on command	2
Some weakness in movement of extremities	1
Unable to voluntarily move extremities	0
Hemodynamic Stability	
Blood pressure <15% of baseline MAP value	2
Blood pressure 15%–30% of baseline MAP value	1
Blood pressure >30% of baseline MAP value	0
Respiratory Stability	
Able to breathe deeply	2
Tachypneic with good cough	1
Dyspneic with weak cough	0
Oxygen Saturation Status	
Maintains value >95% on room air	2
Requires supplemental oxygen (nasal prongs)	1
Saturation <90% with supplemental oxygen	0
Postoperative Pain Assessment	
None or mild discomfort	2
Moderate to severe pain controlled with intravenous analgesics	1
Persistent, severe pain	0
Postoperative Emetic Symptoms	
None or mild nausea with no active vomiting	2
Transient vomiting or retching	1
Persistent, moderate to severe nausea and vomiting	0
Total[a]	14

[a]Pediatric patients must score 14 to bypass the phase 1 (PACU) recovery unit to be admitted directly to the step-down care unit.
MAP, mean arterial pressure; *PACU,* postanesthesia care unit.
From White PF, Song D. New criteria for fast-tracking after outpatient anesthesia: a comparison with the modified Aldrete's scoring system. *Anesth Analg.* 1998;88:1069–1072.

Beyond PACU: Postoperative Monitoring in the General Care Setting

Adult postoperative patients who are taking opioids are a subset of the inpatient population at particular risk for failure to rescue because of respiratory depression[200]; postoperative respiratory failure represents nearly 11% of all inpatient safety events[201] and

has the greatest mortality rate per 100 discharges of all classified safety events.[202] A study in adult, noncardiac surgical patients who were continuously monitored with pulse oximetry found that 21% had oxyhemoglobin saturation (SpO_2) of 90% for an average of ≥10 min/h and 8% had average of ≥20 min/h, and 8% had SpO_2 <85% for ≥5 min/h. A further 3% of postsurgical patients had SpO_2 less than 80% for 30 minutes or longer.[203] This increased risk prompted the Anesthesia Patient Safety Foundation to advocate continuous electronic physiologic monitoring for all inpatients receiving postoperative opioids.[204] While equivalent data or recommendations for the pediatric population are missing, there is little reason to assume that these data should be different in children.

Historically, the selective monitoring of children perceived to be at an increased risk for adverse events ("condition monitoring") because of comorbidities, surgical procedures, or opioid use has mostly failed. Recent research in pharmacogenomics as well as error analysis has provided more insight as to why condition monitoring is an inadequate approach to address the problem. Clinicians have been aware of interindividual variation in response to opioids, and advances in pharmacogenetics have provided the scientific background for these variations. The FDA has proscribed the use of codeine in patients after tonsil and adenoidectomies as a result of the single-nucleotide polymorphisms (SNPs) in cytochrome P4502D6, in whom ultrarapid metabolizers experience greater morphine conversion and greater plasma concentrations. The estimated prevalence of ultrarapid metabolizers varies from 1% to 29%, depending on ethnicity (see Chapters 6 and 7).[205] Many of these genetic variations are yet to be discovered but certainly contributed to unanticipated adverse events. According to The Joint Commission's Sentinel Event Database (2004–2011), 47% of respiratory depression events were wrong dosing medication errors, 29% were related to improper monitoring of the patient, and 11% were related to other factors, including excessive dosing, medication interactions, and adverse drug reactions (http://www.jointcommission.org/assets/1/18/SEA_49_opioids_8_2_12_final.pdf, last accessed 04/09/2016).[206] These data provide some insight into why risk stratification and selective, individual monitoring has failed. Future mitigation of drug errors by bar coding medication and their administration as well as medication reconciliation efforts may minimize adverse respiratory events and make selected monitoring a viable option in the future.

There have been some very successful implementations of surveillance systems to dramatically reduce inpatient adverse events by using pulse oximetry–based surveillance reaching back almost a decade. However, the understanding of surveillance monitoring and its approach of applying principles of population health medicine to hospital wards is still in its infancy.[207–209] Using a pulse oximetry surveillance system in an orthopedic inpatient unit, a research group at Dartmouth decreased unanticipated ICU transfers by 50% and activations of the rapid response by 65%. Using a static alarm–based threshold system for heart rate and oxygen saturation, the system redirects attention of nursing staff to these physiologic deteriorations via a paging system, prompting early intervention.[207] Routine surveillance using pulse oximetry for all inpatients on general care units has been institutional policy at Dartmouth since 2009 for adults and since 2012 for children. Because of the physiologic developmental changes in heart rate in children, creating static alarm triggers is more complex in children than in adults. Table 47.10 shows the alarm thresholds used at Children's Hospital at Dartmouth. Strategies to manage alarm fatigue and alerting for actionable events have been described for adults, but they apply equally for children.[207,208] The introduction of pediatric patient surveillance at Dartmouth has decreased the use of the rapid response team because of earlier detection of physiologic deterioration, similar to that in adults.

TABLE 47.10 Patient Surveillance Alarm Thresholds

Age	Heart Rate (beats/minute)	Oxygen Saturation (%)
0–6 months	80–235	80
6–12 months	70–220	80
1–5 years	60–200	80
5–12 years	55–180	80
>12 years	50–140	80

A pulse oximetry-based system used at the Children's Hospital at Dartmouth.

The role and importance of surveillance monitoring and the needed expertise of pediatric anesthesiologists and intensivists is likely to expand in the future. With the rapid adoption of telemedicine, surveillance monitoring of pediatric patients is likely to exponentially grow not only in the inpatient general care setting, but also is likely to expand to the home setting as length of stay in the hospital will continue to decline.

ACKNOWLEDGMENT

The authors wish to thank A. J. de Armendi, MD, I. D. Todres, MD, and J. P. Cravero, MD, for their prior contributions to this chapter.

Anderson BJ, Woolard GA, Holford NH. Pharmacokinetics of rectal paracetamol after major surgery in children. *Paediatr Anaesth*. 1995;5:237-242.

The authors conducted a pharmacokinetic study in 20 children from 12 months to 17 years of age and demonstrated that paracetamol reached therapeutic plasma concentrations 1 to 2 hours after administration at a dose of 40 mg/kg. Anderson's research group subsequently defined the use of paracetamol in various forms of administration (e.g., oral, rectal, intravenous) in children of all ages.

Boat AC, Spaeth JP. Handoff checklists improve the reliability of patient handoffs in the operating room and postanesthesia care unit. *Paediatr Anaesth*. 2013;23(7):647-654.

The authors demonstrate improvement in effective communication through the implementation of checklists in the postoperative period.

Choong K, Arora S, Cheng J, et al. Hypotonic versus isotonic maintenance fluids after surgery for children: a randomized controlled trial. *Pediatrics*. 2011;128:857-866.

This important paper addresses the issue of postoperative hyponatremia in children. The authors randomly assigned 258 children to two groups receiving isotonic or hypotonic maintenance solutions. Children in the isotonic group had hyponatremia at a rate of 22.7% (vs. 40.8%), with no increased risk for hypernatremia.

Coté CJ, Posner KL, Domino KB. Death or neurologic injury after tonsillectomy in children with a focus on obstructive sleep apnea: Houston, we have a problem! *Anesth Analg*. 2014;118(6):1276-1283.

This paper reported 16 children who died or suffered neurologic injury within 24 hours of their tonsillectomy. Thirteen died at home, one on the ward that evening, but most importantly two died in PACU after monitors were removed; one in his father's lap and the other in bed next to mom. These cases illustrate the insidious nature of OSA and why such children require the utmost attention to opioid dosing and monitoring with a need for postoperative admission and monitoring for those with severe OSA.

Data presented by the authors are frequently used for admission requirements of formerly preterm neonates.

Cravero JP, Beach M, Thyr B, Whalen K. The effect of small dose fentanyl on the emergence characteristics of pediatric patients after sevoflurane anesthesia without surgery. *Anesth Analg*. 2003;97:364-367.

The authors performed a prospective, randomized, blinded trial in which they studied patients undergoing magnetic resonance imaging with general inhaled sevoflurane anesthesia through a laryngeal mask airway. They concluded that small doses of opioids decrease emergence agitation without increasing unwanted side effects.

Gan TJ, Diemunsch P, Habib AS, et al. Consensus guidelines for the management of postoperative nausea and vomiting. *Anesth Analg*. 2014;118(1):85-113.

The authors review the available literature concerning postoperative nausea and vomiting. They use strength of evidence criteria when possible and expert opinion when data are lacking.

Hicks CW, Rosen M, Hobson DB, et al. Improving safety and quality of care with enhanced teamwork through operating room briefings. *JAMA Surg*. 2014;149(8):863-868.

The authors describe methods to improve operating room communication and provide examples of successful methods.

Kain ZN, Caldwell-Andrews AA, Maranets I, et al. Preoperative anxiety and emergence delirium and postoperative maladaptive behaviors. *Anesth Analg*. 2004;99:1648-1654.

This study is extremely unusual in its ability to correlate perioperative anxiety with the incidence of emergence agitation. Preoperative anxiety is significantly related to the incidence of emergence agitation, and the incidence of agitation is related to the rate of postoperative maladaptive behaviors. This study argues strongly for identifying children at risk for emergence agitation and provides some evidence for why it is worth the effort to prevent or ameliorate this phenomenon.

McNicol ED, Tzortzopoulou A, Cepeda MS, et al. Single-dose intravenous paracetamol or propacetamol for prevention or treatment of postoperative pain: a systemic review and meta-analysis. *Br J Anaesth*. 2011;106:764-775.

The authors performed a meta-analysis of 36 randomized, controlled trials and 3896 patients to study the effect of a single, intravenous dose of acetaminophen. They found that 37% of patients with acute postoperative pain had pain relief for about 4 hours.

Summary and Future of Pediatric Sedation

The Evolution of Pediatric Sedation and the Anesthesiologist's Role

Perhaps more than ever, the care of children in the hospital setting requires the provision of sedation in a timely and effective manner. Many children who require an imaging procedure or invasive test before surgery will not tolerate the procedures without sedation. In addition, children with neurologic, gastroenterologic, or oncologic (medical) illness require repeated tests and procedures for a single course of treatment that may be uncomfortable or invasive. In some, sedation is required because of age, anxiety, or developmental delay. A responsive and accommodating sedation service that helps accomplish these procedures in a safe, efficient, and effective manner is an indispensable component of a functional hospital or health system.

The provision of sedation care for children undergoing tests and procedures outside the operating room continues to evolve. Forty years ago, physical restraint without medications was the preferred method to achieve these objectives in children, but today, that approach is completely eschewed and supplanted with sedation in an atmosphere of respect and safety that is on par with the quality of care provided to children undergoing surgery.[1–4] At the same time, we must recognize that the sheer numbers of children who require sedation exceed the capacity of pediatric anesthesiologists to provide all of this care; partnership with other types of physicians and nurses who are capable and willing to deliver pediatric procedural sedation is required. Furthermore, economic pressures in medicine demand systems that optimize efficiency, throughput, and effectiveness of the care provided. While anesthesiologists may find the practice of sedation only moderately challenging, understanding the environment, guidelines, and organizational issues involving sedation practice for ourselves and our partners is critical if we are to improve the overall delivery of this care to children globally.

Sedation/analgesia for painful procedures performed outside the operating room (OR; e.g., bone marrow aspiration, lumbar puncture, repair of minor surgical wounds, insertion of arterial or venous catheters, burn dressing changes, fracture reduction, bronchoscopy, and endoscopy) requires the same attention to detail as for procedures performed in the OR because the level of sedation needed is usually deep sedation or general anesthesia, particularly for children 6 years of age and younger, as well as for those at any age with developmental delay. Children undergoing diagnostic studies (e.g., computed tomography [CT], magnetic resonance imaging [MRI], positron emission tomography [PET], electroencephalography [EEG], electromyography) and those who require high doses of ionizing radiation require deep levels of sedation or general anesthesia because they must remain absolutely motionless (sometimes with breath-holding).[5] Given these requirements, a coordinated team approach is required to provide safe, optimal conditions for the procedure.

The need for sedation services goes beyond the very young and developmentally challenged patients usually associated with this requirement. Older children and adolescents without developmental delay may also require sedation to undergo a procedure/investigation in a confined space (e.g., MRI scans) because of claustrophobia. Other procedures, such as sexual abuse examinations or urinary catheterization, are more emotionally disturbing than painful, but they still require sedation to control anxiety and fear that can ultimately lead to long-term emotional/psychological harm if they were performed without anxiolytics. Furthermore, a child's emotional state may be worsened by parental anxiety, separation from parents, and the pain (or anticipation of pain) from the procedure (see Chapter 3). Distraction, guided imagery, and the use of videos and music have proven beneficial in this respect, although they may be insufficient to provide the conditions needed to complete all procedures in their entirety.[6–10]

The pharmacologic armamentarium for sedation for diagnostic and therapeutic procedures has greatly expanded over the past 10 years to include potent sedative hypnotics, opioids, and dissociative agents. The determination as to which physicians can use these medications and what qualifications are needed to provide deep sedation/anesthesia has been the subject of some debate.

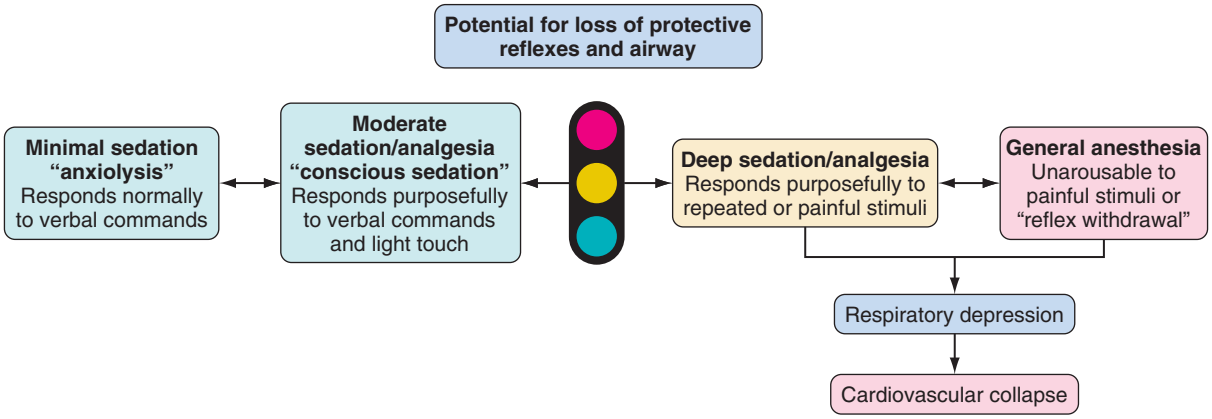

FIGURE 48.1 The sedation continuum. A patient may readily pass from a light level of sedation to deep sedation or general anesthesia. Health care providers must be prepared to increase vigilance and intensity of monitoring consistent with the depth of sedation.

Although the final determination of how this care will be provided remains contentious, the clear trend is toward liberalization of the use of drugs such as propofol, dexmedetomidine, remifentanil, and ketamine.[11] One driving force for this change is the demand for efficient sedation and analgesia outside the OR. Pressure comes from many sources, including hospital administrators, insurance companies, medical specialists, and families, because failures and missed appointments significantly increase hospital costs and frustrate parents.[12] Failed sedations for diagnostic or therapeutic procedures are no longer accepted as part of the sedation process; the use of more potent medications decreases the chance of inadequate sedation. All of these factors have led to the "professionalization" of pediatric sedation with the creation of pediatric sedation services, many of which are led by pediatricians, hospitalists, emergency medicine physicians, intensivists, and dentists. Examples of the changing landscape of sedation abound. A 2005 survey of pediatric sedation practice in 116 children's hospitals in the United States and Canada[13] reported that anesthesiologists exclusively provided the sedation in only 26% of institutions. Similarly, the Pediatric Sedation Research Consortium (PRSC), a collaborative of hospitals heavily committed to improving pediatric sedation, noted that most sedation in the participating institutions (over 100,000 encounters) was delivered by organized sedation services of which anesthesiologists were involved in only 19%.[14] When specifically evaluating the use of propofol in a cohort of 50,000 encounters, the PRSC noted that anesthesiologists were involved only 10% of the time.[15] Despite this changing landscape of sedation, anesthesiologists are still charged by the federal government and the Joint Commission of Hospital Accreditation (JCAHO) in the United States to exercise oversight of sedation practices.[16] To provide effective leadership, anesthesiologists must have a full appreciation of the issues involved in this dynamic area of practice. This chapter focuses on the current definitions of sedation for diagnostic and therapeutic procedures and the goals, risks, and guidelines for creation of safe conditions for children who require sedation for procedures outside the OR.

Sedation Depth

THE CONCEPT OF LEVELS OF SEDATION

Several organizations have defined levels of sedation.[17–20] The definitions of the American Academy of Pediatrics (AAP), the American Society of Anesthesiologists (ASA), JCAHO, and the American Academy of Pediatric Dentistry (AAPD) are the most frequently cited and agreed-upon position statements.[18,19,21–23] These organizations defined sedation and analgesia for procedures as a continuum, including minimal sedation (anxiolysis), moderate sedation, deep sedation, and general anesthesia (Fig. 48.1). All of these definitions are created with the appreciation that a child's depth of sedation may easily pass from one level to another and without easily identifiable signs of any change in condition.[24] The definitions that follow are taken from JCAHO (2010)[25] and are in agreement with the current AAP, AAPD, and ASA definitions[18,19,21]:

- *Minimal sedation (anxiolysis):* A drug-induced state during which patients respond to verbal commands. Although cognitive function and coordination may be impaired, cardiorespiratory functions are unaffected (Video 48.1).
- *Moderate sedation* (previously called "conscious sedation" or sedation/analgesia): A drug-induced depression of consciousness during which patients respond purposefully to verbal commands, either alone or accompanied by light tactile stimulation. No interventions are required to maintain a patent airway, and spontaneous ventilation is adequate. Cardiovascular function is usually maintained (Video 48.2).
- *Deep sedation:* A drug-induced depression of consciousness during which patients cannot be easily aroused but respond purposefully after repeated or painful stimuli. **(*Note:* reflex withdrawal from a painful stimulus is not considered a purposeful response.)** The ability to independently maintain respiratory homeostasis may be impaired. Patients may require assistance in maintaining a patent airway and spontaneous ventilation may be inadequate. Cardiovascular function is usually maintained (Video 48.3).
- *General anesthesia:* A drug-induced loss of consciousness during which patients are not arousable, even to painful stimuli. The ability to independently maintain respiratory homeostasis is often impaired. Patients often require assistance in maintaining a patent airway, and positive-pressure ventilation may be required because spontaneous ventilation is depressed or neuromuscular function is compromised. In addition, cardiovascular function may be impaired (Video 48.4).

In clinical practice, procedures that require sedation in children may require deep sedation or general anesthesia for pain control (bone marrow biopsies) or movement control (MRI scans). They

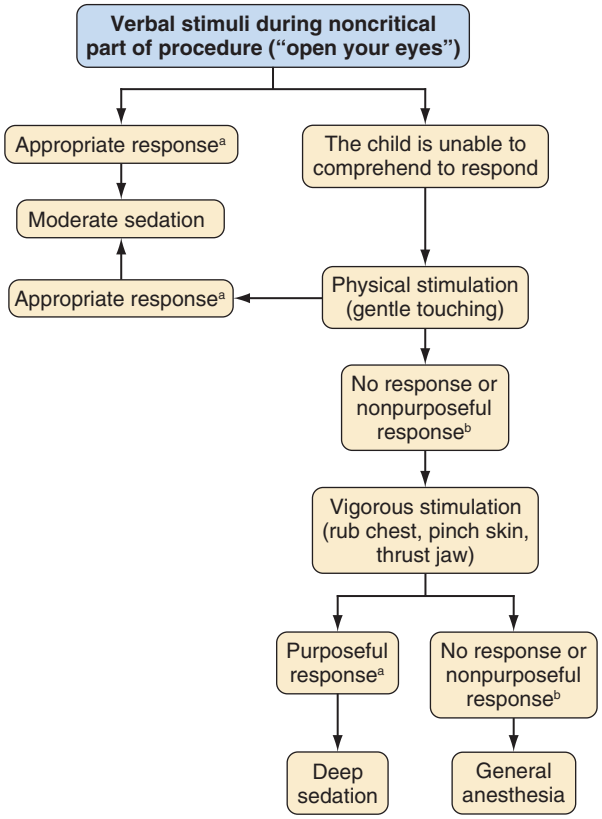

FIGURE 48.2 Sedated children must be continuously evaluated for depth of sedation and appropriateness of response. As diagrammed here, sedation is a continuum. Note that a purposeful response to voice or light touch is consistent with moderate sedation. A purposeful response to pain is consistent with deep sedation. A nonpurposeful response to pain is consistent with general anesthesia. However, such stimulation often defeats the purpose of the sedation, thus rendering these assessments less helpful unless patient movement is acceptable. None of the current sedation guidelines require such assessments. [a]*Purposeful:* opens eyes, talks back, pushes you out of the way. [b]*Nonpurposeful:* winces, shrugs shoulders, nonspecific withdrawal to pain.

TABLE 48.1 Ramsay Scale

Level	Characteristics
1	Patient awake, anxious, agitated, or restless
2	Patient awake, cooperative, orientated, and tranquil
3	Patient drowsy, with response to commands
4	Patient asleep, brisk response to glabella tap or loud auditory stimulus
5	Patient asleep, sluggish response to stimulus
6	Patient has no response to firm nail-bed pressure or other noxious stimuli

TABLE 48.2 Modified Ramsay Sedation Scale

Score	Characteristics
1	Awake and alert, minimal or no cognitive impairment
2[a]	Awake but tranquil, purposeful responses to verbal commands at conversation level
3[a]	Appears asleep, purposeful responses to verbal commands at conversation level
4[b]	Appears asleep, purposeful responses to verbal commands but at louder than usual conversation level or requiring light glabellar tap
5[b]	Asleep, sluggish purposeful responses only to loud verbal commands or strong glabellar tap
6[c]	Asleep, sluggish purposeful responses only to painful stimuli
7[d]	Asleep, reflex withdrawal to painful stimuli only (no purposeful responses)
8[d]	Unresponsive to external stimuli, including pain

[a]Minimal sedation.
[b]Moderate sedation.
[c]Deep sedation.
[d]General anesthesia.

are rarely performed in a child under "moderate sedation." Often moderate sedation is used inappropriately. It is not always easy to accurately describe the depth of sedation based on the child's responses to stimulation (Fig. 48.2). In addition, there are problems with classifying responses when they occur. A child who is under moderate sedation should respond to touch or firm rubbing by an appropriate response, such as saying "ouch," pushing your hand away, or pulling up the covers. *The lack of a purposeful response is a sign that the child has progressed to a deeper sedation level and should lead to an escalation of monitoring and personnel.*[26–29] These differences are seldom appreciated and often lead to inappropriate care. Not surprisingly, an audit in a large pediatric hospital reported that their target level of either moderate or deep sedation was achieved in only 50% to 75% of patients; an awake state was achieved in 12% to 28% of the children, and general anesthesia was reached in 35% of children.[24]

SEDATION SCORING SYSTEMS

There are several validated scoring systems available for assessing sedated patients and grading their level of sedation. The Ramsay scale was described by Ramsay and colleagues[30] in 1974 for the purpose of monitoring sedation with alphaxalone-alphadolone (Table 48.1). It continues to be the most widely used scale for assessing and monitoring sedation in daily practice, as well as in clinical research. It spans the continuum of sedation but does not clearly separate purposeful from nonpurposeful responses. The Ramsey scale has been modified to more clearly coincide with the AAP and JCAHO guidelines (Table 48.2).[31] A score of 2 to 3 is anxiolysis, 4 to 5 is moderate sedation, 6 is deep sedation, and 7 to 8 is general anesthesia.

The Observer's Assessment of Alertness/Sedation (OAA/S) scale[32] is often cited as a scale for sedation. It is scored as follows: 1, no response to shaking; 2, responds to mild prodding; 3, responds to name called loudly; 4, lethargic response to name; and 5, readily responds to name. Its inability to clearly categorize deep levels of sedation and lack of a clear differentiation between purposeful and nonpurposeful responses limit its usefulness. A more useful clinical scale is the University of Michigan Sedation Scale (UMSS).[33] It is an assessment tool that has been validated against the OAA/S scale and other scales of sedation (Table 48.3). This scale has proven useful in children with significant learning impairment and delays.[34] It separates patients into the sedation categories in line with those defined by the AAP, ASA, and JCAHO.

These responsiveness-based assessment tools require intermittently stimulating the child during the procedure to categorize patients. Unfortunately, poking or prodding the child to determine

the depth of sedation defeats the purpose of sedation in many situations (e.g., infants, developmentally delayed children, or procedures requiring immobility). The authors of the guidelines that reference levels of sedation do not require frequent testing of sedation depth. Rather the responsiveness-based definitions are meant to provide a road map for safety that bases the level on the behavior of the patient in response to the procedure itself, with the understanding that a nonresponding child requires an increased level of vigilance.[12] Unfortunately, infrequent testing leaves the sedation provider uncertain about the depth of sedation for significant periods of time during a test or intervention. Concerns regarding these types of assessment tools have led to the suggestion by some experts that there is a need to revise the sedation continuum and to use other monitoring parameters (such as physiologic status) to assess level of sedation.[35] Still others have suggested that the use of an observational scale that simply codifies the "state" of the child at any time during the sedation/procedure is more useful than stimulation (Table 48.4).[36]

For many years, the "holy grail" of sedation has been the noninvasive sedation monitor that would accurately detect and record the depth of sedation without stimulating the child or interfering with a procedure. Over the past 15 years, several monitors have been developed to assess the depth of sedation or anesthesia in a nonstimulating, continuous manner. Examples of the monitors include the BIS (bispectral index) monitor (Medtronic/Covidien, Minneapolis, MN); Narcotrend monitor (Narcotrend-Gruppe, Hannover, Germany); Danmeter AEP monitor/2 (Danmeter DK-5000, Odense C, Denmark); Patient State Monitor (PSA-4000, Pfizer/Hospira, Lake Forest, IL), the Cerebral State Monitor (Danmeter DK-5000, Odense C, Denmark); and the Entropy module (GE Healthcare/Datex-Ohmeda, Chicago, IL). While each of these has shown some level of utility, the most broadly applied (and thoroughly studied) of these is the BIS monitor, which uses a proprietary method for processing the EEG signal and converting that reading into a number between 0 and 100, which has been correlated with the depth of sedation. The BIS was derived from empirically estimating processed EEG parameters that best predicted OAA/S scale levels in adult volunteers receiving a wide variety of anesthetics, analgesics, and sedatives.[37] BIS values in adults who are awake range from 95 to 100; when lightly to moderately sedated 70 to 95; when deeply sedated with a small probability of explicit recall 60 to 70; and general anesthesia, 40 to 60.[38–40]

Attempts to correlate BIS values with the depth of sedation in children have been met with varying success, particularly when attempting to distinguish moderate from deep sedation.[41–44] In part, these difficulties relate to two factors: (1) the algorithms have been validated only in adults, and (2) many of the anesthetics and drugs used to anesthetize and sedate children have not been adequately studied with the BIS monitor, even in adults. Other issues with the use of the BIS in children include the following:

1. BIS values are not age specific and are relatively inaccurate in children younger than 1 year of age.[45,46]
2. BIS readings may differ from one side of the head to the other.
3. BIS readings are diminished in developmentally delayed children.[47]
4. BIS is completely inaccurate with ketamine sedation because of ketamine-induced central excitation.[48,49]
5. BIS readings are inaccurate during sedation with dexmedetomidine.[50]

Finally, practical problems with the use of BIS-type monitoring include the following:

1. It is not feasible for many procedures, such as MRI scans.
2. BIS is not applicable for procedures involving the mouth and airway (endoscopy, dental, bronchoscopy), because the monitor creates artifacts or is in the way of the proceduralist.
3. Muscular activity around the head creates artifact. Overall, the lack of specificity for levels of sedation, low quality of BIS data, and the lack of information for different age groups or specific drugs preclude recommendation of the BIS for use in procedural sedation in children at this time.[39]

TABLE 48.3 University of Michigan Sedation Scale (UMSS)

Score	Characteristics
0	Awake and alert
1	Minimally sedated: tired/sleepy, appropriate response to verbal conversation and/or sound
2	Moderately sedated: somnolent/sleeping, easily aroused with light tactile stimulation or a simple verbal command
3	Deeply sedated: deep sleep, arousable only with significant physical stimulation
4	Unarousable

TABLE 48.4 The Dartmouth Operative Conditions Scale (DOCS)

PATIENT STATE	OBSERVED BEHAVIORS			
Pain/Stress	**(0)**	**(1)**	**(2)**	
	Eyes closed or calm expression	Grimace or frown	Crying, sobbing, screaming	
Movement	**(0)**	**(1)**	**(2)**	**(3)**
	Still	Random little movement	Major purposeful movement	Thrashing, kicking, biting
Consciousness	**(0)**	**(–1)**	**(–2)**	
	Eyes open	Ptosis, uncoordinated, "drowsy"	Eyes closed	
Sedation Side Effects	**(–1)**	**(–1)**	**(–1)**	**(–1)**
	Spo_2 < 92%	Noise with respiration	Respiratory pauses >10 seconds	BP decrease of > 50% from baseline

Patients are scored in four state categories at any one time during sedation for a procedure. The sum of the scores in all four categories is used to determine the DOCS score for any discrete point during a sedation encounter. BP, blood pressure; Spo_2, oxygen saturation as measured by pulse oximetry.

Similar limitations exist for the other monitors of sedation/anesthesia depth. While they may be helpful in specific instances or clinical situations, their general use is not advised.

Sedation Depth Versus Sedation Risk

Sedation scales and sedation depth monitors attempt to quantify the depth of sedation but do not directly measure the "risk" of sedation. While the depth of sedation is defined by response to stimulation, the *important assessment of the child is not the response to stimulation, but the ability to protect and maintain the airway*.[51,52] In fact, each sedative drug or a particular dose of a drug may provide pain relief but may also obstruct the airway or depress ventilation. For example, propofol is a potent, effective sedative that confers no analgesia but has marked effects on the airway tone and respiratory drive.[53] Conversely, dexmedetomidine provides less intense sedation than propofol but modest pain relief with minimal depression of respiration and minimal compromise of airway morphology. In contrast, ketamine produces intense analgesia and decreases the responses to stimulation, but infrequently obstructs the airway or depresses respiratory effort even at very large doses (Table 48.5).[54]

There are also aspects of the *patient* that affect risks for airway-related adverse events as much as sedation depth. For instance, a child with obstructive sleep apnea (OSA) or obesity is much more likely to obstruct his or her airway during deep sedation than one who does not have this comorbidity.[55] A history of prematurity has been shown to increase the risks associated with sedation throughout childhood and adolescence.[56] Furthermore, other comorbidities such as congenital heart disease, airway anomalies, lower respiratory tract disease, and upper respiratory tract infection increase the risk of general anesthesia, and one would expect that they would also increase the risk of sedation, although they have not been studied specifically in this regard. Similarly, the *procedure itself* can increase the risk for a child. A bronchoscopy or upper gastrointestinal endoscopy carries much greater risks of airway-related events than a noninvasive diagnostic test.[57] The environment of the procedure can also increase risk. The MRI scanner (where the observer is remote from the airway during the scan and ferromagnetic objects are forbidden) is a significantly more difficult environment than one where the sedation provider can be situated at the airway and all monitors and rescue equipment are available (as per standard routine). In summary, when assessing the risk of sedation, one must consider the multidimensional aspects of sedation that include the planned level of sedation, existing comorbidities in the child, the procedure to be performed, and the environment in which the procedure will be performed.

The safety of sedation must also focus on appropriate discharge readiness and the subtle differences in recovery from sedation. Adverse events, including deaths, have occurred after premature discharge after procedural sedation.[52] These events were most often associated with sedating medications with a prolonged duration of effect such as chloral hydrate (Fig. 48.3).[51] With this in mind, a simple "maintenance of wakefulness" score (infants had to stay awake for at least 15 to 20 consecutive minutes in a quiet environment before discharge) ensured that more than 90% of children had returned to baseline levels of consciousness, compared with only 55% of children assessed as "street ready" according to usual hospital discharge criteria.[58]

TABLE 48.5 Examples of Sedative Drugs That Have Varying Effects on Response to Pain and Airway Protection

Response to Pain Does Not Predict Airway Maintenance
All Drugs Are Different

	Response to Pain	Airway Maintenance
Fentanyl	↓↓	↓
Propofol	±	↓
Ketamine	↓	±
Dexmedetomidine	↓	+

↓↓, large decrease in response to pain or large effect on airway patency; ↓, some decrease in response to pain or some effect on airway patency; ±, minimal to no effect on response to pain or effect on airway patency; +, no effect on airway patency.

Guidelines

With the definitions of depth of sedation in mind, multiple organizations have produced guidelines for the conduct of sedation in pediatric patients. The first sedation guideline was published in 1985 from the Committee on Hospital Practice and the Section on Anesthesiology of the AAP.[59] The guideline emphasized systems issues pioneered in anesthesiology, such as the need for informed consent, appropriate fasting before sedation, frequent measurement and charting of vital signs, the availability of age- and size-appropriate equipment, the use of continuous physiologic monitoring (pulse oximetry), the need for basic life support skills, as well as proper recovery and discharge procedures. A 2002 amendment of these guidelines[60] eliminated the use of the confusing term *conscious sedation* and replaced it with the term *moderate sedation*. The AAP's guideline was updated again in 2006.[18] It unified the definitions of sedation depth used

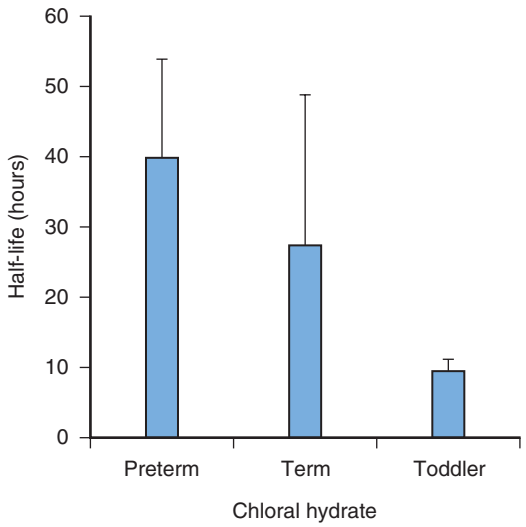

FIGURE 48.3 β-Elimination half-life of the active metabolite of chloral hydrate, trichloroethanol, in preterm infants, term infants, and toddlers. Note the extremely prolonged half-lives and the large standard deviations in all age groups. Although often thought of as a short-acting sedative, chloral hydrate can have profoundly long sedative effects, with a real possibility of resedation after a procedure when the child is left undisturbed. It is for this reason that we recommend a longer period of observation in a step-down area before discharge.

by the ASA and the JCAHO and emphasized further refinements of a systematic approach to sedation that included the following:

- No administration of sedative medications without the safety net of medical supervision (i.e., no sedative medications given at home).
- Careful presedation evaluation to include review of pertinent medical and surgical conditions.
- Careful history for ingestion of nutraceuticals and other medications that may alter drug metabolism and prolong sedation.
- Appropriate fasting guidelines for elective and urgent procedures. There should be a balance between the depth of sedation and the risk for those who are unable to fast because of the urgent nature of the procedure.
- Focused airway examination with particular attention to anatomic airway abnormalities and enlarged tonsils.
- Understanding the pharmacokinetic and pharmacodynamic effects of sedation medications and drug interactions.
- Appropriate training and skills in airway management for sedation providers to allow for rescue. Deep sedation requires training in Pediatric Advanced Life Support (PALS).
- Immediate availability of size- and age-appropriate airway, monitoring, and resuscitation equipment.
- Appropriate emergency medications and reversal agents available for sedation in all cases.
- Sufficient personnel to carry out the procedure *and* monitor the child.
- Appropriate physiologic monitoring during and after the procedure; use of capnography is encouraged.
- A "time-out" should be performed before sedation.
- Recovery personnel, monitoring, and discharge criteria with return to baseline condition before discharge.
- Continuous quality improvement to track common markers of potential safety issues, such as desaturation events, airway obstructions, laryngospasm, unplanned hospital admission, unsatisfactory sedation, and medication errors.
- Use of simulators to practice management of rare adverse events.
- Assume that all children younger than 6 years of age will be deeply sedated for painful procedures or those that are not painful but prolonged.

The most recent version of the AAP guidelines was published in 2016,[61] in which the guidelines for sedation used by pediatric medical and dental practitioners were unified with the same language, the same definitions, and the same goals. The new version added clarifications regarding respiratory monitoring modalities, particularly that continuous capnometry is recommended for moderate sedation and required for deep sedation, provided updated information from the medical and dental literature, and suggested methods for further improvement in safety (incorporating checklists, human simulation training) and documentation. Other important changes included that the responsible practitioner for moderate sedation must have the skills to rescue a child with apnea, laryngospasm, airway obstruction, and perform successful bag-mask ventilation. The practitioner who practices deep sedation must have these same skills and be able to perform tracheal intubation and cardiopulmonary resuscitation. Additionally, the skilled observer for either moderate or deep sedation must be trained in PALS **and be capable to assist with any emergency**. Three decision trees that guide the management of airway obstruction, laryngospasm, and apnea were added.

This recent guideline further emphasized the following:

- *Patient Evaluation.* Clinicians should be familiar with the sedation-related aspects of the patient's medical history. These include (1) abnormalities of major organ systems; (2) previous adverse effects with sedation and general anesthesia; (3) drug allergies, current medications, and drug interactions; (4) time and nature of oral intake; and (5) history of tobacco, alcohol, or substance abuse. A focused physical examination, including vital signs, auscultation of the heart and lungs, and evaluation of the airway, is recommended.
- *Preprocedural Preparation.* Patients should be informed of and agree to sedation, including its risks, benefits, limitations, and alternatives. Sufficient time should elapse before a procedure to allow gastric emptying for elective procedures in healthy children as per the ASA guidelines: minimum fasting intervals of 2 hours after clear liquids, 4 hours after breast milk, 6 hours after infant formula, nonhuman milk, and a light meal (dry toast, tea without milk), and 8 hours after fatty food. If urgent, emergent, or other situations impair gastric emptying, the potential for pulmonary aspiration of gastric contents must be considered when determining the target level of sedation, delay of the procedure/investigation, or the need to secure the airway (e.g., tracheal intubation).
- *Monitoring Level of Consciousness.* Monitoring of verbal commands should be routine during moderate sedation, with the exception of young children and developmentally impaired, uncooperative patients, or when the response would be detrimental. During deep sedation the response to a more profound stimulus should be sought to ensure that the patient has not drifted into general anesthesia.
- *Physiologic Monitoring.* All patients undergoing sedation/analgesia should be monitored by pulse oximetry with appropriate alarms. In addition, respiration should be continuously monitored by observation or auscultation. End-tidal carbon dioxide ($ETCO_2$) is encouraged for moderately sedated children and now required per AAP guideline for all patients receiving deep sedation and for those whose ventilation could not be directly observed during moderate sedation. It should be noted, however, that the ASA standards for basic monitoring were amended in 2012 to include $ETCO_2$ monitoring of those sedated at moderate and deeper levels of sedation.[61,62] In addition, the guidelines recommended that blood pressure should be determined before sedation/analgesia is initiated where possible and at regular intervals during the procedure, unless such monitoring interferes with the procedure (e.g., pediatric MRI, in which stimulation from the blood pressure cuff could arouse an appropriately sedated child). Electrocardiographic (ECG) monitoring should also be used in all children during deep sedation, and during moderate sedation, in those with significant cardiovascular disease, or those who are undergoing procedures in which dysrhythmias are anticipated.
- *Recording of Monitored Parameters.* For both moderate and deep sedation, the child's level of consciousness, respiratory status, and hemodynamic variables should be assessed and recorded at a frequency commensurate with the type and amount of medication administered, the duration of the procedure, and the medical condition of the child. At a minimum, this should be (1) before the beginning of the procedure; (2) after administration of sedative/analgesic agents; (3) at regular intervals during the procedure; (4) during initial recovery; and (5) immediately before discharge. If recording is performed automatically, device alarms should be set to alert the care team to critical changes in patient status.

- *Availability of an Appropriately Trained and Skilled Individual Responsible for Patient Monitoring.* A designated individual, other than the practitioner performing the procedure, should be present to monitor the child throughout procedures performed with sedation/analgesia. During deep sedation, this individual should have no other responsibilities. However, during moderate sedation, this individual may assist with minor, interruptible tasks once the patient's level of sedation/analgesia and vital signs have stabilized, provided that adequate monitoring for the child's level of sedation is maintained.
- *Training of Personnel.* Individuals responsible for children who receive sedation/analgesia should understand the pharmacology of the medications that are administered, as well as the role of pharmacologic antagonists for opioids and benzodiazepines. Individuals who monitor children who receive sedation/analgesia should be able to recognize the associated complications. At least one individual capable of establishing a patent airway and positive-pressure ventilation, as well as a means for summoning additional assistance, should be present whenever sedation/analgesia is administered.
- *Availability of Emergency Equipment.* Pharmacologic antagonists, as well as appropriately sized equipment for establishing a patent airway and providing positive-pressure ventilation with supplemental oxygen, should be present whenever sedation/analgesia is administered. Suction, advanced airway equipment, and resuscitation medications should be immediately available and in good working order. A functional defibrillator should be immediately available whenever deep sedation is administered and when moderate sedation is administered to those with mild or severe cardiovascular disease.
- *Use of Supplemental Oxygen.* Equipment to administer supplemental oxygen should be present when sedation/analgesia is administered. Supplemental oxygen should be considered for moderate sedation and should be administered for deep sedation unless specifically contraindicated for a particular child or procedure. If hypoxemia is anticipated or develops during sedation/analgesia, supplemental oxygen should be administered.
- *Combinations of Sedative/Analgesic Agents.* Combinations of sedative and analgesic agents may be administered as indicated for the procedure being performed and the condition of the child. Ideally, each component should be administered individually to achieve the desired effect (e.g., additional analgesic medication to relieve pain; additional sedative medication to decrease awareness or anxiety). The propensity for combinations of sedative and analgesic agents to cause respiratory depression and airway obstruction emphasizes the need to appropriately reduce the dose of each component, as well as the need to continually monitor respiratory function (Fig. 48.4).
- *Recovery Care.* After sedation for diagnostic and therapeutic procedures, the children should be observed in an appropriately staffed and equipped area until they are near their baseline level of consciousness and are no longer at increased risk for cardiorespiratory depression. Oxygenation should be monitored periodically until they are no longer at risk for hypoxemia. Ventilation and circulation should be monitored at regular intervals until the children are suitable for discharge. Discharge criteria should be designed to minimize the risk of central nervous system (CNS) or cardiorespiratory depression after discharge from observation by trained personnel.
- *Consultation and Availability of an Anesthesiologist.* Whenever possible, appropriate medical specialists should be consulted before sedating children with significant comorbidities. The choice of specialists depends on the nature of the underlying condition and the urgency of the situation. For severely compromised or medically unstable children (e.g., anticipated difficult airway, severe obstructive pulmonary disease, or congestive heart failure), practitioners who are not trained in the administration of general anesthesia should consult an anesthesiologist (Table 48.6).

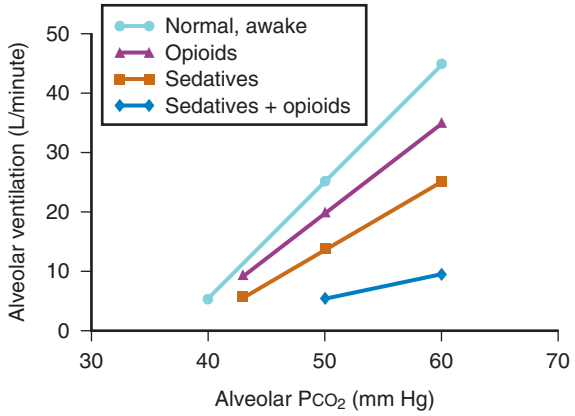

FIGURE 48.4 Relationship between ventilation and carbon dioxide is represented by a family of curves. Each curve has two parameters: an *x*-intercept and a slope. Sedatives and opioids increase the intercept and decrease the slope. The combination of sedatives and opioids produce the most profound effect. (From Yaster M, Nichols DG, Deshpande JK, Wetzel RC. Midazolam-fentanyl intravenous sedation in children: case report of respiratory arrest. *Pediatrics* 1990;86(3):463–467.)

The ASA also has numerous statements and guidelines for sedation by physicians other than anesthesiologists. The "Practice Guidelines for Sedation and Analgesia by Non-Anesthesiologists" was last updated in 2002 and, in many respects, is in concert with the AAP guidelines.[63] The ASA currently has 10 different statements discussing sedation guidelines available through their website (http://www.asahq.org). Some statements specifically address questions related to the provision of moderate and deep sedation by nonanesthesiologists as well as the use of medications such as propofol by nonanesthesiologist sedationists. Most pertinent of these is the 2010 document "Statement on Granting Privileges for Deep Sedation to Non-Anesthesiologist Sedation Practitioners."[64] The guidelines include the following:

1. Formal training in administration of deep sedation during residency training (within 2 years) or an Accreditation Council for Graduate Medical Education accredited training program
2. Experience and competency in managing sedated patients
3. Clinical experience with more than 35 patients
4. Knowledge of ASA guidelines
5. Advanced cardiac life support training
6. Quality assurance tracking

Separate privileging is required for the care of children. The exact nature of these requirements are not specified, but pediatric sedation training over and above baseline competencies is advised.

Other organizations, notably the American College of Emergency Physicians (ACEP), have published their own sedation guidelines and clinical practice advisories for sedation.[65–69] These guidelines are distinguishable from the AAP and ASA guidelines in several respects, including the definition of the continuum of sedation. The ACEP guideline prefers the term "procedural

TABLE 48.6 Guidelines for the Consultation of an Anesthesiologist

1. Medical Problems
   - ASA physical status III or IV
   - Pulmonary: airway obstruction (tonsils/adenoids)—loud snoring, obstructive sleep apnea. Poorly controlled asthma, congenital or acquired anomalies of the airway or face (Trisomy 21, Pierre Robin syndrome, Treacher Collins syndrome, Crouzon disease, tracheomalacia)
   - Morbid obesity (≥2 times ideal body weight, BMI >30 kg/m^2)
   - Cardiovascular: cyanosis, repaired or unrepaired congenital heart disease with significant symptoms of cyanosis or congestive heart failure
   - Prematurity: less than 60 weeks postconception age at time of sedation
   - Residual pulmonary, cardiovascular, gastrointestinal, neurologic problems
   - Neurologic: developmental disabilities, poorly controlled seizures, central apnea
   - Gastrointestinal: uncontrolled gastroesophageal reflux
   - Severe liver or renal disease
2. Procedures requiring deep sedation in patients with a full stomach
   - Emergency procedures
3. Management problems
   - Severe developmental delay
   - Patients who are difficult to control
   - Severe attention-deficit disorder (paradoxically, the child may develop increased agitation during or after the procedure)
4. History of failed sedation
   - Oversedation (loss of airway reflexes)
   - Inability to adequately sedate
   - Hyperactive (paradoxical) response to sedatives

ASA, American Society of Anesthesiologists; *BMI*, body mass index.

sedation." It is defined *"as a technique of administering sedatives, analgesics, dissociative agents, alone or in combination to induce a state that allows the child to tolerate unpleasant procedures while maintaining cardiopulmonary function."* It is intended to result in a depressed level of consciousness but one that allows the child to *"independently and continuously"* control his or her own airway. This guideline was updated in 2014 to address several issues with the following recommendations[70]:

1. Do not delay procedural sedation in adults or children in the emergency department based on fasting time. Preprocedural fasting for any duration has not reduced the risk of emesis or aspiration when administering procedural sedation and analgesia.
2. Capnography may be used as an adjunct to pulse oximetry and as a clinical tool to detect hypoventilation and apnea earlier than pulse oximetry and/or clinical assessment alone in children undergoing procedural sedation and analgesia in the ED.
3. During procedural sedation and analgesia, a nurse or other qualified individual should be present to continually observe and monitor the patient, in addition to the provider performing the procedure. Physicians who are working or consulting in the emergency department should coordinate procedures requiring procedural sedation and analgesia with the emergency department staff.
4. Ketamine and etomidate can be safely administered individually to children and propofol can be administered to both children and adults for procedural sedation and analgesia in the emergency department. A combination of propofol and ketamine can be safely administered to children and adults for procedural sedation and analgesia.

The ACEP suggests a very different clinical practice advisory for the fasting interval before sedation based on analysis of reports from the sedation literature and expert consensus. The suggested time frames for fasting start with a 3-hour baseline and vary based on the urgency of the procedure and the planned depth of sedation. In addition, the practitioner can be directing the sedation and performing the procedure, and there is vague language regarding the nurse observer. **The result is a strategy that differs significantly from the standard recommendations from the AAP and ASA.**[71]

It is mandatory that sedation policies used in hospitals conform to JCAHO standards that have been derived from the Department of Health and Human Services (DHHS) Centers for Medicare & Medicaid Services (CMS). These requirements are consistent with the AAP/ASA guidelines but are more explicit in terms of the oversight of sedation services. The standards require documentation (e.g., medical history, physical status, and record-keeping during the procedure and the recovery from the procedure), a fasting protocol, and informed consent procedures that are mandatory for all those undergoing sedation, regardless of the nature, duration, patient's history, and location of the procedure. Similarly, the sedation personnel, monitoring equipment, and recovery facilities must meet uniform standards within an institution. Hospitals risk losing federal funding if they fail to comply. In the most recent CMS regulations published in 2011,[16] the leadership and responsibilities for the delivery of deep sedation are assigned to a "qualified doctor of medicine or osteopathy who leads the department of anesthesia services." This would logically fall under the purview of the Chair of the Department of Anesthesiology in most cases; however, there are many small or unique hospitals where such a position does not exist. In such cases, the hospital administration must designate a physician who will fill this role and meet these qualifications (Fig. 48.5).

Under the CMS directives, deep sedation is placed under anesthesia services and *subject to the anesthesia administration requirements at 42 CFR 482.52(a):* whereas *minimal and moderate sedation* are placed under analgesia/sedation and therefore not subject to anesthesia administrative requirements. To ensure continuity and equanimity of sedation care, CMS states that there should be one anesthesia service that has responsibility for oversight of all anesthesia services. Anesthesia must be administered by a (1) qualified anesthesiologist; (2) certified registered nurse anesthetist (CRNA) or anesthesiologist assistant (AA) with appropriate supervision; (3) doctor of medicine or osteopathy (other than an anesthesiologist); and (4) dentist, oral surgeon, or podiatrist who is qualified to administer anesthesia under state regulations. Credentialing and privileging must be done per hospital policy and is the responsibility of the hospital's director of anesthesia services. The appropriateness and quality of anesthesia, including sedation, must be reviewed and approved by the director of anesthesia services. The standards for sedation require that each hospital develop specific appropriate protocols for patients receiving sedation, but these guidelines offer little detail on the exact content of the protocols (those are left to the individual organizations). These protocols must include delineation of the following:

1. Qualified individuals in sufficient numbers to perform and monitor patients during and after the procedure. A registered nurse must supervise perioperative nursing care.
2. Competency-based education, training, and experience in evaluating patients. These must include the following:
   a. Evaluating patients before the sedation.

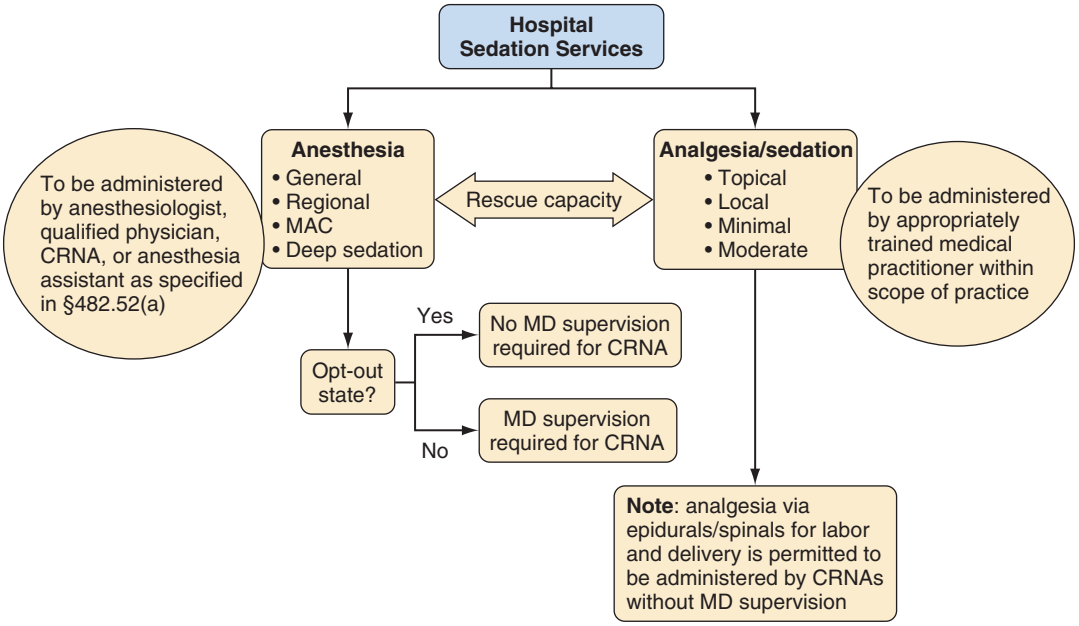

FIGURE 48.5 Centers for Medicare & Medicaid Services organizational chart showing deep sedation under the category of "Anesthesia" and supervised by "Hospital Sedation Services." *CRNA*, certified registered nurse anesthetist; *MAC*, monitored anesthesia care; *MD*, physician.

   b. Performing moderate and deep sedation, including rescuing patients who slip into a deeper than desired level of sedation. These include the following:
      i. Moderate sedation–personnel are qualified to rescue patients from deep sedation and are competent to manage a compromised airway and to provide adequate oxygenation and ventilation.
      ii. Deep sedation–personnel are qualified to rescue patients from general anesthesia and are competent to manage an unstable cardiovascular system, as well as a compromised airway and inadequate oxygenation and ventilation.
3. Appropriate equipment for care and resuscitation.
4. The following must occur before moderate or deep sedation:
   a. Appropriate needs of the patient are assessed.
   b. Preprocedural education is provided to the patient according to a plan of care.
   c. A time-out is conducted immediately before starting, as described in universal protocol.
   d. A licensed independent practitioner plans or concurs with the planned procedure.
5. Appropriate monitoring of vital signs during and after the procedure, including, but not limited to, heart rate and oxygenation using pulse oximetry, respiratory frequency and adequacy of pulmonary ventilation, monitoring of blood pressure at regular levels, and cardiac monitoring (by ECG or use of a continuous cardiac monitoring device) in patients with significant cardiovascular disease or when dysrhythmias are anticipated or detected.
6. Documentation of care before, during, and after the procedure.
7. Monitoring of outcomes. In particular, analysis of data is performed on adverse events or patterns of adverse events during moderate or deep sedation.

The guidelines for sedation are actually quite similar among the various organizations and government entities that are responsible for these standards. It is critical that anesthesiologists who oversee and coordinate this care be familiar with the various guidelines and help their colleagues meet or exceed them.

Goals of Sedation

The goals of pediatric sedation are similar to the goals of operative anesthesia[18,29]:

- Guard the child's safety and welfare. This includes ensuring appropriate airway maintenance and cardiovascular stability.
- Minimize physical discomfort and pain.
- Control anxiety and minimize psychological trauma.
- Control movement to allow the safe and efficient completion of the procedure.
- Return the child to a state in which he or she is safe for discharge from medical supervision, as determined by recognized criteria.

It is notable that most of the literature describing various strategies for pediatric sedation focuses on the completion of the procedure rather than the entire spectrum of the goals just outlined. Anesthesia professionals are in a unique position to advocate for a more complete appreciation of the overall goals of sedation that should meet the high standards that have been set in the OR environment. To this end, a useful analysis of issues relating to overall "quality" of sedation is provided by a report from the Society for Pediatric Sedation in which sedation quality is placed in the context defined by the Institute of Medicine[72]: effectiveness, efficiency, family centeredness, timeliness, and equity (in addition to safety) when considering "quality" in the context of sedation.

The Concept of "Safety"

"Safety" in pediatric sedation is multidimensional. Although the adverse events related to the airway hold the greatest risk to cause immediate harm to the child, several additional risks should be considered.

A growing area of concern is the effect of drugs (used for sedation or anesthesia) on the developing brain and the possible association with neuroapoptosis and/or subsequent learning/behavioral deficiencies[73–79] (this topic is covered in detail in Chapter 25). The U.S. Food and Drug Administration (FDA) has been particularly concerned about this issue, warning in editorials in 2011 and again in 2015 of the uncertain effects of sedatives and anesthetics on the developing brain,[80,81] using solid evidence from newborn animals but very weak evidence from studies in humans (see Chapter 25). At face value, the newborn animals appeared to be disproportionately handicapped neurocognitively by even a brief exposure to anesthesia compared with the very mild and inconsistent evidence from humans, which is curious. Specific advisories on the use of anesthesia in young children have been vague and generally recommend that the use of anesthesia for procedures in the first three years after birth should be based on a balance of the known risks of delaying the procedure versus the uncertain risk of harm from anesthetics on the developing brain in humans. The FDA Advisory Committee Background Document to the Anesthetic and Life Support Drugs Advisory Committee (ALSDAC) from March 10, 2011, issued a caveat that exposure to anesthesia drugs should be precluded for purely elective procedures in children younger than 3 years of age.[82]

Practitioners who deliver sedation must balance the risks of inadequate versus excessive sedation. Adverse events related to *inadequate* sedation are more difficult to track than the immediate risk of oversedation; however. this issue should not be discounted–several studies have associated untreated procedural pain with long-term adverse behaviors in animals and children. Specifically, painful experiences in childhood have been linked to excessive pain responses and behaviors later in life.[83–85] In addition, a stressful anesthesia induction has been associated with greater maladaptive behaviors for up to 2 weeks after the experience.[86] The incidence of these behaviors decreases with the use of appropriate preoperative sedation. Similar sequelae have been reported after repeated invasive procedures in pediatric intensive care units (ICUs).[87] Taken together, these data suggest that "less sedation" is not a solution to the various potential adverse effects related to the delivery of sedation in children.

The risks and markers associated with adverse *over*sedation events have been the subject of multiple studies. In 2000, a retrospective review of 95 cases of sedation-related deaths and critical incidents derived from the FDA adverse drug event reporting system, the U.S. Pharmacopeia, and a survey of pediatric specialists[51] revealed that the overwhelming majority of critical events were preventable and caused by operator error or lack of robust rescue systems rather than by specific medications. Drug interactions were the most common causative factor, followed by drug overdose, inadequate monitoring, inadequate cardiopulmonary resuscitation skills, inadequate evaluation before sedation, and premature discharge from medical supervision. The report emphasizes that most sedation complications are related to adverse respiratory events (80%); a majority progressed to cardiac arrest, indicating a lack of rescue skills on the part of the practitioners. A disproportionately large number of severe complications and deaths occurred when sedation was performed in offices outside hospitals (29/60 deaths or neurologic injury occurred during dental procedures), pointing to inadequate rescue planning and training. There was no relationship with class of drug or route of administration, although there was a positive correlation with complications when three or more sedating medications (pointing to drug interactions) were administered.[52]

Another method for analyzing sedation safety is the review of cases performed in a single institution using a particular drug or technique. The literature on pediatric sedation includes a huge number of these studies reporting relatively small numbers of patients (N <200) receiving a variety of sedative medications in a number of settings. Almost all of these reports end with the conclusion that the described technique resulted in successful completion of the procedures and no fatalities.[88–100] Negative trial results are almost never published. Most studies are retrospective and describe different frequencies of transient airway obstruction or oxygen desaturation. In sum, these trials indicate that young age, increased ASA status, and certain procedures such as endoscopy and bronchoscopy have greater rates of adverse events. The sample size of some older studies limits their external validity to evaluate major adverse events or critical incidents, although more recent evidence is more heartening.[101] Accordingly, single-institution trials offer information on sedation techniques but infrequently provide as robust evidence on risk and outcomes as multi-centered, comprehensive studies and databases.[99,102–104]

Simulation may be used to test the abilities of practitioners to diagnose and treat low-frequency adverse effects that occur during pediatric sedation and the ability of systems to rescue patients.[105,106] In one of these studies, a simulated scenario of laryngospasm was programmed so that the physiologic variables either degraded with time after the event if inappropriate interventions were undertaken or improved with time if an effective intervention was performed. The event was videotaped in three different sedation locations. Hypoxia and hypotension lasted less than 90 seconds in the postanesthesia care unit but more than 360 seconds in the emergency department and radiology (CT scanner) settings.[107] Such studies demonstrate that analysis of simulated low-frequency adverse events can identify areas and practitioners within the hospital that need improvement in their rescue systems to improve patient safety.

The advent of the electronic medical record and improved data sharing has allowed the capture of data from the large numbers of pediatric sedation encounters that can lead to an enhanced understanding of the nature and frequency of adverse sedation events. The PRSC consists of a group of more than 30 institutions in North America that shares prospective data on pediatric sedation.[14] Analysis of the first 30,000 records identified demographics, procedures, sedation techniques, outcomes, and adverse events as follows:

1. There were no deaths and only one cardiac arrest was reported.
2. Unanticipated admission occurred infrequently, 1 per 1500 sedations.
3. Vomiting occurred in 1 per 200 sedations, including one aspiration.
4. Stridor, laryngospasm, wheezing, and apnea occurred in 1 per 400 procedures.
5. Airway or ventilatory manipulations were required in 1 per 100 sedations.[107]

Risk factors for adverse events included age younger than 3 months, ASA physical status 3 or greater, and multiple drug combinations for sedation. The PRSC has also reviewed the incidence of adverse events in 49,386 propofol sedation and/or anesthesia encounters for procedures outside of the OR.[15] Propofol was delivered by multiple providers (anesthesiologists, intensivists, emergency medicine physicians, pediatricians, and radiologists). No deaths were recorded. CPR was required in two children and aspiration occurred in four children. The most prominent type of adverse event was related to the airway and occurred in 1 of 65 sedations; 1 in 70 children required airway rescue. Desaturation

(< 90% for more than 30 seconds) occurred 154 times per 10,000 sedations/anesthetics; central apnea or obstruction occurred 575 times per 10,000 sedations, and unexpected admissions occurred 7 times per 10,000 sedations. When all possible adverse events were considered, anesthesiologists reported fewer events than other medical specialists, with an odds ratio of 1.38 (95% confidence interval [CI] 1.21-1.57, P < 0.001).[15] No difference among providers was noted when outcome analysis was limited to major complications. The authors concluded that propofol sedation and/or anesthesia when given in carefully constructed sedation services (i.e., following the AAP sedation guideline with well-trained providers) can result in effective sedation with an acceptable (low) incidence of severe adverse events. They emphasize that the safety of this practice is contingent on the ability to quickly and safely rescue patients from less serious events.

TRAINING AND SYSTEM ISSUES FOR PEDIATRIC PROCEDURAL SEDATION

Education is vital to maintain safety. An institution-wide ongoing educational program on sedation, emphasizing physician (and dentist) responsibility, nursing responsibility, guidelines, and the pharmacology of drugs, should be readily available to all individuals who care for sedated children. Teaching modules, videos, handouts, simulations, and hands-on supervision have been used to supplement such programs.[101] Most institutions have adopted a computerized teaching module that includes a review of hospital policy, equipment, personnel, pharmacology of drugs used, and rescue from deeper levels of sedation. A quiz must be successfully completed at the end of the computerized teaching module. The module is part of the orientation and hospital privileging procedure for each physician and nurse and must be successfully completed before they can administer sedation; the module must be reviewed and successfully completed every 2 years. Staff privileging requirements should include training in PALS or equivalent because this is now a requirement of the 2016 AAP sedation guideline. Further information on the nature of training required for sedation credentialing is sparse. One survey of institutions that provide sedation services for children reported that 51% provided a specific training packet for sedation, whereas 59% depended on sedation training during fellowship, and 49% documented a specific number of procedural sedation encounters.[108]

Specialty organizations are also becoming involved in training of sedation providers. The Society for Pediatric Sedation provides an extensive "primer" on pediatric sedation on its website (http://www.pedsedation.org). This organization also provides a credentialing course for pediatric sedation that uses a test of knowledge based on its written materials (see previous discussion) and the completion of a full-day "Sedation Provider Course," which includes lectures, interactive sessions, and human patient simulation sessions (developed from data relating to pediatric sedation adverse events) to teach and test core competencies. Hands-on simulation-based courses such as this have been shown to improve provider confidence and perceived ability to care for pediatric procedural sedation patients.[109]

Education should also emphasize the limits of sedation and appropriate referral to an anesthesiologist. Of particular concern is upper airway obstruction that would likely become worse with the administration of sedatives (see Table 48.6).[51] Tonsil and adenoid hypertrophy is common in children aged 2 to 12 years and is associated with loud snoring or OSA. OSA occurs in 1% to 3% of all children, in up to 12% of adolescents, is 3-fold more frequent in African American children, and 5-fold more frequent in obese children.[110] Parents often report that their child snores loudly and then "stops breathing." These children are at increased risk for airway obstruction and should be referred to an airway specialist (anesthesiologist, pediatric intensivist, pediatric emergency medicine specialist) if sedation is required for their procedures. They may also require postsedation overnight admission and monitoring (see also Chapters 4 and 33).[63,111–113] Children with developmental disabilities should raise concern for sedation because they are at increased risk for airway obstruction during sedation and anesthesia.[114] Problems for which consultation with an anesthesiologist or other expert is suggested are listed in Table 48.6.

The importance of nursing in the provision of safe and effective sedation for children cannot be overemphasized. Nurses are the "front line" in sedation safety and frequently are the part of the sedation team that identifies variation in policy compliance. Their support and education is mandatory. In addition, state nursing restrictions on nurses administering certain drugs (such as propofol and ketamine) must be taken into consideration.

Quality improvement is a critical piece of ensuring optimal training and sedation system functioning. Compliance can be monitored by the medical and dental staff office, the department of nursing, as well as a committee charged with the responsibility of continuing quality improvement. Nursing and medical staff offices should monitor compliance with educational certification for appropriate credentialing. It is the responsibility of the department chairperson and nursing supervisors to ensure individual staff compliance. Finally, variance reports should be generated when sedation policy is not followed or when a critical incident occurs. The appropriate institutional committee reviews each incident and informs the sedation committee. The committee should seek system problems and fixes for organizational issues that contribute to care failure. (e.g., inadequate presedation assessment, inadequate monitoring leading to delay in problem recognition, or inadequate recovery procedures). Tracking common problems, such as the need for bag-mask ventilation, apnea, unplanned hospital admissions, or unsatisfactory sedation, can provide direction for developing changes in policy that will prevent more severe but much less frequent events from occurring (Fig. 48.6). This type of critical incident analysis allows recommendations to be made for future adverse event prevention.[115–117]

DOCUMENTATION

A single documentation interface that is used wherever sedation is delivered within an institution will allow for uniformity of care and compliance with sedation policy. The sedation interface should be organized such that the practitioners have a practical guide to the sedation policy. The very act of following and completing the sedation record will ensure compliance with hospital policy (E-Fig. 48.1). The near-universal application of electronic medical records now allows demographic, allergy, and comorbidity data to be gathered from other areas of the electronic medical record and automatically adds vital signs before and during the intervention (Video 48.5). Appropriate electronic record documentation for sedation includes various dropdown menus, which allow the practitioner to access rating scale information and automatically enter vital signs (Video 48.5).

To be in line with standard guidelines on sedation, documentation surrounding sedation should include all of the following:

- *Presedation responsibilities.* During this time, the responsibilities of the registered nurse include evaluation of the child to include learning assessment, NPO (nothing by mouth) status, allergies, current medications, and review of medical problems. The licensed independent practitioner verifies this information with

OPS: OBJECTIVE PAIN SCALE - Operational Definitions - For a score ≥ 6, patient receives a narcotic analgesic

BEHAVIOR		SCORE	DEFINITION
Blood Pressure (Systolic)	= 10% preop	0	
	>10 - 20% preop	1	
	>20% preop	2	
Crying	Not crying	0	Awake and not crying or asleep.
	Crying but responds to TLC	1	Crying is controlled by being touched, reassured or held by nurse/parent.
	Crying does not respond to TLC	2	Crying uncontrollably. Measures to comfort child are unsuccessful.
Movement	None	0	Asleep or if patient is awake, lying or playing quietly.
	Restless	1	Child unable to sit or lie still. Frequent position changes. No threat of self harm.
	Thrashing	2	Child kicking and/or squirming. Potential for self harm. Has to be protected or restrained for safety.
Agitation	Asleep or calm	0	Asleep or awake and calm.
	Mild	1	Tense, voice quivering. Responds rationally to questions and/or responds to attempt to console.
	Hysterical	2	Does not appear rational, eyes wide. May be clinging to nurse/parent. Does not respond to attempts to console.
Verbal Evaluation or Body Language			
Asleep or states no pain (Preverbal child-No special posture)		0	
Mild pain or cannot localize (Preverbal child-Flexing extremities)		1	Complains of general feeling of discomfort, but unable to describe location of pain or states pain is mild in nature. Legs drawn up. Arms may be folded across body.
Moderate pain and can localize (Preverbal child-Holding location of pain)		2	Complains of pain that is bothersome and is able to point to or describe location of pain. Holding, guarding, or touching location of pain. Infants with legs drawn up, fists clenched.

WONG-BAKER FACES PAIN RATING SCALE
(recommended for persons age 3 years and older)

NUMERIC PAIN RATING SCALE:
(for older children and adolescents)

Explain to the person that each face is for a person who feels happy because he has no pain (hurt) or sad because he has some or a lot of pain.

Face 0 is very happy because he doesn't hurt at all.
Face 2 hurts just a little bit.
Face 4 hurts a little more.
Face 6 hurts even more.
Face 8 hurts a whole lot.
Face 10 hurts worst.

Ask the person to choose the face that best describes how he is feeling.

PAIN CHARACTER:
S = Sharp
T = Throbbing
D = Dull

FREQUENCY:
C - Constant
I - Intermittent
O - Occasional

INTERVENTIONS:
PCA = Pump
POS = Position change
COM = Comfort Measure
MED = Medication

TREATMENT OUTCOMES:
N = No Relief
MI = Minimal Relief (Relief for < 1hr)
MO = Moderate Relief (Relief for 1-2 hrs)
MA = Maximum Relief (Relief for 3-4 hrs)

INPATIENT / OUTPATIENT MODERATE SEDATION FLOWSHEET INSTRUCTIONS

- The department performing the procedure initiates the Sedation Flowsheet.
- All required sections must be completed, including the signature, title and initials of those who provide documentation.
  NPO guidelines: If NPO guidelines cannot be met, the benefit of proceeding must be weighed against the risk of harm.
- The LIP must reassess the patient immediately prior to the administration of the sedation medications.
- All entries for medications and assessments must be timed and initialed with signature/title/initials written in the appropriate boxes below the "Medication" and "Assessment" sections.
- **Medication orders for Inpatients** are written on an inpatient order sheet, transcribed onto the MAR and sent to the Pharmacy.
- **Medication orders for Outpatient & EMTC patients** are written on the Sedation Flowsheet.
- **Narcotic Medication orders:** LIP must write order per hospital policy. Before administration 2 RN's or an RN/LIP must separately verify patient weight, calculate dose in writing, and document amount/administration volume.
- **Presedation Procedural Pause: Verify informed consent, ASA-PS classification, assessment & reassessment has been completed prior to the administration of the sedating agent(s).**
- The patient must receive continuous heart rate and SaO_2 monitoring until recovered and returned to pre-sedation level. Continuous respiratory rate and cardiac monitoring is required if deep sedation occurs.
- Each assessment box must be completed at the appropriate timed intervals *(see table below).*
- PCT's and Technicians may obtain and document vital signs per RN direction.
- The timed interval assessments *(see table below)* will continue until the patient is fully recovered from the sedation medication and has returned to the pre-sedation level.
- Assessments that cannot be obtained due to a need for the patient to remain undisturbed during the procedure will be documented as such *(see "N" in the item keys).*
- **IF THE PATIENT ASSESSMENT INDICATES THAT DEEP SEDATION HAS OCCURRED, THE FOLLOWING MUST BE DONE:**

One care provider must remain at bedside to continuously monitor patient as their sole responsibility. Appropriate interventions will be provided as needed (e.g., position airway, Administer oxygen if needed, etc.).
Patient assessments must be performed and documented Q 5 minutes until patient transitions to the moderate sedation level, at which time the assessments may return to Q 15 minutes (see also table below).

SEDATION LEVEL	CHARACTERISTICS OF THE DRUG-INDUCED SEDATION LEVEL	REQUIRED CONTINUOUS MONITORING	REQUIRED FREQUENCY OF FULL ASSESSMENT
Minimal (Anxiolysis)	• State when pain & anxiety is diminished / eliminated • Cognitive function and coordination may be impaired • Ventilatory and cardiovascular functions unaffected • No significant risk of losing protective reflexes	Patients who are not undergoing a diagnostic or therapeutic procedure & are receiving narcotics, sedatives or other medications that place them at risk for cardio/respiratory depression will be placed on cardiac/resp and/or pulse ox monitor	(see CH PC#: TM:#: "Cardiac/Respiratory and Pulse Oximetry Monitoring on Acute Care Units)
Moderate (Conscious) Chloral Hydrate > or equal to 50 mg/kg is considered moderate sedation	• Depression of consciousness • Responds purposefully to verbal commands, either alone or accompanied by light tactile stimulation • Able to maintain patient airway without interventions • Spontaneous ventilation is adequate • Cardiovascular function is usually maintained	Heart rate, SaO_2 and ventilation monitored via direct visualization or capnography; Needs cardiac monitor if significant cardiovascular disease or when dysrhythmia anticipated or detected	**ASA I & II:** Q 15 minutes *(or more frequently if indicated)* until returned to pre-sedation level **ASA III, IV:** Q 5 minutes until returned to pre-sedation level
Deep	• Depression of consciousness • Patient cannot be easily aroused • Responds only to repeated painful stimuli • May require assistance in maintaining patient airway • Spontaneous ventilation may be inadequate • Cardiovascular function is usually maintained	H R, RR, SaO_2 & Vent. Monitored via direct visualization or capnography; Cardiac Monitor if significant CV disease or when dysrhythmia anticipated or detected. Deep sedation is performed in cardiac cath, upper endoscopy, bronchoscopy, & anesthesia sed. service.	Q 5 minutes until returned to moderate sedation level
Anesthesia	• Loss of consciousness • Not arousable, even by painful stimulation • Often require assistance in maintaining patient airway • Often has impaired ability to independently maintain ventilatory function due to depression of spontaneous ventilation or neuromuscular function • May require positive pressure ventilation • Cardiovascular function may be impaired	Page anesthesia. (pager 6001)	As per anesthesia protocols.

- The patient must meet ALL "Discharge from Sedation Criteria" before monitoring/vital sign assessments cease.
- At the discretion of the LIP/RN, the sedated patient may be transferred to a patient care area within the Hospital. Appropriate monitoring and assessment will continue during and after transport until "Discharge from Sedation Criteria" is met ***The RN or Physician will continue appropriate monitoring & assessment during the transfer process.***
- The nurse/physician discharging the patient from sedation must sign the discharge section.
- The parent/legal guardian must sign the discharge section to indicate that instructions were received and understood.

18407 (Rev. 11/04)

E-FIGURE 48.1, cont'd

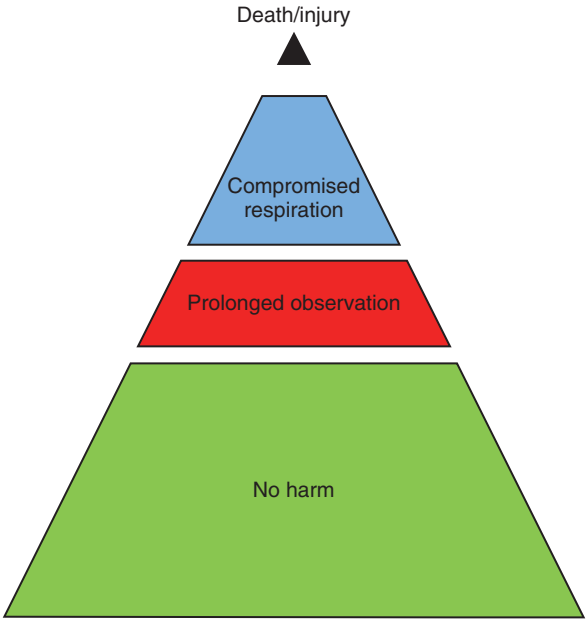

FIGURE 48.6 The sedation accident pyramid. The majority of adverse sedation events result in no harm. A smaller number result in no harm but require prolonged observation. An even smaller number result in the need for some intervention, usually related to respiration (repositioning the head, a jaw thrust, bag or mask respirations, or intubation). A very small number result in injury or death because the sentinel event was missed or inadequately treated. The latter cases are the types that occasionally are reported in newspapers, but in general go unreported. The reported cases likely represent just the tip of the pyramid in terms of events that could have indicated a developing problem.

emphasis on assessing the airway. A sedation plan is identified and informed consent is obtained. The licensed independent practitioner assigns an ASA physical status and reassesses the child immediately before the procedure.

- *Presedation pause.* A time out should be performed immediately before sedation medications are given. The time out includes a process of verbal confirmation of the patient and procedure identification, verification of informed consent, as well as ASA physical status and confirmation of the procedure and site of the procedure. No medications are administered without completion of the time out. One advantage of the electronic form is that it forces the licensed independent practitioner to verify time out before it allows further access to the rest of the sedation flow sheet.
- *During sedation.* The time-based flow sheet identifies the type of stimulation needed to elicit a response, as well as which monitors should be used and how frequently the vital signs should be recorded for both moderate and deep sedation. Table 48.7 summarizes monitoring, documentation, personnel, and equipment during sedation.
- *Postsedation.* The criteria for discharge from the sedation area, pain score, and disposition of the child, as well as discharge teaching, are specified. This includes documentation and signature by the licensed independent practitioner and nurse. Space is given for additional documentation and medications given.

Most importantly, both the paper and electronic form have critical parts of the sedation policy for immediate bedside review. This includes pain assessment scales, NPO guideline variations, reassessment by the licensed independent practitioner before sedation, and the opioid medication order verification. A table that defines the levels of sedation, required monitors, and frequency of monitoring is also present. This, in addition to the online availability of the hospital policy, ensures that sedation practitioners have all information available to be in compliance to safely and successfully sedate children.

Sedation services, however they are configured, may find it helpful to create information sheets on presedation assessment, telephone interviews, and postsedation follow-up. An example of a radiology-nursing database that consists of presedation telephone information, presedation instructions, NPO guidelines, health history, and postexamination telephone call information is shown in E-Figs. 48.2 and 48.3. Samples of presedation and postsedation instruction sheets for pediatric dentistry are shown in E-Figs. 48.4 and 48.5, respectively. These forms are available in Spanish and are explained via interpreters if necessary.

Specific Sedation Techniques

A *sedation treatment plan* that addresses the requirements for analgesics, anxiolytics, or both is necessary for each child, according to the procedure being performed and the anxiety of the child and family. Psychological techniques to allay anxiety and distract children's attention from the procedural environment (computer [e.g., iPad] games/movies, cuddling, parental support, child-life specialists, warm blankets, a gentle reassuring voice, and hypnosis) are extraordinarily useful adjuncts to the sedation plan.[6–10] At times, distraction alone can suffice to produce conditions amenable to accomplishing a simple nonpainful procedure.

Many of the drugs used for sedation and analgesia in children are not approved by the FDA for use in children under certain ages (e.g., fentanyl <2 years; morphine <12 years, bupivacaine <12 years, propofol <2 months, and dexmedetomidine <18 years of age). Although midazolam is approved even in preterm infants, the reversal agent flumazenil is *not* approved in children younger than 1 year of age. The lack of "approval" by the FDA does not imply that a drug can/should not be used; rather, it only means that the manufacturer never carried out the appropriate studies to gain FDA approval.[26,118–121] A number of legislative changes are intended to improve drug research in children and improve drug labeling; however, some of the drugs are no longer under patent protection, and there is no motivation for drug companies to study their use in children.[122–124]

It is important to review the child's presedation medications. It is particularly important to note any chronic opioid or benzodiazepine medications that the child may be taking. Tolerance to either of these medication classes can significantly increase the required dose of sedative medications to achieve the desired depth of sedation. On the other hand, protease inhibitors (e.g., nelfinavir, ritonavir, saquinavir) are potent inhibitors of the cytochrome P450 CYP3A metabolic pathway. This pathway is responsible the metabolism of many sedatives, including midazolam, and may markedly prolong duration of action and may lead to life-threatening respiratory depression. Erythromycin and some calcium channel blockers may also inhibit the cytochrome system and delay metabolism of midazolam.[125–127]

Sedation medications can have significant interactions with other classes of drugs. Dexmedetomidine should not be combined with digoxin (or other atrioventricular node conduction blockers) in infants because severe bradycardia may result.[128] Although not always appreciated as the source of potent interactions, herbal

DIAGNOSTIC IMAGING & RADIOLOGY

DISCHARGE TEACHING INFORMATION SHEET

The following medications were given to your child for sedation:

Chloral Hydrate_____ **Benadryl_____** **Nembutal_____**

Versed_____ **Fentanyl_____** **Propofol by Anesthesia MD_____**

Please review the following instructions with your nurse prior to discharge:

1) Your child will need assistance to walk, sit or crawl until the medication is worn off. Please hold onto your child's hand or carry your child at all times until the medication is worn off.

2) DO NOT allow your child to walk, sit, or crawl alone until your child is steady. Limit activity for the remainder of the day. Encourage quiet play. No toys with wheels, no swimming, no playing outside for the remainder of the day.

3) Please keep your child away from unsafe objects or areas of your home such as stairs, furniture, corners, bath tubs.

4) Increase your child's diet slowly from clear liquids to semi-solids to solids.

5) Do not feed unless child is fully awake.

6) If your child falls asleep on the way home be sure to position your child's head tilted back or to the side while sitting up in the car. Do not allow your child's head to fall forward while sleeping. If your child feels sick to his stomach at any time, place him on his side.

CONTACT CHILDREN'S HOSPITAL IF ANY OF THE FOLLOWING OCCUR:

difficulty swallowing **dizziness** **excessive vomiting**

Radiology Nurses are available from 7 am to 7 pm at 000-000-0000
After 7 pm you may call 000-000-0000 for assistance.

Thank you for choosing Children's National Medical Center. Please expect a follow-up call from our Nursing Staff during the next business day.

DEPARTMENT OF PEDIATRIC DENTISTRY

PREOPERATIVE INSTRUCTIONS FOR DENTAL TREATMENT UNDER SEDATION

1. WHAT IS SEDATION?

Your child needs to receive a mild sedative prior to receiving dental treatment. This sedative is given as a liquid by mouth or as a suppository one-half to one hour prior to the scheduled dental appointment.

2. HISTORY AND PHYSICAL EXAM

Your child needs a complete physical examination within one month of the sedation appointment. The examination is performed by your primary care physician, who must fill out completely the Short Hospital Admission Form that we give you. You are responsible for bringing to us the completed Short Hospital Admission Form. WITHOUT THE COMPLETED FORM, THE SEDATION APPOINTMENT WILL BE CANCELED.

3. NO SOLID FOOD BY MOUTH AFTER MIDNIGHT BEFORE THE SURGERY

Your child may drink clear liquids (apple juice, water, Kool-aid™) until 4 hours before the procedure.

4. IF YOUR CHILD BECOMES ILL

If your child has any signs of a cold, such as a runny nose, cough or congestion, please call the clinic at 000-000-0000. Please also call us if your child is exposed to any communicable disease such as measles, mumps or chicken pox within 3 weeks of the sedation appointment.

5. AFTER THE SEDATION APPOINTMENT

After the sedation appointment, please expect your child to be drowsy and require support. Someone should be available to drive the patient home. Plan on limited activity. You will need to give your child water, clear fluids and soft foods until he/she is able to tolerate a normal diet.

6. PLEASE ARRIVE AT THE DENTAL CLINIC PROMPTLY AT_____ ON _____, _____.

You must plan on remaining in the Dental Clinic during your child's entire dental appointment.

E-FIGURE 48.4 Sample preoperative instructions for parents or guardians of patients who will receive dental treatment under sedation. (Courtesy Children's National Medical Center, Washington, D.C.)

POSTOPERATIVE INSTRUCTIONS FOLLOWING DENTAL TREATMENT UNDER SEDATION

1. OBSERVATION

Carefully observe your child until all sedative effects have disappeared. Watch your child closely for signs of breathing difficulty.

2. DIET

You may give your child small amounts of water and clear fluids (broths, soda or juices), or soft foods (Jell-O, sherbet) until he/she appears hungry and able to tolerate his/her regular diet. Remember that your child's lip and tongue will be numb—wait for the numbness to wear off before allowing your child to eat.

3. ACTIVITY

Your child should remain fairly quiet and rest for the remainder of today. Avoid any strenuous activity. He/she may resume regular activities tomorrow.

4. MEDICATION

Pain medication is usually not necessary but Tylenol may be given for minor discomfort.

5. CALL THE DENTAL CLINIC AT 000-000-0000 IF:

a. temperature over 101 degrees
b. persistent vomiting
c. persistent drowsiness or dizziness
d. difficulty with breathing
e. unusual bleeding
f. any other concern

YOUR CHILD'S FOLLOW-UP APPOINTMENT IS AT_____ ON_____

E-FIGURE 48.5 Sample postoperative instructions after dental treatment under sedation for parents or guardians of treated children. (Courtesy Children's National Medical Center, Washington, D.C.)

TABLE 48.7 Recommended Intensity of Monitoring, Documentation, Personnel, and Equipment for Different Levels of Sedation[316]

	Moderate Sedation	Deep Sedation
Monitoring	Pulse oximetry ECG recommended Heart rate Blood pressure Respiration Capnography recommended	Pulse oximetry ECG required Heart rate Blood pressure Respiration Capnography required
Documentation	Name, route, site, time of administration, and dosage of all drugs administered. Continuous oxygen saturation, heart rate, and ventilation (capnography recommended). Parameters recorded q10 minutes	Name, route, site, time of administration, and dosage of all drugs administered. Continuous oxygen saturation, heart rate, and ventilation (capnography required). Parameters recorded at least q5 minutes
Personnel	An observer who will monitor the patient but who may also assist with interruptible tasks—trained in pediatric advanced life support (PALS)	An independent observer whose only responsibility is to continuously monitor the patient—trained in PALS and capable of assisting with any emergency event
Responsible practitioner	Skilled to rescue a child with apnea, laryngospasm, and/or airway obstruction including the ability to open the airway, suction secretions, provide continuous positive airway pressure (CPAP), perform successful bag-valve-mask ventilation. Recommended that at least one practitioner should be skilled in obtaining vascular access in children.	Skilled to rescue a child with apnea, laryngospasm, and/or airway obstruction including the ability to open the airway, suction secretions, provide CPAP, perform successful bag-valve-mask ventilation, tracheal intubation, and cardiopulmonary resuscitation; training in PALS required. At least one practitioner skilled in obtaining vascular access in children immediately available.
Equipment	Pulse oximeter, blood pressure device, stethoscope, capnometer Rescue cart and equipment immediately available properly stocked with rescue drugs and age- and size-appropriate equipment required	Pulse oximeter, blood pressure device, stethoscope, ECG monitor, capnometer Rescue cart and equipment immediately available properly stocked with rescue drugs and age- and size-appropriate equipment required
Other Equipment	Suction equipment Adequate oxygen source/supply	Suction equipment Adequate oxygen source/supply Defibrillator required
Emergency checklists	Recommended	Recommended
Dedicated recovery area: With a rescue cart properly stocked with rescue drugs and age- and size-appropriate equipment with dedicated recovery personnel and adequate oxygen supply	Recommended. Initial recording of vital signs may be needed at least every 10 minutes until the child begins to awaken, then recording intervals may be increased.	Recommended. Initial recording of vital signs may be needed at least 5-minute intervals until the child begins to awaken, then recording intervals may be increased to 10-15 minutes.

medicines can enhance or shorten sedative medication activity.[129–133] Herbal medicines (e.g., St. John's wort or echinacea) may alter drug metabolism through inhibition of the cytochrome P450 system, resulting in prolonged drug effect and altered (increased or decreased) blood drug concentrations. Kava may augment the effects of sedatives, and valerian may itself produce sedation (see also E-Table 4.4).[134]

Several drug classes need to be considered when formulating a plan for procedural sedation. The needs of the procedure and the child will affect the exact choice of drugs in each case. Paramount among the considerations is the issue of whether or not the procedure is accompanied by significant pain. If it is painful (bone marrow biopsy, central line placement), some form of analgesia (with local anesthetics or a systemic drug that offers analgesia) is indicated to achieve all of the goals for the procedural sedation. If the procedure strictly requires sedation and motion control (MRI scans, CT scans), a pure sedative approach is often sufficient and preferable.

LOCAL ANESTHETICS

Local anesthetics play a critical role in analgesia for painful procedures and greatly reduce requirements for systemic opioids. Unlike most drugs used in medicine, local anesthetics must be physically deposited at their site of action to produce their effect. For most blocks and local skin infiltration, epinephrine (1 : 200,000 [5 µg/mL]) is used as a vasoconstrictor to increase the duration of blockade, decrease bleeding, and reduce systemic toxicity by decreasing vascular uptake. *Historically, the combination of local anesthetics and epinephrine has NOT been advised for digits or the penis. Today the combination is considered safe as long as the concentration of epinephrine is ≤1/200,000.*[135–137] Local anesthetics should be prepared only in labeled syringes immediately before use. No more than the maximum allowable dose (mg/kg) should be prepared in the syringe to minimize the risk of an accidental overdose (see Table 42.2). Local anesthetics can be extremely useful in obtunding airway reflexes when sprayed in the oropharynx or glottis before bronchoscopy or gastrointestinal endoscopy.

Local anesthetics can be administered in the sedated child by subcutaneous (SC) infiltration, field blocks, ultrasound guided nerve blocks, and IV regional anesthesia. A discussion of these topics and treatment of local anesthetic use and toxicity is found in Chapters 42, 43, and 44. Topical administration of local anesthetics is useful for planned sedation patients. EMLA cream is a eutectic mixture of local anesthetics (lidocaine 2.5% and prilocaine 2.5%) (AstraZeneca Pharmaceuticals LP, Wilmington, DE). When placed on the skin for 40 to 60 minutes,[138,139] it is useful for reducing the pain of skin incision, IV cannula insertions, lumbar punctures, and circumcision.[140–142] EMLA must be used with some caution as absorption of excessive amounts of prilocaine can cause methemoglobinemia if applied in inappropriate doses or on mucosal surfaces.[29] That is, for children weighing <10 kg, apply to a maximum of approximately 100 cm^2 surface area; for those 10–20 kg, apply to a maximum of approximately 600 cm^2 surface area; and for those >20 kg, apply to a maximum of approximately 2000 cm^2 surface area. EMLA cream can cause blanching of the skin and local vasoconstriction, which can make IV access difficult.

Other topical anesthetics include ELA-Max and LMX4 (Ferndale Healthcare, Ferndale, MI); these are 4% liposomal lidocaine preparations with onset within 30 minutes. Penetration is slightly deeper than EMLA cream.[143] The S-Caine Patch (ZARS, Inc., Salt Lake City, UT) is a eutectic mixture of 70 mg of lidocaine and 70 mg tetracaine in a bioadhesive layer that contains a heating element. A 20-minute application is effective in lessening pain from venipuncture procedures.[144] Amethocaine (Ametop) is a topical cream of 4% tetracaine (40 mg tetracaine base per gram of gel) that anesthetizes the skin in 20 to 30 minutes without causing vasoconstriction or other sequelae. It is available internationally in the United Kingdom, Canada, Australia, as well as in several other countries (from Smith & Nephew Canada, Mississauga, Ontario). A systematic review of amethocaine versus EMLA cream yielded a weak endorsement of amethocaine over EMLA cream for first-time IV cannulation.[145]

ANXIOLYTICS AND SEDATIVES

Chloral hydrate has historically been a widely used sedative. It is currently not commercially available in the United States but continues to be used internationally and in some U.S. hospitals where it is compounded (Table 48.8).[146–149] Its most common use is as a sedative to facilitate nonpainful diagnostic procedures, such as EEG, CT, or MRI.[148] It is rapidly and completely absorbed when given orally. Rectal administration is erratically absorbed and therefore not recommended. The onset of sedation is 30 to 60 minutes, and the usual clinical duration is 1 hour. Although it has a long history of successful use, it can cause respiratory depression and airway obstruction. Deaths have been associated with its use as a sole sedative agent and when combined with other sedatives; particularly problematic were situations where the drug was administered in an unmonitored setting (such as a car seat).[51,113,150–153] One large series showed a 0.6% incidence of respiratory depression, especially at larger doses (75–100 mg/kg).[154] Chloral hydrate acts primarily through its active metabolite trichloroethanol, which is formed in the liver and erythrocytes.[155] Trichloroethanol has a half-life of 10 hours in toddlers, 18 hours in term infants, and 40 hours in preterm infants (see Fig. 48.3).[156] Agitation and restlessness more than 6 hours in one-third of children sedated with chloral hydrate has been reported, 5% of whom did not return to baseline activity for 2 days after the procedure![58,157]

Benzodiazepines are commonly used in pediatric sedation. They are anxiolytic, amnestic, sedative hypnotics with anticonvulsant activities. Their high lipid solubility at physiologic pH accounts for the rapid CNS effects. As opposed to diazepam, midazolam is delivered in a water-soluble form (pH 3.5), which markedly decreases the incidence of pain on injection and thrombophlebitis.[155] However, the resulting decrease in fat solubility delays transport into the CNS (peak EEG effect 4.8 minutes for midazolam vs. 1.6 minutes for diazepam; Fig. 48.7).[158,159] Benzodiazepines exert their effects by occupying the benzodiazepine receptor that modulates γ-aminobutyric acid (GABA), the major inhibitory neurotransmitter in the brain. The clearance of benzodiazepines is decreased in neonates and also by liver enzyme inhibition that occurs during concomitant use of erythromycin, cimetidine, or protease inhibitors.[126]

When administered at the recommended doses, benzodiazepine-sedated patients become compliant but do not lose consciousness (minimal to moderate sedation). This level of sedation has limited application for achieving ideal procedural conditions for most interventions. Benzodiazepines provide no analgesia; analgesic medications must be added for painful procedures. On the other hand, benzodiazepines have the advantage of providing potent anterograde amnesia that correlates with the onset of slurred speech.[160,161] Midazolam is the preferred drug for pediatric sedation

TABLE 48.8 Sedation Regimens for Children

Drug Regimen	Dose/Route	Onset (minutes)	Duration (minutes)	Comments
Pentobarbital	4–6 mg/kg IV or PO	IV: 2–5 PO: 20–60	IV: 15–45 PO: 60–240	Long history of safety. Slow onset. Prolonged emergence. May have paradoxical excitement. Half-life increased by valproic acid and MAO inhibitors. Contraindicated in porphyria.
Midazolam	0.25–0.75 mg/kg PO 0.05 mg/kg IV 0.2 mg/kg intranasal 0.1–0.15 mg/kg IM	15–30 1–3 10–15 10–15	60–90 60–90 45–60	Paradoxical response infrequent. Intranasal route very irritating. Increased respiratory depression when used with opioids; reduce midazolam dose by 25%. Prolonged duration with protease inhibitors. Antagonist: flumazenil.
Chloral hydrate	50–100 mg/kg PO (maximum not to exceed 2 g)	30–60	60–120	Very popular for nonpainful radiologic procedures in small children when IV not available. Effects unreliable over 1–2 years of age. Prolonged sedation and paradoxical responses noted. Respiratory depression and obstruction reported with tonsil hypertrophy and anatomic abnormalities. Moderate sedation guidelines required. Markedly prolonged half-life in neonates. Contraindicated in porphyria.

TABLE 48.8 Sedation Regimens for Children—cont'd

Drug Regimen	Dose/Route	Onset (minutes)	Duration (minutes)	Comments
Etomidate	0.1–0.4 mg/kg IV	<1	5–15	No analgesic effect. Larger doses cause general anesthesia, respiratory depression, and loss of airway. Stable cardiovascular profile. Few data in children. Must be credentialed for deep sedation/anesthesia. No reversal drug. Causes adrenal suppression ~12 hours.
Methohexital	0.25–0.50 mg/kg IV 20–25 mg/kg rectal 10 mg/kg IM	<1 10–15 10–15	10–20 30–60 30–60	Avoid if temporal lobe epilepsy or porphyria. IV doses quickly lead to general anesthesia. Rectal doses cause high frequency of apnea and should be avoided. Deep sedation/anesthesia credentialing. Contraindicated in children <3 months of age, psychosis, stimulation of oropharynx, increased intracranial pressure, head injury, glaucoma.
Dexmedetomidine	IV: 1–2 µg/kg bolus (over 10 minutes) Infusion: 1–2 µg/kg per hour	10	Clinical 30 minutes to 1 hour; half-life 1.5–3 hours	Mimics natural sleep. Rapid bolus may cause hypertension. Minimal respiratory depression. Dose-dependent hypotension and bradycardia. Use with caution with digitalis medications. Glycopyrrolate treatment of bradycardia may induce sustained hypertension of unknown mechanism.
Fentanyl with propofol	Fentanyl 1–2 µg/kg IV with propofol 50–150 mg/kg per minute infusion IV	1–2	30–60	Child may rapidly become anesthetized with loss of airway. Advanced airway management skills required, with appropriate credentialing.
Midazolam with fentanyl	Midazolam 0.02 mg/kg IV with fentanyl 1–2 µg/kg IV	2–3	45–60	Commonly used for painful procedures. Careful titration needed to avoid deep sedation/anesthesia with apnea and hypoxia. Reduce dose of fentanyl when combined with benzodiazepine. Reduce dose with protease inhibitors.
Ketamine	3–4 mg/kg IM 1–2 mg/kg IV 4–6 mg/kg PO	5 1 10–20	30–60 30–60 30–90	Nausea and vomiting common after procedure. Laryngospasm, apnea, agitation, hallucinations reported but uncommon. Midazolam may not prevent emergence delirium. Anticholinergic may be used to control secretions. Larger doses can produce state of general anesthesia. Usually causes tachycardia, hypertension, and bronchodilatation. Paradoxical hypotension in critically ill patients. No antagonist available. Advanced airway management skills required, with appropriate credentialing.
Propofol	Bolus 1–2 mg/kg Infusion 50–250 µg/kg per minute	30 seconds	5–15 minutes after discontinuation	Profound, dose-related respiratory depressant. Assume deep sedation/anesthesia when using in children. Infusions >5 hours may cause propofol infusion syndrome. Caution when used in mitochondrial myopathies. Pain on injection mitigated by IV lidocaine. Advanced airway management skills required, with appropriate credentialing.
Remifentanil	0.1–0.25 µg/kg per minute	1	10–15	Difficulty in titration frequently leads to apnea and general anesthesia. Few studies in children. Exclusively used by anesthesiologists.
Nitrous oxide	50% in 50% oxygen for "minimal sedation"; up to 70% used by some for moderate sedation	<5	On discontinuing	Requires specialized equipment for delivery, monitoring, and scavenging. Use alone (50% in oxygen or less) or with local anesthesia is considered "minimal sedation." Greater doses or addition of other sedatives/analgesics require a minimum of "moderate sedation" guidelines. Contraindications include respiratory failure, altered mental status, otitis media, bowel obstruction, and pneumothorax. No antagonist available.
Opioid antagonist: naloxone	0.01–0.1 mg/kg IV or IM Max 2 mg/dose May repeat every 2 minutes	1–2	IV: 20–40 IM: 60–90	Specifically antagonizes opioid effects. Should not be used for routine reversal of opioid effect. Adverse reactions: nausea, vomiting, tachycardia, hypertension, delirium, pulmonary edema. Reversal after long-term opioid use may lead to acute withdrawal. Children may renarcotize 1 hr after IV dosing.
Benzodiazepine antagonist: flumazenil	IV 0.01–0.02 mg/kg. May repeat every 1 minute to 1 mg	1–2	30–60	Specific benzodiazepine antagonist. Does not antagonize opioids or other sedatives. Resedation may occur in 1 hour. Prolonged observation (2 hours) required. Not for routine sedation reversal. Children using benzodiazepine to control seizures or drug dependency may have exacerbations with flumazenil.

IM, intramuscularly; *IV*, intravenously; *MAO*, monoamine oxidase; *PO*, by mouth.

Data modified from Cravero JP, Burke GT. A review of pediatric sedation. *Anesth Analg.* 2004;99(5):1355–1364; Krauss B, Green SM. Procedural sedation and analgesia in children. *Lancet* 2006;367(9512):766–780; and Coté CJ, Stafford MA. *The Principles of Pediatric Sedation*. Boston: Tufts University School of Medicine; 1998.

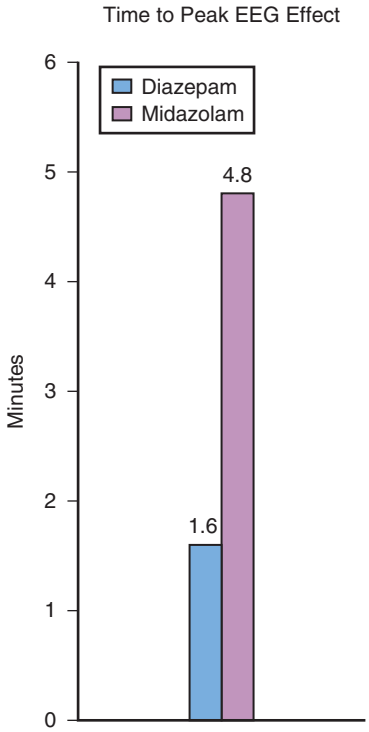

FIGURE 48.7 Time to peak electroencephalographic (*EEG*) effect of diazepam versus midazolam in adults. Note that it takes nearly three times longer to achieve a peak EEG effect after intravenous (IV) midazolam than after IV diazepam. This is likely caused by the difference in fat solubility; because midazolam is less fat-soluble than diazepam, midazolam does not cross biologic membranes as easily. The clinical importance of this observation is the need to wait 3 to 5 minutes between IV doses of midazolam to avoid stacking of doses and excessive drug effect. (Data from Bührer M, Maitre PO, Crevoisier C, Stanski DR. Electroencephalographic effects of benzodiazepines: II. Pharmacodynamic modeling of the electroencephalographic effects of midazolam and diazepam. *Clin Pharmacol Ther.* 1990;48(5):555–567.)

because of its brief and more consistent half-life compared with diazepam.[162–167] The time to peak effect after IV administration of midazolam is 2 to 4 minutes, with a duration of 45 to 60 minutes. Midazolam can be given IV, intranasally (IN), sublingually, orally, or rectally (see Table 48.8). Nasal administration is well documented and can be very effective; however, it causes nasopharyngeal burning[168]; preadministration of intranasal lidocaine can decrease the irritation.[169] Rectal administration is usually well tolerated in children who have not been toilet trained, but absorption may be irregular owing to many factors, including superior versus inferior hemorrhoidal vein absorption within the rectum.

Benzodiazepines produce mild respiratory depression and upper airway obstruction.[170–172] Small doses of oral midazolam (0.3 mg/kg) that produce minimal sedation were associated with a 6.5% decrease in functional residual capacity and a 7.4% increase in respiratory resistance.[173] Respiratory depression may become marked in children who are neurologically impaired or in children with OSA, although premedication with oral midazolam (0.5 mg/kg) carries an extremely small risk of transient hemoglobin desaturation.[174] The combination of benzodiazepines and opioids can produce a "superadditive effect" on respiratory depression where the total depressant effect from the combination of drugs is much greater than the sum of their anticipated individual effects.[175,176]

Benzodiazepines may have a paradoxical effect in 1% to 15% of children depending on age and personality, rendering the child combative rather than cooperative. A history of this type of paradoxical response should be elicited before administering a benzodiazepine.

Flumazenil is a specific benzodiazepine-receptor antagonist that rapidly reverses the sedative, paradoxical, and respiratory effects of benzodiazepines.[177–181] Children who take benzodiazepines for seizures or drug dependency may experience symptoms rapidly if flumazenil is given.[182] It should also be used with caution in children with increased intracranial pressure and in those taking drugs that decrease the seizure threshold (e.g., cyclosporine, theophylline, and lithium). Because of these concerns, flumazenil should not be administered for the routine reversal of the sedative effects of benzodiazepines but should be reserved for emergency reversal of respiratory depression. The recommended dose of flumazenil is 10 µg/kg up to 200 µg every minute to a maximum cumulative dose of 1 mg IV. Antagonism begins within 1 to 2 minutes after administration and lasts approximately 1 hour. Because resedation after 1 hour may occur, any child who receives flumazenil must be carefully monitored for at least 2 hours. It should be noted that flumazenil does not antagonize respiratory depression induced by opioids.[183]

BARBITURATES

Pentobarbital is an intermediate-acting barbiturate that is now infrequently used. It provides excellent sedation, hypnosis, and amnesia without analgesic. The onset of sedation is 3 to 5 minutes with a peak effect by approximately 10 minutes and duration of action of 1 to 2 (or more) hours. Respiratory obstruction, transient desaturation, and hypotension occur infrequently.[184,185] Barbiturates reduce the threshold for pain in children, so it is best avoided in painful procedures. Recovery after pentobarbital is often protracted, leaving children in a disinhibited state for extended periods. This may lead to a prolonged recovery and, in some cases, the need for restraint (see Table 48.8).[147]

OPIOIDS

Opioid analgesics are rarely effective sedatives in isolation, but their use is essential to manage painful diagnostic and therapeutic procedures. Opioids confer a degree of sedation, but the sedation is usually inadequate to perform procedures in children; thus they are usually combined with sedatives (see Fig. 48.1).[175,186] Combinations require particular caution in infants and children with upper airway obstruction (e.g., tonsil and/or adenoid hypertrophy, Trisomy 21, mucopolysaccharidosis).

Morphine may be used for painful procedures with prolonged duration or when pain is expected after the procedure.[187] Morphine may be given orally (0.2–0.5 mg/kg), IV (0.05–0.1 mg/kg [maximum 0.3 mg/kg]), or intramuscularly (IM) (0.1–0.2 mg/kg), and diamorphine may be given nasally.[188–190] Times to peak effect for oral, IV, and IM administration are 60 minutes, 1 to 2 minutes, and 10 to 30 minutes, respectively.

Fentanyl is the opioid of choice for sedation/analgesia for most procedures in children because of its brief duration of action. It may be given IV, IN or IM.[191–195] IV fentanyl is approximately 50 to 100 times more potent an analgesic than morphine but without amnesic properties. Its high lipid solubility allows for a rapid onset of action (within 30 seconds) and time to peak effect, 2 to 3 minutes. It has a brief clinical duration of 20 to 40 minutes when given in small doses, owing to its rapid redistribution to skeletal muscle, fat, and other inactive sites. Unlike morphine, it

has no active metabolites. Fentanyl is frequently used in combination with a short-acting anxiolytic (midazolam). IV doses of fentanyl usually begin at 0.5 to 1 μg/kg. Serial doses may be titrated every 5 to 10 minutes to effect, to a maximum dose not exceeding 5 μg/kg.[196] Fentanyl can also be administered IN at a dose of 1.5 μg/kg, It has been effective at this dose for emergency department procedures.[191,193–195] When carefully titrated and appropriately monitored, fentanyl has few adverse effects. Chest wall rigidity is a centrally mediated idiosyncratic reaction that can interfere with breathing but can be antagonized with either naloxone or muscle relaxants; it is rarely observed in sedation practice.[197–199] Other adverse reactions from fentanyl include bradycardia, dysphoria, delirium, nausea, vomiting, pruritus, urinary retention, hypotension, and smooth muscle spasm. Close postprocedural observation is required because respiratory depression can outlast analgesia (see Table 48.8).

Remifentanil an ultra-short-lived, rapid-acting, potent, lipophilic opioid that is metabolized by plasma and tissue esterases and must be administered as a continuous infusion. It has a half-life of 3 to 6 minutes that is independent of the duration of infusion. Remifentanil has been used for intraoperative and procedural sedation by anesthesiologists and in intubated children in the ICU.[200–205] If postoperative pain is anticipated, another analgesic should be administered before stopping the infusion of remifentanil. Children may develop a degree of opioid tolerance after several hours of infusing remifentanil.[206] Accordingly, provision for pain control after procedures must be anticipated and instituted before emergence from sedation/anesthesia. Remifentanil is also associated with a substantial incidence of apnea, hypoxemia, and chest wall and glottic rigidity, and is not recommended as a sole agent for pediatric sedation (see Table 48.8).[202,204,207] Remifentanil may be administered together with propofol to provide total intravenous anesthesia and sedation (see Chapter 8).

Opioid antagonists reverse the respiratory and analgesic effects of opioids and should be readily available when opioids are used (see Table 48.8). Naloxone (Narcan) is the most commonly used antagonist[208] and may be given IV, IM, or SC.[209] The initial dose for respiratory depression is 10 μg/kg titrated to effect every 2 to 3 minutes. A dose of 10 to 100 μg/kg up to 2 mg may be required for respiratory arrest. Adverse reactions from the rapid reversal of opioid effects include nausea, vomiting, tachycardia, hypertension, delirium, and pulmonary edema.[210–212] Children who have been receiving long-term opioid therapy should be given opioid reversal agents in small doses and with extreme caution because withdrawal seizures, sympathetic overdrive, and delirium may occur. Children given a single dose of IV naloxone may have a recrudescence of the respiratory depression 1 hour later. It is for this reason that the same IV dose is administered IM; otherwise *the child should be observed for a minimum of 2 hours after the IV naloxone.* Nalmefene (Revex), like naltrexone, is a μ-receptor antagonist and weak κ- agonist that boasts a greater half-life (~10 hours) than naloxone.[213] Although experience in children is limited, it accelerates recovery from sedation.[214] Because of its relatively long half-life, it outlasts the effects of fentanyl and may oppose pain treatment for several hours.

α_2-ADRENOCEPTOR AGONIST: DEXMEDETOMIDINE

Dexmedetomidine is highly lipid soluble and quickly crosses the blood-brain barrier. Its mechanism of action in the CNS is via stimulating receptors in the medullary vasomotor center, which decreases sympathetic tone. It also stimulates central parasympathetic outflow and decreases sympathetic outflow from the locus ceruleus of the brainstem. The decreased outflow from the locus ceruleus increases activity of the inhibitory GABA neurons, which cause sedation and analgesia.[215] Currently, dexmedetomidine is only approved by the FDA for procedural sedation in adults, although it is used off-label to sedate children. In addition to its IV use, it has been administered via the buccal, IN, and IM routes in children.[216–220] When administered in clinical doses, it causes limited effects on ventilation and may mimic natural rapid-eye-movement sleep.[221–223] Because rapid IV boluses can cause transient systemic hypertension, the initial loading dose must be given as a 10-minute infusion and may be followed by a continuous infusion. When given in the recommended fashion, it decreases blood pressure and heart rate in a dose-dependent manner. It should be used with caution in children with preexisting bradycardia, atrioventricular conduction defects, hypotension, and decreased cardiac output.[224–226] It has been associated with severe bradycardia in infants receiving digoxin and β-blockers, and those with preexisting AV nodal conduction delays.[128] Dexmedetomidine has seen a rapid increase in pediatric sedation over the past 10 years largely owing to its lack of respiratory depressant effects.[227–230] To date, dexmedetomidine does not cause neuroapoptosis (unlike all other sedatives). It has been suggested to have neuroprotective properties[231–233] and may therefore hold a unique advantage for sedation in young children when these effects are of greatest concern. Sedation after IV administration has a relatively rapid onset of 10 minutes and a half-life of 1½ to 3 hours. Its minimal effect on respiration has led to its use alone in nonpainful procedures (e.g., EEG, CT, and MRI), in children with Down syndrome and children with OSA. It has also been used in combination with ketamine and propofol for painful procedures (e.g., cardiac catheterizations and complex regional pain syndrome).[234,235] However, caution is advised in children with known congenital heart disease, as it depresses sinus and atrioventricular node function and may pose an increased risk for children prone to bradycardia.[234–238] When analyzed by MRI, the dose-response effects of dexmedetomidine (1–2 μg/kg per hour) on the morphology of the upper airway in children[239,240] revealed minimal changes in the dimensions of the dimensions of the upper airway. Infants and children 5 months to 16 years of age also show minimal effects on respiration.[54] These characteristics make dexmedetomidine a popular choice for children with OSA.[239,240]

Dexmedetomidine has intermediate potency when compared with other sedatives such as etomidate or propofol. The effective dose in children is greater than that in adults. Many studies have investigated the dose of dexmedetomidine needed to successfully complete as close to 100% of the tests and procedures that required sedation. At the top end of the dosing range, a loading dose of 3 μg/kg administered over 10 minutes IV followed by an infusion of 2 μg/kg per hour minimized the need for rescue with pentobarbital (2.4%) for sedation for MRI.[241] At these doses, mean arterial pressure was maintained in all children and oxygen saturation remained greater than 95%; however, 30 of the 747 (4%) experienced bradycardia to less than the 20th percentile for age. No adverse effects were noted, nor were any treatments required. Full recovery may be slow with high doses of dexmedetomidine.[242] Caution should also be used when administering glycopyrrolate to treat the bradycardia from dexmedetomidine because severe and sustained hypertension after traditional doses of 5 μg/kg glycopyrrolate have occurred (e.g., blood pressure 161/113 mm Hg in a 3-year-old).[243] An alternative approach to improving success with dexmedetomidine[244] included a loading dose of 1 μg/kg dexmedetomidine over 10 minutes followed by an infusion of

0.5 µg/kg per hour plus a 0.1-mg/kg bolus of midazolam. With this regimen, a high rate of success with only small changes in $ETCO_2$ and minimal hemodynamic effect has been demonstrated. Combination of propofol with dexmedetomidine has proven highly effective and is associated with few adverse effects.[245] Other investigators reported that a combination of ketamine, propofol, and dexmedetomidine in the cardiac catheterization lab was very effective.[246] Combination regimens offer a preferable mix of successful sedation with few adverse events, although there are insufficient data to recommend a specific regimen to maximize the sedation with dexmedetomidine.

KETAMINE

Ketamine, available since the 1960s, is one of the few sedatives that produces sedation, amnesia, and analgesia. The clinical appearance is that of a child who has open eyes (usually with horizontal nystagmus) but does not respond to pain—the "dissociative" state. Ketamine preserves cardiovascular function and exerts limited effects on respiratory mechanics, allowing spontaneous respirations in most children.[247] Although it is certainly not a new drug, ketamine has experienced a resurgence in popularity for procedural sedation, particularly in the emergency department. Clinical practice guidelines from American College of Emergency Physicians proposed a distinct classification of sedation for ketamine as "Dissociative Sedation"[248,249] because it has unique properties that do not neatly fit into the current definitions of sedation or anesthesia. To date, this reclassification has not been accepted by the AAP, ASA, AAPD, or regulatory agencies.[249–252]

IM and IV ketamine (with and without midazolam) are frequently used for closed fracture reductions and other painful minor procedures in the emergency department (see Table 48.8).[252–254] In a recent systematic review of 41 publications in which ketamine was used for procedural sedation in children (13,876 sedations) in the emergency department, adverse events were infrequent. The most common adverse events were vomiting and agitation, with frequencies of 55 and 18/1000 sedations, respectively.[255] Hypoxia occurred in 1.5% of sedations, apnea in 0.7%, laryngospasm in 2.9/1000 sedations, and 0 cases of aspiration. In a retrospective review of 173 children younger than 2 years of age who were sedated for minor procedures in the emergency department with ketamine/midazolam or morphine/midazolam for the majority of cases, the frequency of complications was 6%, of which all but one were related to ketamine/midazolam. Most were considered minor in severity (3 desaturated, 4 vomited, 1 developed stridor, 2 failed sedation), although one infant (2 months of age) developed bradycardia necessitating tracheal intubation.[256] In a prospective study by the PRSC of more than 22,000 sedations in children (median age 5 years, range <1 month–22 years) with ketamine in radiology and sedation suites, 7.3% experienced adverse events and 1.8% experienced serious adverse events.[257] Two patients with cardiac arrests were successfully resuscitated. Risk factors for adverse events included cardiac and gastrointestinal diseases, lower respiratory tract infections, and coadministration of propofol and anticholinergics.

Ketamine (1–3 mg/kg IV) has also been studied in children undergoing gastroendoscopy procedures, with transient laryngospasm occurring in 8.2%, emesis in 4.1%, emergence agitation in 2.4%, partial airway obstruction in 1.3%, apnea and respiratory depression in 0.5%, and excessive salivation in 0.3%.[95] The analgesic effects of ketamine make it very appealing for use during burn dressing changes. In one study, 4.9% of the ketamine sedations resulted in adverse outcomes, of which 2.9% required an intervention. Eight events were related to the airway.[258] Ketamine sedation/analgesia has a very long history of safety, perhaps offering advantages over other sedation regimens, although these studies indicate that potentially life-threatening events can and do occur even with ketamine sedation. Ketamine is also associated with nonpurposeful motion, which limits its usefulness when immobility is necessary (e.g., use during MRI scans).

Ketamine is contraindicated in a number of clinical scenarios. Human studies support a trend to increase global and regional cerebral blood flow in healthy patients[259] and warrant a relative contraindication for this drug in children with significantly increased intracranial pressure, particularly without controlled respirations. Similarly, ketamine is contraindicated in those with head injury, open globe injury, hypertension, and psychosis. Although it does not directly decrease the ventilatory drive, ketamine decreases the ventilatory response to hypercarbia. Ketamine is associated with a small, but significant rate of laryngospasm and coughing that may require definitive airway management.[260] No antagonist is available. Recovery from ketamine is notable for a greater incidence of emesis and agitation than other sedatives.[255,260,261]

Typical starting doses[262] of ketamine are 3 to 4 mg/kg IM, 0.25 to 1.0 mg/kg IV, and 4 to 6 mg/kg orally.[263–265] The onset after IM injection is 2 to 5 minutes, with a peak at approximately 20 minutes; duration can be 30 to 120 minutes. Onset after IV administration occurs in less than 1 minute, with a peak effect in several minutes and duration of action of approximately 15 minutes. Oral doses of 4 to 6 mg/kg are usually combined with atropine and have an effect in 30 minutes and last up to 120 minutes.[29] In a dose-ranging study of ketamine in the emergency department, doses of 1.5 to 2 mg/kg IV provided similar sedation and satisfaction after the procedures.[266] Although anticholinergics have been recommended when ketamine was used for procedural sedation in the emergency department,[267] recent studies from the emergency department have not only refuted the need for anticholinergics during ketamine sedation but also suggested that the use of anticholinergics may actually increase the odds of adverse events.[257] It is unclear how the use of an anticholinergic could increase the number of adverse events.

Etomidate is a carboxylated imidazole that is primarily used as an induction agent for anesthesia. Its mechanism is thought to be potentiation of GABA inhibitory neurotransmission via alteration of chloride conductance. Loss of consciousness occurs in 15 to 20 seconds. Recovery results from redistribution within 5 to 10 minutes. It is hydrolyzed in the liver to inactive metabolites and excreted (90%) in the urine.[155] Etomidate produces sedation, anxiolysis, and amnesia similar to the barbiturates and propofol. Its major advantage is its lack of adverse cardiovascular effects. It has been used in adults and children for procedural sedation, although the endpoint of sedation is not well described and often is a state of general anesthesia.[91] Etomidate has been compared with pentobarbital for CT sedation. Adverse events were more common with pentobarbital (4.5%) than etomidate (0.9%).[268] Etomidate with fentanyl has been compared with ketamine with midazolam for reduction of limb fractures in children in the emergency department. The combination of etomidate and fentanyl led to a quicker recovery but was less effective in reducing observed patient distress.[269,270] Transient adrenal suppression can occur after etomidate,[271–275] which is why it is infrequently used in acutely ill children.

Propofol is widely used for pediatric sedation and anesthesia with an onset within 30 seconds. It has no analgesic properties, but it does have antiemetic and antipruritic properties. Although

small doses of propofol (25–50 μg/kg per minute) can provide moderate sedation in adults, children require larger doses (150–250 μg/kg per minute). It is generally best administered by titration with an infusion pump. Adverse reactions include increased salivary and tracheobronchial secretions, myoclonic movements, anaphylactic reactions, and bacterial contamination. Pain on injection can be lessened by several strategies, although the two most effective strategies are pretreatment with nitrous oxide (N_2O) by inhalation, or a mini-Bier block with 1 mg/kg lidocaine applied for 1 minute.[276,277] Hypotension is mild and usually not clinically significant. Cases of fatal metabolic acidosis, myocardial failure, and lipemic serum have been reported in children who received propofol infusions (propofol infusion syndrome [PRIS]) for more than 48 hours at doses exceeding 5 mg/kg per hour (83 μg/kg per minute), with sporadic cases, which may have been exacerbated by an underlying mitochondrial disorder of the syndrome, appearing after only 5 to 6 hours in some cases.[278–283]

Propofol is also a profound respiratory depressant that may cause apnea. Respiratory complications have been reported in 8% to 30% of children.[284] In a study of propofol sedation (2.5–3 mg/kg IV loading dose with an infusion up to 200 μg/kg per minute) in 105 painful procedures in the pediatric ICU, 21% of the children required airway repositioning, 17% had apnea, 5% had hypotension, and 45% had events that required intervention.[98] In the emergency department, propofol was administered to 113 children in a dose of 4.5 mg/kg in addition to fentanyl 1 to 2 μg/kg[285] that proved to be sufficient to ensure the children were motionless during the reduction of fractures. The net effect was an incidence of desaturation of 21%, laryngospasm in 1%, and a supplemental oxygen requirement in 25%. In a study of sedation by nonanesthesiologists for bone marrow procedures, lumbar punctures, and esophagoscopies titrated propofol to a target of "not arousable"; 21 children from 27 weeks to 18 years of age were studied. Propofol at doses of 520 μg/kg per minute conferred 100% sedation with BIS readings of 45 or less (consistent with general anesthesia).[286] These responses to stimulation, effects on the airway, doses of propofol, and BIS levels are beyond the range of deep sedation and more in keeping with the definition of general anesthesia, with the inherent risk of loss of the airway. More recent studies that reviewed large numbers of sedation encounters involving propofol sedation by a variety of physicians (working in elective sedation services) document that propofol can be used with much fewer severe adverse outcomes (and much smaller doses) than previously reported.[15,104,287,288] In these studies of more than 100,000 total propofol encounters, the rate of significant airway events was less than 2.5%.[100,289]

There has been increasing use of a combination of ketamine (10 mg/mL) with propofol (10 mg/mL), so-called ketofol, for painful procedures in the emergency department and for oncology patients.[290–295] This combination is administered in incremental doses of 0.5 mg/kg of each drug at approximately 1-minute intervals. Other mixture proportions of these two drugs have also been investigated[296] and a better ratio of racemic ketamine to propofol may be 1 : 3 for brief procedures (5–20 minutes).[296,297] While experience with this combination of drugs is growing, the limited number of prospective studies at this point preclude assessment of safety and efficacy. A literature review found insufficient evidence to recommend routine use of this combination.[294]

Methohexital is a short-acting oxybarbiturate that is rapidly metabolized and redistributed, and has a rapid recovery (see Table 48.8).[298] Induction of anesthesia occurs with IV doses of 1 to 2 mg/kg. Apnea, hiccups, and methohexital-induced seizures in children with temporal lobe epilepsy have been reported.[299] IM methohexital has been used in doses of 8 to 10 mg/kg, but the onset of sedation is slow[300] and it is not generally recommended. Rectal methohexital (20–25 mg/kg [from a 100-mg/mL solution]) can induce deep sedation in 7 to 11 minutes[301] with a duration of action of about 30 to 45 minutes.[302] Absorption through the rectal route is erratic.[303] The variability of absorption, tendency to deep sedation, and airway problems have decreased the use of methohexital in favor of newer drugs administered by other routes. This medication should be used only by individuals with advanced airway skills, because upper airway obstruction and apnea may readily occur.[304]

Nitrous oxide (N_2O) is a potent inhalation analgesic with a peak effect in 3 to 5 minutes and very rapid return to baseline when discontinued (see Table 48.8). A premixed tank of no more than 50% N_2O is available (Entonox). Administration of N_2O can be used for "minimal sedation" under the following AAP guidelines:

1. N_2O can be used only in ASA physical status I or II patients.
2. Only 50% N_2O or less is used.
3. Inhalation equipment must have the capacity to deliver 100% oxygen and never less than 25% oxygen.
4. A calibrated oxygen analyzer must be used. The child is able to maintain verbal communication throughout the procedure.

Although 50% N_2O in oxygen usually produces "minimal" sedation, the addition of any sedatives or hypnotic may rapidly produce a deeper level of sedation and require increased monitoring and vigilance.[152,170] N_2O is frequently used by dentists for sedation. The results of a recent questionnaire reported that all dentists performed treatments on patients under sedation during their training and that the majority used N_2O sedation.[305,306] Adverse reactions, drug interactions, and special concerns are listed in Table 48.8.

Summary and Future of Pediatric Sedation

Pediatric sedation has evolved from a clinical "orphan"–with few champions and almost no formal organization–to a well-documented field with clear standards and guidelines for practice. We are in an era where safe, effective, (and efficient) pediatric sedation is demanded by our patients and our professional colleagues. Appropriately, procedural sedation is expected to provide the same level of safety and effectiveness associated with the operating room. At the same time, anesthesiologists must recognize that the literature is replete with reports of *other* pediatric specialists working in sedation systems that provide care with potent medications and excellent outcomes.[227,307–315] Anesthesiologists continue to provide the ultimate "backup" for these services and take on the most challenging sedation cases, while recognizing the capabilities of other professionals. Anesthesiologists must explore ways to collaborate with these other specialists and help them develop optimal sedation monitoring techniques/drug regimens that will result in the best possible sedation results for all patients undergoing sedation for procedures and tests.

Coté CJ, Notterman DA, Karl HW, et al. Adverse sedation events in pediatrics: a critical incident analysis of contributory factors. *Pediatrics*. 2000;105(4 Pt 1):805-814.

Landmark study that collated severe adverse outcomes from multiple sources and allowed the identification of sedation practices that led to injury and death. In particular, it highlighted the need for appropriate personnel, monitors, and rescue capability to ensure safety.

Coté CJ, Wilson S, American Academy of Pediatrics, American Academy of Pediatric Dentistry. Guidelines for monitoring and management of pediatric patients before, during, and after sedation for diagnostic and therapeutic procedures: update 2016. *Pediatrics*. 2016;138(1).

These are the most recent American Academy of Pediatrics Sedation Guidelines that now require the use of capnography for all deeply sedated children and encourage its use for moderately sedated children. Important changes are that the responsible practitioner for moderate sedation must have the skills to rescue a child with apnea, laryngospasm, and airway obstruction, and perform successful bag-mask ventilation. The practitioner who practices deep sedation must have these same skills and be able to perform tracheal intubation and cardiopulmonary resuscitation.

Cravero JP, Beach M, Gallagher SM, et al. The incidence and nature of adverse events during pediatric sedation/anesthesia for procedures with propofol outside the operating room: report from the Pediatric Sedation Research Consortium. *Anesth Analg*. 2009;108(3):795-804.

A review of nearly 50,000 sedation encounters using propofol by a variety of sedation providers. The participating providers were highly trained members of organized sedation services with advanced airway education and ongoing quality improvement efforts. Adverse events and requirements for airway interventions are analyzed. The information is useful in understanding the critical competencies necessary for the safe use of this drug.

VASCULAR CANNULATION IS AN IMPORTANT PROCEDURE in the anesthetic and perioperative management of children. Its routine use was introduced in the 1950s.[1] The indications are to provide routes to administer fluids, drugs, and blood products, monitor cardiopulmonary function, and access blood for laboratory testing. Although establishing vascular access may be extremely difficult at times, especially in the very young or small child, no child should be denied an indicated procedure because of an operator's inability to access the vascular system; appropriate consultation should be sought as necessary. Regardless of the procedure or the person in whom the procedure is attempted, gloves should be worn to maintain clean or sterile technique and to protect health care professionals from exposure to blood and sharps.[2–6] An update from the Pediatric Perioperative Cardiac Arrest Registry suggests that lack of good vascular access may contribute to an underestimation of the fluid requirement or blood loss and inadequate replacement of fluid or blood in anesthetized children, thus underscoring the importance of appropriate and adequate vascular access and monitoring.[7,8]

Venous Cannulation

PERIPHERAL INTRAVENOUS CANNULATION

Indications

Percutaneous intravenous (IV) access should be present in almost all anesthetized children for the following reasons[9,10]:

- To provide a route for postoperative pain management.
- To administer drugs, fluids and electrolytes, glucose, and blood products, including resuscitation medications.
- To measure central venous pressure; the accuracy of this measurement does not vary according to the location of the catheter[11] but does depend on ensuring direct continuity between the central and peripheral circulation.[9,12] This can be assessed by providing a large, sustained inspiration or occluding the venous return of the extremity, which both cause an increase in the peripheral pressure.[11,13,14] Hypothermia may impair the accuracy of such measurements.[15]

Equipment

- Alcohol pads or chlorhexidine swabs
- Gloves
- Tourniquet
- Gauze
- Clear plastic dressing (Tegaderm, 3M Medical-Surgical Division, St. Paul, MN, or OpSite, Smith & Nephew, Inc., Largo, FL)
- Tape
- Arm board

Consider the possible need for latex-free equipment. In cases of difficult access, the availability of a transillumination light source (Karl Storz, 485 B Type, Tuttlingen, Germany) may improve the success rate of catheter placement.[16] Ultrasonography also may be used to obtain peripheral venous access at the basilic, cephalic, or brachial veins.[17–19] Finally, new near-infrared and infrared technology is available to aid in the identification of peripheral veins (AccuVein, AccuVein, Inc., Huntington, NY; VeinViewer, Christie Digital Systems, Cypress, CA).[20]

Practical Suggestions

1. Awake IV line placement can be facilitated by any combination of good patient rapport, eutectic mixture of local anesthetics (EMLA) cream (lidocaine 2.5% and prilocaine 2.5%), lidocaine and tetracaine patch, lidocaine by iontophoresis, lidocaine by topical cream, topical tetracaine (Ametop), ethyl chloride spray, and/or premedication.[21–30]
2. Prefilling the cannula with saline solution may reduce menisci tension and allow a more rapid blood flashback.
3. A butterfly needle can be inserted for induction, followed by an appropriate-sized catheter after anesthesia.
4. A T-connector (Abbott, Inc., Chicago, IL) may be used to minimize the fluids necessary to flush drugs administered through the IV line; this is particularly important for infants.[31]
5. A calibrated burette should be used to limit the total infusion and provide a means to titrate fluids accurately in infants and young children.
6. A flow-limiting infusion pump may be used for preterm and full-term neonates.
7. Flow rates may be significantly changed by catheter brand, tubing type, and addition of extensions and stopcocks (see also E-Figs. 52.1 and 52.2).[32]
8. One-way valves in the IV tubing to prevent backflow of drugs or infusions.

9. Air filters also may be useful for children at risk for paradoxical gas embolization.

Complications

Hematoma from a failed vascular cannulation is usually of no serious consequence. Infection or thrombosis may be limited by aseptic technique.[33–35] One study of 642 Teflon catheters in 525 patients showed that the risk of catheter complications in children was extremely small and would not be reduced significantly by routine replacement of the catheters.[36] Catheter life span is unrelated to the insertion site, cannula size, or brand in infants younger than 12 months of age.[37,38]

Skin sloughing is usually caused by subcutaneous infiltration of calcium, potassium, or hypertonic solutions; it may be avoided by frequent inspection of the IV line for swelling in the subcutaneous tissues before injecting medications.[39] The risk of subcutaneous infiltration increases with the administration of medications versus no medications and with parenteral nutrition solutions compared with 5% or 10% dextrose solutions, but the risk of infiltration is no different with solutions that contain potassium (≤20 mEq/L vs. >20 mEq/L). In addition, there is no difference between gravity-controlled versus infusion delivery devices.[40] There are insufficient data to support the routine use of heparin to prolong the patency of peripheral IV catheters in neonates and children.[41]

The severity of extravasation injuries depends on many factors, including pH, osmolarity, the diluent, vasoactive properties, and cytotoxic properties. The treatment of extravasation injuries varies with the extent of the injury from simple cessation of the IV solution and removal of the IV catheter while aspirating as much infiltrate as possible, to limb elevation, application of heat or cold packs, saline washout, topical treatments or injections (topical lidocaine, prilocaine, nitroglycerine, antimicrobials, subcutaneous or intradermal hyaluronidase, phentolamine, sodium thiosulfate or dexamethasone), assessment of compartment pressures, escharotomy, and in some cases, skin grafting.[42–46]

CENTRAL VENOUS PRESSURE MEASUREMENT

Some studies in children and adults describe a reasonable correlation between the venous pressure transduced in peripheral IV catheters and central venous catheters, even in critically ill children. Hypothermia (peripheral vasoconstriction) decreases the accuracy of such measurements, but it is useful to understand that transducing the pressure of a peripheral vein may provide valuable information regarding right-sided cardiac filling pressures.[9,10,15,47–49]

ESTABLISHING A LARGE INTRAVENOUS CATHETER IN SMALL PATIENTS

Indications

The following procedure is used for any child in whom there is the potential for massive, rapid hemorrhage:

1. Prepare and drape the appropriate area using standard sterile techniques.
2. Perform a standard IV cannulation of an antecubital, saphenous, or external jugular vein with a small IV catheter (e.g., 22-gauge).
3. Pass a small, flexible guidewire (e.g., 0.018 inch) through the IV catheter, remove the catheter, and with a No. 11 blade, make a small incision at the entry point of the wire at the skin.
4. Pass the next larger size IV catheter over the wire to dilate the vein and leave in place; stiff IV catheters are more effective. An alternative is to use a small dilator from a pulmonary artery catheter introducer and leave the sheath in place. The wire is removed, and the next larger size wire is inserted (0.025 inch). The catheter (or sheath) is removed, leaving this larger wire within the vein. This process may be repeated with larger catheters and wires until the desired size cannula or sheath is reached. An alternative is to leave progressively larger pulmonary artery introducer sheaths in the vein; both techniques provide a reasonably rapid method of establishing a large-bore IV infusion site.

Rapid Infusion Catheters and Introducer Sheaths

Special rapid volume catheters (6F and larger; Arrow International, Reading, PA) allow venipuncture with a needle or small IV catheter, passage of a guidewire, and then introduction of a dilator and sheath, with fewer steps required.

Intravenous Cutdown

Indications

- Percutaneous cannulation is unsuccessful.
- Percutaneous cannulation is tenuous.
- The catheter in place is inadequate for the planned surgical procedure.

The most common sites for insertion are the saphenous vein at the medial malleolus and the brachiocephalic vein at the antecubital fossa. This procedure may require considerable time to perform and has limited utility for emergent access.[50]

Complications

IV cutdown has a high incidence of infection and therefore should be used only on a short-term basis.

Saphenous Vein Cannulation

The saphenous vein is often a reliable point for IV access in infants and children that may be directly visualized or cannulated with a "blind" technique (Fig. 49.1). It is consistently found lateral to the medial malleolus of the ankle one-half to one finger breadth over the anterior quadrant.

1. Cleanse the area in the standard fashion after a tourniquet is applied to the lower extremity below the knee.
2. The saphenous vein may or may not be palpated, and visualization may not be possible.
3. Enter the skin at a 30-degree angle at the expected site of the saphenous vein at the level of the medial malleolus, with the tip of the needle directed toward the upper two-thirds of the calf. If no evidence of venipuncture is seen on insertion, slowly withdraw the needle because the flash of blood often occurs while exiting the vein.
4. If unsuccessful on the first attempt, fan medially and then laterally from the same insertion point, slowly advancing and withdrawing the catheter until blood return is obtained.
5. Once a flashback is seen, gently advance the entire unit 2 to 3 mm into the lumen before twisting and advancing the catheter off the needle.

Safety Intravenous Catheters

In the United States, federal law requires that retractable or sheathed needles designed to reduce the potential for needlestick injury are available for use by health care personnel (Table 49.1).[51] A study that compared traditional IV catheters with safety devices found that a larger proportion of children younger than 3 years of age required more than one safety catheter to successfully gain IV access. The retractable IV catheter was associated with an almost fourfold greater incidence of splattering and spilling of

blood compared with traditional catheters.[52] The excess splatter occurs when the powerful spring-loaded mechanism rapidly retracts the needle into the housing of the safety device; therefore sheathed catheters are regarded as inherently safer because they require no action on the part of the operator to protect the needle tip. Note that U.S. federal legislation requires that these devices be available, but the ultimate decision to use them rests with the physician operator. *Therefore, the type of catheter should not be dictated by the hospital but rather by the individuals who place the catheters.*

CENTRAL VENOUS CATHETERIZATION

Indications

- To provide a secure means to administer fluids and blood when major shifts in intravascular volume are anticipated (e.g., multiple trauma, intestinal obstruction, burns).
- To monitor cardiac filling pressures.
- To infuse drugs and fluids that are sclerosing to peripheral veins (e.g., antibiotics, vasoactive drugs, or hyperalimentation fluids).
- To access blood for laboratory sampling.
- To measure mixed venous acid-base balance, to estimate cardiac output (Fick principle) or measure cardiac output (dye dilution).
- To aspirate air emboli from the heart.

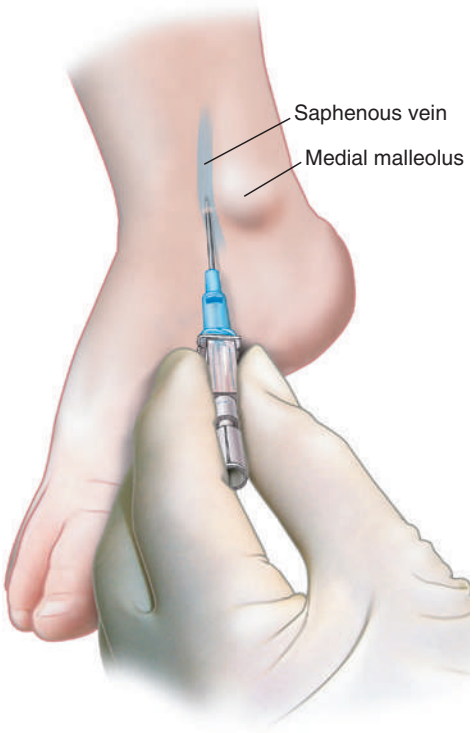

FIGURE 49.1 Long saphenous vein cannulation.

The common sites for central venous cannulation are the external and internal jugular veins, the subclavian and brachiocephalic veins, the femoral vein in infants and children, and the umbilical vein in neonates. Approaches such as the internal jugular and subclavian veins should be used with extreme caution in the presence of a bleeding diathesis as stopping bleeding may be difficult. The percutaneous approach to central venous cannulation is most successful using a modified Seldinger technique (Fig. 49.2).[53,54] The advantages of this technique are that it avoids the need for a cutdown, only one venipuncture is made with a thin-walled, small-gauge needle, a guidewire directs the catheter within the blood vessel, introducing a large catheter through the small venipuncture site minimizes the chances of significant hematoma formation even after systemic heparinization, and the procedure often can be accomplished when access is required emergently. Whenever a central line is inserted into the heart from above, care must be taken to ensure that the catheter tip is positioned at the junction of the superior vena cava and the right atrium, because other positions have been associated with perforation of large vessels and the myocardium (Fig. 49.3) and with triggering of ventricular arrhythmias.[55]

Ultrasound guidance, pressure waveform analysis, or electrocardiographic guidance may help prevent complications related to central catheter placement.[56,57] Ultrasound-guided access assists successful cannulation of the internal jugular vein,[56] the infraclavicular axillary vein,[57] and the subclavian vein.[58,59] In a meta-analysis of 18 trials with 1646 infants, children, and adults, two-dimensional ultrasound guidance yielded better outcomes than the landmark method.[60] In contrast, a review of 5434 landmark-guided approaches by fully trained anesthesiologists collected over 22 years (⅓ < 1 year of age) at 1 institution, 95% of which were internal jugular, reported a 99.5% success rate. Success also depended on experience and the child's age: the success rate was less in junior faculty and smaller children.[61] The greatest benefit with ultrasound was to cannulate the internal jugular vein rather than the subclavian or femoral veins.[60] See Chapter 43 and Videos 49.1 and 49.2 for ultrasound-guided techniques.

TABLE 49.1 Comparison of Intravenous Safety Mechanisms

Safety Mechanism	Operator Activation Required	Syringe Attachment	Rapid Flash	Bulky	Advantages	Disadvantages	Devices (Manufacturers)
Retractable needle	Yes	No	Yes	Yes	Unobstructed and rapid blood flash Similarity in use to non-safety devices	Bulky Requires operator activation No syringe attachment	Angiocath Autoguard (Becton Dickinson Medical, Franklin Lakes, NJ) Secure IV (Span America Medical Systems, Inc., Greenville, SC)
Blunted needle	No	Yes	No	No	Passive action requiring no operator activation Syringe attachment possible	Slow blood flash if needle has been partially withdrawn	Introcan Safety IV Protectiv and Acuvance (Smiths Medical, Kent, UK)

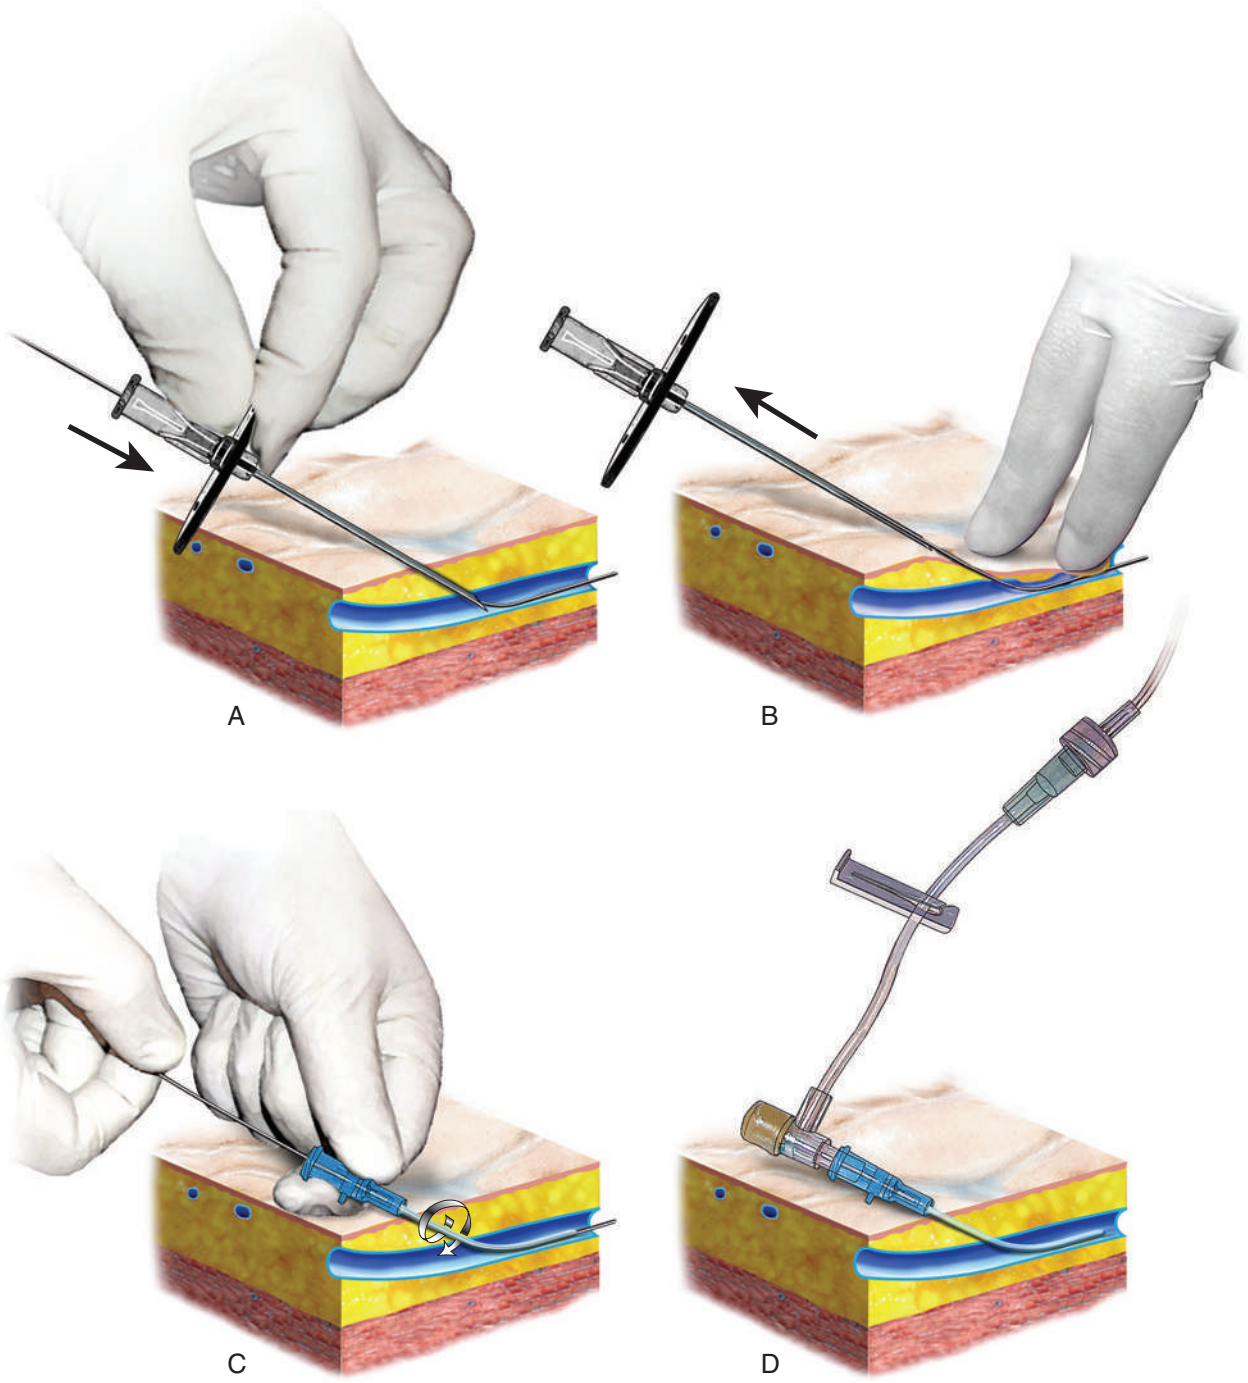

FIGURE 49.2 A, Seldinger technique for catheter placement. The needle is inserted into the target vessel, and the flexible end of the guidewire is passed freely into the vessel. **B,** The needle is then removed, leaving the guidewire in place. **C,** The catheter is advanced with a twisting motion into the vessel. **D,** The wire is removed, and the catheter is connected to an appropriate infusion or monitoring device. (Redrawn with permission from Schwartz AJ, Coté CJ, Jobes DR, et al. Central venous catheterization in pediatrics. Scientific exhibit, American Society of Anesthesiologists, New Orleans, 1977.)

Complications

Pneumothorax, arrhythmia, hematoma, bleeding, infection, thrombosis, inadvertent arterial puncture, cardiac tamponade, air embolus, thoracic duct injury, and malposition are all possible complications associated with central venous cannulation. Data in adults suggest that the smallest catheter and placement from the left subclavian approach may have the least complication rate; similar studies have not been conducted in children.[62] The infection rate reported after 1056 central venous catheters were inserted into 289 children with burn injury varied from 2.0% to 7.3% for catheters in place for less than 11 days, but that rate increased dramatically to 15.8% to 37.5% for catheters left in

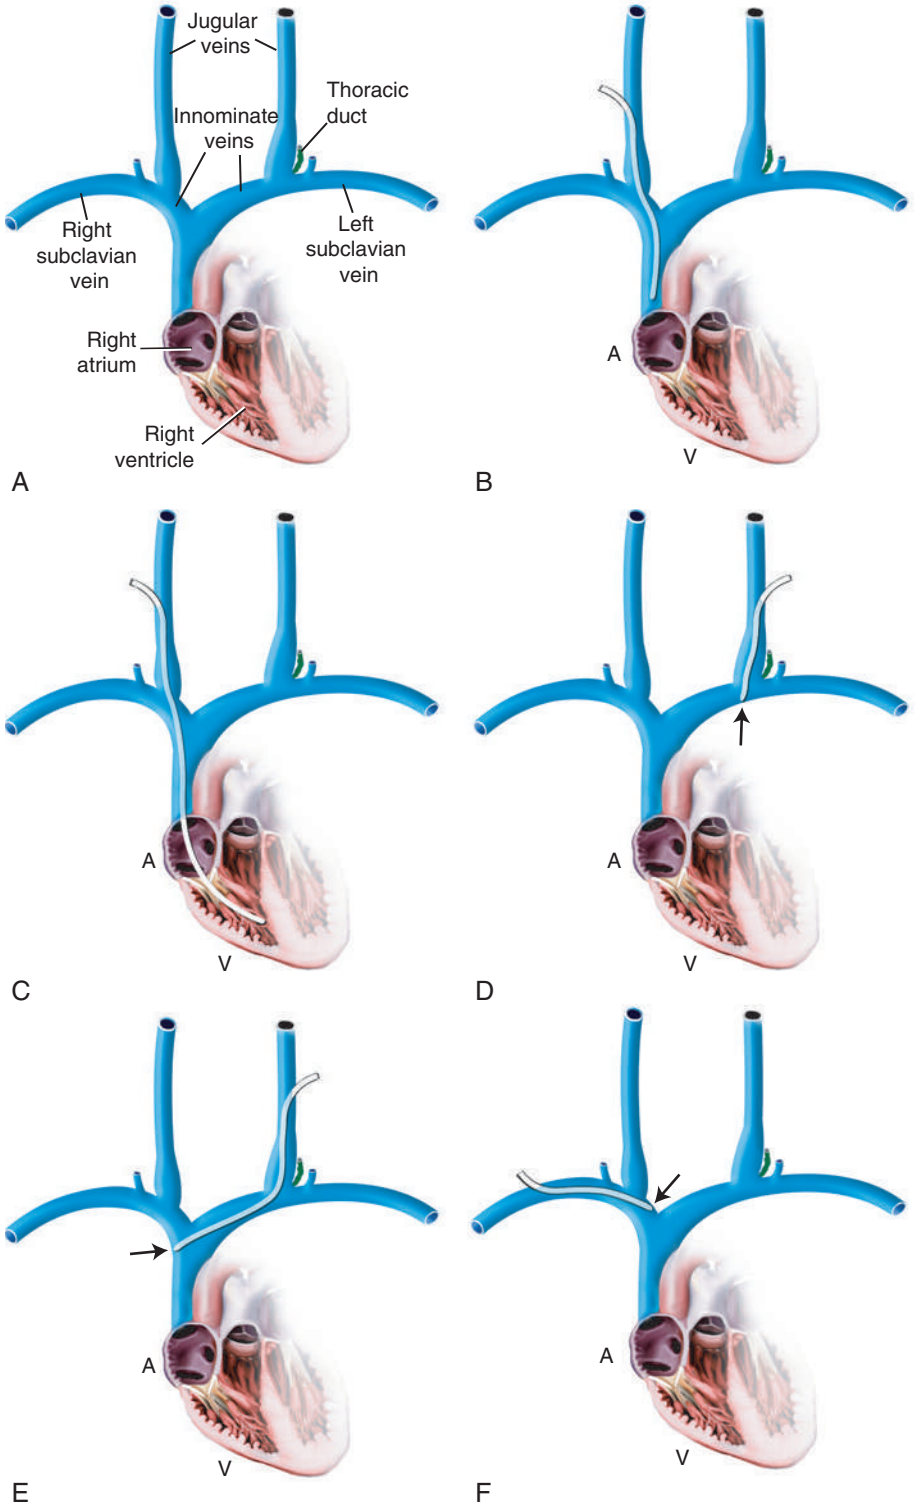

FIGURE 49.3 Proper and improper central venous pressure catheter placement. **A,** Normal vascular anatomy. **B,** Proper location for right internal jugular catheter (i.e., high right atrium or superior vena cava). **C,** Ventricular location of any catheter is dangerous and contraindicated. **D,** A short left-sided internal jugular catheter may erode through the innominate vein (*arrow*). **E,** A left-sided internal jugular catheter striking the lateral wall of the superior vena cava (*arrow*) may erode through it and must be partially withdrawn or advanced. **F,** A short right subclavian catheter may strike the lateral wall of the innominate vein (*arrow*) and erode through it; this catheter should be advanced or withdrawn.

Continued

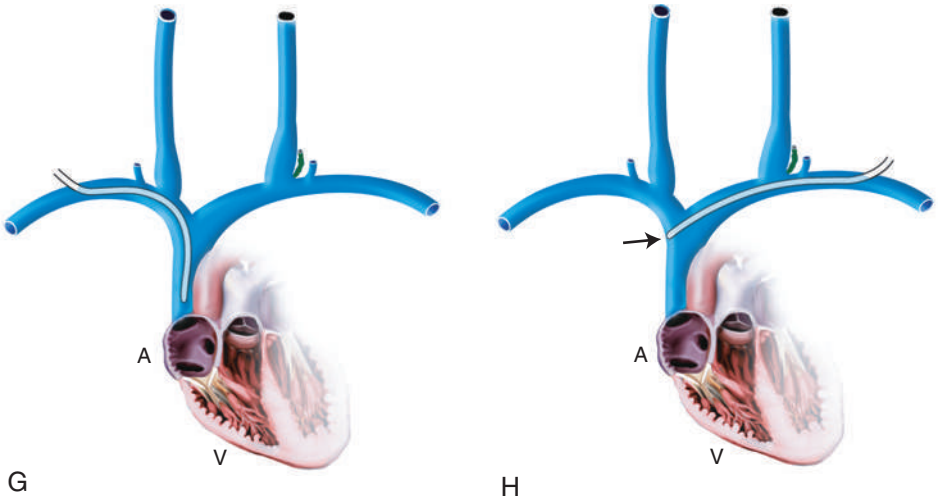

FIGURE 49.3, cont'd G, Proper location for a right subclavian line. **H,** A short left subclavian line may erode through the superior vena cava (*arrow*); this catheter should be advanced or withdrawn. *A,* atrium; *V,* ventricle.

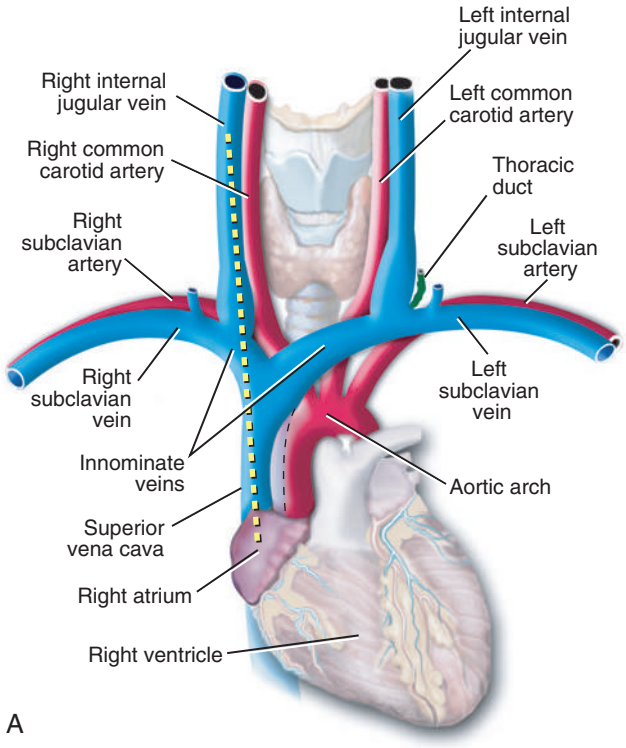
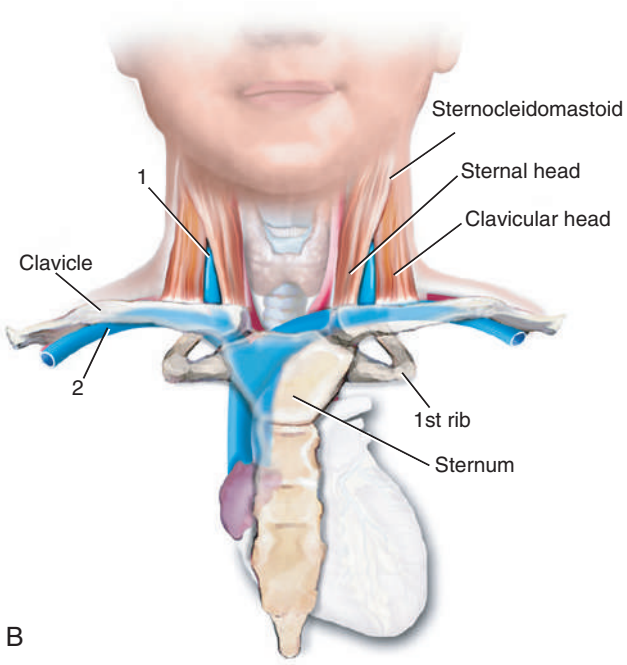
place for 12 to 14 days.[63] A randomized study that compared the success rate of insertion of the internal jugular versus subclavian approach in 280 pediatric cardiac surgical patients found a similar success rate with the two approaches, although the incidence of positive catheter tip culture results (22% vs. 3.4%) and bloodstream infection (6.9% vs. 0%) were greater with the internal jugular approach.[64] The first attempt success rates were similar with the two approaches (64% vs. 69%). However, the rate of arterial puncture was greater in the internal jugular group (8% vs. 2%) but success rate overall (91% vs. 82%) was greater in the subclavian group. The frequency of catheter malpositions was greater with the subclavian route (17% vs. 1%). In a separate study, catheter-associated bloodborne infections diminished dramatically after initiation of a rigorous hand hygiene program.[65]

Aseptic Technique



Contamination of catheters during insertion may result in catheter colonization or bacterial infection. Evidence suggests that the use of maximum barrier precautions during placement, including the use of sterile gloves, long-sleeved gowns, full-size drapes, and a nonsterile mask and cap, decrease the risk of catheter-related infection.[33,35,66,67] The efficacy of chlorhexidine versus povidone-iodine for preventing bacteremia remains unclear, and the safety of chlorhexidine in infants and children has not been fully established.[68] For older infants and children, chlorhexidine may be safe and effective, but it can cause severe local contact dermatitis in low-birth-weight infants[69,70]; its use in older children has been shown to reduce the incidence of catheter-associated infection compared with povidone-iodine.[71,72] In a case-controlled, prospective, active surveillance study in a pediatric intensive care unit (ICU), independent risk factors for central line–associated bloodstream infection were the duration of central venous catheterization in the ICU, nonoperative cardiovascular disease, gastrostomy tube, parenteral nutrition, central line placement in the ICU, and red blood cell transfusion.[73]



External Jugular Vein Catheterization

1. Place the child in the Trendelenburg position with the head turned 45 degrees away from the side of cannulation.
2. Place a pillow or rolled sheet under the shoulders to extend the head and allow complete access to the neck.
3. Under aseptic conditions, venipuncture and catheter insertion are completed according to the techniques shown in Fig. 49.2. A J-wire is usually more useful to circumvent the plexus of veins at the clavicle.[74,75]
4. Suture or tape appropriately and cover with an occlusive dressing. Many catheters will not pass beyond the clavicle or will pass into the axillary vein; success is generally more often attained on the right side.[76,77] If a shorter catheter is used, infusion and pressure monitoring are very dependent on the position of the head.[78] Continuous free-flowing infusion is best maintained when the head is turned away from the side of catheter insertion. This vein is particularly valuable in children with difficult peripheral venous access and in an emergent situation that suddenly develops intraoperatively that requires establishment of additional IV access.

Internal Jugular Vein Catheterization

Numerous approaches and techniques are used for internal jugular vein cannulation.[79–82] A high approach using the apex of a triangle formed by the two bellies of the sternocleidomastoid muscle and the clavicle may be used as a landmark for insertion (Fig. 49.4). With the use of the Seldinger technique, the success rate, even in neonates, approaches 75% on the first attempt and 90% to 95% on the second attempt.[53] Cannulation of the right side virtually ensures a central location because the internal jugular vein, the superior vena cava, and the right atrium are in a straight line (see Fig. 49.4). Left-sided cannulation risks injury to the thoracic duct and possible pneumothorax because the apex of the lung is more cephalad on the left. In addition, if the catheter inserted on the left is too short, it is not unusual for the tip to rest against the wall of the superior vena cava, be position dependent, and possibly erode through the wall of the vessel. Fig. 49.3 illustrates desirable and less desirable sites for catheter tips that may avoid or result in perforation. The principal advantage of the high approach is that the most common complication (arterial puncture, approximately 10%) is easily recognized and usually treated uneventfully.

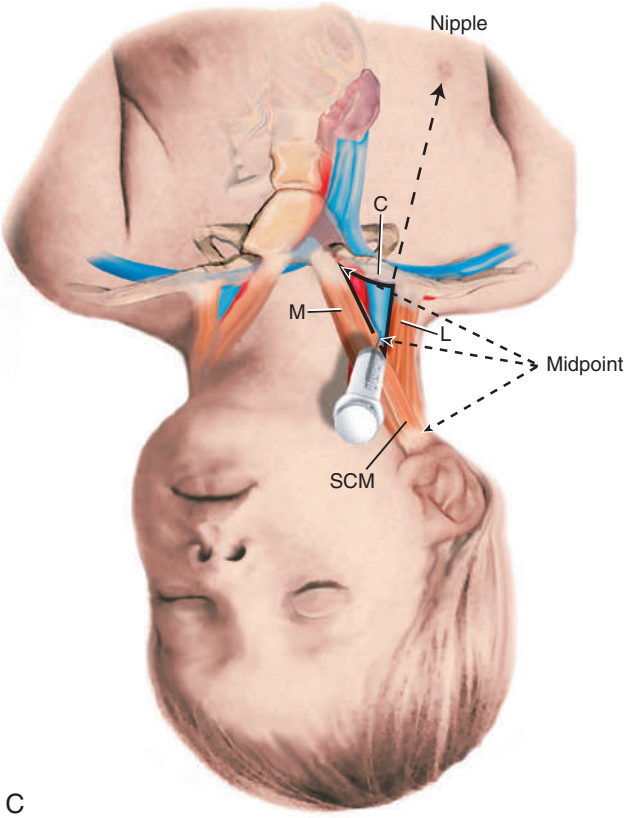


FIGURE 49.4 A, The anatomic relationships of major chest and neck structures. Note how the internal jugular vein is in close proximity to the carotid artery. Also, note that a nearly straight line is formed by the internal jugular vein, innominate vein, superior vena cava, and right atrium (*yellow dashed line*); thus it is rare for a right internal jugular catheter to migrate anywhere but to the right atrium. **B,** The relationship of external anatomic landmarks to the anatomy illustrated in **A**. Note the triangle formed by the two bellies of the sternocleidomastoid muscle and the clavicle. *1,* The preferred point of needle insertion at the apex of this triangle for internal jugular vein puncture. *2,* The point of needle insertion for subclavian vein puncture. **C,** The anatomic landmarks as they would appear to an anesthesiologist. The needle is introduced at the apex of the triangle outlined in **C** and is directed at an angle of 30 degrees to the skin toward the ipsilateral nipple. This point of entry is generally half the distance between the mastoid process and the sternal notch. *C,* clavicle; *M* and *L,* medial and lateral bellies of the sternocleidomastoid muscle (*SCM*).

In one study, the effects of a simulated Valsalva maneuver (positive inspiratory pressure of 25 mm Hg for 10 seconds), liver compression, and Trendelenburg position individually or in combination on the cross-sectional area of the right internal jugular vein were studied. The mean increase in cross-sectional area of the right internal jugular vein was maximized at 17.4% ± 16.1% from baseline when all three maneuvers were combined.[83] The magnitude of this maneuver varied with the age of the child: the effect was greatest in children 1 to 6 years of age and clinically negligible in infants younger than 12 months of age. The effect on ease of catheter placement was not investigated, but a larger-sized vessel should improve the success rate.[83] For neonates, a study using skin traction in infants weighing less than 5 kg showed that a technique using tape for skin traction combined with ultrasound guidance increased internal jugular cross-sectional area and decreased the time to place the catheter.[84–86]

Technique

1. Position the child as for external jugular vein cannulation but with a rolled towel under the center of the back to allow the head to be slightly extended (see Fig. 49.3 and Videos 49.1 and 49.2 for positioning and the use of ultrasound to guide insertion). The head is turned slightly away from the side of insertion; *turning the head too far to the side may compress the vein and move the vein in closer proximity to the carotid artery.*
2. Locate the apex of a triangle formed by the two bellies of the sternocleidomastoid muscle. This point is usually where the external jugular vein crosses the sternocleidomastoid muscle or the midpoint between the mastoid process and the sternal notch.
3. Palpate the carotid artery. Introduce the needle just lateral to this artery at an angle of 30 degrees to the skin surface. If the internal jugular vein is superficial, a less acute angle may be indicated. While continuously aspirating, advance the needle toward the ipsilateral nipple a distance of no more than 2.5 cm. If no blood is freely obtained, slowly withdraw the needle while maintaining aspiration. The needle can compress the vessel on entry, and it straightens during withdrawal, allowing free aspiration of blood.
4. Once venipuncture is accomplished, carefully remove the syringe and occlude the end of the needle (to prevent entraining air if the child is breathing spontaneously) until a flexible guidewire is inserted (see Fig. 49.2).[54] The wire should advance easily. However, if the wire cannot be advanced, the needle has passed out of the vessel lumen or its tip rests against the vessel wall. In this situation, the wire and needle should be withdrawn simultaneously to avoid shearing the wire. If the wire passes without difficulty, then cannulation proceeds as demonstrated in Figs. 49.2 and 49.4. The location of the catheter tip should be confirmed with a radiologic study and optimally repositioned as necessary (see Fig. 49.3).
5. Suture the catheter in place, and protect the area with an occlusive dressing.

Contraindications

- A bleeding diathesis (relative contraindication); in life-threatening emergencies, the benefit may outweigh the risk.
- Contralateral pneumothorax.
- Increased intracranial pressure (Trendelenburg position and venous occlusion by the catheter may increase intracranial pressure); this is a relative contraindication and ultrasound-guided insertion may provide a great advantage because Trendelenburg position may not be required.
- Aberrant vessels (e.g., cervical aortic arch).

Subclavian Vein Catheterization

The subclavian vein is a site frequently used for central vein cannulation.[87,88] Success rates greater than 80% have been reported even in neonates.[89–91] The advantages include fixed landmarks, ease of securing the line to children for long-term management, and patient comfort. Disadvantages include pneumothorax and hemothorax.[92,93] If this site is chosen, we suggest obtaining a chest radiograph after the catheter is inserted and before surgery begins to preclude an unrecognized intraoperative tension pneumothorax. The use of the Seldinger technique (our preference) may reduce the incidence of damage to intrathoracic structures compared with other techniques. As with left-sided internal jugular vein cannulation, if a left subclavian catheter tip rests against the wall of the superior vena cava, it can erode through, resulting in hemothorax or hydrothorax (see Fig. 49.3H). In a comparison of neutral versus lowered shoulder position in 361 adult patients, neutral position significantly reduced the incidence of misplacement of the catheter tip (ipsilateral internal jugular or brachiocephalic vein) with no difference in the rate of arterial puncture or pneumothorax.[94] This maneuver remains to be tested in children. As described earlier, the jugular approach was associated with a greater incidence of positive catheter tip culture results (22% vs. 3.4%) and bloodstream infection (6.9% vs. 0%) compared with the subclavian approach.[64] Importantly, although there was no significant difference in first-attempt success (64% vs. 69%), the frequency of arterial punctures was significantly greater with the internal jugular vein approach (8% vs. 2 %), but catheter malposition was greater with the subclavian approach (17% vs. 1%). A Cochrane review of 13 studies with 2360 procedures compared ultrasound cannulation of femoral or subclavian access with landmark techniques and found no difference in complications or success rate, although the experience of the clinicians was not examined.[95]

Technique

1. Prepare and position the child as previously described for external jugular vein puncture.
2. Insert a needle immediately inferior to the clavicle at a point one-half to two-thirds its length from the sternoclavicular junction; while "hugging" the undersurface of the clavicle, the needle is directed toward the suprasternal notch while continuously aspirating.
3. As soon as free blood flow is obtained, proceed as in Fig. 49.2. If the Seldinger technique is not used, then first locating the subclavian vein with a small-gauge finder needle is recommended.
4. Suture the catheter in place, and apply an occlusive dressing.

If the child's ventilation is controlled, the risk of pneumothorax may be decreased by momentarily ceasing ventilation so that the apex of the lung is away from the needle tip while probing for the subclavian vein. Once successful venipuncture has been achieved, maintaining positive end-expiratory pressure reduces the possibility of air embolism. Optimal depths for right subclavian catheterization have been studied in infants 2 to 5 kg using transesophageal echocardiography and were found to be 40 to 55 mm for catheter tip placement at the junction of the superior vena cava and the right atrium.[96] Contraindications are the same

as for internal jugular vein catheterization (see Video 49.1 for illustration of technique).

Brachiocephalic Vein Catheterization

The brachiocephalic vein offers the advantage of being far removed from the intrathoracic structures.[97] The main disadvantage is that a significant number of catheters introduced at this site do not pass centrally—that is, they are caught in the axilla or pass up the jugular vein (internal or external).[98–100] Other disadvantages include significant catheter migration with movement of the arm and possibly an increased incidence of infection. This approach is commonly used by radiologists and pediatric nurses for placement of peripherally inserted central catheters (PICCs), which can be used on a long-term basis.[101–103] These catheters often markedly improve patient care and the quality of life for the child because of the reduced need for peripheral venous access and the reduced number of venipunctures for blood testing. One study examined an ultrasound supraclavicular approach in infants weighing 0.7 to 10 kg; they had a 98.9% success rate with more punctures needed on the right than the left.[104] The routine use of heparin to prevent catheter thrombosis and occlusion is not supported by published studies, but the data are inadequate to reach a conclusion one way or the other.[105]

Technique

1. Prepare and drape the arm with aseptic technique.
2. Cannulate the brachiocephalic vein either by using the modified Seldinger technique (special long catheters and wires for this purpose) or by passing a catheter through a needle (Intracath CVC Catheter, Argon Medical, Plano, Texas). If the catheter cannot be threaded once the vein is entered, initiating rapid IV fluid administration, cephalad positioning of the arm, and anterior displacement of the shoulder may assist advancement. If percutaneous techniques are not possible, direct venous cutdown may be performed.

Femoral Vein Catheterization

The femoral vein may also be used for access to the central circulation.[106] When trainees placed such lines, the ultrasound approach was superior to the palpation/landmark approach,[107] although in more experienced hands, ultrasound did not improve the success rate.[95] The catheter must pass into the thorax to provide accurate measurements of the cardiac filling pressures. Nonetheless, there is a reasonable correlation with central filling pressures even when the catheter tip rests within the abdomen.[108] Occasionally, the catheter is inadvertently advanced into a vertebral vein; this can be confirmed with a lateral radiograph. One advantage of this route is that the vein is large and presents easy access distant from the vital intrathoracic structures (Fig. 49.5). Disadvantages include difficulty in securing the catheter to the child, kinking of the catheter with leg flexion, and problems in maintaining insertion site sterility. Short-term catheterization can provide large-bore venous access for the duration of a procedure with expected large and rapid blood loss if other veins are not accessible. Surprisingly, this site is not associated with a greater incidence of catheter-related sepsis compared with other insertion sites.[63,109] This site is not appropriate if disruption of inferior vena cava blood flow is possible (e.g., Wilms tumor resection with invasion of the inferior vena cava, abdominal trauma). The tip of the catheter should be located either low in the atrium or inferior to the level of the diaphragm but superior to the level of the renal veins to reduce the potential for renal vein thrombosis. Use of this technique also has been reported to be safe in infants weighing less than 1000 g with the caution of careful catheter advancement to avoid cardiac perforation.[110]

Technique

1. Prepare and drape the groin using an aseptic technique with the legs at 90-degree angles ("frog-leg position") (see Fig. 49.5B). Place a roll under the hips, thereby slightly elevating the hip, to provide optimal conditions
2. Palpate the femoral artery at a point midway between the pubic tubercle and the anterior superior iliac spine (see Fig. 49.5, *A*).

   Using the Seldinger technique, enter the vein at a point just medial to the femoral artery and 1 to 2 cm below the inguinal ligament. Insert a catheter as in Fig. 49.2. As for the brachiocephalic vein, special long catheters and wires are needed to achieve a central location (see Video 49.2). As with many vascular access methods, ultrasound guidance can be quite useful.[107,111–113]
3. Protect the catheter insertion site as previously described (see discussion of internal jugular vein catheterization). If an alternative technique is used (e.g., catheter through the needle), maintain compression of the cannulation site until hemostasis is ensured. The saphenous vein may be cannulated by direct venous cutdown at its junction with the femoral vein if percutaneous techniques are unsuccessful.

INTRAOSSEOUS INFUSION

The administration of IV fluid into the medullary cavity of long bones is a proven method for volume resuscitation in a hypovolemic child and even in teenagers.[114–121] This method can effectively deliver drugs to the central circulation as quickly as using peripheral IV infusion sites.[122] It is a particularly valuable emergency route of drug administration, even in the hands of emergency medical technicians[123–125] and as part of emergency department resuscitation of pediatric trauma patients.[118,126] Complications such as cellulitis, abscess, fractures, and osteomyelitis have been reported in less than 1% of cases, and this technique does not appear to affect later growth of the tibia with proper insertion technique,[127–129] but the time required for bone healing is unknown.[130] Compartment syndrome may occur if the needle is misplaced. These complications relate in part to duration of infusion, underlying medical conditions, and aseptic technique. The major difficulties with this technique are due to failure to adhere to proper landmarks[131] and bending and clotting of the needle. This technique is used in an emergency situation if several attempts at peripheral or central venous cannulation have failed (suggested "if you cannot achieve reliable access quickly," which generally means after three attempts or 90 seconds).[132,133] Sites for insertion include the upper medial tibia just below the tibial tuberosity, the lower medial tibia just superior to the medial malleolus (to avoid growth plates), the lower femur, and the anterior iliac crest. Intraosseous infusions are discontinued once an alternative IV infusion site has been secured. This technique has been successfully used for resuscitation of burn victims.[134,135] Intraosseous devices should not be used in a fractured leg. For the most recent, complete information, please refer to a review directed to the anesthesiologist caring for pediatric patients.[136]

Technique

1. Palpate the tibial tuberosity.
2. Locate a point on the medial surface of the tibia at least 1 to 2 cm below and medial to the tibial tuberosity for the

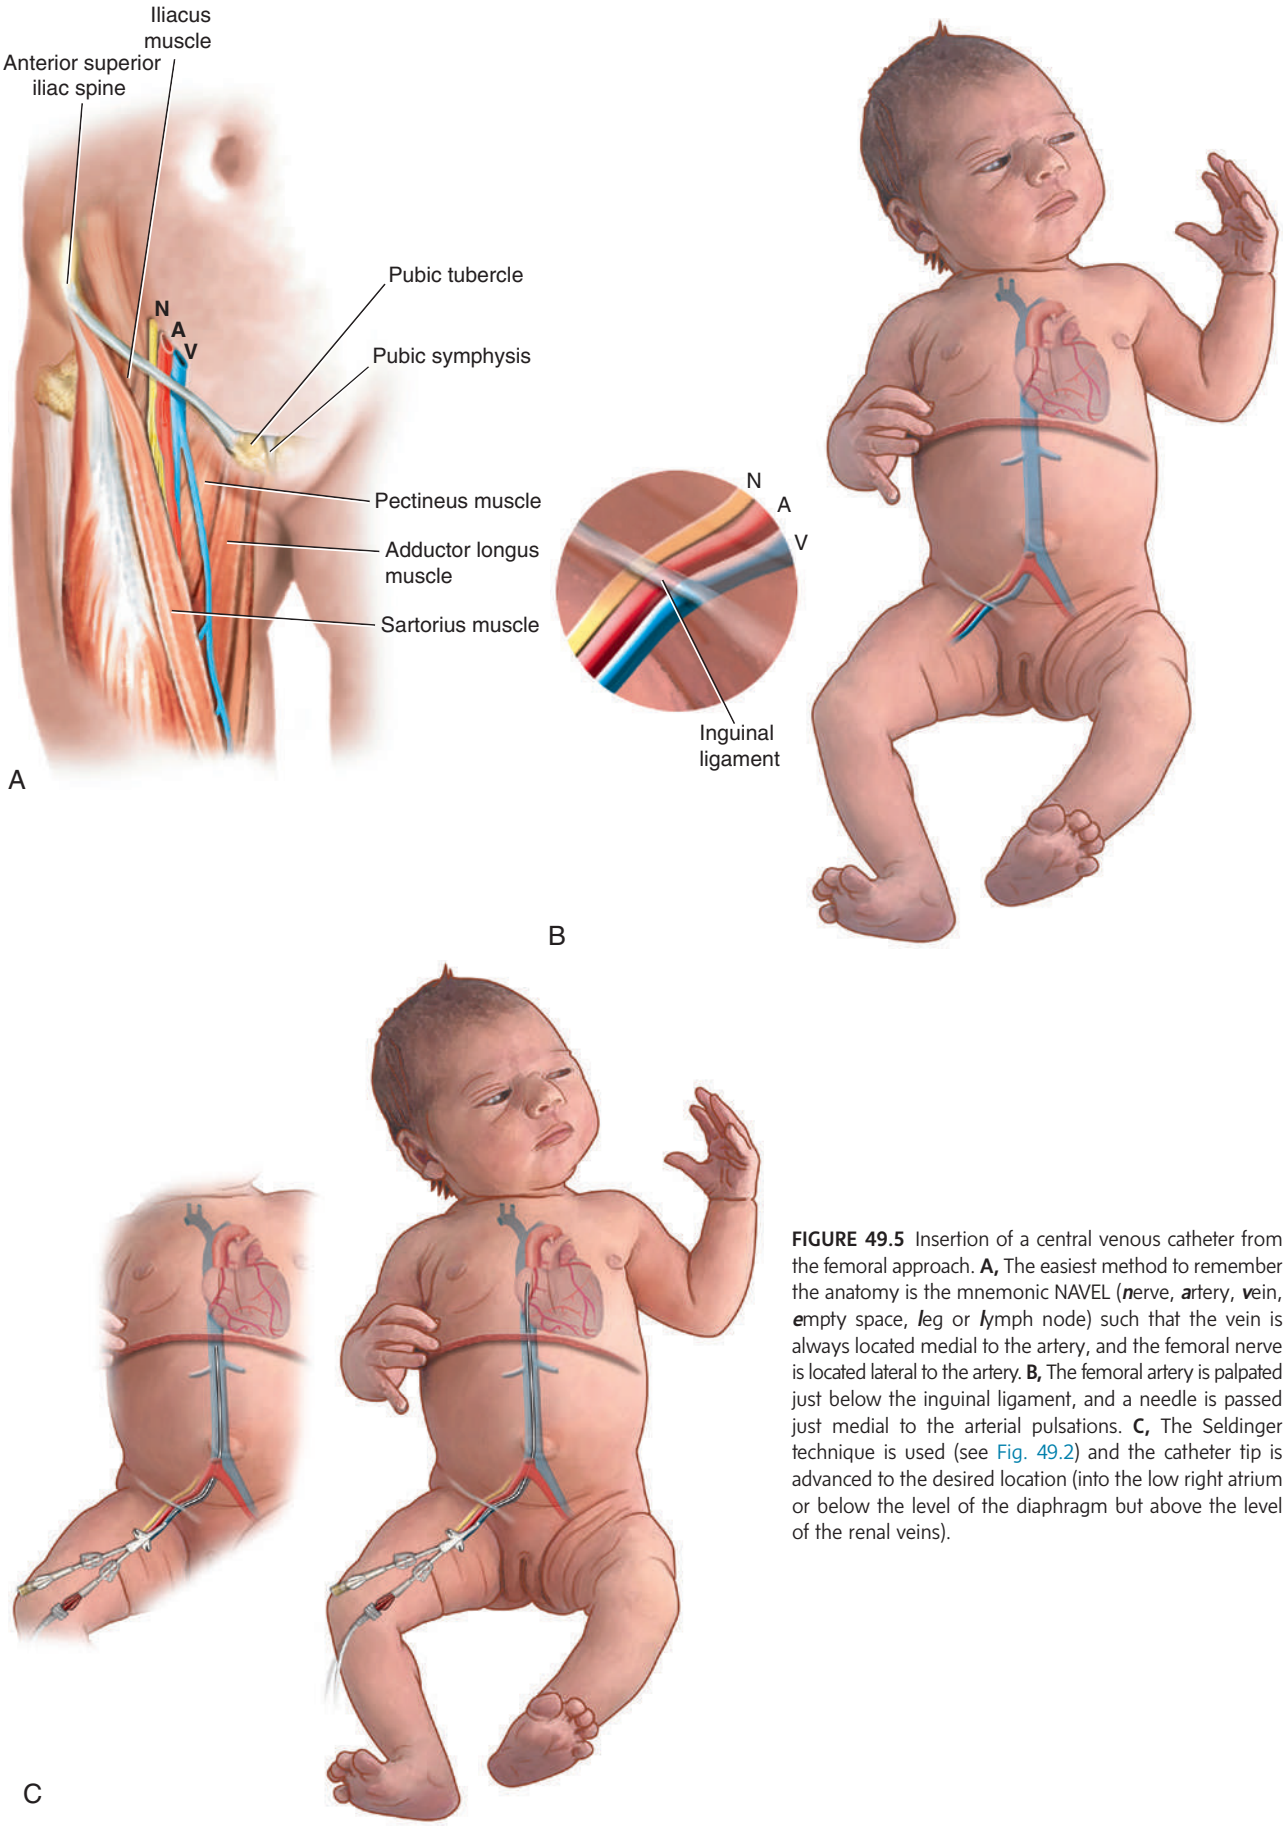

FIGURE 49.5 Insertion of a central venous catheter from the femoral approach. **A,** The easiest method to remember the anatomy is the mnemonic NAVEL (***n***erve, ***a***rtery, ***v***ein, ***e***mpty space, ***l***eg or ***l***ymph node) such that the vein is always located medial to the artery, and the femoral nerve is located lateral to the artery. **B,** The femoral artery is palpated just below the inguinal ligament, and a needle is passed just medial to the arterial pulsations. **C,** The Seldinger technique is used (see Fig. 49.2) and the catheter tip is advanced to the desired location (into the low right atrium or below the level of the diaphragm but above the level of the renal veins).

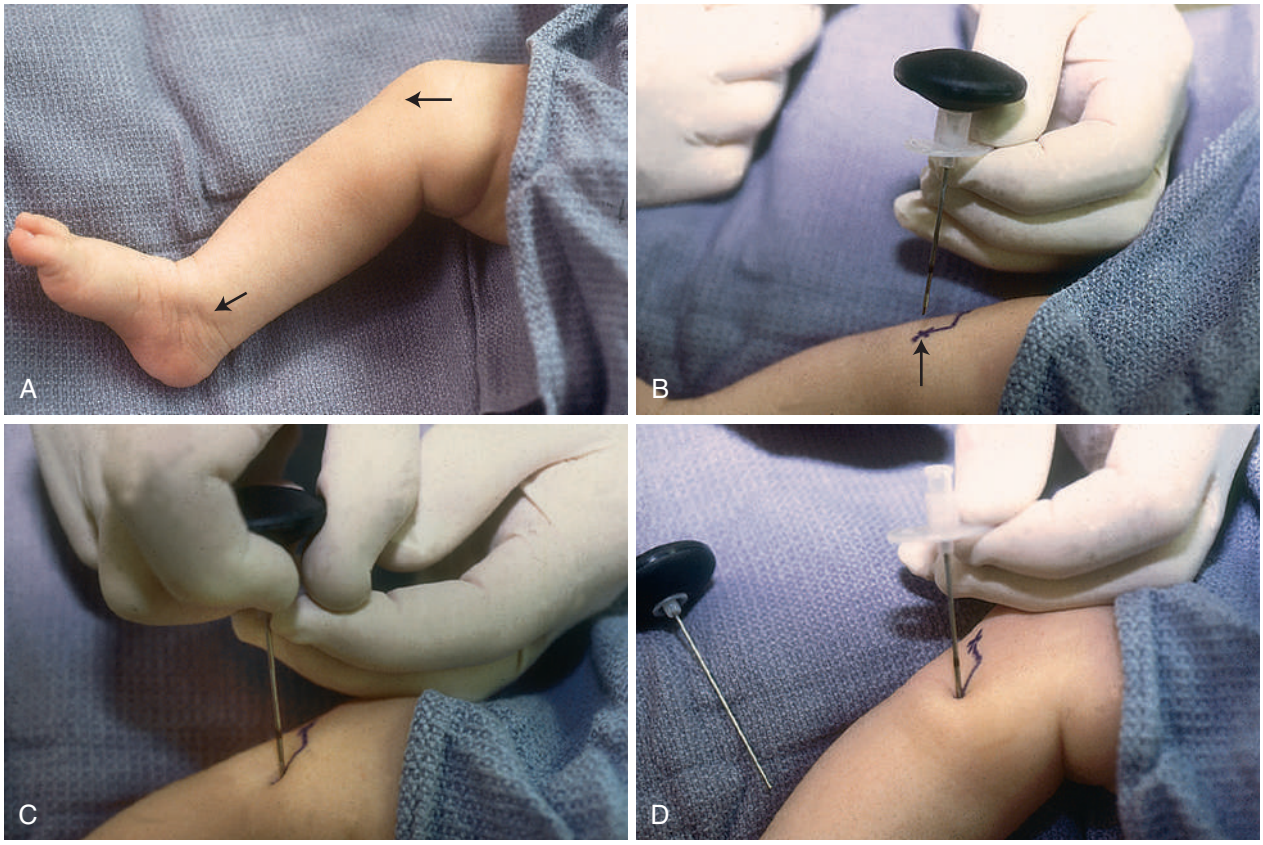

FIGURE 49.6 A, The intraosseous needle may be inserted in either of two locations: at a point 1 to 2 cm below and medial to the tibial tuberosity or at the medial malleolus (*arrows*). **B** and **C,** The leg is prepared, and the intraosseous needle punctures the skin (note the *X mark (arrow)* connecting the tibial tuberosity with the point of needle insertion); the needle is advanced with a twisting motion in a caudal direction. **D,** The stylet is removed, and the selected solution is infused.

site of needle puncture, because the mantle of the tibia is thin at this location (Fig. 49.6A).

3. Use a special short needle with a stylet to puncture the mantle of the tibia at a 75-degree angle directed toward the feet to avoid the epiphyseal plate (see Fig. 49.6B and C). A styleted spinal needle also may be used.
4. The appropriate position is readily achieved with the loss of resistance; take care to avoid advancing the needle too far (i.e., out the opposite side or against the opposite mantle of the tibia). The needle is usually quite stable if properly positioned.
5. Attach standard IV infusion equipment. Fluid should flow freely without extravasation (see Fig. 49.6D).

A mechanical handheld, battery-powered intraosseous needle insertion device that works much like an electric drill (Fig. 49.7) is the EZ-IO (Teleflex Medical Inc., Research Triangle Park, NC). Several sizes of intraosseous needles (depth of insertion) are available to limit the depth of insertion (determined by patient weight); we recommend that this device be immediately available in all operating rooms[137] and prenatal ICUs because this is the simplest and easiest means for establishing emergent intraosseous access (even in out of hospital venues).[138–143] The specially designed IV fluid low-profile adapter (already primed with IV fluid) is then attached to the sheath, providing clear access for drugs, fluid, or blood administration.

UMBILICAL VEIN CATHETERIZATION

Indications

The umbilical vein provides convenient access to the central circulation of a neonate to restore blood volume and to administer glucose and drugs. This procedure is often carried out blindly with later radiographic confirmation of correct position. A large fraction of catheters are initially malpositioned, which if unrecognized, can lead to life-threatening complications.[144–148] Monitoring changes in the ECG may be helpful (see further). A change in the configuration of the electrocardiogram (ECG) suggests that a small QRS complex reflects catheter position below the diaphragm; a normal-sized QRS complex with a small P wave was associated with location within the inferior vena cava at the thoracic level; and the appearance of a tall P wave indicated positioning within the right atrium.[144] Umbilical vein catheterization also provides a route for the procedure of exchange transfusion and for measuring central venous pressure.

Equipment

- Umbilical artery catheter sizes 3.5F and 5F
- Scalpel and blade
- Fine-curved forceps
- Mosquito hemostats
- Umbilical tape
- Scissors
- Sutures with needle (3-0 silk)

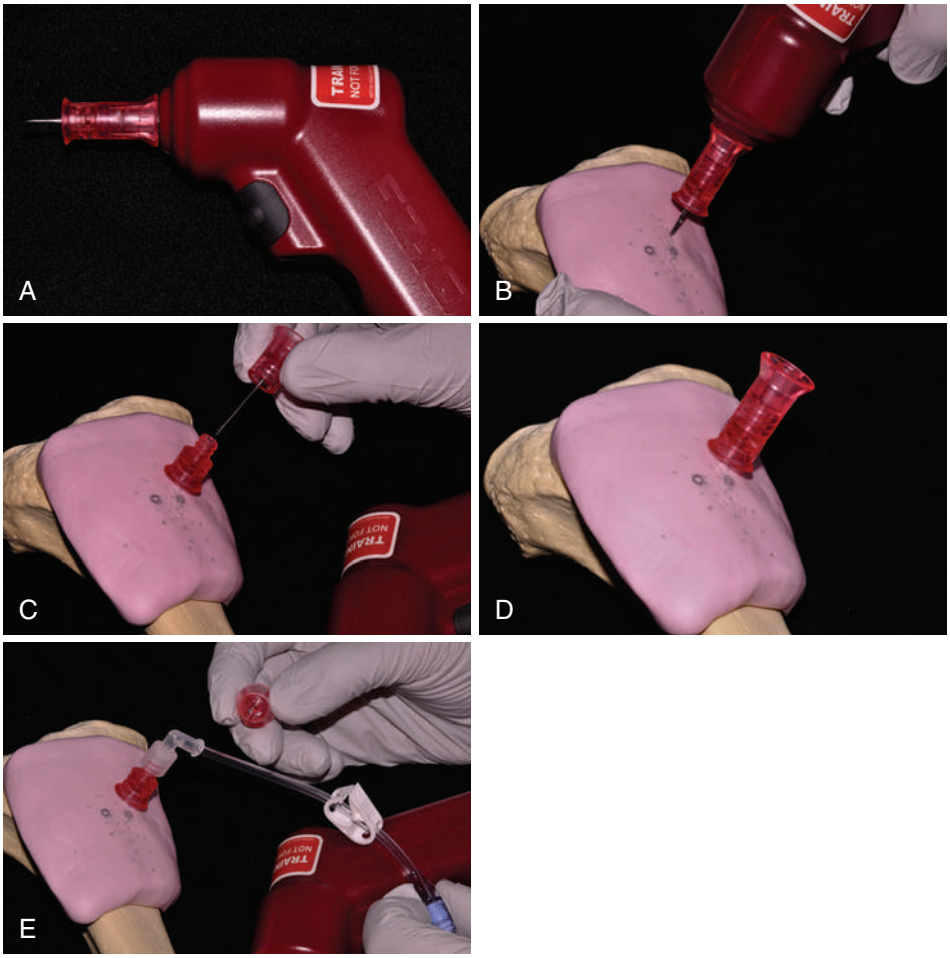

FIGURE 49.7 A, The EZ-IO (Teleflex Medical Inc., Research Triangle Park, NC) is a battery-powered intraosseous needle insertion device that works much like an electric drill. **B,** After appropriate preparation of the skin, at a point 1 to 2 cm below and medial to the tibial tuberosity, the intraosseous needle is directed down and away from the epiphyseal plate. **C,** After successful insertion of the needle and its sheath, the needle is removed, leaving the tip of the metal sheath lodged within the bone marrow cavity. **D,** The intraosseous system is ready for connection and use. **E,** The specially designed intravenous fluid adapter (already primed with intravenous fluid) is then attached to the sheath, providing clear access for drugs, fluid, or blood administration. (Courtesy Charles J. Coté, MD.)

- Antiseptic solutions (e.g., povidone-iodine and alcohol)
- Three-way stopcocks
- 10-mL syringe
- Sterile drapes
- Infusion solution of 10% dextrose in water, with 1 to 2 units of heparin per milliliter at 1 mL/hour
- Calibrated transducer/monitoring system if used for central venous pressure measurement

Technique

1. Prepare and drape the umbilicus with sterile technique; cut the cord approximately 1 cm above the umbilicus. The umbilical vein orifice is more patulous and thin walled than the two umbilical arteries (Fig. 49.8).
2. Holding the catheter filled with heparinized solution 2 cm from the tip, gently introduce it into the vein. In some situations, forceps can aid in directing the catheter. Traction of the umbilical stump *caudad* may help to advance the catheter (see Fig. 49.8). The catheter is passed a distance that approximates the length between the umbilical stump and the right atrium. Blood should freely aspirate into a syringe. Inability to withdraw blood may occur if the tip of the catheter is resting against a vessel wall or if a clot is present within the catheter lumen. *It is important that the tip of the catheter be placed in the proper position—that is, at the junction of the inferior vena cava and right atrium.* A radiograph confirms proper catheter position. Monitoring changes in the configuration of the ECG during insertion may allow for a more accurate placement within the right atrium but is limited to neonates with a normal tracing.[144] At times, the catheter may fail to traverse the ductus venosus and become wedged in the liver. This position is potentially dangerous because portal necrosis and subsequent cirrhosis may result should hyperosmolar or sclerosing solutions be injected (calcium, sodium bicarbonate, 25%–50% glucose).[148–150] A low position might be acceptable for short-term use if it is not possible to pass the catheter centrally, but the distance of insertion should

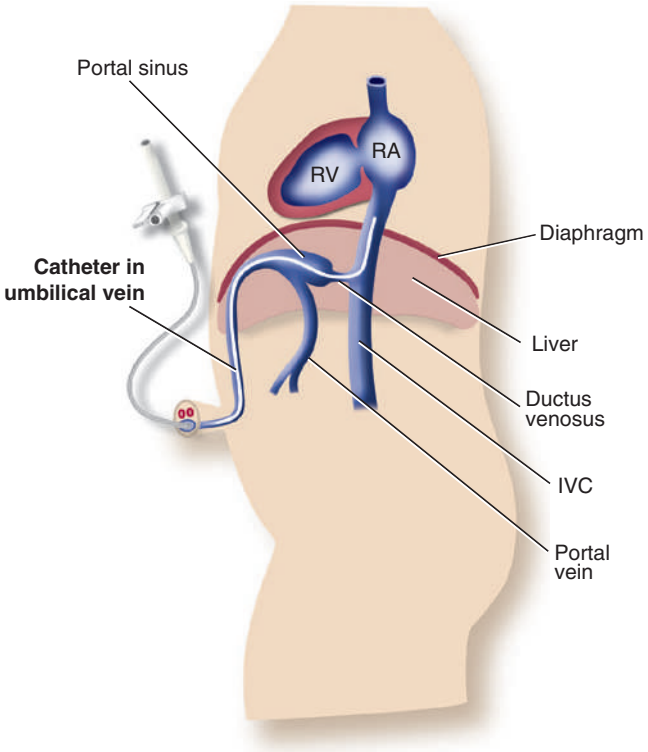

FIGURE 49.8 Umbilical vein catheterization. The umbilical vein is thin walled and patulous, whereas umbilical arteries are thicker walled and of smaller diameter. *Caudal* traction on the umbilical stump may facilitate catheter advancement. The catheter should be advanced through the liver into the central circulation within the low right atrium (*RA*) before administration of any medications. *IVC,* Inferior vena cava; *RV,* right ventricle.

be no more than 3 to 4 cm or just until blood is freely aspirated.

3. Suture the catheter in place, cover the insertion site with antibiotic ointment, and tape it to the abdominal wall. The catheter is then connected to a constant-infusion system and should be removed as soon as the indications for its insertion have passed. Complications appear to relate in part to the duration of insertion.[146,148,151]

Complications

- Thrombosis of portal or mesenteric veins[148,152]
- Infection (septicemia)[146]
- Endocarditis
- Pulmonary infarction (misplacement of the catheter into the pulmonary vein through a patent foramen ovale)
- Portal cirrhosis and esophageal varices later in life[153–156]
- Cardiac tamponade[157]
- Liver abscess and subcapsular hematoma[145,158]

Arterial Cannulation

UMBILICAL ARTERY

The umbilical artery in a neonate is a convenient site for monitoring arterial blood pressure, blood gases, and pH. It provides emergency access to an infant's circulation for restoration of blood volume and administration of glucose and drugs.[159–162] Continuous monitoring of arterial O_2 saturation is also possible.[163]

Equipment

The materials used for cannulation are identical to those described for umbilical venous catheterization. Equipment is required for continuous monitoring of blood pressure. *End-hole rather than side-hole catheters may have a smaller incidence of thrombosis or associated ischemic events.*[164]

Technique

1. Prepare and drape the area with sterile technique; cut the umbilical cord approximately 1 cm above the umbilicus. The two umbilical arteries are identified (Fig. 49.9). The cut vessel ends have thicker walls, are smaller than the vein, and are usually in spasm. The artery is entered in the manner described for umbilical vein catheterization, except that *cephalad* traction is applied to the umbilical stump (see Fig. 49.9A) to encourage *caudal* direction of the catheter. The catheter should course through the umbilical artery into the iliohypogastric artery and then into the descending aorta. Proper positioning of the catheter tip is crucial. If the catheter is advanced too far up the aorta, it may pass through the ductus arteriosus and into the pulmonary artery. If this situation is not recognized, blood pressure and blood gas measurements may be misleading. Care should be taken to ensure the placement of the catheter tip in the descending aorta (at T7 to T9). Early reports suggested that a cephalad position, at or above the level of the diaphragm, is easier to maintain but predisposes infants to increased risk of embolization to renal or mesenteric vessels (see Fig. 49.9B).[165–168] However, positioning just above the bifurcation of the descending aorta–that is, at L3 to L5 (see Fig. 49.9A) (below the origin of the renal arteries and visceral branches of the aorta) has not been supported by a Cochrane review; a cephalad position is recommended.[169] The caudad position is difficult to maintain, and the catheter tip may slip into one of the iliac arteries, resulting in tissue ischemia (see Fig. 49.9C).
2. Confirm the position radiographically. Once the catheter is properly positioned, the system is connected to a constant-infusion pump and heparinized fluids (10% dextrose in water or normal saline solution) are infused. Suture and tape the catheter and apply antibiotic ointment as for umbilical vein catheters. A Cochrane review of the use of heparin suggested that low-dose heparinization of the infusate (0.25 unit/mL) reduces the likelihood of catheter occlusion compared with intermittent flushing with heparinized solutions.[170]

Complications

Using the umbilical artery as a source for blood pressure monitoring and blood gas analysis only and reserving alternative sites for glucose and drug administration may minimize complications. Changes in cerebral blood flow are associated with intraventricular hemorrhage and have been documented to occur with umbilical artery blood sampling; fewer changes in cerebral blood flow occur with low-positioned catheters.[171] The incidence of documented intraventricular hemorrhage appears to have a stronger relation with age than with catheter position and is not associated with the use of low-dose heparin.[170,172] The use of an alternate site for monitoring may reduce complications.[173] Other complications are as follows:

- Accidental disconnection of stopcocks and catheters or vessel perforation can lead to potentially dangerous exsanguination.[174]

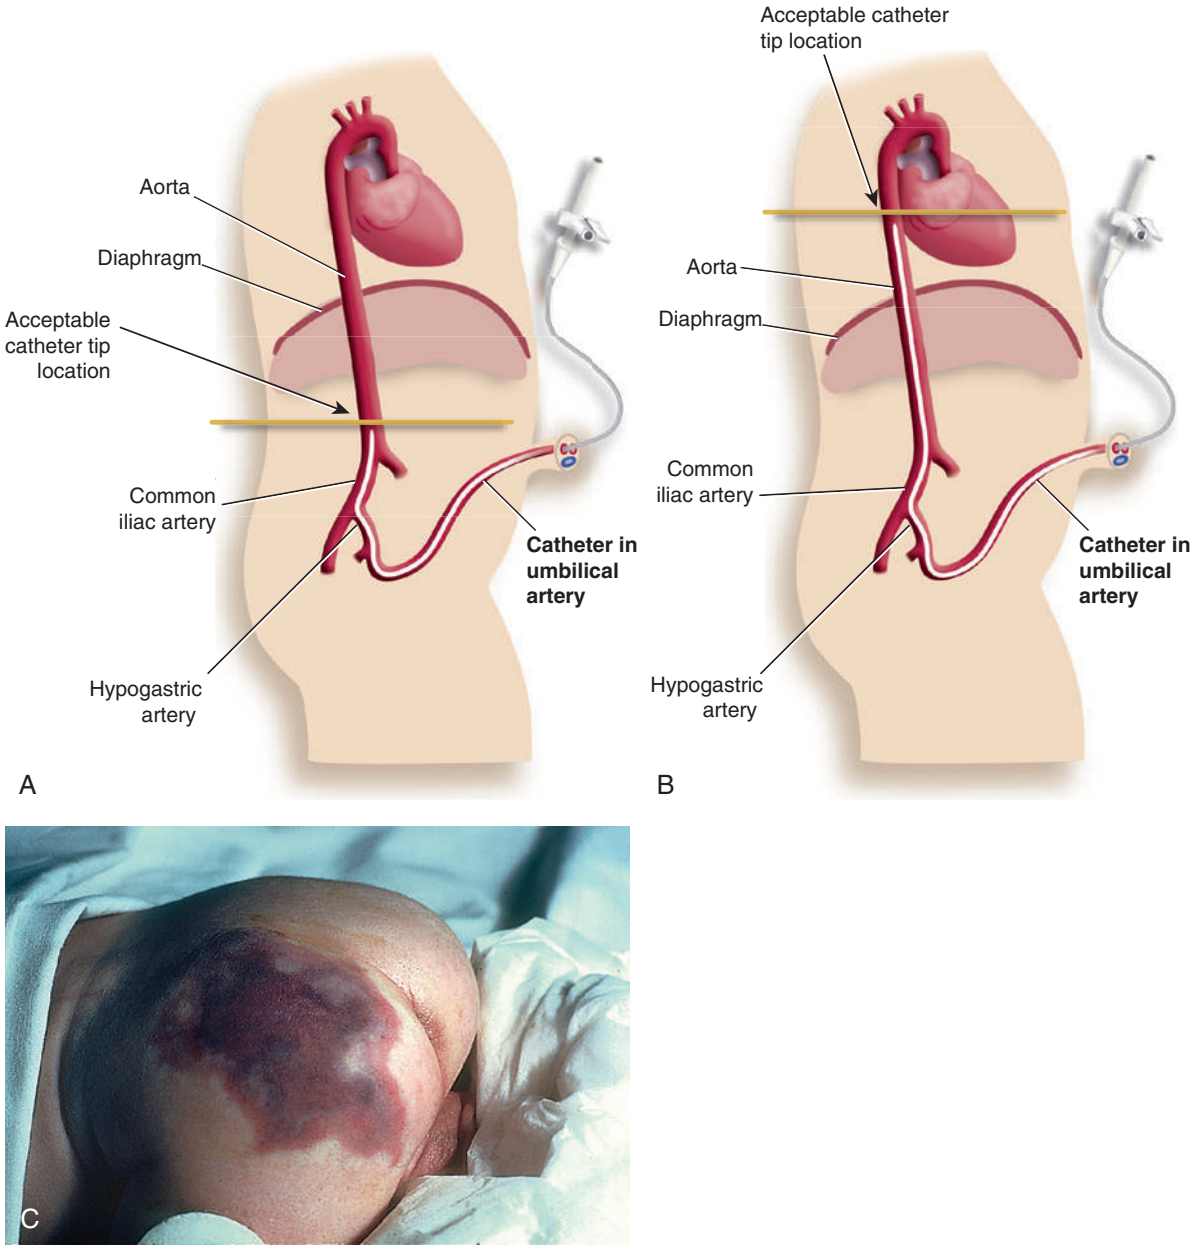

FIGURE 49.9 Umbilical artery catheterization. *Cephalad* traction on the umbilical stump may facilitate catheter advancement. **A,** The catheter tip at L3-4 just above the aortic bifurcation and below the renal arteries is one acceptable location (*arrow to yellow line*). **B,** An alternative acceptable location is in the descending aorta between T7 and T9 (*arrow to yellow line*). **C,** An area of necrosis in the left buttock that resulted from a catheter migrating into the internal iliac vessel, occluding one of its branches.

- Blood clots may embolize retrograde or, more likely, distally, leading to ischemia or infarction of the infant's gut, kidneys, or lower limbs (see Fig. 49.9C).[175]
- Vascular spasm is usually transitory and may be resolved by withdrawal of the catheter. Several cases of flaccid paraplegia have been reported resulting from spasm or embolic phenomena.[176]
- The infant is always at risk for sepsis; therefore clear indications for the insertion of this catheter are mandatory. The catheter should be removed at the earliest possible time. A Cochrane review failed to establish a role for prophylactic antibiotics in reducing catheter-related infections.[177]
- Hypertension as a result of renal artery emboli may cause ischemia and infarction of the kidney.[168,178]
- Aortic thrombosis may occur.[179]

RADIAL ARTERY

Radial artery cannulation is a reasonable alternative to umbilical artery cannulation in a neonate and is the primary site of arterial cannulation in infants and children in most pediatric institutions. Percutaneous radial artery cannulation is widely practiced, with minimal morbidity.[146,180–185] The use of ultrasound may improve success rate.[186] Failure to cannulate the artery percutaneously may be followed successfully by direct arterial cutdown. Children with

Down syndrome (trisomy 21) have abnormal radial vessels (both size and location, 16% to 19%), which can make arterial cannulation particularly difficult; some children with Down syndrome have a single median artery.[187,188] The ulnar artery also has been used as an alternative site for arterial catheterization when attempts at insertion in other locations have been unsuccessful; to ensure adequate perfusion of the hand, this site should not be used if previous attempts at cannulation of the ipsilateral radial artery had been attempted.[189]

Indications

Indications for radial artery cannulation include monitoring of arterial blood pressure, arterial blood gases, and pH. The right radial artery is preferred in neonates because it is representative of preductal blood flow.

Technique (Video 49.3)

1. Confirm the adequacy of ulnar artery collateral flow by the modified Allen test (Fig. 49.10A). The color of the hand is noted. The hand is passively clenched, and the radial and ulnar arteries are simultaneously compressed at the wrist (see Fig. 49.10B). The ulnar artery is then released, and flushing (reperfusion) of the blanched hand is noted (see Fig. 49.10C). If the entire hand is well perfused while the radial artery remains occluded, indicating adequate collateral flow, catheterization of the radial artery is performed. Note that the sensitivity of the Allen test is approximately 73%, with a specificity of 97%.[190–192] Many have abandoned the Allen test because of its poor sensitivity as a predictor of ischemia of the hand if the test failed and they simply avoid cannulating the ulnar artery.
2. Secure the hand using an arm board with slight extension of the wrist to avoid excessive median nerve stretching. The fingertips should be left exposed when the hand is taped down so that any peripheral ischemic changes from spasm, clot, or air can be observed.
3. Observe the course of the radial artery in a neonate with the aid of a fiberoptic light source directed toward the lateral side or dorsal aspect of the wrist. Use of a Doppler device or visualization via ultrasound[186] may also be of great value.[193,194]
4. Use a 20-gauge needle to make a small skin puncture over the maximal pulsation of the radial artery, usually at the second proximal wrist crease. This step eases passage of the cannula by reducing resistance offered by the skin and prevents a burr from forming on the catheter tip as it passes through the dermis. A method to avoid accidental puncture of the artery is to pull the overlying skin laterally to make the skin nick.
5. Perform cannulation with a 24- or 22-gauge catheter either on direct entry of the artery at an angle of 15 to 20 degrees or on withdrawing the cannula after transfixion of the artery (Fig. 49.11A to C). A wire (0.018 inch) may be used as an aid to advance 22-gauge and nontapered 24-gauge catheters.
6. Attach the catheter firmly to a T-connector to permit continuous infusion of isotonic saline solution (1 unit/mL) at the rate of 1 to 2 mL/hour via a constant-infusion pump (see Fig. 49.11D). The catheter is securely taped in place. A pressure transducer is connected to allow continuous arterial pressure monitoring. To ensure accurate blood pressure measurement, it is essential that the transducer is calibrated to the neonate's or child's heart level, that all air bubbles are removed from the system, and that no more than 3 feet of tubing is used between the neonate or child and the transducer to minimize artifacts caused by the monitoring tubing.[195]
7. Obtain blood samples by clamping off the distal end of the T-connector, cleaning the injection port of the T-connector with povidone-iodine, introducing a 22-gauge needle, and withdrawing 1 mL of blood. A sample of blood is obtained by heparinized syringe, with minimal blood

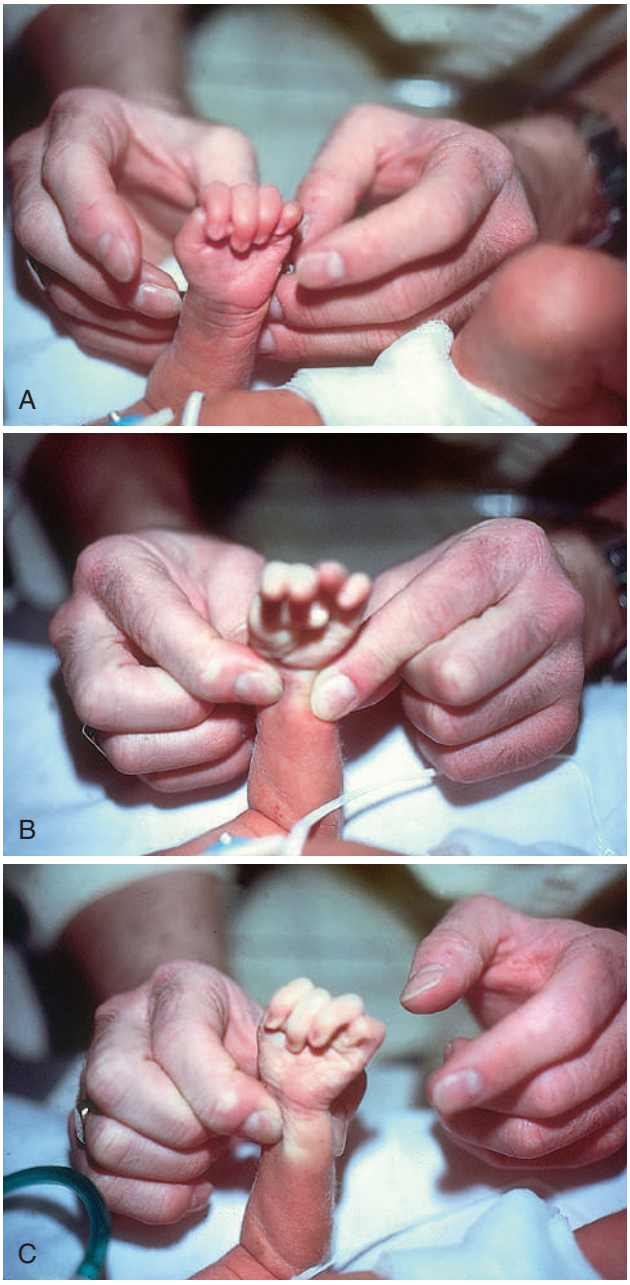

FIGURE 49.10 Modified Allen test. **A,** Color and perfusion of the hand are noted. **B,** The hand is first passively clenched, and then both radial and ulnar vessels are occluded. **C,** The ulnar artery is released while the radial artery remains occluded. If flow through the ulnar artery and collateral arch in the hand is adequate, the color and perfusion should rapidly return. If not adequate, then simply do not cannulate the radial artery.

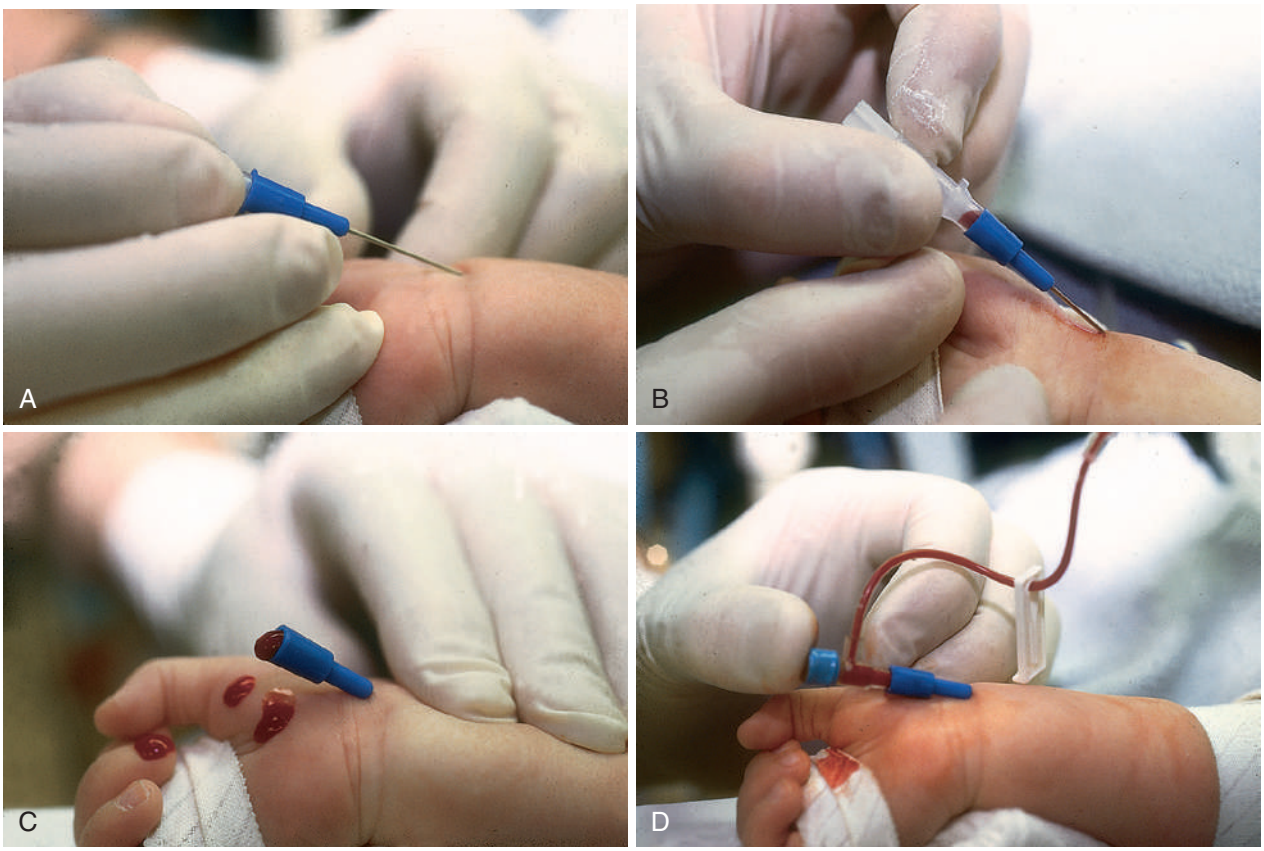

FIGURE 49.11 A, After adequate collateral circulation has been ensured, the radial artery is palpated and the appropriate catheter is advanced into the vessel. **B,** After blood return is noted, the catheter is threaded over the needle and into the artery. **C,** Pulsatile backbleeding confirms intraarterial position. **D,** A T-connector with appropriate flush solution is connected; the catheter is aspirated to clear air bubbles and then gently flushed. Antibiotic ointment and benzoin are applied. The injection port should be clearly marked as "arterial" to minimize accidental drug administration into the artery. A Luer-Lok connection is preferred to prevent accidental disconnection.

loss and minimal manipulation of the system.[180,196] An alternative is the use of a 3-mL syringe on a three-way stopcock: aspirate 2 to 3 mL, clamp the system, and then take the sample of blood from the T-connector as just described. After sampling, the clamp is released, the aspirated blood is readministered, and continuous infusion is resumed or flush is run into the 3-mL syringe and then the system is gently manually flushed intermittently with the syringe but the flush syringe is changed just once per 24 hours. This method of sampling maintains a closed system with reduced potential for sources of infection. Bolus flushes should be very brief or a slow infusion because prolonged flushing in neonates and infants may flush a crystalloid solution retrograde to the brain and cause a stroke. Disastrous results may occur if an air bubble or blood clot should accompany a bolus flush.[197–201] *All arterial lines must be clearly identified (red tape) to avoid accidental infusion of hypertonic solutions and sclerosing medications.*

Complications

- Infection at the site of the catheter insertion, with possible septicemia.
- Arterial thrombus formation. This depends on the size of catheter inserted, the material of which it is constructed, the technique of insertion, and the duration of cannulation.
- Emboli. A blood clot or air may embolize to the digits, resulting in arteriolar spasm or more serious ischemic necrosis.
- Disconnecting the catheter from the infusion system. Blood loss may be life-threatening, especially in an infant.
- Ischemia. The radial artery cannula should be withdrawn if ischemic changes develop.
- Vasospasm. Usually transient but requires careful observation.

The method just described is the traditional percutaneous radial artery cannulation at the ventral aspect of the wrist. The radial artery on the dorsal aspect of the wrist within the anatomic snuff box may be used as an alternative site.[202] Once an attempt at cannulation of the radial artery is made, the ipsilateral ulnar artery should not be instrumented to ensure adequate perfusion of the entire hand. Strict indications for inserting radial artery catheters are necessary, and their removal must be considered at the earliest possible time.[165–168]

AXILLARY ARTERY

Even though axillary arterial cannulation is reported to be used in children as a site when radial or lower extremity access fails, there are few studies specifically related to the risks and benefits of axillary access. In a study of 96 arterial catheters in 56 adult surgical ICU patients, catheter-related infections were increased with prolonged insertion.[203] The infection rate at axillary sites was greater than at the radial and femoral sites. There is only one

publication of axillary arterial monitoring in pediatric patients and it reported no major complications in 16 children.[204] Seven of these patients were neonates with the duration of insertion from 5 to 15 days. There were no differences in systolic blood pressures in either arm after the line was removed or during the time the line was in place. In general, an ultrasound guided technique is highly recommended to minimize damage to surrounding structures (brachial plexus).

TEMPORAL ARTERY

When the radial artery has been previously cannulated or is inaccessible, the temporal artery may be used.[205] Cerebral infarction has been described as a complication of this technique. It appears to be related to retrograde embolization of air or a blood clot.[206] An advantage of this sampling site is that it provides preductal blood gas values. However, in our experience, the tortuous course of the artery and the resultant apposition of the distal tip of the catheter and the arterial wall have caused difficulties in freely drawing blood samples.

FEMORAL ARTERY

Femoral catheterization in infants and children includes a greater risk of vascular injury or thrombosis resulting in ischemia[207] and is not recommended if other peripheral sites are available. In situations in which peripheral arterial cannulation is impossible (e.g., in burned patients, children with poor peripheral perfusion, children with congenital heart disease), the femoral artery should be used rather than not having any invasive arterial monitoring; the remote possibility of a complication must be balanced versus a greater likelihood of life-threatening complications owing to less than ideal monitoring.[208]

Technique

1. Locate the femoral artery by palpation at the groin; this can be confirmed with ultrasonic guidance. Anatomically, it is situated midway between the anterior superior iliac spine and the pubic tubercle (See also Fig. 49.5).
2. After sterile preparation of the skin, insert a catheter of appropriate size into the femoral artery using the Seldinger technique. The artery is entered at the point of maximal pulsation, approximately 1 cm below the line joining the anterior superior iliac spine and the pubic tubercle.
3. After cannulation, connect the catheter to a continuous-flow system and pressure transducer. The catheter is sutured in place, the insertion site is covered, and an occlusive dressing is applied. The possibility of fecal and urinary contamination makes this last step particularly important.

Complications

- Infection
- Emboli of clot and air, leading to ischemic necrosis of the lower limb
- Poor arterial puncture technique, leading to osteoarthritis of the hip joint; severe trauma to the femoral artery has resulted in gangrene of the lower limb, retroperitoneal hemorrhage, and arteriovenous fistula formation.[209–211] Up to approximately 24% of children will have no resolution of thrombosis and approximately 1% may have partial arrest of bone growth, likely as a result of thrombus formation.[212,213]
- Vasospasm is usually transient but requires careful observation.

DORSALIS PEDIS AND POSTERIOR TIBIAL ARTERY

The dorsalis pedis and posterior tibial arteries are additional sites for arterial cannulation in children when more desirable locations are inaccessible. Collateral circulation should always be checked. Ultrasound guidance may be helpful.[214] If cannulation is attempted or performed in one artery in the foot, the ipsilateral artery should not be instrumented to ensure adequate collateral blood flow.

Technique

The artery is cannulated in the same manner as for the radial artery at a point of maximal pulsation. An understanding of the anatomy of the dorsalis pedis and posterior tibial arteries before attempting this procedure is important. If percutaneous cannulation is impossible, the cutdown technique may be performed. The complications are similar to other arterial line sites of insertion.

This randomized, prospective study compared the success rate for placement of central venous catheters via the internal jugular route with subclavian routes in 280 children scheduled for cardiac surgery. There was no significant difference in the success rate at first attempt (64% vs. 69%), but the rate of arterial puncture was significantly higher in the internal jugular group (8% vs. 2%) and success rate overall was greater in the subclavian group (91% vs. 82%). However, catheter malposition was greater with the subclavian route (17% vs 1%). Overall, the risk of catheter-associated infection complications was greater with the internal jugular route (22% vs. 3.6%).

Carter JH, Langley JM, Kuhle S, Kirkland S. Risk factors for central venous catheter-associated bloodstream infection in pediatric patients: a cohort study. *Infect Control Hosp Epidemiol.* 2016;37(8):939-945.

This was a within-institution study reviewing their experience from 1995 to 2013 involving 5648 patients that revealed a central line–associated bloodstream infection rate of 3.87/1000 in-hospital line days. Over time there was an 84% reduction in these infections that was primarily related to a vigorous hand hygiene campaign.

Siddik-Sayyid SM, Aouad MT, Ibrahim MH, et al. Femoral arterial cannulation performed by residents: a comparison between ultrasound-guided and palpation technique in infants and children undergoing cardiac surgery. *Paediatr Anaesth.* 2016;26(8):823-830.

This was a randomized prospective study that compared ultrasound-guided with palpation-guided placement of femoral arterial lines in 106 pediatric patients. The number of successful cannulations of first attempt was greater in the ultrasound group (24/5 vs. 13/53), and the time to successful cannulation was also shorter (301 ± 234 seconds ± 420 ± 248 seconds). The ultrasound-guided technique when used by residents was superior to the palpation-guided technique.

50 Infectious Disease Considerations for the Operating Room

ANDRE L. JAICHENCO AND LUCIANA CAVALCANTI LIMA

Causative Agent
Host
Methods of Transmission
Air Transmission
Contact Transmission
Accidents With Cutting or Piercing Devices
Strategy for Preventing Infection Transmission in Health Care Institutions
Measures for Prevention of Infection Transmission in the Operating Room
Prevention of Airborne Pathogen Transmission
Standard Precautions
Antimicrobial Prophylaxis

THE RABBIT HOLE THAT IS THE PERIOPERATIVE ENVIRONMENT is not well understood by the majority of our general pediatric colleagues. Similarly, the rabbit hole of the primary care clinic or the pediatric inpatient ward is not well understood by the majority of our anesthesiology colleagues. A pediatric patient may repeatedly enter the rabbit hole over the course of a hospital admission, a journey fraught with dangers of airway mishaps, respiratory and/or cardiac arrests, hemorrhage, profound anxiety and stress experienced by the young patient and his or her family, as well as infection risks.[1]

Anesthesiologists have long been patient safety advocates. It is not surprising that anesthesia providers in the 21st century have taken on increasing responsibility for preventing health care–associated infections (HAIs), including surgical site infections (SSIs). Anesthesia providers practice in a nonsterile environment within the operating room (OR) and frequently contact areas of the patient known to have a high rate of contamination such as the axilla, nares, and pharynx. There are two recognized but poorly implemented interventions: preoperative patient skin and other bacterial reservoir decontamination and hand hygiene by anesthesia providers.[2]

Anesthesia providers have an impact on bacterial transmission and infection rates. Specifically, anesthesiologists are known to contaminate their work environment within the OR. Contamination of the work environment includes contamination of intravenous (IV) access ports. Without encouragement, anesthesiologists perform hand hygiene less frequently than once per hour during a case, but with reminders, the rate of hand hygiene is more frequent. Improved hand hygiene reduces contamination of the work area and IV access ports from 32% to 8%, which in turn significantly reduces HAIs.[3,4]

The transmission of infection depends on the presence of three interconnected elements: a causative agent, a source, and a mode of transmission (Fig. 50.1). Understanding the characteristics of each element provides the practicing anesthesiologist with methods to protect susceptible patients and themselves to avoid spreading infection.

There has always been concern about the transmission of infectious agents to the patient from the anesthesiologist and vice versa.[5] In addition, there are many sites within the hospital environment where moist or desiccated organic material with the ability to host potentially pathogenic microbes may survive for extended periods of time (Table 50.1) [6,7]; some may even resist the usual cleaning and disinfection techniques.[8] Their transmission from the source to the host may occur via indirect nonapparent mechanisms (e.g., most commonly through hand contact).

Causative Agent

The infectious vector may be any microorganism capable of causing infection. The pathogenicity is the ability to induce disease, which is characterized by its *virulence* (infection severity, determined by the germ morbidity and mortality rates) and the level of *invasiveness* (capacity to invade tissues). No microorganism is completely avirulent. An organism may have a very low level of virulence, but if the host (i.e., patient or health care provider) is highly susceptible, infection by the organism may cause disease. The risk of infection increases with the *infecting dose* (the number of organisms available to induce disease), the *reservoir* (the site where the organisms reside and multiply), and the *infection source* (the site from where it is transmitted to a susceptible host either directly or indirectly through an intermediary object). The infection source may be a human (e.g., health care providers, children, visitors, housekeeping personnel) with a symptomatic or an asymptomatic infection during the incubation period. The source may also be temporarily or permanently colonized (the most frequently colonized tissues are the skin, digestive, and respiratory tracts).

Host

The presence of a susceptible host is an important element in the chain of infection that paradoxically results from advances in current medical therapies and technology (e.g., children undergoing organ transplantation or chemotherapy, or extremely premature neonates) and the presence of children with diseases that compromise their immune systems (e.g., AIDS, tuberculosis, malnutrition, or burns). The organism may enter the host through the skin, mucous membranes, lungs, gastrointestinal tract, genitourinary tract, or the bloodstream via IV solutions, after laryngoscopy, or from surgical wounds. Organisms may also infect the individual because of work accidents with cutting or piercing devices. The development of

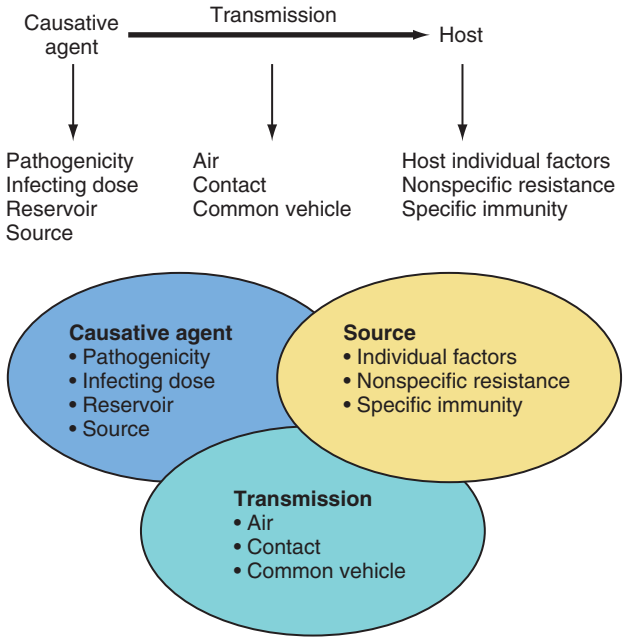

FIGURE 50.1 Elements of the chain of infection.

infection is influenced by the host defense mechanisms that may be classified as either nonspecific or specific:

- *Nonspecific defense mechanisms* include the skin, mucous membranes, secretions, excretions, enzymes, inflammatory responses, genetic factors, hormonal responses, nutritional status, behavior patterns, and the presence of other diseases.
- *Specific defense mechanisms or immunity* may occur because of exposure to an infectious agent (antibody formation) or through placental transfer of antibodies; artificial defenses may be acquired through vaccines, toxoids, or exogenously administered immunoglobulins.

Methods of Transmission

Microorganisms are transmitted in the hospital environment through a number of different routes; the same microorganism may also be transmitted via more than one route. In the OR, the three main routes of transmission are through the air and by direct and indirect contact.

AIR TRANSMISSION

Airborne infections that may infect susceptible hosts are transmitted via two mechanisms: droplets and droplet nuclei.

Droplets

Droplet contamination is considered a direct transmission of organisms because there is a direct transfer of microorganisms from the colonized or infected person to the host. This generally occurs with particles whose diameters are greater than 5 µm that are expelled from an individual's mouth or nose, mainly during sneezing, coughing, talking, or during procedures such as suction, laryngoscopy, and bronchoscopy (Fig. 50.2). Transmission occurs when the microorganism-containing droplets, expelled or shed by the infected person (source), are propelled a short distance (usually not exceeding 60 cm or about 2 feet through the air) and deposited on the host's conjunctivae or oral or nasal mucous membranes. Droplets remain suspended for only a short duration and distance from the source, but this may be affected by temperature, humidity, force of expulsion, and air currents. Larger particle sizes contact the mucosa of the upper airway, whereas aerosols are capable of penetrating into the lower respiratory tract. Infectious agents vary in their affinity for receptors in different regions of the respiratory tract.[9,10] When a person coughs, the exhaled air may reach a speed of up to 965 km/hour (600 mph).[11] However, because the droplets are relatively large, they tend to descend quickly and remain suspended in the air for a very brief period, thus obviating the need for special handling procedures for the OR air. Examples of droplet-borne diseases include influenza, respiratory syncytial virus (RSV), severe acute respiratory syndrome (SARS), diphtheria, *Haemophilus influenzae*, *Neisseria meningitidis*, mumps, pertussis, rhinovirus, rubella, and Ebola. Droplet precautions include communication of infectious risk

TABLE 50.1 Nosocomial Pathogens and Environmental Contamination

Pathogen	Types of Environmental Contamination	Organism Survival Time
Influenza virus	Aerosolization after cleaning; fomites	24–48 hours on nonporous surfaces
Parainfluenza virus	Clothes and nonporous surfaces	10 hours on nonporous surfaces; 6 hours on clothes
Norovirus	Extensive environmental contamination, possible aerosolization	≤14 days on fecal specimens, ≤12 days on carpets
Hepatitis B virus	Environmental contamination with blood	7 days
Coronavirus-SARS	Possible results from emergency department specimens; super-spreading events	24–72 hours on fomites and fecal specimens
Candida	Fomite contamination	3 days for *Candida albicans* and 14 days for *Candida parapsilosis*
Clostridium difficile	Extensive environmental contamination	5 months on hospital floors
Pseudomonas aeruginosa	Drain sink contamination	7 hours on glass slides
Acinetobacter baumannii	Extensive environmental contamination	33 hours on laminated plastic surfaces
MRSA	Extensively contaminated burn units	≤9 weeks after drying; 2 days on laminated plastic surfaces
VRE	Extensive environmental contamination	≤58 days on working surfaces

MRSA, Methicillin-resistant *Staphylococcus aureus; SARS*, severe acute respiratory syndrome; *VRE*, vancomycin-resistant enterococci.
Modified from Hota B. Contamination, disinfection, and cross-colonization: are hospital surfaces reservoirs for nosocomial infection? *Clin Infect Dis*. 2004;39(8): 1182–1189.

FIGURE 50.2 Droplets expelled during sneezing. (From http://www.vaccineinformation.org/flu/photos.asp.)

TABLE 50.2 Body Fluids and Diseases They May Transmit

Body Fluid	Disease Transmitted
Blood	HBV, HIV, HCV, CMV, EBV, NANBH
Seminal fluid	HIV, HBV, CMV
Vaginal discharge	HIV, HBV, CMV
Saliva and sputum	HSV, TB, CMV, respiratory diseases
Cerebrospinal fluid	Encephalopathic organisms (see Table 50.5), HIV
Breast milk	HIV, HBV, CMV
Urine	CMV, EBV, HBV
Feces and intestinal fluid	HAV, gastrointestinal diseases (see Table 50.5)

CMV, Cytomegalovirus; *EBV,* Epstein-Barr virus; *HAV,* hepatitis A virus; *HBV,* hepatitis B virus; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *HSV,* herpes simplex types I and II; *NANBH,* non-A, non-B hepatitis; *TB,* tuberculosis.
Modified with permission from Browne RA, Chernesky MA. Infectious diseases and the anaesthetist. *Can J Anesth.* 1988;35(6):655–665.

between caregivers, single room isolation, gown, glove, mask, and eye protection. Patients undergoing surgery must be brought directly to the OR and recover in isolation. Some medical interventions (intubation, extubation, biphasic airway pressure [BiPAP], continuous positive airway pressure [CPAP], bronchoscopy, sputum induction, open airway suction) are categorized as aerosol-generating procedures. When performing an aerosol-generating procedure on a patient with an infectious disease that can be transmitted through droplets, the recommendation is to maximize protection by using airborne precautions.[10]

Droplet Nuclei

Droplet nuclei result from the evaporation of droplets while suspended in the air. Unlike droplets, the nuclei have an outer layer of desiccated organic material and a very small diameter (1–5 μm) and remain suspended in air indefinitely. The microorganisms contained within these nuclei may be spread by air drafts over great distances, depending on the environmental conditions (dry and cold atmosphere, with limited or no exposure to sunlight favoring the spread).[12] In contrast to droplets, which are deposited on mucous membranes, droplet nuclei may enter the susceptible host by inhalation; examples of droplet nuclei–borne diseases include tuberculosis, varicella, and measles, zoster, smallpox, SARS, and Middle Eastern respiratory syndrome.[10]

CONTACT TRANSMISSION

Direct and indirect contacts are the most significant and frequent methods of hospital infection transmission.

Direct Contact

This type of disease transmission involves direct physical contact between two individuals. The physical transfer of microorganisms from an infected or colonized person to a susceptible host may occur from child to health care provider or from health care provider to child during professional practice (e.g., venous cannulation, laryngoscopy, burn care, or suction of secretions). Health care providers working in the OR may be exposed to skin contamination by body fluids. This is an issue of grave concern because of the potential exposure of health care providers to patients with unrecognized infections, especially hepatitis B virus (HBV), hepatitis C virus (HCV), and human immunodeficiency virus (HIV). Hepatitis B is a highly infectious virus that requires a small amount of blood (10^{-7}–10^{-9} mL) to transmit the disease. The incidence of skin contamination of anesthesiologists and related personnel by blood and saliva is substantial. One study examined 270 anesthetic procedures during 7 consecutive days. The blood of 35 patients (14%) contaminated the skin of 65 anesthesiologists in 46 incidents. Of these contamination events, 28 (61%) occurred during venous cannulation. Of anesthesiologists who had been contaminated by blood, 5 of 65 (8%) had cuts in the skin of their hands.[13] The importance of this observation is that seroconversion of health care providers has been reported after skin contamination by infected blood from HIV carriers[14] and HBV infection after blood splashing into health care workers' (HCWs') eyes.[15] Scabies, pediculosis, and herpes simplex are among the diseases most frequently transmitted by direct contact.[16–23] Meticulous hand washing before and after every patient contact and routine use of barriers such as gloves and eye protection are essential basic methods for protecting ourselves even during routine procedures such as starting an IV line or performing laryngoscopy.[4]

Indirect Contact

Indirect contact involves the transmission of microorganisms from a source (animate or inanimate) to a susceptible host by means of a vehicle (e.g., an intermediary object) contaminated by body fluids. Tables 50.2 and 50.3 provide examples of diseases associated with bodily fluids to which HCWs may be exposed. The vehicle for transmission may be the hands of a health care provider who is not wearing gloves or a provider who fails to wash his or her hands after providing care to a child.[3,24–26] This type of contact can also come from health care providers who touch (with or without gloves) contaminated monitoring or other patient care devices (e.g., blood pressure cuffs, stethoscopes, electrocardiographic cables, or ventilation systems [respirators, corrugated tubes, Y-pieces, valves]) that are used without proper cleaning or disinfection between each use.[27–29]

Knowledge about the transmission of the spread of bacteria from patients to HCWs' hands and to the hospital environment (Fig. 50.3) has driven many interventions that have reduced patient risks for developing HAIs.[30]

TABLE 50.3 Infectious Agents That May Be Found in the Operating Room

Viral Hepatitis	**Viruses**
Hepatitis A virus	Rhinovirus
Hepatitis B virus	Influenza
Hepatitis C virus	Parainfluenza
Hepatitis delta virus	Adenovirus
Non-A, non-B hepatitis	Respiratory syncytial virus
Human immunodeficiency virus	Measles
Cytomegalovirus	Rubella
Epstein-Barr virus	Cytomegalovirus[a]
Herpes simplex virus	
Respiratory Bacteria	**Gastrointestinal**
Streptococcus	Viruses: hepatitis A virus, rotavirus, adenovirus, enterovirus
Pneumococcus	Bacteria: *Giardia*,[a] *Cryptosporidium, Isospora*[a]
Meningococcus	Fungi: *Candida*[a]
Diphtheria	
Mycobacterium[a]	**Central Nervous System**
Legionella[a]	Viruses: Human immunodeficiency virus,[a] herpes simplex virus,[a] Epstein-Barr virus[a]
Fungi	Parasites: *Toxoplasma*[a]
Candida[a]	Fungi: *Cryptococcus*
Nocardia[a]	
Cryptococcus[a]	
Parasites	
Pneumocystis[a]	

[a]Opportunistic infections in immunocompromised patients, especially those with acquired immunodeficiency.

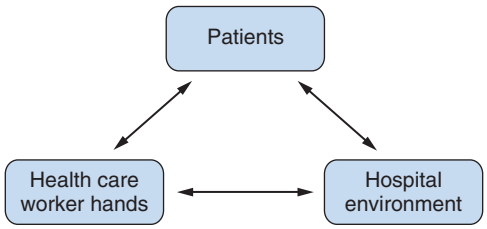

FIGURE 50.3 Epidemiologic links for transmission of multidrug-resistant organisms. (From Munoz-Price LS, Weinstein RA. Fecal patina in the anesthesia work area. *Anesth Analg*. 2015;120(4):703–705.)

Studies on vancomycin-resistant enterococci established the importance of a domino effect of contamination in intensive care units (ICUs) and inpatient wards: spread of vancomycin-resistant enterococci that colonize patients' gastrointestinal tracts ("rectal carriage"), to patients' skin, to the hospital environment, to hands of HCWs, and then to other patients. The skin contamination of patients with enteric organisms inspired the rather graphic description, the patient's "fecal patina."[31] Also referred to as a "stool veneer," this coating with enteric organisms is limited not only to patients' skin but also extends to surfaces in the surrounding environment that are touched, and thereby contaminated, by patients and by HCWs. The environmental contamination spreads out from the patient in a target-like concentric pattern, with the densest contamination closest to the rectum of patients who have rectal carriage of the problem bacteria. This interplay among organisms on patients' body surfaces, hospital environment, and HCWs' hands constitutes the foundation for the development of infection control interventions in the field of hospital epidemiology.[30]

Characterization of the transmission dynamics of frequently encountered gram-negative bacteria in the anesthesia work area environment[32] demonstrates that the spread follows an epidemiologic pattern similar to that seen in ICUs and inpatient wards: from patient, to environment and HCWs' hands, and to other patients (Fig. 50.4). In this report, provider hands were less likely to serve as a transmitter of infection than contaminated environmental or patient skin surfaces. These findings have clinical implications for the risk of colonization and subsequent HCIs—for example, SSIs. This calls attention to the need to develop and enforce strict hand hygiene guidelines for personnel who are providing anesthesia care, but more importantly the need to increase compliance with environmental disinfection of the OR (between cases and terminal cleaning), and to study further the directions of the spread of pathogens in the OR and anesthesia work areas. This study unequivocally underscores our need to improve cleaning procedures in the OR and equipment surfaces to reduce infection risk.

There are also reports of equipment, fomites, and drugs (mainly propofol) that have resulted in hospital-acquired infections.[20,33–51] Propofol is widely used for both inpatient and outpatient anesthesia. This hypnotic agent is a nutrient-rich drug. It is hypothesized that propofol increases bacterial contamination of IV stopcocks and may compromise safety of IV tubing sets when continued to be used after propofol anesthesia. There is a covert incidence of IV stopcock bacterial contamination during anesthesia that is aggravated by the prior presence of propofol. Propofol may increase the risk for postoperative infection because of bacterial growth in IV stopcock dead spaces.[52] Other facets that may also contribute to infection include the following:

- Up to 40% of anesthetic equipment in direct or indirect contact with a child (blood pressure cuffs, cables, oximeters, laryngoscopes, monitors, respirator settings, and horizontal and vertical surfaces) may be contaminated with blood because of inadequate cleansing procedures between uses.[6,7,27,53,54]
- In some institutions, up to 8% of the Bain circuits that were reused without previous sterilization were contaminated.[55]
- Contamination of syringe contents has occurred with glass particles during ampule opening, which in turn may compromise the sterility of the contents, presumably because of the passage of bacteria contained on glass particles into the solution.[56–58]
- IV tubing has both blood contamination as well as contamination by blood from syringes used to inject medications. This can occur with the absence of visible blood reflux in the tubing or syringe. Simply replacing the needle on a syringe that will be reused is ineffective in preventing cross-infection; it is essential to not use the same syringe in multiple patients.[59]
- Refilling both glass and plastic syringes several times has also been shown to result in contamination of the contents; single use is therefore recommended.[59,60]
- Some drug formulations, especially propofol, can sustain bacterial growth under certain conditions. Thus great care should be given to aseptic technique when transferring drugs from the vial to a syringe and to use the contents of the syringe within 4 hours.[61–65] Propofol vials should not be used for multiple patients because of concerns for cross-contamination, particularly since not all countries have added antimicrobials to the propofol emulsion.[66,67]

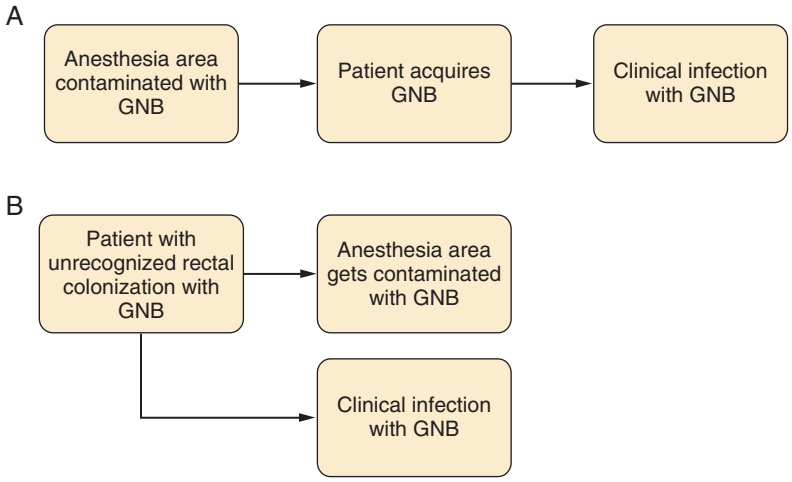

FIGURE 50.4 Possible explanations of subsequent clinical infections caused by the same organism cultured in the anaesthesia work area. **A,** Contaminated environment exposes patient to gram-negative bacilli (GNB) with the subsequent development of a clinical infection. **B,** Patient with unrecognized rectal colonization undergoes surgery, contaminating the anesthesia area with his/her endogenous GNB, and later develops a clinical infection with the same organism. (Data from Loftus RW, Brown JR, Patel HM, et al. Transmission dynamics of gram-negative bacterial pathogens in the anesthesia work area. *Anesth Analg.* 2015;120(4):819–826.)

- Needles that have been used for spinal or epidural anesthesia were contaminated with coagulase-negative staphylococci (15.7%), yeasts (1.5%), enterococci (0.8%), pneumococci (0.8%), and micrococci (0.8%), suggesting that there may be needle contamination despite standard skin preparation and cleansing.[68] It is unclear whether these skin organisms can be transmitted and cause an infection during administration of a neuraxial block.
- Blood and saliva frequently contaminate the skin of anesthetic personnel during routine anesthetic practice.[13]
- Violations of contemporary guidelines for preventing infections (e.g., hand washing, wearing gloves, surgical masks, ocular protection, scrubs, or syringe reuse) by anesthesiologists are frequent.[4] Anesthesia staff are aware that they work in a potentially infectious environment, but they commonly do not adopt appropriate protective measures to reduce infections in both themselves and their patients (11%–99%).[27,69–71]

ACCIDENTS WITH CUTTING OR PIERCING DEVICES

Percutaneous contamination from a cutting or piercing accident is the most effective means to transmit bloodborne pathogens. Evidence suggests that this is the main route of HIV, HBV, and HCV infection,[72–74] especially if the injury is caused by hollow-bore needles that were used to draw blood or establish IV access.[75,76] Over 20 other bloodborne pathogens have been transmitted by this means, including those causing herpes, malaria, and tuberculosis.[77] The risk of exposure to blood and bloodborne pathogens is greater for health care personnel (HCP) than for people who do not work around blood. An exposure to infected blood, tissue, or other potentially infectious body fluids can occur by percutaneous injury or contact with mucous membrane or nonintact skin. The risk of infection after an exposure depends on a number of variables and appears to be greater with exposure to a larger quantity of blood or other infectious fluid; prolonged or extensive exposure of nonintact skin or mucous membrane to blood or other infectious fluid or concentrated virus in a laboratory setting; exposure to the blood of a patient in an advanced disease stage or with a higher HIV viral load; a deep percutaneous injury; a procedure wherein the sharp was in the vein or artery of an infected source patient; an injury with a hollow-bore, blood-filled needle; and limited or delayed access to postexposure prophylaxis. After exposure, the risk of infection varies for specific bloodborne pathogens. For HBV, if the source patient has active HBV and the HCP do not already have immunity, the risk for infection after percutaneous injury is between 1% and 30%. If the source patient has active HCV, the risk of hepatitis C transmission is approximately 1.8% (range 0%–7%) after a percutaneous injury. If the source patient has HIV infection, the risk of HIV transmission is approximately 0.3% after a percutaneous exposure and 0.09% after a mucous membrane exposure. The risk of HIV transmission for an exposure with nonintact skin has not been determined and is estimated to be less than the risk after a mucous membrane exposure.[78]

Anesthesia staff lacking HBV protective antibodies are at great risk for acquiring the disease.[79,80] These infection rates underscore the need for the use of "safe" needles and the need to advocate the use of "needleless" systems even though they are significantly more expensive.[81,82] This also emphasizes the need for meticulous handling and disposal of needles and other sharp instruments, as well as the use of special "sharps boxes" designed to minimize accidental needlesticks (e.g., "mailbox"-type boxes that do not allow the hand to enter the disposal area).[83–98] The U.S. Centers for Disease Control and Prevention (CDC) has estimated that in the United States there are approximately 385,000 cutting and piercing accidents annually among HCP in hospitals; 25% of these occur in the OR.[77] However, the actual prevalence is thought to be much greater, because many of these events are unreported. The distribution of these accidents among anesthesiologists is shown in Fig. 50.5A; the distribution of the items most frequently associated with cutting and piercing injuries in health care providers is shown in Fig. 50.5B. Should such an accident occur (e.g., needle puncture, exposure to nonintact skin, or mucous membrane

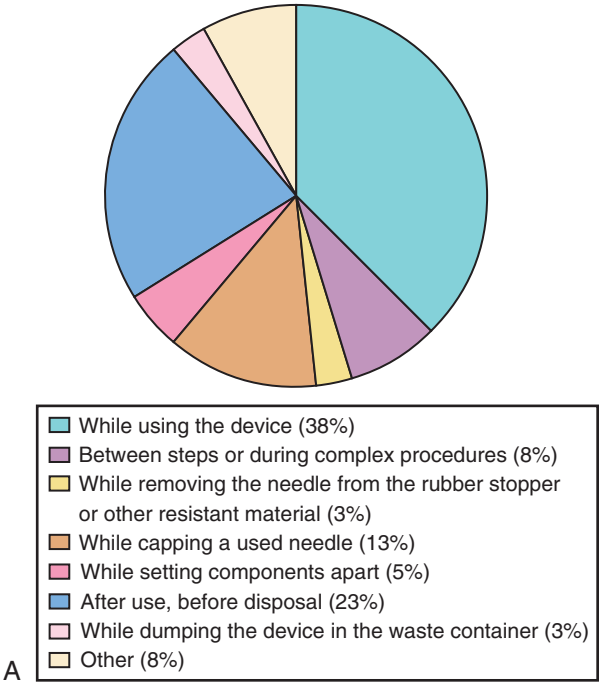

FIGURE 50.5 **A,** Percentage distribution of percutaneous injury to anesthesiologists caused by contaminated cutting or piercing devices. **B,** Percentage distribution of items associated with percutaneous injuries in health care work.

exposure), there are now specific recommendations regarding immediate assessment of risk, assessment of the exposure source (chart review, inform the patient that an accident has occurred and ask permission to determine HBV, HCV, and HIV serologic status), and rapid initiation of appropriate antiviral treatment of the HCW.[82] It is advised to obtain as much information regarding the patient as possible–if the patient is known–to (1) obtain a sample of blood from the patient for determination of potential carrier state (Table 50.4) and (2) report to the health service for immediate institution of prophylaxis and follow-up (Table 50.5), especially for HIV exposure (Tables 50.6 and 50.7).

Strategy for Preventing Infection Transmission in Health Care Institutions

Institutional administrative measures aimed at developing, implementing, and monitoring specifically designed accident prevention policies and procedures are important for reducing and preventing transmission of infectious agents in health care centers. To this end, centers should consider the following:[77,99,100]

- Include infection control as a major goal in the organizational mission statement and implement safety programs, both for patients and HCWs.
- Provide sufficient administrative and financial support to carry out this mission.
- Provide sufficient administrative and financial support for the microbiology laboratory and implement an infection surveillance plan, especially for postsurgical infections.
- Establish a multidiscipline cross-functional team (e.g., a team manager, an epidemiologist, a representative from industrial health, and a person trained in quality control) to identify health and safety issues within the institution, analyze trends, assess outcomes, implement interventions, and make recommendations to other members of the organization.
- Provide sufficient administrative and financial support to develop and implement education programs for health care providers, patients, and their families. One positive example of such education is that anesthesiologists who have read the CDC's Universal Precaution Guidelines for the Prevention of Occupational Transmission of HIV and HBV have developed better hygienic practices.[69]
- Provide HCWs with hepatitis A and B vaccine and document that an appropriate immunologic response was achieved. Provide hepatitis A and B immune globulins (HAIG, HBIG) for those exposed who do not have established immunity.[8]
- Provide a health care service for employees for counseling and postexposure prophylaxis should an exposure to HIV occur.[101]
- Provide regular surveillance of HCWs to determine established immunity to infectious diseases such as tuberculosis, measles, mumps, rubella, and chickenpox. Lack of immunity may require immunization; several studies have demonstrated the cost-effectiveness of immunization (for prevention of disease) versus the cost of replacement of HCWs who have become infected.[73,102–107]

Measures for Prevention of Infection Transmission in the Operating Room

PREVENTION OF AIRBORNE PATHOGEN TRANSMISSION

Airborne pathogens may be transmitted through the OR heating, ventilation, and air conditioning systems. It is vital to have in place proper systems to (1) remove contaminated air, (2) facilitate air management requirements to protect susceptible health care providers and children against hospital-related airborne pathogens, and (3) minimize the risk of airborne pathogens being transmitted by children. Many regulatory institutions, such as the National Institute for Occupational Safety and Health; the American Society of Heating, Refrigerating and Air-Conditioning Engineers; the CDC; and the American Institute of Architects (AIA), have developed standards and guidelines for OR ventilation systems. As in any other environment, ventilation in the OR is an important issue to control infection from microbiologic pollutants. Most

TABLE 50.4 Guide to Postexposure Prophylaxis and Prevention of Infection Transmission

PEP Step 1: Treat Exposure Site

- Use soap and water to wash areas exposed to potentially infectious fluids as soon as possible after exposure.
- Flush exposed mucous membranes with water.
- Flush exposed eyes with water or saline solution.
- Do NOT apply caustic agents, or inject antiseptics or disinfectants into the wound.

PEP Step 2: Report and Document

- Date and time of exposure.
- Details of the incident: where and how the exposure occurred, exposure site(s) on HCP's body; if related to sharp device, the type and brand of device.
- Details of the exposure: type and amount of fluid or material, severity of exposure.
- Documentation of counseling following exposure and postexposure management plan.
- Details about the exposure source: If the source patient is known or unknown; whether the source material contained HIV, HBV, or HCV; if the source patient is HIV-infected, determine stage of disease, CD4 cell count, HIV viral load, history of antiretroviral therapy, and antiretroviral resistance information as available.
- Details about the exposed HCP: hepatitis B vaccination and vaccine-response status (HBsAb titer); other medical conditions that may influence choice of prophylactic agent(s) if needed; current medications, and drug allergies; pregnancy status or lactation status.

PEP Step 3: Evaluate the Exposure

- The exposure should be evaluated for the potential to transmit HBV, HCV, or HIV based on the type of body substance involved, the route, severity and frequency of exposure.
- Significant exposures to any of the following may pose a risk for bloodborne pathogen transmission and require further evaluation: blood, semen, vaginal secretions, cerebrospinal fluid, synovial fluid, pleural fluid, peritoneal fluid, pericardial fluid, amniotic fluid.
- Body fluids that do NOT pose a risk of bloodborne pathogen transmission unless visibly contaminated with blood include: urine, stool, tears, saliva, gastric secretions or vomitus, sweat, nonpurulent sputum, nasal discharge

PEP Step 4: Evaluate the Exposure Source

When source patient is known:

- Test source patient for HBsAg, HCV antibody, and HIV antibody.
  - Use a rapid HIV antibody test. Use of fourth-generation HIV antigen/antibody testing is recommended if available.
  - HIV viral load assessment for routine screening of source patient is NOT recommended.
  - If the source person is NOT infected with a bloodborne pathogen, further follow-up testing of the exposed HCP is not necessary. Follow state regulations related to informed consent and confidentiality.
- For patients who cannot be tested, consider medical diagnoses, clinical symptoms, and history of risk behaviors.

When source patient is NOT known/unable to be tested immediately:

- Evaluate the likelihood of high-risk exposure:
  - Consider the likelihood of bloodborne pathogen infections among patients in the exposure setting: What is the community infection rate? Does the clinic/hospital unit care for a large number of HIV-, HBV-, or HCV-infected or at-risk patients?
  - Is there a high suspicion for HIV infection and the patient is unable to be tested immediately?
- Do not test discarded needles for bloodborne pathogens; the reliability of these findings is not known.

The "window period":

- To date, there has not been a documented case of occupational HIV transmission from a source patient with a negative HIV antibody test result with risk factors for HIV acquisition.
- Postexposure prophylaxis should be considered only if the source patient has risk factors and has been determined to have symptoms consistent with acute HIV infection.

HBV, hepatitis B virus; *HBsAg,* hepatitis B surface antigen; *HCV,* hepatitis C virus; *HCP,* health care personnel; *HIV,* human immunodeficiency virus.
From Mountain Plains AIDS Education and Training Center. PEP Steps, A Quick Guide to Postexposure Prophylaxis in the Health Care Setting (April 2006); PEP Steps: A Quick Guide to Postexposure Prophylaxis in the Health Care Setting (March 2014).

wound contamination in the OR is the result of the patient's skin flora and bacteria shed on airborne particles from the OR personnel. Room ventilation affects the distribution of these airborne particles in four ways: total ventilation (dilution), air distribution (directional airflow), room pressurization (filtration barrier), and filtration (contaminant removal). As the air flows of the room increase, the greater the dilutional effect on airborne particles. Balancing this phenomenon is important because while increased flow increases the effectiveness of air exchange, the resultant turbulent flow increases microbial distribution throughout the room. Low-velocity unidirectional flow minimizes the spread of microbes in the room. Directional flow can be inward, from the outside into the OR (negative pressure), or outward, from the OR to the outside (positive pressure). Negative-pressure ventilation is used for highly infective rooms in the hospital (e.g., isolation rooms for tuberculosis patients), and positive-pressure ventilation is used for protective environments (e.g., ORs and rooms with immunocompromised patients). Most hospital ORs are currently designed with high-efficiency particulate air (HEPA) filtration systems to maximize removal of airborne contaminants. OR ventilation systems should operate at all times, except during maintenance. During unoccupied hours, air exchange can be reduced as long as positive pressure is maintained in each OR. Air is delivered to each OR from the ceiling, with downward movement toward several exhaust or return ducts near the floor. This design helps provide steady movement of clean air through the breathing and working zones.

The AIA has specific guidelines for the location of outside fresh air inlets to minimize contamination from exhaust systems and noxious fumes. A greater air inflow rate and a larger air-inlet area are desirable for contaminant control, but these approaches are detrimental to the thermal comfort of the staff and patient.[108] The AIA recommends an air-change rate in an OR of 20 to 25 air changes per hour (ACH) for ceiling heights between 9 feet

TABLE 50.5 Factors to Consider in Assessing the Need for Follow-Up After Occupational Exposure

Type of Exposure
• Percutaneous injury • Mucous membrane exposure • Nonintact skin exposure • Bites resulting in blood exposure to either person involved
Type and Amount of Fluid/Tissue
• Blood • Fluids containing blood • Potentially infectious fluid or tissue • Direct contact with concentrated virus
Infection Status of Source Patient
• If positive for HBsAg testing for exposed person's vaccination status. • If positive for HCV antibody, consider measuring HCV viral load. • If positive for HIV antibody, consider obtaining HIV viral load testing, and evaluating clinical status of patient.
Susceptibility of Exposed HCP
• Hepatitis B vaccine and vaccine response status • HBV, HCV, and HIV status—baseline testing for HbsAb, anti-HCV, and HIV antibody should be completed as early as possible (preferably within 72 hours)
Accessibility of PEP and Follow-Up
• PEP should be initiated within 2 hours of the exposure. • The eficacy of PEP initiation is thought to diminish after 24 to 36 hours following an exposure.
Laboratory Tests Used for Evaluation
• If the fourth-generation combination HIV Ag/Ab assay is used to test the source patient, HIV follow-up testing can be completed 4 months after exposure.

HBV, hepatitis B virus; *HBsAb,* hepatitis B surface antigen; *HCV,* hepatitis C virus; *HIV,* human immunodeficiency virus; *PEP,* postexposure prophylaxis.

(2.74 meters) and 12 feet (3.66 meters). Some controversy exists between engineers and clinicians over the need for laminar airflow ventilation in the OR to further minimize airborne infection. Careful mathematical analyses of airflow suggest that laminar airflow is not necessary. Clinical studies are confirmatory. Similarly, the use of ultraviolet light to cleanse the room air is no longer recommended.[109] Table 50.8 shows the 2003 Healthcare Infection Control Practices Advisory Committee and CDC general recommendations for ventilation system specifications for the OR.[12] Children with tuberculosis require special consideration because of the high risk of occupational transmission of *Mycobacterium tuberculosis*,[110,111] especially after the emergence of multidrug-resistant strains (Table 50.9). An easy preventive measure is to screen all children before coming to the OR to determine recent exposure to infectious disease such as measles, mumps, rubella, and chickenpox because these infections can pose a significant risk to HCWs and patients, especially those who are immunocompromised.[73,106] Another potential source for airborne spread of pathogens is through the anesthesia circuit; this may be reduced by the use of circuit filters. However, at present there are no regulatory requirements to use such devices, and performance characteristics vary widely.[28,29,112–116]

STANDARD PRECAUTIONS

Standard precautions[117] assume that any person or patient is potentially infected or colonized by microorganisms that could be transmitted and cause an infectious process. Standard precautions must be implemented with all patients and include the following:

- *Universal precautions–blood and body fluid precautions*, developed to reduce bloodborne pathogen transmission
- *Body substance isolation*, designed to reduce the risk of pathogen transmission by moist body substances

Standard precautions are used to reduce the transmission of all infectious agents from one person to another, thus protecting health care providers and children against exposure to the most common microorganisms. Standard precautions are implemented for any contact with blood and body fluids, secretions, and excretions (except sweat), whether or not they contain visible blood, as well as for any contact with nonintact skin, mucous membranes, and intact skin that is visibly soiled with blood and/or body fluids. *Prevention is primary.* All HCPs should be familiar with standard precautions: wash hands frequently and thoroughly before and after patient care; use personal protective equipment: gloves, gowns, boots, shoe covers, eyewear, masks, and shields, as appropriate for the patient care situation; gloves must be worn when any kind of venous or arterial access is being performed; use sharps with caution: plan ahead (use sharps in a safe environment with a sharps container nearby), dispose of used sharps in puncture-proof receptacles immediately after use, do not recap needles, and use safety devices if available. All HCPs should be vaccinated with the hepatitis B vaccine series and should undergo testing for HBsAb response after completion of the series to document adequate protection. Employees who have not gone through the vaccination series previously should be offered the hepatitis B series through their employer at no cost.[118] Summaries of standard precautions, droplet precautions, airborne precautions, and contact precautions are available on line.[100,119–121]

Hand Washing

Overall hand hygiene compliance across health care providers remains less than 50%, with anesthesia providers identified as a particularly noncompliant group (one study found a compliance rate of only 23%).[122] Bacterial contamination of anesthesia providers has been directly linked to high-risk bacterial transmission events to IV stopcocks and 30-day postoperative infections.[24]

The vast majority of SSIs are caused by *Staphylococcus aureus*. Transmission of specific staphylococcal phenotypes within and between patients is a major contributor to SSIs and HAIs.[3,4,123] The role of anesthesia-provider hand contamination in transmission of *Enterococcus* to the workstation and patient biome is concerning, even though it was not associated with actual infection, because of rising rates of antibiotic-resistant organisms and the observation that *Enterococcus* is becoming a more prevalent pathogen.[3,124] Two approaches are indicated: improved methods of patient reservoir decontamination and more effective and frequent decontamination of provider hands. Hand hygiene is a well-known and effective solution to the problem of bacterial transmission within and across patients. Compliance with the current "5 moments" World Health Organization guidelines could make a major inroad into reducing provider hand and workspace contamination. One study found that only 20% of anesthesia providers demonstrated complete knowledge regarding WHO hand hygiene guidelines.[125] Failure of providers to recognize prior contact with the environment and prior contact with the patient as hand hygiene opportunities contributed to this low percentage. Several cognitive factors were associated

TABLE 50.6 Recommended HIV Postexposure Prophylaxis for Percutaneous Injuries

	INFECTION STATUS OF SOURCE				
Exposure Type	**HIV-Positive Class 1**[a]	**HIV-Positive Class 2**[a]	**Source of Unknown HIV Status**[b]	**Unknown Source**[c]	**HIV-Negative**
Less severe[d]	Recommend basic 2-drug PEP	Recommend expanded ≥3-drug PEP	In general, no PEP warranted; however, consider basic 2-drug PEP[e] for source with HIV risk factors[f]	In general, no PEP warranted; however, consider basic 2-drug PEP[e] in settings in which exposure to HIV-infected persons is likely	No PEP warranted
More severe[g]	Recommend expanded 3-drug PEP	Recommend expanded ≥3-drug PEP	In general, no PEP warranted; however, consider basic 2-drug PEP[e] for source with HIV risk factors[f]	In general, no PEP warranted; however, consider basic 2-drug PEP[e] in settings in which exposure to HIV-infected persons is likely	No PEP warranted

HIV, human immunodeficiency virus; *PEP,* postexposure prophylaxis.
[a]HIV-positive class 1: asymptomatic HIV infection or known low viral load (e.g., <1500 ribonucleic acid copies/mL). HIV-positive class 2: symptomatic HIV infection, AIDS seroconversion, or known high viral load. If drug resistance is a concern, obtain expert consultation. Initiation of PEP should be delayed pending expert consultation, and because expert consultation alone cannot substitute for face-to-face counseling, resources should be available to provide immediate evaluation and follow-up care for all exposures.
[b]For example, deceased source person with no samples available for HIV testing.
[c]For example, a needle from a sharps disposal container.
[d]For example, solid needle or superficial injury.
[e]The recommendation "consider PEP" indicates that PEP is optional; a decision to initiate PEP should be based on a discussion between the exposed person and the treating clinician regarding the risks versus benefits of PEP.
[f]If PEP is offered and administered and the source is later determined to be HIV-negative, PEP should be discontinued.
[g]For example, large-bore hollow needle, deep puncture, visible blood on device, or needle used in patient's artery or vein.

with a reduced risk of incomplete knowledge, including providers responding positively to washing their hands after contact with the environment, disinfecting their environment during patient care, believing that they can influence their colleagues, and intending to adhere to guidelines. These results suggest that anesthesia providers have knowledge deficits pertaining to opportunity-based hand hygiene in the intraoperative arena[125]–specifically, after interactions with patient skin surfaces and the surrounding environment, the two most important reservoirs of intraoperative bacterial transmission.

Hand washing is considered the most important and cost-effective individual intervention in the prevention of HAIs in children and health care providers.[126] Its importance in medical practice had not been universally accepted, despite the pioneering work by Oliver Wendell Holmes[127] (1843) and Ignaz Semmelweis[128]

TABLE 50.8 Ventilation System Specifications for the Operating Room

- Minimize the circulation of people during surgeries. It has been proved that the level of microbes in the operating room air is directly proportional to the number of people moving inside the room.
- Maintain humidity under 68% and temperature control to prevent environmental conditions that favor the development of germs.
- Maintain positive pressure compared with corridors and surrounding areas to prevent microorganisms from entering the operating room.
- Provide at least 15 air changes per hour in the operating room, 20% of which should be fresh air. Air should be recirculated through a high-efficiency particulate air (HEPA) filter.
- Air should be introduced at ceiling level and disposed of at ground level.

From Centers for Disease Control and Prevention. Guidelines for environmental infection control in health-care facilities: recommendations of CDC and the Healthcare Infection Control Practices Advisory Committee (HICPAC). *MMWR Recommendtions and Reports* 2003;52(RR10):1–42. TABLE 50.9 Precautionary Procedures for Patients with Infectious Tuberculosis

Follow Precautionary Procedures for Infectious TB Patients Who Also Require Emergency Surgery. Category IB, IC

1. Use an N95 respirator approved by the National Institute for Occupational Safety and Health without exhalation valves in the operating room. Category IC
2. Intubate the patient in either the AII room or the operating room; if intubating the patient in the operating room, do not allow the doors to open until 99% of the airborne contaminants are removed. Category IB
3. When anesthetizing a patient with confirmed or suspected TB, place a bacterial filter between the anesthesia circuit and the patient's airway to prevent contamination of anesthesia equipment or discharge of tubercle bacilli into the ambient air. Category IB
4. Extubate and allow the patient to recover in an AII room. Category IB
5. If the patient has to be extubated in the operating room, allow adequate time for ACH to clean 99% of airborne particles from the air, because extubation is a cough-producing procedure. Category IB

Use Portable, Industrial-Grade HEPA Filters Temporarily for Supplemental Air Cleaning During Intubation and Extubation for TB Patients Who Require Surgery. Category II

1. Position the units appropriately so that all room air passes through the filter; obtain engineering consultation to determine the appropriate placements. Category II
2. Switch the portable unit off during the surgical procedure. Category II
3. Provide fresh air as per ventilation standards for operating rooms; portable units do not meet the requirements for the number of fresh ACH. Category II

If possible, schedule TB patients as the last surgical cases of the day to maximize the time available for removal of airborne contamination. Category II

No recommendation is offered for performing orthopedic implant operations in rooms supplied with laminar airflow. Unresolved issue

Maintain backup ventilation equipment (e.g., portable units for fans or filters) for emergency ventilation of operating rooms, and take immediate steps to restore the fixed ventilation system. Category IB, IC (AIA: 5.1)

ACH, air changes per hour; *AII*, airborne infection isolation; *HEPA*, high-efficiency particulate air.

Centers for Disease Control and Prevention. Guidelines for environmental infection control in health-care facilities: recommendations of CDC and the Healthcare Infection Control Practices Advisory Committee (HICPAC). 2003. http://apps.who.int/iris/bitstream/10665/44102/1/9789241597906_eng.pdf

(1846), who separately recognized that the contaminated hands of physicians performing autopsies were the vectors responsible for the spread of puerperal fever caused by streptococci. They demonstrated that hand washing before delivering a baby reduced the risk of infectious transmission and maternal mortality by 90%! Unfortunately, the scientific basis for hand washing was not established until the introduction of the germ theory of disease by Louis Pasteur[129] and the discovery of the microorganism that caused anthrax *(Bacillus anthracis)* by Robert Koch[130] in the late 19th century. More than one-and-a-half centuries later, and with strong evidence that health care providers are a leading source of hospital acquired infections,[3,24,131] the average frequency of hand hygiene episodes fluctuates with the method used for monitoring and the setting where the observations are conducted. Hand washing per hour may vary over 30-fold. On the other hand, the average number of opportunities for hand hygiene per HCW varies markedly between hospital wards; nurses in pediatric wards, for example, had an average of eight opportunities for hand hygiene per hour of patient care, compared with an average of 30 for ICU nurses. In some acute clinical situations, the patient is cared for by several HCWs contemporaneously and, on average, as many hand hygiene opportunities per patient per hour of care have been observed per provider as in a postanesthesia care unit (PACU) admission. The number of opportunities for hand hygiene depends largely on the process of care provided[132]: revision of protocols for patient care may reduce unnecessary contacts and, consequently, improve hand hygiene opportunities. In 11 observational studies, the duration of hand cleansing episodes by HCWs ranged, on average, from as little as 6.6 seconds to 30 seconds. In 10 of these studies, the hand hygiene technique monitored was hand washing, while handrubbing was monitored in one study. In addition to washing their hands for very short time periods, HCWs often failed to cover all surfaces of their hands and fingers. Therefore the number of hand hygiene opportunities per hour of care may be very large and, even if the hand hygiene compliance rate is large, the applied cleansing technique may be inadequate. Adherence of HCWs to recommended hand hygiene procedures varies from unacceptably poor (5%) to relatively good (89%) with an overall mean rate of 38.7% in the ICU, OR, and PACU.[133–139] A number of investigators reported improved adherence after implementing various interventions, but most studies had only short follow-up. Few studies have reported sustained improvement. There are hospital-wide predictors of poor adherence to recommended hand hygiene measures during routine patient care. These include professional category, hospital ward, time of day/week, and type and intensity of patient care, defined as the number of opportunities for hand hygiene per hour of patient care. Nonadherence was the least among nurses and during weekends. Nonadherence was greater in ICUs compared with internal medicine, during procedures that carried a substantial risk of bacterial contamination, and when intensity of patient care was high. In other words, the greater the demand for hand hygiene, the poorer the adherence. The poorest adherence rate (36%) was found in ICUs, where indications for hand hygiene were typically

more frequent (on average, 22 opportunities per patient-hour). The greatest adherence rate (59%) was observed in pediatrics, where the average intensity of patient care was smaller than elsewhere (on average, 8 opportunities per patient-hour). The results suggest that full adherence to guidelines is unrealistic and that easy access to hand hygiene at the point of patient care, (i.e., in particular, alcohol-based handrubbing) could help improve adherence to hand hygiene.

Perceived barriers to adherence with hand hygiene practice recommendations include skin irritation caused by hand hygiene agents, inaccessible hand hygiene supplies, interference with HCW–patient relationships, patient needs perceived as a priority over hand hygiene, wearing of gloves, forgetfulness, lack of knowledge of guidelines, insufficient time for hand hygiene, high workload and understaffing, and the lack of scientific information showing a definitive impact of improved hand hygiene on HAI rates. Lack of knowledge of guidelines for hand hygiene, lack of recognition of hand hygiene opportunities during patient care, and lack of awareness of the risk of cross-transmission of pathogens are barriers to good hand hygiene practices. Furthermore, some HCWs believed that they washed their hands when necessary even when observations indicated that they did not. The risk of pathogen transmission via the hands is proportional to the power of the number of times a child is touched.[140] Table 50.10 presents a summary of the indications for and the strength of supporting evidence for hand washing and antisepsis.

TABLE 50.10 Indications for Hand Hygiene

1. Wash hands with soap and water when visibly dirty or visibly soiled with blood or other body fluids (IB) or after using the toilet (II).
2. If exposure to potencial spore-forming pathogens is strongly suspected or proven, including outbreaks of *Clostridium difficile*, hand washing with soap and water is the preferred means (IB).
3. Use an alcohol-based handrub as the preferred means for routine hand antisepsis in all other clinical situations described in terms 4(a) to 4(f) listed below, if hands are not visibly soiled (IA). IF alcohol-based handrub is not obtainable, wash hands with soap and water (IB).
4. Perform hand hygiene:
   a. before and after touching the patient (IB);
   b. before handling an invasive device for patient care regardless of whether or not gloves are used (IB);
   c. after contact with body fluids or excretions, mucous membranes, non-intact skin, or wound dressings (IA);
   d. if moving from a contaminated body site to another body site during care of the same patient (IB);
   e. after contact with inanimate surfaces and objects (including medical equipment) in the immediate vicinity of the patient (IB);
   f. after removing sterile (II) or nonsterile gloves (IB).
5. Before handling medication or preparing food, perform hand hygiene using an alcohol-based handrub or wash hands with either plain or antimicrobial soap and water (IB).
6. Soap and alcohol-based handrub should not be used concomitantly (II).

Category IA. Strongly recommended for implementation and strongly supported by well-designed experimental, clinical, or epidemiologic studies.
Category IB. Strongly recommended for implementation and supported by some experimental, clinical, or epidemiologic studies and a strong theoretical rationale.
Category IC. Required for implementation, as mandated by federal and/or state regulation or standard.
Category II. Suggested for implementation and supported by suggestive clinical or epidemiologic studies or a theoretical rationale or a consensus by a panel of experts.
Adapted from *WHO Guidelines on Hand Hygiene in Health Care: First Global Patient Safety Challenge Clean Care Is Safer Care.* Geneva: World Health Organization; 2009.

Recommendations for surgical hand preparation are as follows: remove rings, wristwatch, and bracelets before beginning surgical hand preparation (II); artificial nails are prohibited (IB); sinks should be designed to reduce the risk of splashes (II); if hands are visibly soiled, wash hands with plain soap before surgical hand preparation (II); remove debris from underneath fingernails using a nail cleaner, preferably under running water (II); brushes are not recommended for surgical hand preparation (IB); surgical hand antisepsis should be performed using either a suitable antimicrobial soap or suitable alcohol-based handrub, preferably with a product ensuring sustained activity, before donning sterile gloves (IB); if the quality of water is not assured in the operating theatre, surgical hand antisepsis using an alcohol-based handrub is recommended before donning sterile gloves when performing surgical procedures (II); when performing surgical hand antisepsis using an antimicrobial soap, scrub hands and forearms for the length of time recommended by the manufacturer, typically 2–5 minutes. Long scrub times (e.g., 10 minutes) are not necessary (IB); when using an alcohol-based surgical handrub product with sustained activity, follow the manufacturer's instructions for application times. Apply the product to dry hands only (IB); do not combine surgical hand scrub and surgical handrub with alcohol-based products sequentially (II); when using an alcohol-based handrub, use sufficient product to keep hands and forearms wet with the handrub throughout the surgical hand preparation procedure (IB); after application of the alcohol-based handrub as recommended, allow hands and forearms to dry thoroughly before donning sterile gloves (IB).

At present, alcohol-based handrubs are the only known means for rapidly and effectively inactivating a wide array of potentially harmful microorganisms on hands. The WHO recommends alcohol-based handrubs based on the following factors: evidence-based, intrinsic advantages of fast-acting and broad-spectrum microbicidal activity with a minimal risk of generating resistance to antimicrobial agents; suitability for use in resource-limited or remote areas with lack of accessibility to sinks or other facilities for hand hygiene (including clean water, towels, and so on); capacity to promote improved compliance with hand hygiene by making the process faster and more convenient; economic benefit by reducing annual costs for hand hygiene, representing approximately 1% of extra costs generated by an HCI; minimization of risks from adverse events because of increased safety associated with better acceptability and tolerance than other products.[118]

After hand washing, it is very important to dry the hands properly with appropriate paper towels, hot air flow, or both, because the level of pathogen transmission from a HCW's hands to a patient is greatly increased if the hands are wet.[141] Sterile cloth towels are most frequently used in ORs to dry wet hands after surgical hand antisepsis. Several methods of drying have been tested without significant differences between techniques.[118]

Transmission may also occur from patients' wet sites, such as groins or armpits, or when a HCW gets his or her hands wet when opening parenteral solutions. It is critical for health institutions to establish written procedures and protocols to support adherence to the recommended hand hygiene practices.

Gloves

Wearing clean or sterile gloves while caring for children is an effective means of reducing HAIs. Gloves remain a supplementary barrier to infection that should not replace proper hand hygiene.

Gloves protect patients by reducing health care provider hand contamination and the subsequent transmission of pathogens to other children, provided the gloves are changed after providing care to each child. Additionally, when the use of gloves is combined with CDC standard precautions, they protect the health care provider against exposure to bloodborne infections or infections transmitted by any other body fluids, such as excretions, secretions (except sweat), mucous membranes, and nonintact skin. Examination gloves are single-use and usually nonsterile. Sterile surgical gloves are required for surgical interventions. Some nonsurgical care procedures, such as central vascular catheter insertion, also require surgical glove use. In addition to their sterile properties, these gloves have characteristics of thickness, elasticity, and strength that differ from other medical gloves.

The use of gloves in situations when their use is not indicated represents a waste of resources without necessarily reducing cross-transmission. The wide-ranging recommendations for glove use have led to very frequent and inappropriate use. Indications for gloving and glove removal are shown in Table 50.11. Situations that require and that do not require glove use are presented in Fig. 50.6.

Ranked consensus recommendations for the use of gloves, categorized according to the CDC/HICPAC system, include the following[118,142,143]:

- Wear gloves in case of contact with blood or any other potentially infecting body fluid, such as excretions, secretions (except sweat), mucous membranes, and nonintact skin (IC).
- Remove the gloves immediately after providing care to a child. Staff should not wear the same pair of gloves to take care of more than one child, nor should they touch the surfaces of any equipment, monitoring devices, or even light switches. Contaminated gloves can pass blood or other body fluids to working surfaces and are vectors for hepatitis transmission (IB).[72]
- Change gloves when taking care of a child if you must move from a contaminated to a clean body site (II).
- Apply hand hygiene measures immediately after removing the gloves because, despite the use of gloves, hands may get contaminated through small (microscopic) holes in the gloves.[131,144,145] Microbial contamination of hands and possible infection transmission have been reported even with the use of gloves.[146]
- Remove the gloves by using an appropriate technique (so as not to contaminate your hands with the contaminated surface of the gloves).

TABLE 50.11 Indications for Gloving and Glove Removal

Indication
Glove Use
1. Before a sterile condition
2. Anticipation of a contact with blood or another body fluid, regardless of the existence of sterile conditions and including contact with non-intact skin and mucous membrane
3. Contact with a patient (and his/her immediate surroundings) during contact precautions
Glove Removal
1. As soon as gloves are damaged (or non-integrity suspected)
2. When contact with blood, another body fluid, nonintact skin, and mucous membrane has occurred and has ended
3. When contact with a single patient and his or her surroundings, or a contaminated body site on a patient has ended
4. When there is an indication for hand hygiene

From *WHO Guidelines on Hand Hygiene in Health Care. First Global Patient Safety Challenge Clean Care Is Safer Care*. Geneva: World Health Organization; 2009.

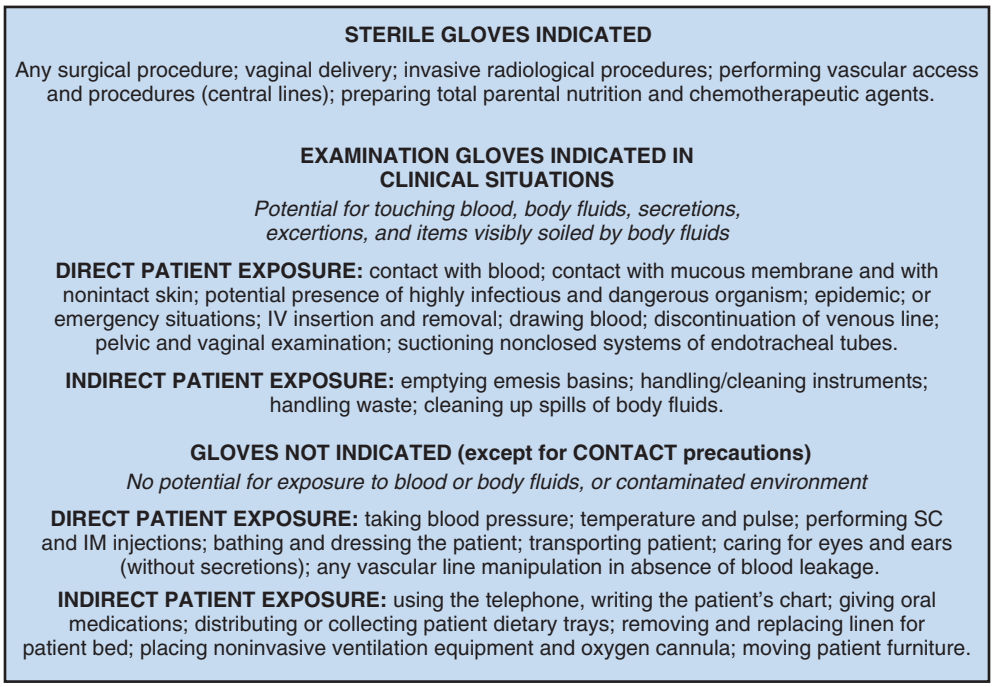

FIGURE 50.6 Situations requiring and not requiring glove use. *IM,* intramuscular; *SC,* subcutaneous. (Adapted from *WHO Guidelines on Hand Hygiene in Health Care: First Global Patient Safety Challenge Clean Care Is Safer Care*. Geneva: World Health Organization; 2009.)

- Alcohol-based handrub dispensers and clean glove boxes (at least two sizes) should be in place near every patient care site (e.g., on top of every anesthesia cart, medication cart, or in the nursing station).
- Disposable gloves should not be washed, resterilized, or disinfected (IB). If gloves are reused, appropriate reprocessing methods should be in place to ensure the physical integrity of the gloves and their full decontamination (II).
- Sterile gloves are much more expensive than clean, disposable gloves and should be used only for certain procedures, such as when hands are in contact with normally sterile body areas or when inserting intravascular or urinary catheters. Clean gloves should be used during any other procedure, including wound dressing.
- Latex-free gloves should be worn when caring for children at risk for latex allergy.

ANTIMICROBIAL PROPHYLAXIS

Surgical antimicrobial prophylaxis is an essential tool to reduce the risk of postoperative infections, and the anesthesia team plays a central role in ensuring the proper timing of drug administration.[147,148] The aim of the perioperative administration of antibiotics is to obtain plasma and tissue drug concentrations exceeding the minimal inhibitory concentration of those organisms most likely to cause an infection. This will reduce the microbial load of the intraoperative contamination; it is not the intent to cover all possible pathogens, because this can lead to the selection of drug-resistant bacteria.

There have been few studies regarding the effectiveness of prophylactic guidelines for prevention of SSIs in children. Currently, prophylactic antibiotic guidelines exist for certain subsets of the pediatric surgical population, but there are no global recommendations, and the guidelines that exist are mostly based on studies from adults or from expert opinion. A retrospective study suggested that the appropriate use of antibiotic prophylaxis was a vital modifiable risk factor and may be the easiest factor to influence. Primary failure to administer the correct dose of antibiotics at the appropriate time resulted in an almost 2-fold increase in the risk of developing an SSI. The importance of correct antibiotic usage and dosing plays a major role in decreasing risk of SSIs in children. Recommendations are provided for adult (age ≥19 years) and pediatric (age 1–18 years) patients. The guidelines do not specifically address newborn (premature and full-term) infants (Table 50.12).[149]

Selection of the Antimicrobial Agent

Although pediatric-specific prophylaxis data are sparse, available data have been evaluated for specific procedures. Selection of antimicrobial prophylactic agents mirrors that in adult guidelines, with the agents of choice being first- and second-generation cephalosporins, reserving the use of vancomycin for patients with documented β-lactam allergies. While the use of a penicillin with a β-lactamase inhibitor in combination with cefazolin or vancomycin and gentamicin has also been studied in pediatric patients, the number of patients included in these evaluations remains small. As with adults, there is little evidence supporting the use of vancomycin, alone or in combination with other antimicrobials, for routine perioperative antimicrobial prophylaxis in institutions that have a high prevalence of methicillin-resistant *S. aureus* (MRSA). Vancomycin may be considered in children known to be colonized with MRSA and decreases MRSA infections.[150] Mupirocin is effective in children colonized with MRSA, but

TABLE 50.12 Antimicrobial Prophylaxis Dosing Recommendations

Antimicrobial	Pediatric Recommended Dose[a]	Recommended Redosing Interval (From Initiation of Preoperative Dose), hours[b]
Ampicilin-sulbactam	50 mg/kg of the ampicilin component (up to 3 g)	2
Ampicilin	50 mg/kg (up to 2 g)	2
Azitreonam	30 mg/kg (up to 2 g)	4
Cefazolin	30 mg/kg (up to 2 g, 3 g if >120 kg)	4
Cefuroxime	50 mg/kg (up to 1.5 g)	4
Cefotaxime	50 mg/kg (up to 1 g)	3
Cefoxitin	40 mg/kg (up to 2 g)	2
Cefotetan	40 mg/kg (upto 2 g)	6
Ceftriaxone	50–75 mg/kg (up to 2 g)	N/A
Ciprofloxacin[c]	10 mg/kg (up to 400 mg)	N/A
Clindamycin	10 mg/kg (up to 900 mg)	6
Ertapenem	15 mg/kg (up to 1 g)	N/A
Fluconazole	6 mg/kg (up to 400 mg)	N/A
Gentamicin[d]	2.5 mg/kg based on dosing weight	N/A
Levofloxacin[c]	10 mg/kg (up to 500 mg)	N/A
Metronidazole	15 mg/kg (up to 500 mg) Neonates weighing <1200 g should receive a single 7.5-mg/kg dose	N/A
Moxifloxacin[c]	10 mg/kg (up to 400 mg)	N/A
Piperacilin-tazobactam	Infants 2–9 months: 80 mg/kg of the piperacilin component (up to 3.375 g) Children >9 months and ≤40 kg: 100 mg/kg of the piperacilin component	2
Vancomycin	15 mg/kg	N/A
Oral Antibiotics for Colorectal Surgery Prophylaxis (Used in Conjunction With a Mechanical Bowel Preparation)		
Erythromycin base	20 mg/kg (up to 1 g)	N/A
Metronidazole	15 mg/kg (up to 1 g)	N/A
Neomycin	15 mg/kg (up to 1 g)	N/A

[a]The maximum pediatric dose should not exceed the usual adult dose.
[b]For antimicrobials with a short half-life (e.g., cefazolin, cefoxitin) used before long procedures, redosing in the operating room is recommended at an interval of approximately two times the half-life of the agent in patients with normal renal function. Recommended redosing intervals marked as "not applicable" (N/A) are based on typical case length; for unusually long procedures, redosing may be needed.
[c]While fluoroquinolones have been associated with an increased risk of tendinitis/tendon rupture in all ages, use of these agents for single-dose prophylaxis is generally safe.
[d]In general, gentamicin for surgical antibiotics prophylaxis should be limited to a single dose given preoperatively. Dosing is based on the patient's actual body weight. If the patient's actual weight is more than 20% above ideal body weight (IBW), the dosing weight (DW) can be determined as follows: DW = IBW + 0.4 (actual weight − IBW).
Adapted from Bratzler DW, Dellinger EP, Olsen KM, et al. Clinical practice guidelines for antimicrobial prophylaxis in surgery. *Am J Health Syst Pharm.* 2013;70(3):195–283.

there are limited data supporting its use perioperatively.[151,152] Most recommendations for adults are the same for pediatric patients. Dosing recommendations in pediatric patients are limited and have been extrapolated from adult data; therefore nearly all pediatric recommendations are based on expert opinion. Pediatric efficacy data are few. Fluoroquinolones should not be routinely used for surgical prophylaxis in pediatric patients because of the potential for toxicity in this population. The same principle of preoperative dosing within 60 minutes before incision has been applied to pediatric patients. Additional intraoperative dosing may be needed if the duration of the procedure exceeds two half-lives of the antimicrobial agent or there is excessive blood loss during the procedure. As with adult patients, single-dose prophylaxis is usually sufficient. If antimicrobial prophylaxis is continued postoperatively, the duration should be less than 24 hours, regardless of the presence of intravascular catheters or indwelling drains. There are sufficient pharmacokinetic studies of most agents to recommend pediatric dosages that provide adequate systemic exposure and, presumably, efficacy comparable to that demonstrated in adults. Therefore the pediatric doses recommended in guidelines are based largely on pharmacokinetic data and the extrapolation of adult efficacy data to pediatric patients. Because few clinical trials have been conducted in pediatric surgical patients, strength of evidence criteria have not been applied to these recommendations. With few exceptions (e.g., aminoglycoside dosages), pediatric doses should not exceed the maximum adult recommended dosages. Generally, if a dose is calculated on a milligram-per-kilogram basis for children weighing more than 40 kg, the calculated dosage will likely exceed the maximum recommended dose for adults; adult dosages should therefore be used for larger children.[153]

The Timing of Antibiotic Prophylaxis

The 2013 revised policy paper on prophylactic antibiotics developed jointly by the American Society of Health-System Pharmacists (ASHP), the Infectious Disease Society of America, the Surgical Infection Society, and the Society for Healthcare Epidemiology of America states:

Successful prophylaxis requires the delivery of the antimicrobial to the operative site before contamination occurs. Thus, the antimicrobial agent should be administered at such a time to provide serum and tissue concentrations exceeding the minimum inhibitory concentration (MIC) for the probable organisms associated with the procedure, at the time of incision, and for the duration of the procedure.[154]

Current evidence suggests that for most β-lactams, a bolus dose at 15 to 45 minutes before incision is ideal and provides maximum interstitial fluid concentrations at the time of initial bacterial seeding (see Table 50.12). Because diffusion distances from capillary to pathogen are greater in obese patients, for this patient subset initiating antibiotic infusion 30 minutes or longer before incision is warranted on theoretical grounds.[155] The initial β-lactam bolus dose should be followed by additional doses at every 1 to 2 half-lives per the ASHP guidelines.[154] The use of a SSI prevention bundle in pediatric patients improves compliance with preincision antibiotic administration and decreases the SSI infection rate.[156]

Allergy to β-Lactams

Several studies have shown that the true incidence of allergy to antibiotics is less than that reflected in medical charts.[157] For surgical procedures where cephalosporins are the prophylaxis of choice, alternative antibiotics should be administered to those children at risk of anaphylaxis to β-lactams, based on their history or diagnostic tests (e.g., skin testing). However, the incidence of severe allergic reactions to first-generation cephalosporins in children with reported allergy to penicillin is rare (but not zero)[158,159]; furthermore, skin testing does not reliably predict the likelihood of adverse reactions to cephalosporins in those with reported allergy to penicillin.[160–162] There is no evidence of any risk of cross-reactivity between penicillin and second- and third-generation cephalosporins. For the most part, "allergies" to oral antibiotics that appear on children's charts (rash, vomiting, gastrointestinal disturbances) are reactions to the additives in the antibiotic formulation, including food dyes, fillers, and other compounds, or a manifestation of the underlying infection. IV administration of small test doses of the pure antibiotic in a fully monitored (and anesthetized) child will determine whether the child is at risk for an allergic reaction to the antibiotic. In the case of surgical procedures where antibiotic prophylaxis is mainly directed at gram-positive cocci, children who are truly allergic to β-lactams (cephalosporins) should receive either vancomycin or clindamycin.[163] However, in those children where the history is consistent with either an IgE-mediated penicillin allergy (urticaria, angioedema, anaphylaxis, bronchospasm) or a severe non–IgE-mediated reaction (interstitial nephritis, toxic epidermal necrolysis, hemolytic anemia, or Stevens-Johnson syndrome) it is advisable to switch out the cefazolin. Cross-sensitivity occurs when the R1 side chains of the penicillins and cephalosporins are similar, which perhaps surprisingly is not the case with cefazolin. Cephalosporins with R1 side chains similar to penicillins include cephalexin, cefaclor, and cefadroxil. The risk associated with use of first- or second-generation cephalosporins with dissimilar side chains, or third- or fourth-generation cephalosporins, "*appears to be very low in patients with mild-to-moderate reactions to penicillin G, ampicillin, or amoxicillin. Dismissing cefazolin use when there is a vague history of any penicillin allergy should be reconsidered.*"[155]

Indications for Prophylactic Antibiotics

Surgical wounds are classified into four categories (Table 50.13). The use of antibiotic prophylaxis for postoperative infections is well established for clean-contaminated procedures. Within the clean category, prophylaxis has been traditionally reserved for surgical procedures involving a foreign body implantation or for any surgical procedure where an SSI would be catastrophic (e.g., cardiac surgery or neurosurgical procedures). However, there is evidence that postoperative infections resulting from procedures not involving prosthetic elements are underreported; estimates show that more than 50% of all complications occur after the patient is discharged and are thus unrecognized by the surgical team. Therefore antibiotic prophylaxis is also recommended for certain procedures, such as herniorrhaphy.[164,165] The direct and indirect costs of these complications may not affect the hospital budget; however, they represent a substantial cost for the community at large. In the case of contaminated or dirty procedures, bacterial contamination or infection is established before the procedure begins. Accordingly, the perioperative administration of antibiotics is a therapeutic, not a prophylactic, measure. The use of antibiotics in children has implications not only for the response to the current treatment but also to future treatments. Thus all medical professionals are jointly responsible for the rational use of antibiotics.

Protocols, although effective, require continuous feedback on their acceptance and SSI results.[166] No surgical protocol can replace

TABLE 50.13 Wound Classification System

Wound Category	Description
Class I/clean	Uninfected wound with no inflammation, and the respiratory, alimentary, genital, or uninfected urinary tract is not entered. Clean wounds primarily are closed and drained, when necessary, with closed drainage. Operative wounds after blunt trauma may be included in this category if they meet criteria.
Class II/clean contaminated	Operative wound in which the respiratory, alimentary, genital, or urinary tract is entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in the category, provided no evidence of infection or major break in technique is encountered.
Class III/contaminated	Open, fresh, accidental wounds; operations with major breaks in sterile technique (e.g., open cardiac massage) or gross spillage from the gastrointestinal tract; and incisions in which acute, nonpurulent inflammation is encountered
Class IV/dirty-infected	Old traumatic wounds with retained devitalized tissue and those that involve existing clinical infection or perforated viscera, suggesting that the organisms causing postoperative infection were present in the operative field before operation.

From Neville HL, Lally KP. Pediatric surgical wound infections. *Semin Pediatr Infect Dis.* 2001;12:124–129.

the judgment of the medical professional; clinical reasoning must be tailored to the individual circumstances. Finally, children with congenital heart disease and a subgroup of those with repaired congenital heart disease may require bacterial endocarditis prophylaxis (see also Tables 16.2 and 16.3).[167]

ANNOTATED REFERENCES

Fernandez PG, Loftus RW, Dodds TM, et al. Hand hygiene knowledge and perceptions among anesthesia providers. *Anesth Analg.* 2015;120(4):837-843.

Anesthesiologists have long been patient safety advocates. It is not surprising that anesthesia providers have taken on increasing responsibility for preventing health care–associated infections. However, the overall hand hygiene compliance across health care providers remains less than 50%, with anesthesia providers identified as a particularly noncompliant group. In this paper, the authors identified risk factors for knowledge deficits among anesthesia providers and characterized anesthesia provider perceptions, attitudes, awareness of individual group performance, workload and type, and accessibility of hand hygiene agents.

Loftus RW, Brown JR, Koff MD, et al. Multiple reservoirs contribute to intraoperative bacterial transmission. *Anesth Analg.* 2012;114(6):1236-1248.

Bacterial cross-contamination is thought to play an important role in the development of health care–associated infections, but the relative importance of the known hospital bacterial reservoirs (health care providers' hands, patient, and environment, including health care equipment) in this process is unknown. A better understanding of how bacterial cross-contamination occurs can provide the basis for the development of evidence-based preventive measures. This paper examined the relative contributions of anesthesia providers' hands, the patient, and the patient environment to stopcock contamination.

Rizzo M. Striving to eliminate catheter-related bloodstream infections: a literature review of evidence-based strategies. *Semin Anesth Perioper Med Pain.* 2005;24(4):214-225.

This paper reviews and emphasizes the need for preventive measures that could help to avoid or reduce most nosocomial catheter-related infections. The use of evidence-based standardized protocols will result in "best practices" and markedly reduce such infections.

Sagoe-Moses CH, Pearson R, Perry J, Jagger J. Risks to health care workers in developing countries. *N Engl J Med.* 2001;345(7):538-541.

Protecting HCWs in developing countries from exposure to bloodborne pathogens will involve some cost. HCWs are a crucial resource in the health care systems of developing nations. In many countries, including those in sub-Saharan Africa, workers are at increased risk for preventable, life-threatening occupational infections. This paper expands on the need for improved support of HCWs throughout the world with appropriate supplies of gloves, barriers, sharps disposal, and the need for accident education programs.

Summary

THE POPULATION IN THE DEVELOPING WORLD CONTINUES TO GROW while world demographics trend toward an aging population in an urbanized, developed world. Children, many orphaned by the ravages of war, human immunodeficiency virus (HIV) infection,[1] and famine, constitute more than one-half of the population in many of these countries.[2] Eighty-five percent will require surgery before their 15th birthday.[3] The burden of surgical disease requires safe anesthesia,[4,5] but provision of safe pediatric anesthesia[6] and intensive care[7–9] in the developing world presents serious challenges.[10–12] Few of these countries have adopted the World Health Organization (WHO) drive for safe surgery.

Poverty, poor educational standards, and limited health resources characterize the developing world.[5,6,13] Debt repayment, housing, education, social services, and health care provision are near-impossible tasks for most governments of these countries. Of the world's poorest countries, 70% are in sub-Saharan Africa, are ravaged by HIV, malaria, Zika virus, and tuberculosis. In addition they are desperately short of health care providers.[4,5]

Pediatric anesthesia in low-income countries has not kept pace with the advances made in developed countries.[4] International standards for the safe practice of anesthesia, adopted by the World Federation of Societies of Anaesthesiologists (WFSA), are seldom met.[14–16] In one survey, only 13% of anesthesiologists were able to provide safe anesthesia for children.[3] Consequently, perioperative mortality and morbidity rates are high by developed world standards,[5,17–21] although local expectations are commensurate with the facilities and quality of the available care.

This chapter outlines some of the many challenges that anesthesiologists face when providing anesthesia for children in a low-income country. Different countries have different problems requiring different solutions. The problems faced in many tropical countries,[8,13] for example, are completely different from those on a tropical island in the South Pacific[22] or West Indies,[23,24] at altitude in Nepal[25] and Afghanistan,[26] or in the humidity of sub-Saharan Africa.[2,3,19,21,27–30] These diverse situations necessitate that generalizations be made. The main differences among these sites are related to the personnel, the spectrum and nature of the disease, the facilities and equipment available, and a tenuous supply of cheap, generic, and perhaps outdated drugs.[10,31]

The Child

Children of the developing world are, for the most part, victims of circumstance: natural disasters, war, refugees, social unrest,[32] and economic crises. For many, medical care or timely access to care can be a remote or nonexistent possibility.[10,25,30,33,34] Fear, poor understanding of medical problems, and poor education often result in delayed presentation. Frequently, prior visits to well-meaning traditional healers expose the child to additional risks caused by potions that may be hepatic or nephrotoxic or enemas that can lead to bowel perforation.[35] Further delays occur when children need to undertake long journeys to the hospital and if the initial diagnosis is incorrect, tertiary referral is often made only when complications occur (Fig. 51.1).[10,30,36,37]

A typical example is acute appendicitis, a relatively uncommon condition in the developing world, where many other causes for a change in bowel habit are initially suspected.[37,38] Most children present for surgery with generalized peritonitis, and perforation is common. In the developing world, the prospect of providing emergent anesthesia for a toxic, acidotic, and dehydrated child is daunting.

Another example is infantile hypertrophic pyloric stenosis, also uncommon in developing countries, where symptoms other than the classic triad of bile-free vomiting, visible peristalsis, and a palpable tumor are more likely. The unsuspecting anesthesiologist, who may have no access to a laboratory[2,13–15] and is limited in the choice of fluid for resuscitation, would be challenged to manage the extreme metabolic derangements in these infants.

Superstition plays a role in compounding the anesthesia risk. For example, rural Vietnamese believe that it is not good to die with an empty stomach. Parents consider surgery to be an enormous risk so they feed their children beforehand. In these circumstances, passage of a nasogastric tube before induction is routine, although it is very unlikely that the stomach can be completely emptied of solids.[24]

Perinatal mortality in some parts of the developing world is 10 times greater than those in developed countries.[5,39–41] The common denominators are early childbearing, poor maternal health, and lack of appropriate and quality medical services.

FIGURE 51.1 Peripheral gangrene of the hand. Severe dehydration in this infant was caused by severe gastroenteritis. Dehydration associated with delayed presentation, hypernatremia, herbal medications, and pneumonia are common contributors to this disastrous outcome.

FIGURE 51.2 Gastroschisis is a major problem in the developing world. The outcome is poor because of a paucity of facilities for neonates. This defect was not diagnosed antenatally, and the patient presented late for closure, which proved difficult. Ventilatory support was not available, and a silo was fashioned. Unfortunately, the child died of overwhelming sepsis a week later.

Although lifesaving practices for most infants have been known for decades, one-third of pregnant women still have no access to medical services during pregnancy, and almost 50% do not have access to medical services for childbirth.[30,34,41] Most parturients give birth at home or in rural health centers,[34] where basic neonatal resuscitation equipment is deficient or nonexistent.[30] Those who require surgery may need to be transferred, but specialized transport teams rarely exist.

In some hospitals, neonates are not candidates for surgery because "they always die,"[42] whereas in others, they undergo surgery without anesthesia[23] because "it's safer" and because some still believe that neonates do not feel pain. When neonates undergo surgery, there are additional challenges, particularly in emergency situations.[23] Appropriately sized equipment is lacking,[36] and it may be extremely difficult to maintain normothermia even in relatively warm climates without improvisation. Regional anesthesia can play a significant role in neonatal anesthesia[30,36,43] and in some centers may be the only choice for anesthesia.[34,44] Apart from providing analgesia without respiratory depression, the need for postoperative ventilatory support for conditions such as esophageal atresia,[45] congenital diaphragmatic hernia,[46] and abdominal wall defects can be reduced by continuous epidural analgesia (Fig. 51.2).

Regrettably, even neonates who receive skilled anesthesia and surgery may die because of inadequate postoperative care.[44] Overwhelming infection, sepsis, respiratory insufficiency, and surgical complications are the main causes of morbidity and mortality.[30,34] The development of highly specialized neonatal anesthesia and surgical services,[7,40–42] essential for a good outcome after neonatal surgery,[30,34,36] is a low priority.

Although the burden of disease is dominated by infections and malnutrition,[4,5] pediatric trauma has a low level of advocacy and is given scant attention.[30,36,47] Socioeconomic advances in some countries have introduced a new danger in the form of faster, more powerful vehicles without the necessary maintenance culture or road discipline. Road traffic accidents are inevitable, and effective systems to handle the polytrauma victims that result are hard to find.[36]

Even simple bone fractures may have disastrous outcomes. Inappropriate management by traditional bonesetters frequently results in compartment syndromes or gangrene.[47] Trauma prevention strategies are given low priority despite the acknowledged impact of trauma on the economy of any country. Many developing countries are at war, and this has led to massive trauma and injuries to children who may be either participants in the fighting or innocent bystanders.

CHILDREN AND WAR

Children may be victims of all aspects of violence. They face an intense struggle for survival because of displacement, separation from or loss of parents, poverty, hunger, and disease. They are vulnerable to the abuse of abandonment, abduction, rape, and forced soldiering. An estimated 300,000 children are used as child soldiers in more than 30 countries.[48] Many sustain physical injuries and permanent disabilities, and a large number acquire sexually transmitted disease, including HIV and AIDS. These HIV-positive child soldiers then become vectors in communities where they are deployed.[49]

For many of these children, acts of violence become their form of normality, and former victims become the perpetrators.[32] Survivors are subjected to the total collapse of economic, health, social, and educational infrastructures. Lost and abandoned children sleep on the streets and are forced to beg for food while trying to find their families. Many become child laborers or turn to crime or prostitution for survival.[50]

Children in war-torn areas sustain bullet, machete, or shrapnel injuries, and others are burned. They often sustain mutilating injuries (Figs. 51.3 and 51.4) that are not commonly seen in civilians.[51] Land mines are responsible for killing or maiming an

FIGURE 51.3 Facial burn injuries are common in the developing world, and these children may require multiple episodes of anesthesia. **A**, Flame burns of the face are invariably associated with inhalation injuries that may necessitate ventilatory support in intensive care facilities, which are not readily available. **B**, Pain management and pain assessment are challenging. The pained expression on this child's face is one of fear (and possible indignation about having the photograph taken) rather than actual pain.

estimated 12,000 civilians per annum. In Angola, a country with the highest rate of amputees in the world, there were an estimated 5.5 land mines for every child. Continuing land mine explosions remain a legacy of this conflict.[51] These blast injuries leave children without feet or lower limbs and with genital injuries, blindness, and deafness–a pattern of injury that has become a post–civil war syndrome encountered by surgeons worldwide.[51] Although the war in Angola is over, the cost of mine removal is beyond the means of local governments. Ironically, artificial limb manufacture has become a developing industry.[51] Tragedies such as these are likely to be repeated in the ongoing conflicts in Afghanistan, Syria, South Sudan, and Somalia.

FIGURE 51.4 Children fare poorly in war. This 8-year-boy bit a detonator he found while playing. Endotracheal intubation proved a major challenge without a fiberoptic laryngoscope, which is a luxury in the developing world.

The terrible psychological effects of war persist even though the armed conflict may be over. Mental and psychiatric disorders with all the ramifications of posttraumatic stress disorder are common among child survivors.

PAIN

Pain management modalities for children in the developed world are vastly different from those available to practitioners working with limited resources.[52] Attempts to apply similar standards are fraught with difficulty. Illiteracy, malnutrition, poor cognitive development, different coping strategies, altitude (e.g., chronic hypoxia),[53] and pharmacogenetic, cultural, and language differences all contribute to the complexity of the problem.[54]

Children of the developing world learn to cope with vastly different problems. Victims of poverty, malnutrition, violence (e.g., war, trauma, abuse), their attitudes toward pain, and pain tolerance are diverse. Children from an impoverished background seem more stoic and indifferent to even severe pain. After cardiac surgery, for example, some appear to need very little pain relief and are easily soothed by lollipops or play therapy.[33] Many can walk from the intensive care unit to the general ward on the first postoperative day.

Pain assessment of children from an impoverished background is difficult[55] (see Fig. 51.3B). Many children in acute pain do not show facial expressions. Is this stoicism or simply a reflection of malnutrition, lack of social stimulation, severity of illness, or even cultural attitude? Language difficulties, cultural barriers, willingness to share information, emotional expressiveness, and outdated attitudes of the caregiver may underpin this quandary. Some cultures convey pain readily, but others teach that expression of pain is inappropriate. Although many pain assessment instruments are available, few have been validated in the developing world.[55–57]

There is an urgent need to develop pain treatment strategies applicable to children of the developing world. Local conditions

dictate their use and applicability. Simple pain management strategies may produce the most benefit with the least risk, whereas more complex techniques–offering greater benefit–require minimum standards of monitoring and regular reassessment to titrate analgesia to the needs of the individual. These devices and the necessary personnel are seldom available for these children. The final choice of analgesia is therefore dictated by economic pressures or by the facilities available rather than what would be considered best for the child.

Human Resources

Anesthesia does not enjoy a high profile and lacks the voice to demand access to basic resources in developing countries. The critical shortage of manpower is a barrier to progress.[5,8] Anesthesia is frequently delivered by nonphysicians,[3,6,58] a reality that has remained constant over many decades. Most anesthetics are still administered by nurses or unqualified personnel who have little medical background and are "trained on the job."[3,36] In many African[5,59] and Asian countries,[5,60] the ratio of doctors to patients is often so small that the ideal of employing a physician specifically to provide routine anesthesia is out of the question.[5,61,62] Salaries are insufficient to attract suitably trained and qualified practitioners for more than short periods. Emigration of scarce trained personnel to developed countries in search of better salaries and improved lifestyles exacerbates these human resource shortfalls.[5,10,58,61–64]

Anesthesia is not perceived as an attractive career for many undergraduates,[63] who receive little or no exposure to the specialty.[64] In some countries, surgery is performed without the "luxury" of anesthesia.[65] Few developing countries can afford specialist anesthesiologists, possibly excepting the principal hospitals. Supervision of "nonphysician anesthesiologists" is invariably inadequate,[66] and access to textbooks, journals, or other medical literature is limited. Internet access is invaluable but depends on a reliable electrical supply, telecommunications network, and a computer.[67,68]

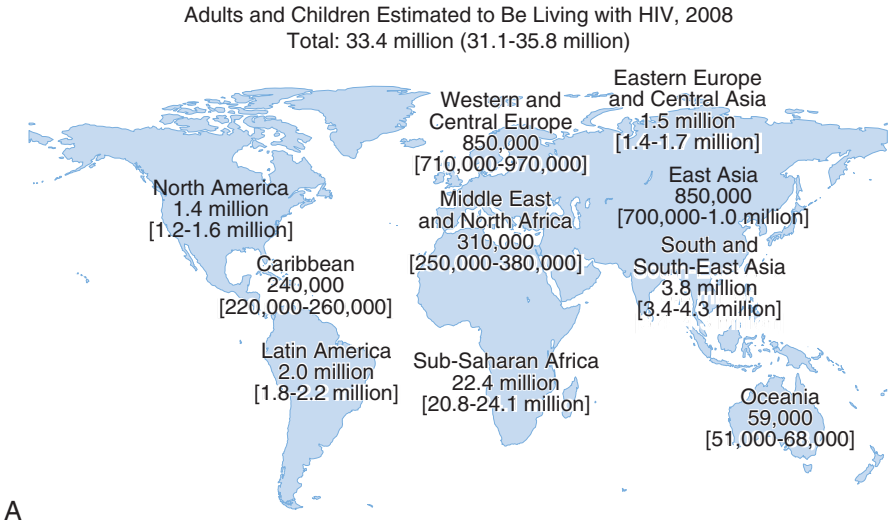
Despite these problems, many individuals provide high-quality anesthesia for a limited range of surgical procedures. Few receive formal training in pediatric or neonatal anesthesia. Inadequately trained anesthesiologists tend to shy away from children, particularly neonates and infants, because of the perceived difficulty or fear. This is understandable in view of the lack of supervision, the severity of the child's condition, and equipment that is more suited for adults. Invariably, the "pediatric anesthesiologist" is someone who may simply have a special interest in or affinity for children, or is allocated to pediatric anesthesia for the day because there is no one else. A genuine pediatric trained anesthesiologist is a luxury.

On a more positive note, the WHO has recognized that surgery is a public health issue and has launched the Safe Surgery Saves Lives campaign.[5,16,17,62,69] The WHO has emphasized that safe surgery does not exist without safe anesthesia.[10,11,16,17] Training anesthesiologists in the skills required for pediatric anesthesia is a slow process. Hopefully the WFSA fellowship programs[6,15,69–76] will snowball so that children undergoing surgery in developing countries will reap the benefit.

Pathology

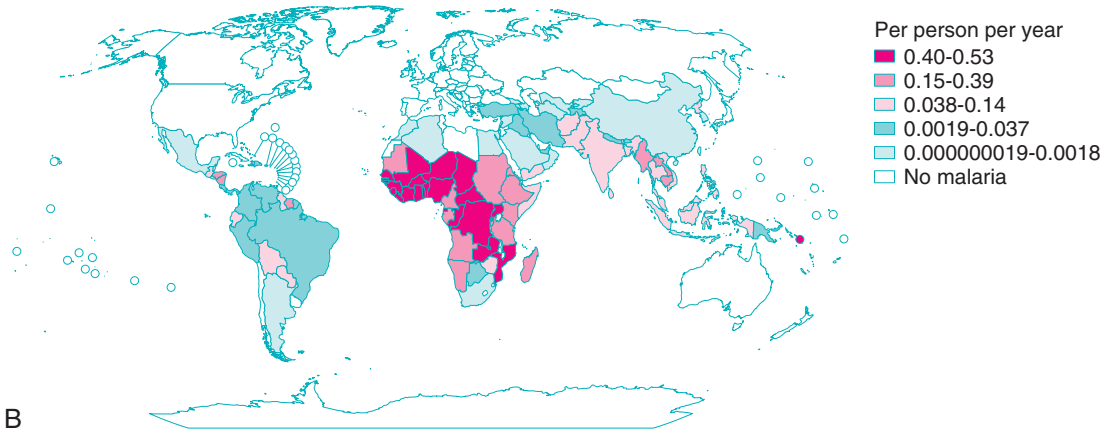
Many pathologic conditions seldom seen in industrialized countries are more prevalent in developing countries because of poor health education, malnutrition, the proximity of livestock to humans, earth-floored homes, poor sanitation, and contaminated water supplies (Fig. 51.5). Some conditions prevalent worldwide and relevant to the anesthesiologist are considered in the following sections.

HUMAN IMMUNODEFICIENCY VIRUS INFECTION AND ACQUIRED IMMUNODEFICIENCY SYNDROME



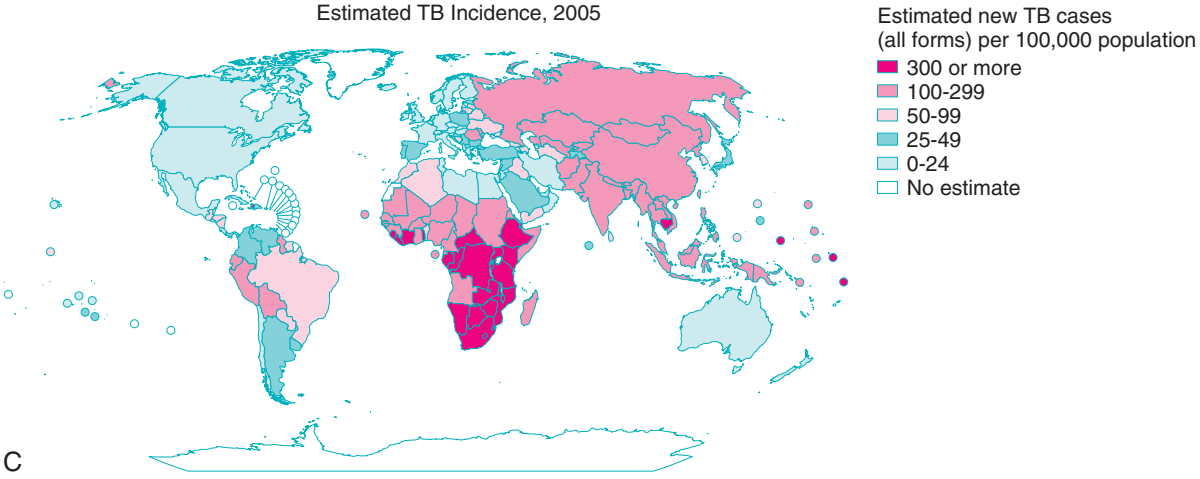
While the world has committed to ending the AIDS epidemic by 2030, an estimated 36.7 million people are living with HIV, 19 million of whom do not know their HIV status. Only half of those who know their HIV status are accessing antiretroviral therapy. Most cases occur in the developing world (90%), with sub-Saharan Africa (24.7 million) and Southeast Asia (4.8 million) making up two-thirds of the global total. Approximately 8% are children (see Fig. 51.5A).[77] More than 35 million have died of HIV-related diseases since the start of the epidemic in 1981, and as a consequence, there are an estimated 15 million orphans in sub-Saharan Africa alone.[77] Worldwide, more than 500 children were newly infected with HIV each day in 2016 (down from 1000 each day in 2010); most of these children are in sub-Saharan Africa.[78] The prevalence of HIV seropositivity varies from one country to another. In these clinical situations, anesthesiologists and surgeons[79] should assume a positive status for every patient until proven otherwise.[36]

Some success has been achieved in slowing the transmission of HIV in developed countries,[79–85] In sub-Saharan Africa today, 90% of those who know their HIV status have received treatment and 76% have achieved viral suppression. Numerous barriers exist to the treatment of HIV-infected children.[77] Treatment has lagged behind that of adults primarily as a result of poor human resources and infrastructure for administration of antiretroviral treatment,[86] but also because of the expense and the lack of pediatric drug formulations.[82] Only an estimated 25% children infected with HIV receive treatment.[77]



Children are infected by vertical transmission from the mother (>90%) or when sexually abused (≈2%) by an infected adult.[87] Transmission through blood products remains a risk, but with the global trend toward volunteer donors and more sophisticated testing of donated blood, this risk is diminishing.

Vertical transmission can occur in utero, during labor and delivery, or postnatally. Risk factors include maternal viral load and breastfeeding.[78,84] Data indicate that mixed feeding (i.e., breastfeeding with other oral foods and liquids) is associated with the greatest risk of transmission.[88] Perinatal transmission rates are dramatically reduced by universal HIV testing of pregnant women, provision of antiretroviral therapy (when needed for maternal health); or prophylaxis, elective cesarean delivery, and avoidance of breastfeeding.[78,84] Highly active antiretroviral therapy (HAART), the triple antiretroviral therapy, has changed HIV from a fatal illness to a chronic disease with decreased mortality rates and improved quality of life[84]; however, these strategies require resources.



In practical terms, it is difficult to differentiate infants who are infected by vertical transmission from those who are not infected because differentiating between actively or passively acquired antibodies is virtually impossible in low-income countries. All children born to HIV-positive mothers have acquired HIV antibodies for the first 6 to 18 months. Only 30% to 40% of the infants who are infected develop AIDS. The presence of HIV antibody is therefore not a reliable indicator of infection. More sophisticated and expensive tests have been developed but are not widely available. All children born to HIV-positive mothers

A

B

C

FIGURE 51.5 **A,** Global distribution of human immunodeficiency virus infection and acquired immunodeficiency syndrome (HIV/AIDS). Developing countries, particularly sub-Saharan Africa, carry the greatest health burden with the poor resources. **B,** The global distribution of malaria is remarkably similar to that of HIV/AIDS. Blood products in these regions carry an enormous risk, even if family members act as donors. **C,** Global distribution of tuberculosis (*TB*) in 2005. (**A,** From *AIDS Epidemic Update,* p. 66; available at http://data.unaids.org/pub/EpiReport/2006/2006_EpiUpdate_en.pdf [accessed September 2017]; **B,** from *World Malaria Report.* Available at http://www.rbm.who.int/wmr2005/html/map3.htm [accessed September 2017]; **C,** from the WHO *World Health Report 2006.* Available at http://www.who.int/whr/2006/en/ [accessed September 2017].)

should be considered infected; if antibody persists beyond 15 months, infection should be assumed.

Progression of the disease depends on the mode of transmission; vertically acquired infection is more aggressive than other forms. Between 20% and 30% of untreated HIV-infected children will develop profound immunodeficiency and AIDS-defining illnesses within a year, whereas two-thirds will have a slowly progressive disease. The course of the disease depends on a variety of factors, including timing of infection in utero, the viral load, the mother's stage of the disease, and whether the mother is receiving antiretroviral therapy. Treatment of children depends on clinical category, CD4 T-cell cell count, viral load, and age at the time of diagnosis. According to the current state of knowledge, after HAART is started, it must be carried on lifelong. This implies great challenges in adherence to avoid development of resistance and to evade long-term adverse effects of HIV therapy. Emerging drug resistance in children in low- and middle-income countries has necessitated new treatment strategies.[82,85]

The clinical manifestation of HIV in infants and children depends on whether they have been managed with antiretrovirals or not.[79,82,85] Most have asymptomatic infections, and the presentation may be subtle, such as failure to thrive, lymphadenopathy, hepatosplenomegaly, interstitial pneumonia, chronic diarrhea, or persistent oral thrush. Some present for the first time with life-threatening disease.

Chronic diarrhea, wasting, and severe malnutrition predominate in Africa, whereas systemic and pulmonary pathologies are more common in the United States and Europe. Recurrent bacterial infections, chronic parotid swelling, lymphocytic interstitial pneumonitis (LIP), and early onset of progressive neurologic deterioration are characteristic of children with AIDS.

Pulmonary disease remains the leading cause of morbidity and mortality.[89–91] Bacterial pneumonia, viral pneumonia, and pulmonary tuberculosis are common, and the course of these infections is more fulminant when associated with HIV infection.[92] As the CD4 T-cell count falls, acute opportunistic infections occur, including *Pneumocystis (carinii) jiroveci* pneumonia (PCP or PJP), cytomegalovirus infection, and the more typical *Haemophilus influenzae*, *Streptococcus pneumoniae*, and respiratory syncytial virus infections.[89,90,92] The classic presentation of PCP is fever, tachypnea, dyspnea, and marked hypoxemia, but in some children, the presentation is more indolent, with hypoxemia preceding clinical or radiologic changes.[93]

LIP is a slowly progressive, chronic form of lung disease found in older children that can lead to an insidious onset of dyspnea, cough, and chronic hypoxia with normal auscultatory findings but with pulmonary lymphoid hyperplasia in AIDS patients. In contrast to the signs in adults, LIP in children may cause acute respiratory failure that is treated with steroids and bronchodilators. The clinical manifestations affecting otolaryngologists[94] and dental surgeons[95] have been outlined. Management of the upper airway may be difficult in the presence of stomatitis and gingival disease. Intubation may be difficult in the presence of acute (i.e., candidal infection) or chronic epiglottitis (i.e., lymphoid hyperplasia), necrotizing laryngotracheitis, Kaposi sarcoma (Fig. 51.6), or laryngeal papillomas (Fig. 51.7). These comorbid respiratory disorders challenge even the most experienced pediatric anesthesiologist (Fig. 51.8).

Cardiac disease is being diagnosed with increasing frequency in children with HIV. The pathogenesis of cardiomyopathy is multifactorial, including pulmonary insufficiency, anemia, nutritional deficiencies, specific viral infections, and drug therapy. Left and right ventricular dysfunction, arrhythmias, and pericardial effusions occur, but pulmonary hypertension is rare.[96] HIV may directly infect the myocardium, leading to early electrocardiographic (ECG) changes and abnormal echocardiograms showing hyperdynamic left ventricular dysfunction or evidence of diminished contractility (e.g., dilated cardiomyopathy, myocarditis).

The gastrointestinal tract is commonly involved,[97] particularly in those living in tropical countries. Affected children show evidence of malabsorption (i.e., "slim"), chronic recurrent diarrhea,

FIGURE 51.6 Human immunodeficiency virus infection and acquired immunodeficiency syndrome (HIV/AIDS) are an increasing problem is developing countries, particularly in sub-Saharan Africa. The skin manifestations in this 8-year-old boy indicate Kaposi sarcoma, an AIDS-defining tumor.

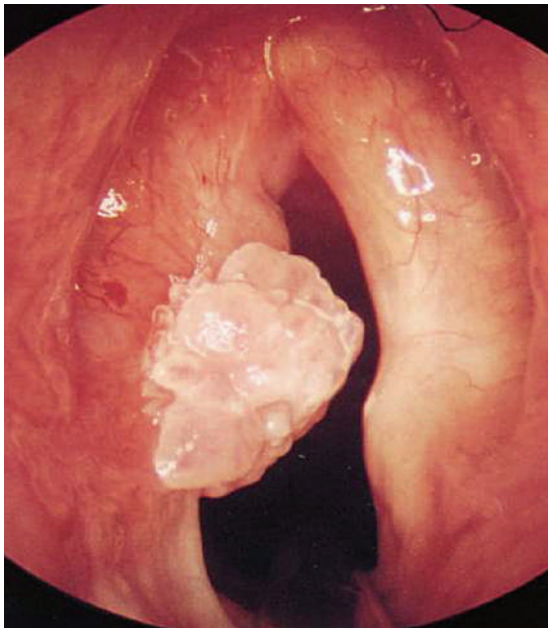


FIGURE 51.7 Laryngeal papilloma. Papillomas, caused by the human papillomavirus, are prevalent in low socioeconomic groups and have the highest incidence in the 2- to 5-year-old age group. This age distribution is changing in the populations exposed to human immunodeficiency virus. Even in well-equipped institutions, anesthesia for these patients can be challenging.

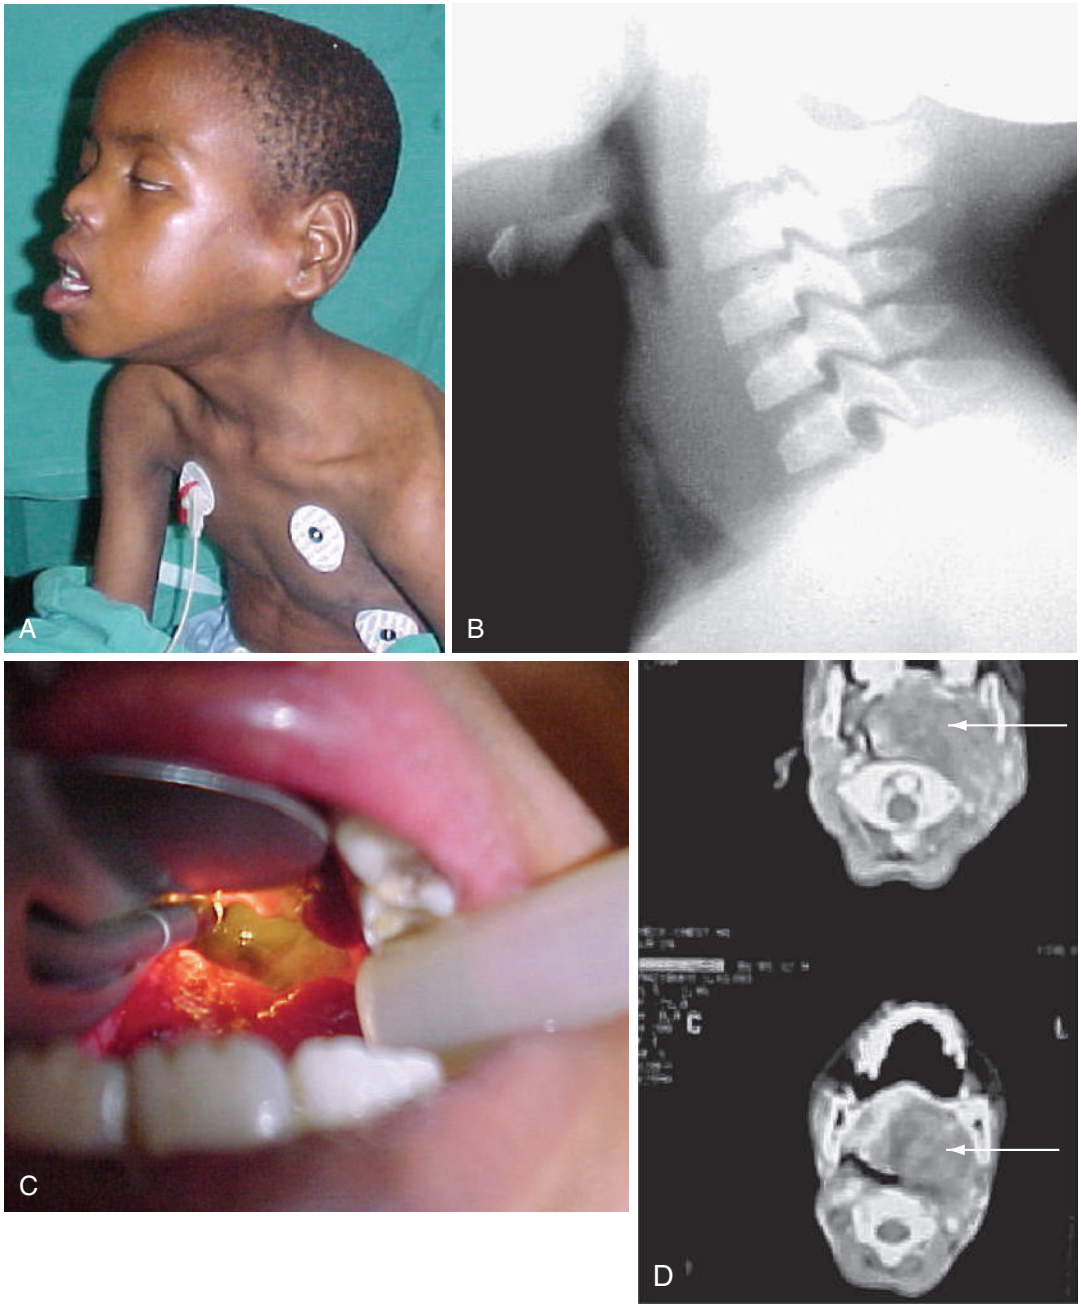

FIGURE 51.8 Kaposi sarcoma is a marker for acquired immunodeficiency syndrome (AIDS). **A,** AIDS was previously considered rare in children, but it may affect the airway at different levels, as shown in this 12-year-old girl. She is clearly fatigued from the respiratory distress caused by Kaposi sarcoma at three levels: base of the tongue, tonsil, and trachea. She also has an underlying pneumonia. Significant supraclavicular recession suggests upper airway obstruction. **B,** The Kaposi sarcoma of the base of the tongue, tonsil, and trachea is shown on a poor-quality, lateral neck radiograph, which illustrates one of the many difficulties faced in remote areas: the lack of high-quality imaging. **C,** Laryngoscopic view of the Kaposi sarcoma at the base of the tongue and the tonsil. **D,** Computed tomography shows a large retropharyngeal Kaposi sarcoma *(arrows)* obstructing the upper airway. The poor quality of the scan reflects inexperienced radiographers using the poor-quality equipment commonly found in developing countries.

dysphagia, failure to thrive, or enteric infection requiring diagnostic endoscopy. From the anesthesiologist's point of view, there is an increased risk of reflux owing to esophagitis caused by infection (e.g., *Candida*, cytomegalovirus) or drugs (e.g., zidovudine). Pseudobulbar palsy, a manifestation of central neurologic involvement, or esophageal strictures may occur.

Nausea and vomiting may have a neurologic, infectious, or drug-related cause. Pancreatitis, lymphomas, or smooth muscle tumors may delay gastric emptying. Hepatomegaly is invariably present, but severe hepatocellular dysfunction is seldom a major problem unless the patient has chronic hepatitis (e.g., hepatitis B or C, cytomegalovirus). Cholestasis and fluctuating transaminase

levels may be caused by HIV infection, poor nutrition, or drugs. In theory, hepatic enzyme dysfunction caused by antiretroviral therapy should affect the metabolism and pharmacokinetics of some anesthetic agents, although there has been a paucity of research on this subject.

Medications used to manage HIV are involved in drug interactions on several levels.[98] The reverse transcriptase inhibitors (e.g., zidovudine) are excreted by the kidneys, and drugs that affect renal clearance reduce excretion. Reverse transcriptase inhibitors may induce CYP3A4 (e.g., nevirapine) or inhibit CYP3A4 (e.g., delavirdine) and affect the clearance of other drugs (e.g., midazolam, levobupivacaine, ketamine, methadone). Protease inhibitors are inhibitors of CYP3A enzyme systems and are substrates and inhibitors of P-glycoprotein transporters. Coagulation status with the concomitant use of warfarin, which is metabolized by CYP2C9, may be altered by enzyme induction (e.g., ritonavir) or competition for clearance pathways (e.g., efavirenz, nelfinavir).[99]

Protease inhibitors also can inhibit specific uridine 5′-diphosphoglucuronosyltransferase (UGT) pathways. This accounts for the increase in bilirubin concentration (i.e., UGT1A1 glucuronidates bilirubin) observed in some patients, although UGT1A6 (i.e., acetaminophen glucuronidation) and UGT2B7 (i.e., morphine glucuronidation) are unaffected.[100] Gastric motility changes related to opioids (e.g., methadone) reduce absorption of some reverse transcriptase inhibitors.

HIV, a neurotrophic virus, can have a devastating effect on the immature brain, which can be further compromised by opportunistic infections or neoplasms that occur as a consequence of the associated immunosuppression.[101] Neurologic impairment is observed in most symptomatic HIV-infected children, commonly as a progressive encephalopathy with developmental delay, progressive motor dysfunction, and behavioral changes. Craniofacial dysmorphic features have been described. Hematologic abnormalities can reflect depression of all cell lines. Anemia may be caused by primary marrow failure, malnutrition, or drugs, whereas thrombocytopenia may reflect an autoimmune disorder.

Universal precautions should be strictly applied for all anesthesia procedures. Extra care should be taken when anesthetizing an HIV-infected child. Precautions should be taken to prevent contamination of the anesthetic circuits; disposable equipment, bacterial filters, and disposable circuits are recommended. The prohibitive cost for most institutions in developing countries limits the use of disposables. Reusable equipment should be cleaned, sterilized, and decontaminated according to the manufacturer's instructions as HIV is sensitive to a wide range of disinfectants.[102]

TUBERCULOSIS

Tuberculosis remains an important cause of morbidity and mortality.[36,103–108] The epidemiology of pediatric tuberculosis is shaped by risk factors such as age, race, immigration, poverty, overcrowding, and prevalence of HIV/AIDS (see Fig. 51.5C).[107,108] HIV and tuberculosis form a dangerous synergy that is difficult to manage because of drug interactions between the antituberculosis and antiretroviral agents.[77,104] Even bacillus Calmette–Guérin (BCG) vaccinations can cause significant complications in immunocompromised HIV patients.[104] The emergence of drug-resistant tuberculosis adds to the burden and is a constant danger to health care workers in general and anesthesiologists in particular.

Primary tuberculosis infection usually does not produce clinical illness in well-nourished, immunized children, whereas reactivated pulmonary tuberculosis is a chronic or subacute disease that may present a variety of challenges for the anesthesiologist, including preventing transmission by contamination of the anesthetic circuits and the risks associated with pleural effusions, pulmonary cavitation, or bronchiectasis.[91,93] Mediastinal and hilar lymphadenopathy may severely compromise the airway.

Primary tuberculosis and its complications are more common in children than in adults. After young children are infected, they are at increased risk for progression to extrapulmonary disease.[107,108] *Mycobacterium tuberculosis* infection can cause symptomatic disease in any organ of the body and is usually a reactivation of a latent site of infection. The most common sites of reactivation are lymph nodes, bones, joints, and the genitourinary tract. Less frequently, the disease may involve the gastrointestinal tract, peritoneum, pericardium, or skin. Tuberculosis meningitis and miliary tuberculosis, both more common in children, carry a high mortality rate.[107] In view of the high prevalence of HIV infection among tuberculous children, HIV testing should be performed in all children with tuberculosis; conversely, tuberculosis should be sought in all HIV-positive children. Tuberculosis is, however, difficult to diagnose in young children, and the search for affordable more sensitive tests continues.[103]

MALARIA

Malaria (see Fig. 51.5B) is a febrile, flu-like illness caused by one of four species of malaria parasites: *Plasmodium falciparum, P. vivax, P. ovale,* and *P. malariae*. Effective and safe prophylaxis against malaria has become increasingly difficult because the species that causes the most severe illness, *P. falciparum*, has become widely resistant to chloroquine and to other antimalarial drugs in some areas.[108] Severe malaria, even when optimally treated, carries a mortality rate of 10% to 25%.[108–110]

Prompt diagnosis and early treatment is an important determinant of outcome. Uncomplicated malaria usually manifests as fever, headache, dizziness, and arthralgia. Gastrointestinal symptoms may predominate and include anorexia, nausea, vomiting, and abdominal discomfort or pain mimicking appendicitis. In children, malaria can manifest with an acute, life-threatening disease or run a chronic course with acute exacerbations. The acute manifestations include three overlapping syndromes: respiratory distress as the result of a severe underlying metabolic acidosis (pH <7.3), usually a lactic acidemia; severe anemia (hemoglobin <5 g/dL) with hypovolemia[111] and thrombocytopenia; or neurologic impairment as a manifestation of cerebral malaria.[109–112] Seizures are an important presenting feature in 60% to 80% of cases. Prolonged seizures refractory to treatment and those that occur on antimalarial treatment are ominous signs and are usually associated with neurologic sequelae or death.[111] Cerebral malaria may also manifest as a prolonged postictal state, status epilepticus, severe metabolic derangement (i.e., hypoglycemia and metabolic acidosis), or a primary neurologic syndrome, ranging from diffuse cortical involvement to brainstem abnormalities.

Children with chronic malaria adjust physiologically to low hemoglobin concentrations but may decompensate rapidly when challenged with a febrile illness or surgery. The characteristic physical findings in children with severe anemia are respiratory distress and a hyperdynamic circulation. Blood transfusion may be administered rapidly in children with metabolic acidosis because most have a depleted intravascular volume.

Although controversial, exchange transfusion has been advocated for severe malaria, particularly for those with cardiorespiratory compromise, hyperparasitemia, or cerebral malaria. The rationale is to remove harmful metabolites, toxins, and cytokines; decrease

the parasite load; remove deformed red blood cells; and restore normal red blood cell mass, platelets, and other clotting factors.[111] Unfortunately, many malaria-endemic areas also have a high prevalence of HIV, adding significantly to the risk of blood transfusions.

Chronic recurrent malarial infections may manifest with splenic enlargement. This may cause delayed gastric emptying and pose an aspiration risk on induction of anesthesia. The spleen may enlarge acutely or rupture spontaneously during coughing, vomiting, or defecation. Rupture during external cardiac massage has also been described. Malaria may cause bloody diarrhea with massive fluid loss resembling dysentery in children.

CARDIAC DISEASE

Pediatric cardiac services typically are too expensive for most developing countries, and the increasing economic divide threatens those services that do exist.[113,114] In North America, each cardiac center serves 120,000 people; by contrast, one center serves 16 million people in Asia and 33 million in Africa.[61] Despite the need, few third-world units can treat the required volume of cases. Unless families have the financial means to travel to a developed country, the options for diagnostic or therapeutic cardiac procedures remain poor.[33,113–115] Medical missions may provide immediate help, but their impact on a developing country is short-term and potentially disruptive. These visiting teams ultimately have little effect on the complex socioeconomic and sociopolitical problems that exist.[114]

Rheumatic heart disease is more common than congenital heart disease in many developing countries,[113–115] reflecting the socioeconomic problems of poverty, overcrowding, malnutrition, and lack of antibiotics. Children often present late with life-threatening symptoms as the result of repeated infections and superimposed endocarditis. The acute deterioration precipitated by endocarditis may be the factor that prompts the search for medical attention. Valve replacement can be lifesaving, but long-term follow-up of anticoagulant therapy is often not feasible.

Congenital heart disease is an additional challenge, and it is common to see congenital heart defects in adults in developing countries. Those who have survived without the benefit of palliative or corrective surgery may present with pulmonary hypertension or endocarditis. Total correction of these defects is usually not feasible, and palliative surgery may be the more effective alternative. Excellent palliation with reasonable quality of life can be achieved relatively cheaply.[114]

TETANUS

Tetanus is a disease characterized by painful tonic muscle spasms, hyperreflexia, and autonomic instability.[116] It is caused by the exotoxin of *Clostridium tetani*, an organism that is ever present in the soil and contaminated wounds. Although rarely seen in developed countries, tetanus is prevalent in countries where children are not routinely immunized. Tetanus neonatorum carries a high mortality rate and is still encountered in areas where it is customary to apply feces to the umbilical cord to stop bleeding.

The clinical manifestations of the disease are not the result of invasive tissue injury but are caused by the production of a potent neurotoxin, tetanospasmin, at the site of the injury. The injury may be trivial and may not even be detectable at the time of presentation. The incubation period is inversely proportional to the distance between the site of the injury and the central nervous system. In children, this usually occurs within 14 days of the injury.

Trismus is the presenting sign in most cases, and sustained trismus produces a characteristic sardonic smile (i.e., risus sardonicus). Persistent contraction of the chest and back muscles presents as opisthotonus. Restlessness and irritability may be followed by tetanic seizures, often precipitated by trivial stimuli (e.g., touch, noise). Glottic or laryngeal spasm can cause sudden death. Late deaths may be caused by nosocomial infection, renal failure, sudden cardiac arrest, or cerebral hemorrhage secondary to the autonomic instability.[116]

Treatment consists of surgical debridement of the wound, administration of human tetanus immunoglobulin, antibiotic therapy, and intensive supportive medical care. Ventilatory support is invariably necessary because the frequent spasms impair ventilation already compromised by sedative therapy. Benzodiazepines and opioids are the mainstay of treatment, but numerous protocols have been studied.[116] Magnesium sulfate effectively reduces spasms as well as circulating catecholamines,[117] whereas clonidine does not.[118] Pain management should also be considered, and I have been encouraged by the use of continuous epidural analgesia for these children. Further advantages of epidural analgesia include good control of autonomic instability, earlier weaning from ventilatory support, and possible reduction in the complication rate.[116] From the anesthesiologist's point of view, trismus is overcome by neuromuscular blocking drugs, removing it as an obstacle for tracheal intubation.

Drugs

The supplies of anesthetic gases and drugs for rural medical facilities are erratic and unreliable.[3,8] The cost of many drugs, particularly those used in modern anesthesia, has increased alarmingly above and beyond the reach of most health care budgets. Anesthesiologists in developing countries therefore are forced to use less expensive anesthetics or generic medications.

Halothane and isoflurane are the most widely available inhalational anesthetics, and halothane is still the mainstay of inhalational anesthesia in many countries.[2,3,10,31,119] Halothane has virtually disappeared from the operating rooms in the developed world and has been replaced by sevoflurane and desflurane. As demand for the less expensive agents such as halothane has waned, some manufacturers seeking profitability have threatened its withdrawal. Although this may make commercial business sense, these agents sustain the anesthesia services for millions of patients in the developing world[2] and their loss would be tragic.

Ketamine is probably the most commonly used intravenous (IV) anesthetic.[3,65,119] Ketamine is simple to use, effective, and relatively safe when used as a sole agent for short procedures, used in combination with neuromuscular blocking drugs, or used to supplement general anesthesia for major surgery. It should be used with midazolam to reduce the psychotomimetic effects and nightmares observed after ketamine use. Benzodiazepines, however, are not always available. Morphine and other opioids may not be permitted in some cultures or even available in some institutions. It is sobering to realize that only 6% of the morphine consumption worldwide is used in the low- and middle-income countries that are home to 80% of the world's population.[52]

The choice of neuromuscular blocking drugs is limited. Suxamethonium, gallamine, curare, alcuronium, and pancuronium are the usual options, and the choice is dictated by their availability or the availability of reversal agents. For this reason, neuromuscular blocking drugs are not commonly used.

The cost of nitrous oxide is prohibitive in terms of storage, erratic delivery, and budgetary constraints.[120,121] Closed or semi-closed anesthetic systems are considered dangerous in an environment where the oxygen supply is erratic,[121] agent monitors are seldom available,[25] and the supply of soda lime and compressed gas cylinders is erratic. Consequently, the potential benefits and cost savings of low-flow anesthesia are lost.[121,122]

Regional anesthesia has many benefits in terms of safety, cost savings, and immediate postoperative analgesia.[a] Children in developing countries usually are very accepting of this form of analgesia. However, there seems to be a general reluctance to perform regional anesthesia in children,[29,36] even in some institutions in the developed world. Possible reasons include lack of training or expertise, fear of failure, and the unavailability of drugs, disposables, and other ancillary equipment such as ultrasound.

Improvisation may be the key. In the absence of appropriate equipment, access to the epidural space can be achieved by using a technique first described before the introduction of pediatric epidural needles into clinical practice. A catheter can be threaded through an IV cannula into the epidural space through the sacral hiatus in neonates and small infants.[125] Cheap, uninsulated needles can be used for peripheral nerve blocks when more expensive, insulated needles are not available.[126]

Blood Safety

An estimated 70% of all blood transfusions in Africa are given to children with severe anemia caused by malaria. Blood transfusion services, when they exist, aim to provide a lifesaving service by ensuring an adequate supply of safe blood.[127–129] Patients, particularly children, in developing countries, face the greatest risks from unsafe blood and blood products.[128–131]

Fewer than 30% of developing countries have a nationally coordinated blood transfusion service. Many do not perform the most rudimentary tests for diseases such as HIV or hepatitis B and C because of economic constraints.[131] Even limited testing doubles the basic cost of a unit of blood. It is estimated that about 6 million tests that should be done globally to check for infections are not done annually.[131]

Many countries still rely on paid donors or family members to donate blood before surgery.[131] In Argentina, for example, up to 92% of the blood supply is derived from family members. Although voluntary, unpaid blood donation has increased to 20% in the past 5 years in Pakistan, family donors represented 70% and paid donors 10% of the blood donors in 2004.[129] Public education about the value of blood transfusion is vital to improve supply.[127,128] Through concerted efforts by the WHO to improve blood safety worldwide over the past decade, the number of voluntary, unpaid donors has increased considerably. For example, voluntary blood donation in China increased from 45% of donations in 2000 to 90% in 2004. Similarly, the rate of voluntary, unpaid donations in Bolivia increased from 10% in 2002 to 50% in 2005. Malaysia, China, and India reached 100% screening of donated blood for HIV by the year 2000.[130]

There are risks in any system.[127,128] Family and paid donors may hide aspects of their health and lifestyle that could make the blood unsafe for different reasons. Family members may feel pressured to donate, whereas paid donors are driven by need and avoid important details about their health status that would negate the transaction. The commercial plasma industry and blood trade can fuel the transmission of HIV. In 1999, for example, 26 million liters of plasma were fractionated for global use,[131] and the major source was paid donors from developing countries. Voluntary, unpaid donors have a greater sense of responsibility to their community and keep themselves healthy to be able to continue giving safe blood. South Africa has had 100% voluntary, unpaid donations since it established a national blood service. With HIV prevalence approaching 30% among the adult population of Africa, only 0.02% of its regular blood donors in South Africa have contracted HIV.

Storage of blood is difficult considering the unreliable and unpredictable electricity supply in many developing countries. To obviate the risk of transmission of malaria, HIV, and other infectious diseases, blood should be transfused only when absolutely necessary. In sophisticated blood transfusion units, the use of predonated autologous blood is an option.[132,133] In poorer countries, this is not practical because malnutrition and chronic anemia are common. There is often a lack of appropriate equipment, and cost is prohibitive. Similarly, intraoperative blood salvage and cell savers appropriate for use in children are not available. Recombinant factor VII, which is being used increasingly to reduce blood use by those who can afford it,[132] is beyond the scope (and cost) of practice in many countries.[133]

Equipment

Electricity is unreliable in many hospitals in the developing world. In some, particularly in rural areas, neither power-line electricity nor a reliable functional backup generator is available.[3,4] Even though recycling disposable equipment such as endotracheal tubes is considered normal practice in many countries, general facilities for infection control, such as running water, disinfectants, or gloves, are also unreliable.[2]

Essential equipment to provide safe anesthesia for children and particularly for neonates is in short supply.[3,25,30,36] Neonatal or pediatric ventilators are virtually nonexistent outside the main centers.[30] Small IV cannulae are a precious commodity, and butterfly needles are still used. Syringe pumps and other control devices are impractical in environments with an erratic electricity supply. Metal or plastic laryngoscopes for children may be available but not well maintained. Batteries may be in short supply and light bulbs unreliable. A full range of pediatric endotracheal tubes is considered a luxury. Laryngeal mask airways in pediatric sizes are usually unavailable. IV fluids are very expensive if not manufactured locally, and many developing countries do not have local production facilities.[10] The choice of IV fluid is therefore limited and in short supply.

Monitoring is very basic: a precordial stethoscope and a finger on the pulse.[2,11] ECG monitoring is used when available but depends on a continuous electricity supply, battery backup, and proper maintenance. Appropriately sized blood pressure cuffs are scarce. Pulse oximetry has been the most useful monitor and should be available in all centers where pediatric surgery is performed.[2,25] Unfortunately, this ideal is far from reality, but it is hoped that the global pulse oximetry project will be rewarded with universal quality improvement.[17]

Anesthetic machines in developing countries fall into two categories: modern, sophisticated machines and simple, low-maintenance equipment. The electronic machines provided by well-meaning donors have a poor track record in austere

[a]References 2, 23, 30, 34, 36, 43, and 123–125.

environments. Sophisticated equipment needs to be understood, but operating manuals printed in foreign languages are not helpful. Sophisticated machines require ongoing maintenance, but individuals trained to repair such equipment are seldom available. Service contracts are not considered viable. Unfortunately, these machines are invariably discarded when the first fault occurs, because guarantees are unlikely to be honored and faults are considered too expensive to repair. Poorly maintained equipment becomes hazardous and potentially life-threatening in untrained hands.

Simplicity and safety have long been the keys to anesthetic equipment in developing countries.[2–4,134] Ideally, a suitable anesthetic machine should be inexpensive, versatile, robust, and able to withstand extreme climatic conditions; able to function even if the supply of cylinders or electricity is interrupted; easy to understand and operate by those with limited training; economical to use; and easily maintained by locally available skills.[134–136] The cheapest, most practical, and most widely used method is inhalational anesthesia administered through an Epstein Macintosh Oxford (EMO) drawover vaporizer (Penlon Ltd., Oxford, UK; Glostavent Penlon Ltd.), or Oxford Miniature Vaporizer (OMV, Penlon Ltd.). Oxygen concentrators supplement oxygen delivery and eliminate the need for expensive oxygen cylinders, whose reducing valves are often faulty or destroyed in these situations. The most appropriate ventilator is the Manley Multivent Ventilator (Penlon Ltd.), which essentially functions like a mechanical version of the Oxford inflating bellows (OIB) and can be used with a drawover system.[136]

A general scheme for inhalational anesthesia, which was first proposed by Ezi-Ashi and colleagues in 1983,[122] for use in developing countries is shown in Fig. 51.9.[134] Applying this scheme, four different modes can be used and modified according to the available supplies and services. The basic mode A is used when there is no

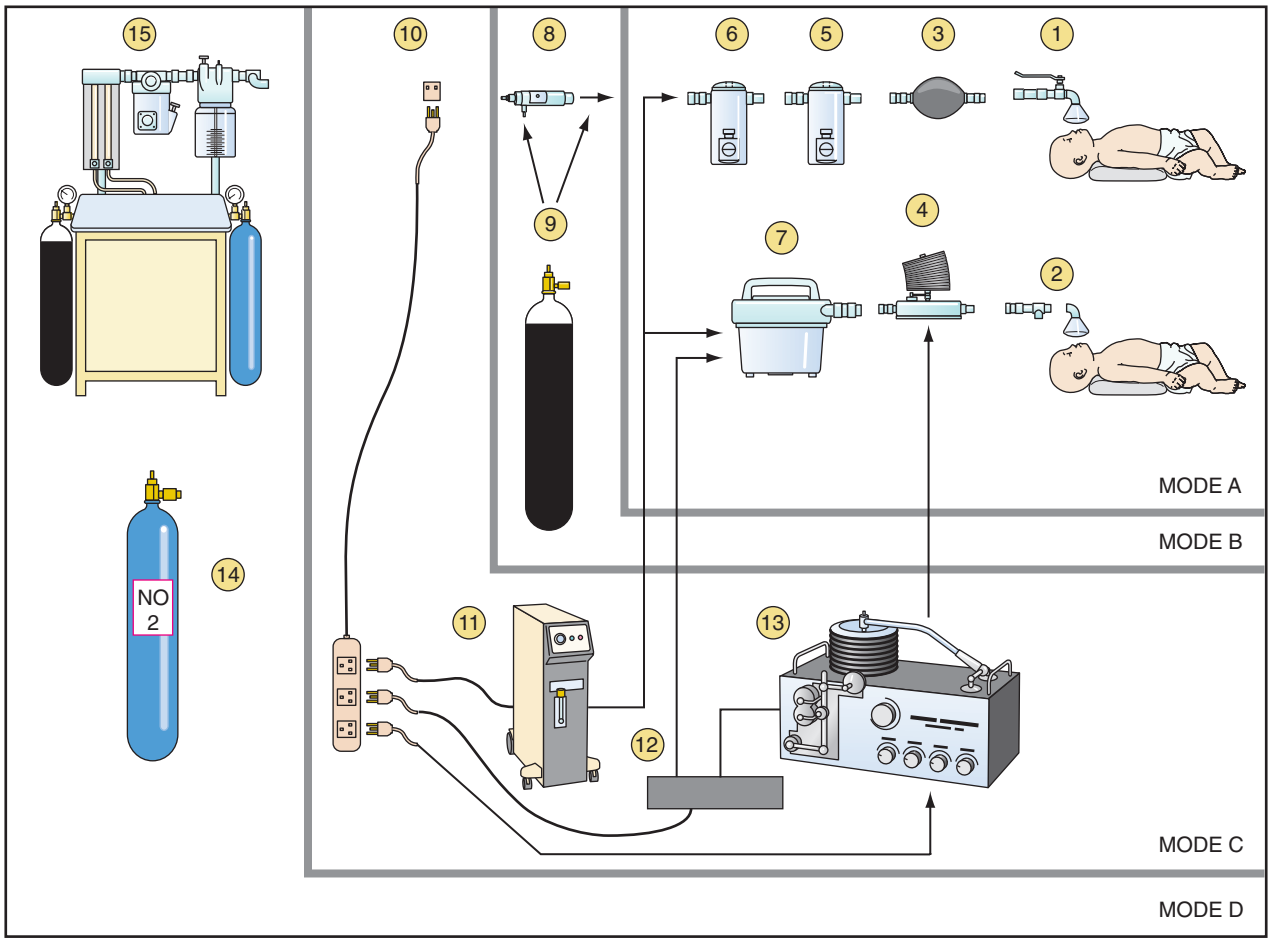

FIGURE 51.9 The schematic diagram shows the use of anesthetic systems, depending on available resources. **Mode A** provides basic inhalational anesthesia with air, spontaneous ventilation, or self-inflating bags. Drawover vaporizers are required. **Mode B** provides oxygen enrichment but requires the availability of oxygen cylinders. Plenum vaporizers can be used. **Mode C** requires electricity to power the oxygen concentrator, air compressor, and ventilator. A mechanical ventilator (e.g., Manley) does not require electrical power. **Mode D** requires a Boyle machine and nitrous oxide cylinders. **1,** T-piece with reservoir tube and face mask. **2,** Ambu Pedi valve. **3,** Self-inflating bag (Ambu). **4,** Oxford Inflating Bellows (OIB). **5,** Oxford Miniature Vaporizer (OMV) with halothane. **6,** OMV with trichloroethylene. **7,** Epstein, Macintosh, Oxford (EMO) vaporizer with ether. These circuits and manual ventilators are interchangeable, and ether, halothane, and trichloroethylene can be used on their own or in series. Farman entrainer (**8**) with an oxygen cylinder (**9**) can be used to supplement oxygen, or an electrical power source (**10**) with an oxygen concentrator (**11**), air compressor (**12**), or Manley ventilator (**13**). Nitrous oxide (**14**) and Boyle apparatus (**15**) allow anesthesia practice equivalent to that of developed countries.

electricity and no supply of compressed gases. The apparatus consists of a low-resistance vaporizer linked by valves to the child to act as a drawover system with room air as the carrier gas. The self-inflating bag or hand bellows makes it possible to provide artificial ventilation while the vaporizer remains as a drawover device. The addition of low-flow oxygen to the inspired gas in mode B depends on the availability of an oxygen cylinder. The addition of a length of reservoir tubing to the circuit enables oxygen to be stored on expiration and to be used on the next inspiration, substantially improving its economy.

When electricity is available, (mode C), operation of the anesthetic apparatus can be extended by permitting the use of an air compressor to provide continuous gas flow (allowing use of a Boyle apparatus and plenum vaporizer), an oxygen concentrator, and ventilators. When nitrous oxide is available (mode D), all types of inhalational anesthesia available in developed countries can be practiced. When services and supplies are interrupted even briefly, it is possible to change from one mode to another without requiring other anesthetic apparatuses.

These techniques may be of little interest to the anesthesiologist working comfortably in the well-maintained, sophisticated environment of developed nations. Their roles, however, are essential in field situations (e.g., war, natural disasters), and all anesthesiologists should be acquainted with their functioning in this unpredictable world (Videos 51.1 and 51.2).

DRAWOVER ANESTHESIA

Drawover anesthesia enables inhalational anesthesia to be administered using atmospheric air as the carrier gas. The essential features of this system consist of a calibrated vaporizer with sufficiently low resistance (i.e., EMO and OMV) to allow the negative pressure created by the child's inspiratory effort to draw room air through the vaporizer during spontaneous ventilation. Positive-pressure ventilation can be provided by means of a self-inflating bag or bellows (OIB), using a valve to prevent the gas mixture from reentering the vaporizer and a unidirectional valve at the child's airway to direct expired gases to the atmosphere, preventing rebreathing (see mode A, Fig. 51.9). In this way, an anesthetic can be administered in the absence of compressed gases. The vaporizer has an inlet for supplementary oxygen that can be attached to the oxygen output tube of an oxygen concentrator or oxygen cylinder when available (see modes B and C, Fig. 51.9).

The EMO and OMV are the more commonly used low-resistance vaporizers. The EMO is calibrated only for ether, but its performance is linear for other agents. The OMV is calibrated for a variety of agents[42,135–137]; despite the lack of temperature compensation, its performance is stable under most conditions. Both vaporizers have been used successfully in pediatric anesthetic practice,[33] but it is recommended that they be converted to form a T-piece for greater safety.

The OMV has been evaluated as a simple drawover system for pediatric anesthesia. Wilson and Bem[42] showed that when a self-inflation bag is used in a drawover mode, more efficient vaporization occurs despite vaporizer cooling. However, the respiratory efforts of neonates or weak infants are insufficient to operate the valve mechanisms of the self-inflating bag (e.g., Ambu bag), necessitating continuous assisted ventilation even in the presence of ether, which stimulates ventilation.

DiaMedica Therapeutics markets a variety of devices specifically designed for use in austere environments where oxygen supply and electricity are unreliable. Examples include a portable anesthesia machine using drawover, which weighs 9.5 kg (Fig. 51.10; Video 51.3) that may be used with or without oxygen, and the vaporizer may be used with halothane, isoflurane or sevoflurane (E-Fig. 51.1). It allows for both spontaneous and controlled ventilation. A portable ventilator (pediatric or adult) may be used with the portable anesthesia machine (Fig. 51.11); the bellows tidal volume is adjusted by the turn of a screw (E-Fig. 51.2). The ventilator is equipped with an internal battery, which remains charged for approximately 100 hours without recharge and can be recharged from a 100/240-V electrical source or a 12-V charger. This is a gas-driven ventilator (Video 51.4), which may be used with an oxygen concentrator; or if no oxygen source. is available a

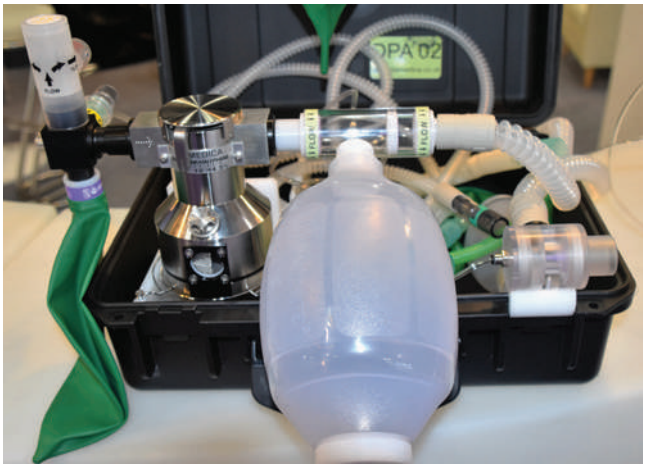

FIGURE 51.10 This portable drawover anesthesia machine weighs 9.5 kg and has a vaporizer capable of delivering halothane, isoflurane, or sevoflurane, packed in a shockproof and waterproof box (47 × 35 × 17 cm). It can work with supplemental oxygen or room air. It may also be used with a portable ventilator for children or adults (see Fig. 51.11). (With permission from DiaMedica Ltd., UK.)

FIGURE 51.11 This is a portable anesthesia ventilator for children or adults. The bellows tidal volume is adjusted by the turn of a screw (see E-Fig. 51.2). The ventilator is equipped with an internal battery, which remains charged for approximately 100 hours without recharge and can be recharged from 100/240-V electrical sources or a 12-V charger. This is a gas-driven ventilator that may be used with an oxygen concentrator, or if no oxygen source is available, a portable battery power pump can run the ventilator using room air. This has a battery life of approximately 20 hours. (See text for further details and video links.) (With permission from DiaMedica Ltd., UK.)

51

E-FIGURE 51.1 Close-up of the DiaMedica drawover vaporizer, which is capable of using halothane, isoflurane, or sevoflurane with either spontaneous or controlled respirations with oxygen or room air if no oxygen is available.

E-FIGURE 51.2 This photo shows that the tidal volume of the DiaMedica portable ventilator for children or adults, which can be used with the portable vaporizer, is adjustable by the simple turn of a screw mechanism on the top of the bellows.

portable battery power pump can run the ventilator using room air. This has a battery life of approximately 20 hours. The full-size machine (Glostavent Helix; E-Fig. 51.3) with all four components–(1) low-resistance drawover vaporizer, (2) gas-driven ventilator, (3) oxygen concentrator (E-Fig. 51.4), and (4) power supply with battery backup–is shown in E-Fig. 51.5 (Videos 51.5 and 51.6).

OXYGEN CONCENTRATORS

Improved oxygen availability, independent of compressed gas and electrical power supply, can be provided by linking oxygen concentrators[138,139] to a drawover anesthetic apparatus as first described by Fenton.[119] Maintenance requirements are low, and servicing is recommended only after approximately 10,000 hours of usage. The benefits are enormous, but a reliable electricity supply is critical.

The concentrator functions by using a compressor to pump ambient air alternately through one of two canisters containing a molecular sieve of zeolite granules that reversibly absorbs nitrogen from compressed air.[119,134,138] The controls are simple and consists of an on/off switch for the compressor and a flow-control knob to deliver 0 to 5 L/minute. Flow of oxygen continues uninterrupted as the canisters are alternated automatically so that oxygen from one canister is available while the other regenerates. A warning light on a built-in oxygen analyzer illuminates if the oxygen concentration is less than 85%, and the concentrator switches off automatically when the oxygen concentration is less than 70%. This action is heralded by visual and audible alarms. Air is then delivered as the effluent gas. Modern machines are relatively silent.

The oxygen output of the concentrator depends on the size of the unit, the inflow of oxygen, the minute volume, and pattern of ventilation. The addition of dead space (or oxygen economizer tube) at the outlet improves the performance, and predictable concentrations of more than 90% oxygen can be obtained with flows between 1 and 5 L/minute, independent of the pattern of ventilation. Much lower concentrations and less predictability were observed when the dead-space tubing was omitted.[140] An example of a ventilator (mode C, Fig. 51.9) that can use a concentrator for gas supply is shown in E-Fig. 51.6. The possible hazards of oxygen concentrators are few if they are positioned in the operating room so that the in-draw area is free from pollutants. Failure of the power supply or failure of the zeolite canisters results in the delivery of ambient air. A bacterial filter at the outlet combined with the use of dust-free zeolite should prevent contamination of the delivered gas. Dirty internal air filters may produce lower oxygen concentrations and must be checked. An oxygen storage tank and booster pumps afford protection against the vagaries in electrical supply.

Visiting Providers

Personality traits compatible with survival have been suggested as a prerequisite for working in the developing world. These traits include an almost pathologic desire for work, a willingness to merge or at least sympathize with different cultures, patience in relating to and teaching people sometimes far removed educationally, the ability to withstand prolonged periods of cultural isolation, and mostly a never-failing ability to improvise and make the best of a bad situation.[141–145] There is no place for risk-taking "cowboy anesthesiologists."[137,145]

International travel, particularly visits to many parts of the developing world, needs careful preparation and planning, whether the anesthesiologist is part of a volunteer organization[33,143–146] or traveling as an individual.[144] Detailed advice[142–147] is beyond the scope of this chapter, but some generalizations are made based on personal experience and that of colleagues. Changing political climates and international health guidelines dictate visa and vaccination requirements. Expert advice should be sought to tailor the traveler's needs according to the individual's medical and immunization history, the duration of stay, and proposed itinerary.

Physical acclimatization to jet lag, altitude sickness, and heat or sun exposure is necessary, as is adjustment to the local culture and cuisine. Social graces acceptable in a Western culture may be deemed offensive in some other cultures. An interpreter is an important ally. The inability to understand a language or the local dialect places a visiting anesthesiologist at a serious disadvantage, particularly when dealing with children. Children often use subtle ways to describe their feelings that even a skilled interpreter may fail to convey.

The hospital environment may be disconcerting for some. In contrast to the familiar comforts of a clean, child-friendly hospital, the visitor may be struck by the relatively shabby, bland appearance of many hospitals in developing countries. The buildings may not have received a coat of paint since they were built, and broken windowpanes provide the only air conditioning. Children are often cared for in adult wards.

In the operating room, the visitor may be faced with anesthetic equipment barely recognizable from its original manufacture or in a state of disrepair with nonstandard improvisations to make it functional. The choice of drugs may be limited, and the names of locally manufactured generic drugs and the presentation of IV solutions may add to the perplexity. Surgical safety may be the next issue. Informed consent as we know it is unlikely, and identification of the child in the absence of parents may not be obvious to the newcomer. A local or itinerant surgeon may suggest an extensive procedure on a malnourished child without consideration for monitoring, blood transfusion, or availability of intensive care or postoperative analgesia in an unmonitored environment. The anesthesiologist is obligated to consider the risks and benefits carefully in such circumstances.

Summary

The provision of safe anesthesia in a developing country will always be challenging, particularly for those who provide anesthesia for children. The challenges vary, and it is wise to expect the unexpected and have the flexibility to improvise in the face of an ever-changing world racked by famine, violence, natural disasters, and political unrest.

Attracting trained anesthesiologists to work in the developing world is difficult.[5,15,62,70–73,144–148] Temporary sojourns with volunteer medical groups are for the most part stimulating, but volunteers are unlikely to return for longer periods, let alone permanently.

Can anything be done to improve the lot of children who undergo anesthesia in the developing world? The Pediatric Anesthesia Fellowship Program established through the WFSA is commendable, but it produces only a small number of trainees each year.[70,72,73] Audits of morbidity and mortality are the first steps toward improvement if action is taken to address the problems uncovered. Publications reflecting outcomes in developing countries have increased over the past decade.[19–21] Purchasing equipment without ensuring subsequent maintenance is wasteful. Disposables

E-FIGURE 51.3 Full-size Glostavent Helix machine with all four components: (1) low-resistance drawover vaporizer, (2) gas-driven ventilator, (3) oxygen concentrator, and (4) power supply with battery backup, which remains charged for approximately 100 hours without recharge and can be recharged from a 100/240-V electrical source or a 12-V charger. (See text and videos for further details.)

E-FIGURE 51.6 The Hyvan anaesthesia machine (Hyvan Anaesthesia, Christchurch, New Zealand; http://hyvan.co.nz/about/), which is being designed for developing countries, can use pipeline oxygen, oxygen cylinders, an oxygen concentrator, or an air compressor for gas supply.

are short-lived items even if they are recycled. Human resources are needed.

Different standards may emerge from different parts of the world. These standards need not necessarily be considered inferior but may open the way for the assimilation of new ideas.[147] The nuances of practice in different communities inevitably vary and may challenge some fondly held beliefs in pediatric anesthesia. A safe anesthetic is not necessarily the most expensive one. It is usually not the agents that we use but the skill with which we use them that determines outcome. It should never be necessary to depart from the dictum *primum non nocere.* Simplicity may be the key, but there is no place for double standards. Guidelines that have evolved over time in the United Kingdom, United States, and Australasia may be untenable in many parts of the world,[145] but every attempt should be made to exercise the same standard of care as expected in developed countries. Our children deserve no less.

ANNOTATED REFERENCES

Chikumbanje S, Bell GT, Kapatuka K, Pollach G. Continuous flow using an entrainer and t-piece vs draw over apparatus for inhalational induction of anesthesia in children. *Paediatr Anaesth.* 2014;24(11):1169-1173.

There are few studies in modern literature that compare circuits that are no longer in use in developed countries. The authors in Malawi compare inhalation induction in children using a Farnham entrainer with the Ayres T-piece (Mapleson F) and a drawover system. There was no difference in oxygen saturation measured by oximetry (SpO_2) recordings, but induction times were slightly (but not clinically significant) longer with the drawover system.

Ekenze SO, Ajuzieogu OV, Nwomeh BC. Challenges of management and outcome of neonatal surgery in Africa: a systematic review. *Pediatr Surg Int.* 2016;32(3):291-299.

This study reviews publications on neonatal surgery from 11 countries in Africa over the past 20 years. Although the overall mortality rate has improved in the past decade, it remains high, around 30%. Although each country has its own problems, delayed presentation, inadequate facilities, a dearth of trained personnel, major neonatal surgery, and an absence of intensive care were the common denominators contributing to this poor outcome.

Hodges SC, Mijumbi C, Okello M, et al. Anaesthesia services in developing countries: defining the problems. *Anaesthesia.* 2007;62(1):4-11.

This paper identifies the difficulties of providing anesthesia in Uganda. The disturbing result was that only 23% of anesthesiologists have the facilities to provide safe anesthesia to adults, 13% for a child, and only 6% for cesarean section.

Walker IA, Merry AF, Wilson IH, et al. Global oximetry: an international anaesthesia quality improvement project. *Anaesthesia.* 2009;64(1):1051-1060.

This paper describes the initial quality assurance program for pulse oximetry in four pilot studies of pulse oximetry in Uganda, Vietnam, India, and the Philippines. The studies determined that formal training in pulse oximetry needed to be a central part of the WHO Safe Surgery Saves Lives project.

This paper describes the fact that approximately 78,000 operating rooms worldwide lack pulse oximetry. It discusses the WHO Safe Surgery Saves Lives Program as well as the Global Pulse Oximetry Program.

Zoumenou E, Gbenou S, Assouto P, et al. Pediatric anesthesia in developing countries: experience in the two main university hospitals of Benin in West Africa. *Paediatr Anaesth.* 2010;20(8):741-747.

This article describes anesthesia in Benin. Cardiac arrests occurred at a rate of 156 per 10,000 cases with a mortality rate of approximately 60%, even in two university hospitals. The authors are to be congratulated for studying this issue to gain more financial support from their government for better equipment and monitoring.

Heating and Cooling Systems

Consider for a moment the design of the surgical gown. It is designed to be a sterile barrier to protect the patient, yet it also must be a barrier to body fluids to protect the wearer. Because it is waterproof, it exchanges air poorly and in turn prevents dissipation of body heat. The surgeon wants to turn down the temperature in the operating room (OR) so the heat is bearable. Consider then the anesthetized infant on the operating table in a cool room. From the moment the infant enters the OR, he or she is partially if not completely uncovered. With a very high surface area to body mass ratio, the infant loses heat through two primary mechanisms: radiation and convection. The OR is unlike an incubator that envelops infants in warm, still air; rather, the cool air of the OR flows continually in a laminar pattern to reduce the risk of infection. Once anesthesia is induced, body heat is redistributed from the central to peripheral compartments through vasodilation. Furthermore, the fluids the child receives, the air that he or she breathes, and the instruments that contact the child's tissues are all colder than the child's body temperature. The neonate and infant in particular are vulnerable to this heat loss, with limited strategies to prevent the decrease in their core temperature.

Several strategies offset heat loss from the child. Before the child enters the OR, the room should be warmed (to >25°C) or as much as tolerable to minimize radiation and convective heat losses. The child should be placed on a forced air warming blanket before the child is unclad. Preferably, inhaled gases and intravenous (IV) fluids should be warmed throughout the surgery.

In some cases, hypothermia is induced deliberately. For example, hypothermia is a necessity for cardiopulmonary bypass[1,2] and continues to be studied for benefit after neonatal asphyxia,[3,4] although the latter has not conferred any benefit after pediatric cardiac arrest or head injury.[5,6] Other than in these specific circumstances, normothermia should be the goal for our patients. Mild to moderate hypothermia may cause apnea in infants, alter the pharmacokinetics of medications, decrease blood clotting and increase surgical site infections,[7] among other complications.[8,9] Conversely, inducing hyperthermia with active warming may

increase the metabolic rate and heart rate, introducing concerns of a malignant hyperthermia reaction, thyrotoxicosis, and other metabolic and drug-related disorders. Therefore basic strategies to maintain normothermia and temperature monitoring should be provided for every patient who undergoes general anesthesia, except for those anesthetized for extremely brief procedures.

Infants and children lose heat through four mechanisms: radiation (39%), convection (34%), evaporation (24%), and conduction (3%).[10] Radiation is the transfer of energy through the generation of electromagnetic waves to solid surfaces such as cold walls. Convection is the transfer of energy from the child by the gas or liquid surrounding it. Convection can be passive, as in still air, or active when air flows past the infant. Evaporation is the loss of heat as liquid is converted to gas. This is typically seen through perspiration but can also occur with major open wounds, and evaporation of cleansing preparation solutions. Conduction is the transfer of energy directly from one body to another and can occur in solids, liquids, and gases. Based on their material, objects are conductors (metals) or insulators (gases).

Patient Warming

FORCED AIR WARMERS

Forced air warming devices remain one of the most common and effective strategies to maintain and increase the child's temperature in the OR. These devices consist of a central unit that regulates the air temperature and forces heated air through a hose to a disposable perforated blanket that can be placed underneath or on top of the child or around the child's head. The device must be used in accordance with the manufacturer's instructions to minimize the risk of thermal injury.[11,12] The device very effectively maintains the child's temperature through the combination of active convection and a plastic wrap or blanket that eliminates radiation and evaporative heat losses. Concerns have been raised that these devices develop internal microbial buildup,[13] that they disrupt laminar airflow in the OR,[14,15] and that they cause surgical infections that involve implanted material.[14] However, despite these concerns,[16] forced air warmers continue to be used in children without reports of increased infection rates. Nonetheless, some surgeons prefer that forced air warmers be powered on only after the child has been prepped and draped (e.g., ventriculoperitoneal catheter insertion), a practice that has been applied to many surgical types. Several manufacturers produce forced air warmers and blankets. The devices all operate in a similar manner and may be considered equivalent in effectiveness: 3M (St. Paul, MN), Celsius Medical (Madrid, Spain), Stryker (Kalamazoo, MI), and Medical Solutions, Inc. (Omaha, NE).

WARMING BLANKETS

Warming blankets include circulating water mattresses placed underneath the child and electrical heat-generating conductive blankets that can be placed either underneath or on top of the child. When placed underneath the child, these devices offer complete access to the child without obstruction, transferring heat by conduction, accounting for only 4% of the heat loss. Warming blankets do not have the associated concern of changing airflow in the OR. Typically, these devices are also reusable and require wipe-down disinfection. Since these devices are in direct contact with the child and have a greater thermal density, care must be taken to avoid surface burns at high temperature settings. Circulating water blankets include the Blanketrol by Cincinnati Sub-Zero (Cincinnati, OH), and the Medi-Therm III by Gaymar Industries (Orchard Park, NY). Manufacturers of non-water–based blankets include Augustine Biomedical (Eden Prairie, MN), Inditherm (Rotherham, United Kingdom), and Novamed USA (Elmsford, NY).

RADIANT WARMERS

Overhead radiant heating units, sometimes referred to as a "french fry light," have become less commonly used in the OR since the introduction of forced air warmers, although they remain in use in the neonatal intensive care unit (NICU) and are built in to many NICU beds. These devices use a temperature sensor on the infant to supply feedback to a servomechanism to adjust the heat output. Without this feedback or if the heating element is placed too close to the neonate, there is a risk of skin burns to the neonate and nearby staff.

PASSIVE HEAT AND MOISTURE EXCHANGERS

Heat and moisture exchangers (HMEs) are reflective filters interposed between the endotracheal tube and the ventilator circuit to preserve the child's temperature and airway humidity. Under the correct circumstances, these devices may maintain body temperature[17] but they cannot increase body temperature. They are less effective at maintaining temperature compared with heated humidifiers in the airway circuit. Even the smallest exchanger can increase the airway dead space and resistance, particularly in neonates,[18] blunting the capnogram until it is almost uninterpretable. These exchangers are effective and useful for preventing the contamination of devices attached to the airway such as pulmonary function testing equipment.

HEATED HUMIDIFIERS

Heated humidifiers or heated breathing circuits are typically a sealed heated wire within one limb of the breathing circuit. Sterile water is introduced into the circuit and the servomechanism controlled heater maintains temperature. These devices are prone to hazards, such as overheating, condensation, changes in the compressible volume of the circuit, leaks in the tubing, and obstruction, if they are not connected correctly. They are superior to any other device for preventing the secretions in the airway from drying out and are universally used with ICU ventilators. However, as the circle breathing circuit supplanted the Mapleson F circuit (Jackson-Rees modification of the Ayre T-piece) in clinical anesthesia care globally, heated humidifiers became anachronistic as it could be difficult to adapt them to the circle circuit. The additional cost and complications of these devices also limit their use except for anesthesia cases of prolonged duration. Manufacturers include Armstrong Medical (Lincolnshire, IL), Carefusion (Becton Dickinson, Franklin Lakes, NJ), Dräger (Telford, PA), Fisher & Paykel (Irvine, CA), Philips Healthcare (Bothell, WA), Teleflex (Morrisville, NC), and Westmed Inc. (Tucson, AZ), among others.

FLUID AND BLOOD WARMERS

When large volumes of IV fluid are infused at a rapid rate, the child's core temperature may decrease precipitously unless a fluid warmer is used. In contrast, when IV fluid is infused at a maintenance flow rate, the effect on the child's temperature is attenuated. One strategy to deliver warmed IV fluid is to warm the IV fluid bags before the fluid is delivered. This can be achieved with blanket warmers already in use in the ORs or with specialized warmers such as the ivNow fluid warmer by Enthermics (Menomonee Falls, WI). The IV fluid bags should be used within a week or two to prevent degradation of the plastic bags. Individuals have warmed IV fluid bags in a standard microwave oven, but

this practice is not recommended because hot spots, overheating, or deterioration of the container might develop.

In general, blood products are stored in refrigerated coolers. When the products are selected for use, they are warmed before administration. Fluid warmers currently marketed are designed to warm crystalloid solutions and blood products. The two main designs for these fluid warmers are a water bath and dry heat. The Level 1 Hotline device (Smiths Medical, Dublin OH) uses a heated water bath and specialized tubing with a sterile inner lumen. Warmed water circulates in the outer lumen, increasing the temperature of the fluid. The Level 1 can deliver warmed fluids with a gravity flow rate up to 83 mL/minute. The dry heat designs use either standard IV tubing or proprietary tubing sets. These are placed in contact with a heat exchanger usually made of metal because of its conductive properties. The device warms the tubing and the fluid as it passes through the tubing. The designs vary in their priming volume, flow rates, portability, and distance they can be placed from the patient. The greater the distance between the device and the patient, the greater the cooling of the fluid before it reaches the patient. Both pressurized and nonpressurized warmers can deliver large fluid flow rates that are commonly necessary for trauma and transplantation surgeries. Nonpressurized warmers that use proprietary tubing sets include the enFlow by Carefusion (Becton Dickinson, Franklin Lakes, NJ) with a 4-mL priming volume and a flow rate up to 200 mL/minute; the Medi-Temp by Stryker (Kalamazoo, MI) with a flow rate up to 500 mL/minute; and the Ranger by 3M (St. Paul, MN) with a flow rate up to 500 mL/minute. Some nonpressurized warmers that adapt to standard IV tubing sets manufactured in Germany include the Nuova/05 by Nuova GmbH (23909 Ratzeburg, Germany) and the Astoflo Plus by Stihler Electronic GmbH (Germany). For massive transfusion of blood, pressurized fluid warmers are used. The Belmont Rapid Infuser RI-2 (Belmont Medical, Billerica, MA) uses electromagnetic induction heating, has an optional blood reservoir, and infuses the warmed fluid with a rapid roller pump. This device can deliver more than 750 mL/minute of warmed blood. The Level 1 h-1200 Fast Flow Fluid Warmer (Smiths Medical, Dublin OH) uses an aluminum heat exchanger, a countercurrent water bath, has two chambers for fluid bags, and uses pressurized air to compress the IV bags and infuse fluids at flows of up to 600 mL/minute, although at the greater rates, the temperature of the IV fluid is not sustained (Fig. 52.1). The flow rate of these devices is limited by the size and length of the inserted venous catheter and, to a lesser extent, by the length of the tubing before the patient (E-Fig. 52.1). These devices have integrated air and pressure detectors that will automatically stop the infusion if a breech is detected. Even with the air detector, it is important to eliminate all air from the bags to avoid the possibility of infusing air into the circulation.

CONTROLLING EXPOSURE

Body temperature can be preserved if the child is covered to reduce radiant and convective heat losses. Plastic wrap used for food is effective, inexpensive, and translucent. Covering the infant's head is an important strategy to prevent heat loss since the infant's head has a large body surface area/volume ratio. Reflective aluminized Mylar blankets are also very effective but more expensive. Using a blanket warmer and uncovering only the necessary small portions of the child during induction and IV placement attenuates heat loss. If the child must be uncovered at any time, warming the air temperature within the OR is effective as it reduces both radiation and convective heat losses. In one study of neonatal and maternal hypothermia, fewer hypothermic neonates (<36°C) were identified when room temperature was 23°C compared with a room temperature of 20°C (5% vs. 19%).[19] Once the neonate has been covered, the room temperature can be reduced.

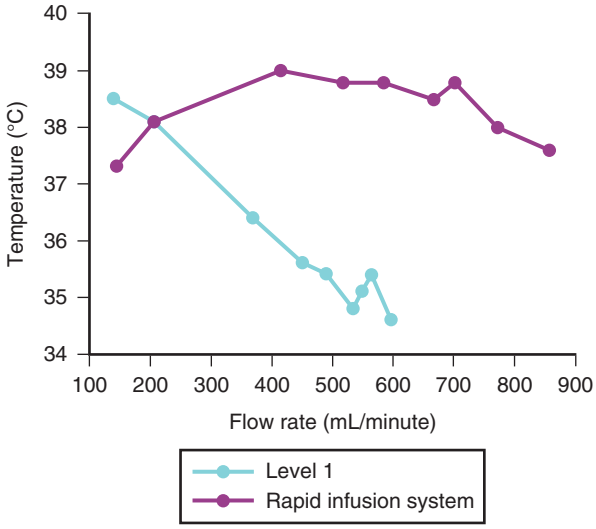

FIGURE 52.1 This figure plots the mean temperature of the fluid at the end of two 2-liter infusions of crystalloid for the Level 1 versus the Rapid Infusion System (RIS). Note that both devices have equivalent warming capacities with flow rates of 200 mL or less per minute, but there is markedly less warming capacity with the Level 1 system at higher flow rates. Note that the RIS was the precursor to the Belmont Rapid Infuser, so the warming characteristics would be similar to those of the RIS. (From Barcelona SL, Vilich F, Coté CJ. A comparison of flow rates and warming capabilities of the Level 1 and Rapid Infusion System with various-size intravenous catheters. *Anesth Analg.* 2003;97[2]:358–363.)

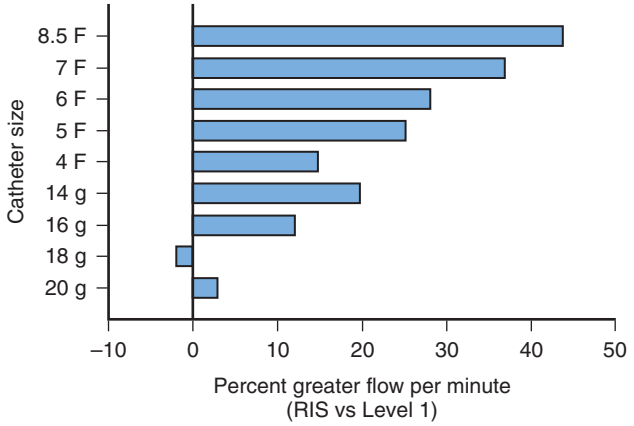
Intravenous Therapy



In most children undergoing elective surgery, IV access is secured after induction of anesthesia and before the airway is secured. For emergency surgeries, an IV induction is usually performed and additional IV access is established after the airway is secured.

The basis for determining the adequacy of IV therapy is Poiseuille's law, which is embodied by the equation for laminar flow as follows:

$$Q = \frac{\pi R^4 (P_2 - P_1)}{8\eta L}$$

Here, the volumetric flow rate (Q) of the fluid is directly related to the fourth power of the radius of the catheter lumen (R) and the pressure difference across the tubing ($P_2 - P_1$) and inversely related to the viscosity of the fluid (η) and the length of the tubing (L). Increasing the radius of the catheter has an exponential effect to increase the fluid flow rate by the fourth power. However, for long catheters such as central venous lines or peripherally inserted percutaneous intravenous central catheters (PICC), additional length and fluid viscosity (as in changing from crystalloid to packed red blood cells [PRBCs]) can substantially increase the resistance to flow and thereby dramatically reduce fluid flow rates, even when the fluid bag is pressurized.

The fluid drip rate from a 500-mL solution bag can range from a macrodrip (10–20 drops/mL) to a microdrip (60 drops/mL).

E-FIGURE 52.1 Percent differences in flow rates for the Rapid Infusion System (RIS) versus the Level 1 for various catheter sizes. Note that the RIS produced greater incremental changes in flow with progressively larger catheters (16 gauge or larger). The Belmont Rapid Infuser system should have performance characteristics similar to those of the RIS. (From Barcelona SL, Vilich F, Coté CJ. A comparison of flow rates and warming capabilities of the Level 1 and Rapid Infusion System with various-size intravenous catheters. *Anesth Analg*. 2003;97[2]:358–363.)

The microdrip set may contain a Buretrol (Baxter International, Deerfield, IL) to finely control the volume of fluid infused and prevent an overdose of IV fluids in neonates and infants. Extension tubing may be small bore in caliber with a small priming volume of 1 to 2 mL or large bore with a larger priming volume of 6 to 10 mL. The latter is recommended as it offers less resistance to flow when fluid resuscitation or blood must be administered. The small-caliber tubing may be "Y'd" into the IV set close to the cannula site to administer drugs to small infants without large volumes of crystalloid. For most neonates and infants, 24-gauge catheters are used, although 22-gauge may be sited in larger veins such as the saphenous. In toddlers and older children undergoing noncomplex surgery, a 22-gauge IV catheter is preferred and for older children to adults 16- to 20-gauge catheters or larger are usually placed. Caution must be used if the caliber of extension tubing is downsized to a small caliber as it may restrict the ability to rapidly transfuse fluids. A three-way stopcock or an access port permits needless injections of medications into the IV tubing.

Fluid can be administered via gravity flow, via mechanical pump, or via an external pressure bag. The addition of a 5-µm bacterial filter increases the resistance and decreases the flow rate. Furthermore, antireflux valves further increase the resistance to flow. However, these valves are essential when infusing fluids or drugs as these may flow retrograde up connected tubing (unnoticed), if an antireflux valve is not in-line. Each medication access point such as the stopcock or needleless hub is a site where air can be introduced; care should be taken to aspirate all air from IV access points (e.g., stopcocks and Luer locks) in all infants and children. The components of the IV set—the tubing, extensions, connectors, and a method of delivery appropriate for the size of the child and the procedure—are determined by individual preferences. There is slight variation among manufacturers, but general flow rates by gravity for IV catheters and central venous lines are listed in Table 52.1; the larger the catheter, the greater the flow rates (E-Fig. 52.2). This information is also printed on the catheter packages.

TABLE 52.1 IV Catheter Flow Rate by Gauge and Length[a]

Gauge	Length (inches)	Flow Rate (mL/minute)

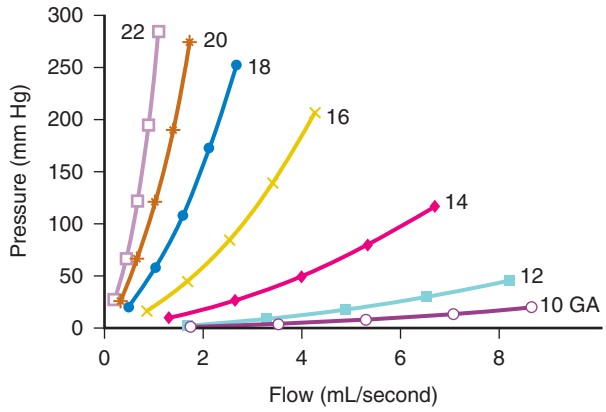
6F Dual (each lumen)		12.5

Information regarding central venous catheters was abstracted from Cook Medical "Quick Reference Guide for Spectrum" catheters (https://www.cookmedical.com/data/resources/4%20CC-BM-ABRMQR-EN-201111.pdf). PICC line information is for the PowerPICC Catheter from Bard Access Systems (Salt Lake City, UT).
[a]The standard by which flow rate is measured (by gravity) is that the intravenous bag of crystalloid is suspended 1 meter above the height of measurement.
[b]Cordis (Milpitas, CA).



MAINTENANCE FLUIDS

For neonates and chronically ill infants in whom there is significant risk of hypoglycemia, a dextrose-containing fluid should be used. If the child is receiving 10% dextrose or a similar solution from the NICU, this infusion should be continued at the same rate during anesthesia in the absence of additional data. If the dextrose infusion rate is decreased, the serum dextrose concentration should be measured periodically throughout anesthesia to preclude the development of hypoglycemia. To prevent fluid overload, consider the use of a pump to control the infusion of IV fluids, with a stopcock close to the cannula to infuse medications. Some have recommended in-line filters in IV lines to prevent morbidity and mortality in neonates associated with contamination of the infusions (bacteria, endotoxins, and others). However, a Cochrane review concluded that there was insufficient evidence to recommend in-line filters in neonates to reduce morbidity and mortality.[20] If vasoactive medications and maintenance fluids are infusing and a separate IV catheter is present, the medications should be flushed as close to the patient as possible in the second IV in order to minimize the risk of injecting boluses of vasoactive medications.

RESUSCITATION

If there is an anticipated need for a large volume of fluids for volume resuscitation, the largest IV that can be easily placed should be used, recognizing that attempting to place a catheter that is too large may result in failure. It is better to have two working 22-gauge IVs rather than multiple puncture sites from failed attempts with an 18- or 20-gauge IV. Table 52.1 indicates that a shorter catheter delivers a greater flow rate than a longer catheter and that a central venous catheter, which is often a long catheter, is usually limited to infuse low fluid flow rates because of resistance caused by their length. PICC lines cannot be used for resuscitation (and may prevent the rapid administration of a bolus of propofol) because of their narrow caliber and extra length (see Table 52.1).

Large-bore tubing used for blood transfusion or resuscitation has the best flow characteristics. There are multiple strategies to

E-FIGURE 52.2 The pressure-flow relationship of intravenous catheters. Note that the pressure-flow relationship is nonlinear; the smaller the catheter diameter, the greater the resistance. (These data appeared, in part, in Philip BK, Philip JH. Characteristics of flow in intravenous catheters. IEEE Trans Biomed Eng. 1986;33[5]:529–531.)

increase the IV flow rate, including using a pressure bag placed around the fluid bag, IV tubing sets with integrated bulb pumps, use of a large (60-mL) syringe[21] and a stopcock to create a pull-push system or large prefilled syringes,[22] and a purpose-built device such as the Level 1 h-1200 Fast Flow Fluid Warmer (Smiths Medical) or Belmont Rapid Infuser RI-2 (Belmont Instrument, Bellerica, MA). If a 20-gauge or larger catheter is already in place, it may be exchanged for an Arrow rapid infusion catheter (Teleflex, Morrisville, NC) that is typically a 7F or 8.5F (internal diameter) 2-inch-long catheter. Fluid resuscitation is limited with the commercially available IV pumps to their maximum flow rates, 999 mL/hour or 16.6 mL/minute. If a pressure infusion bag is used, the IV bag should be de-aired to prevent air from being pumped into the circulation, creating an air embolism, as the bag empties.

The temperature and viscosity of IV fluids greatly affect the infusion rate. Less viscous fluids are infused more rapidly than more viscous fluids (e.g., colloid solutions). Crystalloid solutions are the least viscous fluids followed by colloids, whole blood, and PRBCs. PRBCs may be diluted with normal saline solution to reduce viscosity, improve flow characteristics, and decrease the risk of hemolysis during a rapid infusion.[23]

TOTAL INTRAVENOUS ANESTHESIA AND VASOACTIVE MEDICATIONS

If total IV anesthesia (TIVA) or the use of vasoactive medications is necessary, they are ideally infused through a separate venous access. The speed at which the medication is administered depends on the location of the access point in the infusion line, how much priming volume is present in the tubing, and the speed at which the fluids are infusing (Fig. 52.2). A carrier solution on a pump should be infused at a baseline rate because most vasoactive medications are piggy-backed into the tubing at slow infusion rates. The carrier solution should be adjusted to the child's maintenance infusion rate and the other IV fluids reduced accordingly. Multiple stopcock manifolds allow for the connection of multiple infusions as well as the carrier solution. Fig. 52.3 shows various multiple-drug infusion systems, each of which has slightly different priming volumes, which in turn affect the speed at which medications are infused. Many practitioners prime their medications and then initiate the pumps to run the fluids to the end of the manifold. When connected directly to an IV line, medications should be delivered without delay provided the carrier fluid rate is maintained at the same rate.

Establishing any IV access in infants and toddlers can be difficult, a task that becomes extremely difficult when they are in shock. When peripheral IV access cannot be established quickly and the child is critically ill, placement of an intraosseous catheter should be entertained (see also Chapter 49, Figs. 49.6 and 49.7).

LUER ADAPTERS

Luer-Lok adapters allow for the rapid and secure connection of syringes and IV fluid lines to catheters. This has particular significance in the OR as access to the arterial or venous lines are remote from the caregiver and hidden under the drapes. However, the Luer-Lok adapter is also interchangeable with epidural, spinal and nerve block catheters, feeding tubes, total parenteral nutrition lines, and even sidestream carbon dioxide (CO_2) connectors.[24–26] All of these have the identical six-degree Luer-Lok taper that allows them to be connected interchangeably.[27] This universal connection has led to the accidental injection of drugs not meant for the neuroaxial space into epidural catheters,[28–30] parenteral

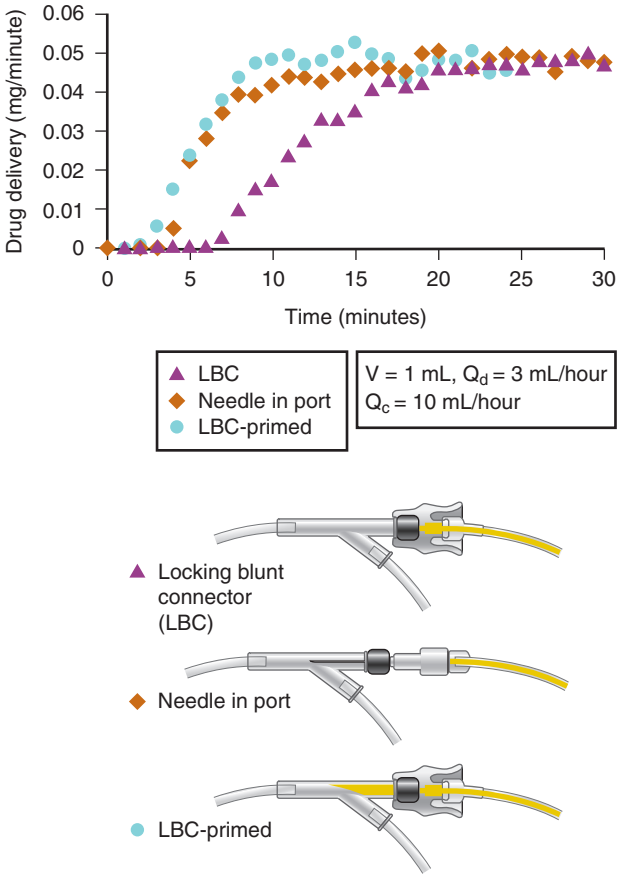


FIGURE 52.2 The time delay in onset of drug delivery to steady-state drug delivery as affected by a needle in an injection port and a locking blunt connector *(LBC)* or "priming" of the dead space of the injection port are illustrated. Note that the time to initiate drug delivery is delayed by several minutes and the time to achieve a steady-state rate of drug administration may be delayed by 10 minutes or longer when the dead space is not primed or a needle is not used to bypass the dead space of the injection port (in this example, the parameters were: carrier rate [Q_c] 10 mL/hour, drug flow rate [Q_d] 3 mL/hour, dead space volume [V] 1 mL). This concept has important implications regarding drug delivery to all patients, but it is particularly important in infants and neonates in whom small volumes of drug may be administered into a relatively large dead space that must be filled before any drug enters the flow of the intravenous fluid and the hourly rate of the carrier is low. (From Lovich MA, Doles J, Peterfreund RA. The impact of carrier flow rate and infusion set dead-volume on the dynamics of intravenous drug delivery. *Anesth Analg.* 2005;100[4]:1048–1055.)

chemotherapy (vincristine) given intrathecally (more than 30 times since 1968),[31] local anesthetics (e.g., bupivacaine) injected intravenously,[32,33] a blood pressure (BP) cuff attached to a Hep-Lock IV set (Baxter Healthcare), gastric feeds, and breast milk infused through a central venous catheter,[34] causing significant morbidity and mortality.[35] Labeling of all catheters at the hub, color coding, and vigilance have been effective, in part, to reduce this risk. However, to address this risk formally, an international, multidisciplinary team convened in 2007 to draft a standard by which Luer-Loks will be modified such that a unique Luer-Lok design will be available for each type of Luer-Lok connection (e.g., IV, gastrointestinal, genitourinary, neurologic, anesthesia breathing circuits, and hemodynamic monitoring [BP cuffs]) that will also prevent cross-connection of tubing meant for different uses.[30,36] This meeting resulted in publication of ISO-80369 standard, which

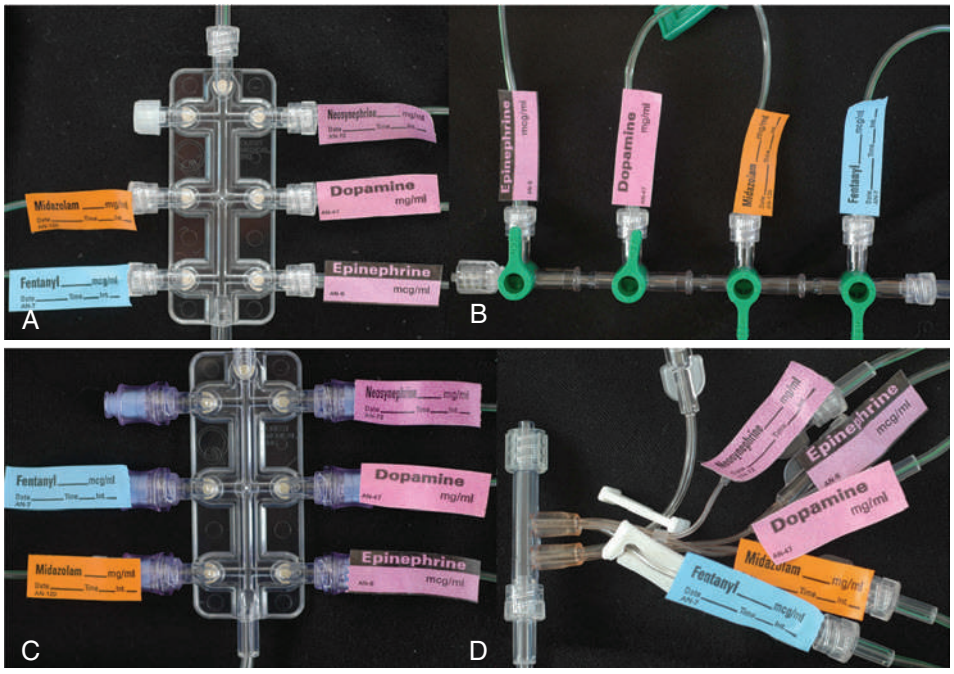

FIGURE 52.3 Several multiple-drug and fluid administration systems are illustrated. Note the wide variation in dead-space volume among the screw-in connectors **(A),** simple stopcocks **(B),** screw-in connectors with one-way valves **(C),** and multiple short tubing connections **(D).** To avoid variations in rate of drug delivery, it is advised to use a dedicated carrier on a pump. To ensure that the initiation of drug delivery is timely, the following steps are necessary: (1) each dead space port must be flushed and primed with the desired infusion as it is attached to the delivery manifolds; (2) after priming, the stopcock is turned to the off position or the tubing is clamped; (3) the carrier portion of the system is then run through or flushed with the carrier intravenous fluid; and (4) the system is attached to the patient with just the carrier ensuring a constant flow to the patient. When the drug infusion is initiated, the stopcock is turned to the on position or the tubing unclamped and each drug infusion pump turned on at the desired rate. This ensures that no drug is accidentally administered and reduces the time to initial drug delivery by priming the dead space of the system for each drug infusion. It should be borne in mind that this system should be connected as closely as possible to the intravenous catheter to avoid further delay in drug delivery because of the need to fill the dead space between the multiple drug manifolds and the entry into a vein. The use of a pump for the carrier solution also prevents retrograde drug infusion.

after several iterations, is about to be set for implementation.[37] This new standard will modify the six-degree Luer-Lok taper to preclude cross-connection of tubing intended for differences uses by creating non–Luer-Lok connectors for non-IV equipment larger or smaller than the standard Luer-Lok connections.

Airway Apparatus

MASKS

Transparent disposable plastic (latex-free) face masks are available in a wide variety of sizes for children of all ages, to deliver oxygen as well as induce and maintain inhalational anesthesia. These air-filled cushioned masks, which can be inflated to fill the cuff, replaced the old Rendell-Baker/Soucek face masks, which had a very small dead space but often failed to seal completely on the faces of some children. With the wide variability in the morphology of children's facies, especially those who are syndromic, the anesthesiologist should prepare cushioned masks that are smaller and larger than the size chosen for the child. The provider should be able to maintain a tight mask seal on the face with the least amount of dead space. Masks vary according to the manufacturer; however, there are few features that would lead us to recommend one over another. Some masks can be purchased already flavored (with fruit such as strawberry), although most anesthesiologists prefer to offer flavors (e.g., watermelon or strawberry lip balms) to the child and let him or her choose their favorite and apply the flavor to the mask. Specialized masks with a built-in port for endoscopy or fiberoptic intubation are also available for specific indications (see E-Fig. 14.13).

OROPHARYNGEAL AIRWAYS

Oropharyngeal airways are hard, non-latex plastic that are preformed in different sizes from 40 mm (infant) to 100 mm (large adult). Care should be taken to choose an airway that is the correct size for the child because an airway that is too small displaces the posterior portion of the tongue or epiglottis into the glottic opening, causing upper airway obstruction. Alternatively, if the airway is too large, the airway device may cause damage to laryngeal structures, causing swelling and potential postoperative obstruction (see Fig. 14.13). An oral airway should always be placed midline, without rotating it as it is inserted as is commonly done in adults, since at every age, children have some loose teeth and others that are ready to fall out. Rotating the hard airway may dislodge one or more teeth, leading to a possible pulmonary aspiration. Misplaced oral airways that obstruct venous and/or lymphatic drainage of the tongue can precipitate acute macroglossia.[38] Additional causes of acute macroglossia include retained throat packs,[39] surgical positioning,[40] and the presence of TEE probes.

NASOPHARYNGEAL AIRWAYS

Nasopharyngeal airways are an additional adjunct to reduce or prevent upper airway obstruction.[41,42] Latex-free nasal airways are available in sizes from 12F to 36F. Care should be taken when placing them in the nose as they may injure the mucosa or dissect adenoidal tissue free, causing bleeding. Selecting the correct size of the airway is important because an excessively large nasal airway can apply pressure to the ala of the nose, which can lead to injury and even alar necrosis. If the ala blanches when the airway is seated, it is likely too large for the diameter of the nostril and should be replaced with a smaller-diameter airway. Some nasal airways have a movable flange to prevent them from being inserted too deeply. The flange should be adjusted before it is inserted. The correct nasal airway size approximation is estimated when the airway extends from the nares to the angle of the jaw or the earlobe. In the absence of an appropriately sized nasal airway, one could cut a tracheal tube to the appropriate length. Note that a cut tracheal tube is stiffer than a commercially available nasal airway and has a greater potential for injury. Prewarming the tracheal tube using hot water may soften the tube and reduce the risk of mucosal injury. The lumen of any nasal airway is limited and can be occluded with secretions and/or blood. Therefore they should be removed as quickly as possible if airway obstruction is diagnosed.

LARYNGEAL MASK AIRWAYS

The reusable (Classic) Laryngeal Mask Airway (LMA, Teleflex) is a supraglottic airway device (SGA) developed by Dr. Archibald Brain in the 1980s. Reusable models of the LMA are still available, although most SGAs used today are single-use, disposable airways. Several different types of LMAs are now available, including the LMA Unique (used in emergency setting), LMA Flexible (soft, malleable wired neck), LMA ProSeal (with a second channel to direct gastric contents away from the airway), and the LMA Supreme (the Proseal with a built-in bite block). All of these airways are currently available, although high-quality studies that compared their advantages and disadvantages (with the exception of the Classic and the ProSeal) are lacking in children.[43] The SGA is a lifesaving airway device that should be used to establish ventilation when either ventilation by face mask or tracheal intubation is difficult or impossible. These devices are usually easy to place by inserting them straight into the hypopharynx, although some prefer to rotate the LMAs 90 degrees as they insert them.[44] Occasionally, the LMA will not advance past the posterior pharynx, especially if the bowl has been deflated. This may occur if there is a step-up in the alignment of the mucosa over the vertebral bodies against which the tip of the LMA abuts. Alternately, the tip of the bowl may have flipped backward, toward the nasopharynx, as the LMA is inserted, preventing it from advancing smoothly. To advance the LMA in both circumstances, the tip of the bowl should be lifted using your finger and the LMA then advanced. The bowl should be inflated until there is no air audible leak at ~16 to 20 cm H_2O peak inspiratory pressure. These airways can be used as the sole airway during anesthesia or as a conduit for bronchoscopy or fiberoptic intubation. There are several manufacturers with small to moderate differences among these devices (see also Figs. 14.18 to 14.20). For routine use in children with normal airways these small differences may not matter; some are specifically designed as a conduit for intubation. Supraglottic devices may have either one or two lumens. Dual-lumen SGAs are placed blindly into the oropharynx. They have two separate cuffs that can be inflated to allow isolation of the trachea (see E-Figs. 14.1 and 14.2). The dual-lumen devices are more typically used for prehospital providers during resuscitation and are not discussed further here. A typical single-lumen SGA is also readily placed blindly into the hypopharynx and makes a nonocclusive seal with the larynx. Single-lumen SGAs have a variety of additional features and design elements, such as nonferrous valves for use in magnetic resonance imaging (MRI); spiral reinforced and flexible, containing a thermoplastic cuff that molds to the airway; drains or sites for drainage of gastric contents; curvature to facilitate fiberoptic intubation; internal bars to prevent the epiglottis from obstructing the lumen; devices specifically designed to facilitate blind endotracheal intubation; and modifications that allow greater airway occlusive pressures during positive-pressure ventilation.

SGAs are available for all age groups from neonates and infants (<5 kg) to children and adolescents (>70 kg). Success rates for inserting the LMA on the first attempt are very high in most age groups, although some report only moderate success rates in neonates and infants (80%).[45] In most infants and children, the epiglottis lies within the bowl of the LMA, without evidence of upper airway obstruction.[46,47] In neonates and infants, it behooves the anesthesiologist to maintain very close vigilance of oxygenation and ventilation as the airway may become compromised quite suddenly and rescue measures must be adopted quickly.

When the LMA was first introduced, most practitioners used it only in children who breathed spontaneously. However, more recently many have adopted the adult practice of using low-pressure volume support and positive end-expiratory pressure (PEEP) with the LMA to minimize the effect of the dead space contributed by the LMA stem and the associated hypercarbia.[48–50] We have had good success with this approach in young children.

ENDOTRACHEAL TUBES

Endotracheal tube (ETT) sizes are polyvinyl chloride in composition, implant tested (based on Z79 standards in rabbits), and non-reusable. ETT sizes range from 2 to 10 mm inner diameter (ID). There may be small differences in wall thickness among manufacturers, although the variability is generally less than that of the anatomy of the upper airway in children of the same age. Additional differences include the bevel angle, tip design, and presence of a Murphy eye. Uncuffed ETTs have been the standard in pediatric anesthesia in infants and children up to 8 years of age for decades, although in the past 10 to 20 years, there has been a shift toward cuffed ETTs, accelerated by the introduction of the Microcuff ETT (Halyard Health, Alpharetta, GA). The reasons behind this shift in practice include the manufacturing of high-volume, low-pressure cuffed ETTs, efforts to reduce OR contamination,[51,52] to decrease anesthetic use with reduced fresh gas flow,[51] to reduce the need to reintubate the airway to prevent a large gas leak,[53] and ICU studies documenting the safety of cuffed ETTs after prolonged tracheal intubation.[54,55] However, Microcuff ETTs completely redesigned the ETT for children, introducing an elliptically shaped cuff that is positioned more distal on the tube, a thinner compliant cuff, and removing the Murphy eye (see Fig. 14.15). The cuff seals at a low pressure (10–12 cm H_2O), is permeable to nitrous oxide (N_2O), and is distal along the shaft of the ETT. Proper positioning is recommended using the markings on the shaft of the tube such that they align with the vocal cords, rather than the number of centimeters at the mandibular gumline.[56]

Several formulas have been developed to predict the ID of the ETT for each age group. The metric most widely used to select the diameter of the ETT is age. In the case of uncuffed

ETTs, Cole originally published his formula in 1957[57] in French catheter gauge, which was subsequently modified by Morgan and Steward in 1982 to:

Uncuffed ETT size (mm ID) = (age (years)/4) + 4 for children 2 years and older.[58]

For infants and children younger than 2 years, most recommend 2.5-mm ID ETT in infants weighing less than 1500 g, 3.0-mm ID for infants 1500 to 3000 g, and 3.5 mm for those who weigh more than 3000 g and full-term.[59]

For cuffed ETTs, Khine published in 1997 that the correct size is:

Cuffed ETT size (mm ID) = (age (years)/ 4) + 3.[52]

Other authors have modified Khine's formula to the size (mm ID) as (age (years)/4 + 3.5) for children older than 1 year.[60]

The outer diameter of cuffed ETTs is 0.5 mm larger than their uncuffed counterparts. One may choose to use the modified Cole formula for the initial ETT size for both cuffed and uncuffed ETTs and subtract 0.5 for the size of the cuffed ETT. Others developed formulas for selecting ETT size based on the child's height.[61,62] Age-based formulas are more accurate than direct comparison with the child's finger width.[63] A number of studies have assessed the accuracy of these formulas,[60,64] but this is a moot point as they should simply be considered a starting point for selecting the correct ETT size. Given the physiologic variability among children, ETT sizes smaller and larger should always be immediately available in the unlikely event that subglottic stenosis is diagnosed or a large trachea is uncovered and the predicted tube size for the child's age is erroneous (see Table 14.2). Some have advocated the use of ultrasound to assess the tracheal dimensions before selecting a tracheal tube to improve the accuracy of the ETT size predicted.[65]

A number of criteria have been proposed to confirm the appropriate fit and placement of the ETT in children. The ETT should pass through the vocal cords and subglottic space without meeting resistance. If resistance is felt, an ETT 0.5-mm ID smaller should be used. Once positioned, many recommend listening for an audible leak between peak inspiratory pressures of 15 and 30 mm H_2O. This pressure range is consistent with the peak inflation pressure for ventilation in most healthy children and maintains mucosal perfusion while avoiding a large gas leak and polluting the OR.[66] The simplest way to test for a leak is to slowly close the adjustable pressure limiting valve until the desired pressure is reached and either listening or placing a stethoscope over the larynx for a leak. However, the leak test is subject to a number of confounding variables, including the head position of the patient and the presence of neuromuscular blockade.[67] Despite these recommendations, several studies have demonstrated that large cuff pressures have not led to subglottic injury and stridor after extubation. If a cuffed ETT is used and there is a substantial leak with the cuff uninflated, then small amounts of air should be injected into the cuff until the leak disappears. If N_2O is used, it can diffuse into the cuff and increase the cuff volume (and pressure). The absence of an initial leak with a cuffed ETT even with the cuff deflated has been associated with postextubation stridor[68] and warrants exchange to the next smaller size ETT. Cuff pressure should be monitored periodically throughout the period of intubation.

A number of specialty ETTs are available, including those for single-lung ventilation, those with preformed curves, for laser surgery near the airway, microlaryngeal tubes for airway surgery, with spiral reinforcement, for neuromonitoring, and with sampling or suction ports (see also Chapters 14, 15, and 33). A preformed oral or nasal Ring, Adair, and Elwyn (RAE) tube allows surgeons to work on the face or in the mouth without the ETT obscuring their view or being at risk for being incised or kinked. They are also useful in head and neck surgery to keep the anesthesia circuit out of the field. It should be noted that the preformed curve has a specific length based on the ETT size predicted from average children. Securing the ETT with the angle of the curve well seated in the mouth or nares may cause the tip of the ETT to be either high or endobronchial, depending on the anatomy of the child. It is essential to pay special attention to the equality of breath sounds after the ETT is taped and the child placed in the position for surgery. Cuffed nasal RAE ETTs begin at 5.0-mm ID, are more difficult to suction through, and more prone to kinking than non-RAE ETTs. Manufacturers of the cuffed oral and nasal RAE ETT aligned the distance from the bend to the tip with an adult-sized ETT of the corresponding diameter rather than pediatric, resulting in longer distances from the bend than corresponds to the distance in the child's airway.[69] This may result in an endobronchial intubation if these ETTs are inserted until the bend is fully inserted into the nares or on the lower lip for the nasal and oral RAE tubes, respectively. As a result of needing to pull back slightly before taping, the bend in these cuffed RAE tubes may sit in the surgical field when the tip of the ETT is properly positioned in the trachea and therefore at risk for kinking (see Chapter 14 for a more in-depth discussion).

For these reasons, smaller versions of these ETTs are not always acceptable for long-term ventilation in the pediatric ICU (PICU); it is worth having this discussion before initiating anesthesia. For children undergoing complex craniofacial reconstructions in which the upper airway may swell postoperatively, their airways should remain intubated for several days and the airway swelling assessed daily for the presence of a leak.

Laser airway surgery places the child at risk for an airway fire. The polyvinylchloride (PVC) of a normal ETT can be damaged by the laser, resulting in mucosal injury or an airway fire. Oxygen and N_2O should both be reduced as much as possible as these are more flammable than air. Designs of specialty ETTs for laser surgery include a flexible stainless steel body, a silicon ETT wrapped in an aluminum material, and rubber tubes with or without metallic wrapping. The use of true natural rubber may put some patients with latex allergies at risk. Previously some institutions have wrapped normal ETTs in metallic tape to reduce the risk of damage to the PVC, but the rough edges of the tape may injure the mucosa. Microlaryngeal ETTs are longer regular ETTs and have a larger cuff providing more space in the airway for surgery; for example, a size 5.0-mm ID microlaryngeal ETT has the length of a 7.0-mm ID ETT. The trade-off is more room for surgical exposure versus a limited increase in airway resistance. Reinforced ETTs have a wire wrapped in a spiral fashion throughout the PVC wall of the ETT. They are often used in circumstances where kinking of the ETT is a risk. A slightly smaller-sized ETT than expected should be selected as reinforced ETTs have a larger outer diameter than the comparable standard ETT of the same size. In addition, a stylet is often needed to manipulate the floppy tube through the larynx. Once in place, a bite block is often used to stabilize the tube and prevent the patient from biting it, which could collapse the lumen.

Another ETT useful in head and neck surgery is the electromyographic ETT that permits neuromonitoring of the recurrent laryngeal nerve during neck dissection or thyroidectomy.[70] This type of specialty ETT is not available in sizes smaller than 6.0-mm

ID. Finally, there are uncuffed ETTs with an extra internal lumen that allows monitoring of airway pressure or exhaled gases (Mallinckrodt Inc., St. Louis, MO).

ETTs have been developed that are designed to reduce ventilator-associated pneumonia in children in the ICU. One such ETT has a suction port that allows continuous aspiration of secretions, whereas another takes advantage of a cone-shaped ETT cuff to prevent microaspiration of airway secretions around the ETT. Evidence for their effectiveness, however, remains weak.[71,72]

Intubation Equipment

LARYNGOSCOPES

A full range of straight (Miller) and curved (Macintosh or Mac) laryngoscope blades for direct laryngoscopy should be available. It is quite possible in a typical pediatric anesthesia practice to use both a Miller 00 and a Mac 4 blade in the same day. Both small and large laryngoscope handles are available to accommodate differences in body habitus among children. The blade and handle combinations should be tested before anesthesia is induced. Backup blades and handles should be immediately available; additional batteries and light bulbs should be in stock. The light source for laryngoscopes has changed over time from a simple light bulb at or near the tip of the blade powered by two D cell batteries to a fiberoptic channel powered by a rechargeable battery that lights a xenon bulb near the tip of the blade. This latter advance has increased the brightness of laryngoscopes and reduced the frequency of bulb changes; however, visual acuity does not appear to improve once illuminance exceeds 700 lux.[73] Disposable laryngoscope handles and blades have also been developed for use on code carts, during transport, and with highly infectious patients. The price of this equipment can be cost-effective if used only occasionally, although in some institutions with large volumes the cost of single-use devices is lower than the need for replacement of lost or stolen handles and blades. MRI-compatible laryngoscopes are also available but are extremely expensive; most use standard laryngoscope handles for use in 2-Tesla magnets but their use is restricted to the side of the magnetic core in zone 4. Laryngoscope blades with a supplemental oxygen channel are available; these delay the time to desaturation[74] in spontaneously breathing infants (see E-Fig. 14.12). This same effect has also been demonstrated with the addition of nasal cannula oxygen during intubation.[75]

A difficult airway cart with all needed equipment should be present in the OR complex (see Table 14.10). These carts should contain fiberoptic bronchoscopes in the three major sizes as well as other airway adjuncts such as LMAs, bougies, and indirect laryngoscopes that use prisms, fiberoptics, or video devices (see also Chapter 14).

Suction Devices

Suction devices include a container for waste and a regulator to control the degree of suction. Although regulators can provide low intermittent suction, systems used in anesthesia are not usually set up this way. Injury can occur to the gastric mucosa if continuous suction is applied to a nasogastric or orogastric tube. Vented tubes (e.g., Salem Sump, Sherwood Medical, St. Louis MO) in a variety of sizes should be available for continuous gastric drainage. If low intermittent suction cannot be provided, we prefer to leave the open end of these tubes sealed in a glove. Suction catheters with a thumb-controlled side port in sizes from 6F to 14 F should be available to suction ETTs. Yankauer tip suction devices are available in small and large sizes and are more effective at clearing material compared with the thumb-controlled catheters. They may be metal or plastic; the latter material is preferable to limit the risk of damaging teeth. Yankauer suction devices should never be inserted into the mouth in the midline (because the child may bite down on it and break or dislodge teeth). Rather, the devices should be inserted between the teeth and the inside of the cheek, reaching the hypopharynx behind the molars or bicuspids. The small size Yankauer works well in infants, limiting damage to the oropharynx. However, if a large amount of material must be cleared, the larger Yankauer is more effective. If a very large volume needs to be suctioned (e.g., gastric bleeding), it is prudent to have two separate suction devices and parallel systems available.

Anesthesia Workstation

An anesthesia machine is a device that allows for mechanical or electronic control of gas titration (O_2 [oxygen], N_2O, and air), titration of anesthetic vapor, and manual or mechanical ventilation. It is also an ergonomically designed workstation that includes storage; a place for computer or hand charting; a work surface for drugs and intubation equipment and patient and machine monitoring; a reservoir bag for hand ventilation with an adjustable pressure limit (APL) valve; a means of scavenging anesthesia and waste gas; and an absorber for CO_2 removal. It is also advisable to have a self-inflating bag readily available should a power failure occur or a patient develop malignant hyperthermia. The anesthesia machine has had a unique role in improving patient safety in the OR. Modern machines cannot deliver a hypoxic gas mixture; they monitor inspired and expired oxygen and anesthesia gases; use an index system to prevent connection of wrong gas lines; and monitor airway pressure and alarms for high pressure, disconnections, high or low minute ventilation, and apnea. The current anesthesia system is a marvel of design that is a very long way from the nonrebreathing open anesthesia systems of the past. The classic example of an open system is the Ayre T-piece, which uses a simple tube as a reservoir for gas (Fig. 52.4). Modifications to this type of system resulted in open breathing circuits that are part of the Mapleson classification (Fig. 52.5);

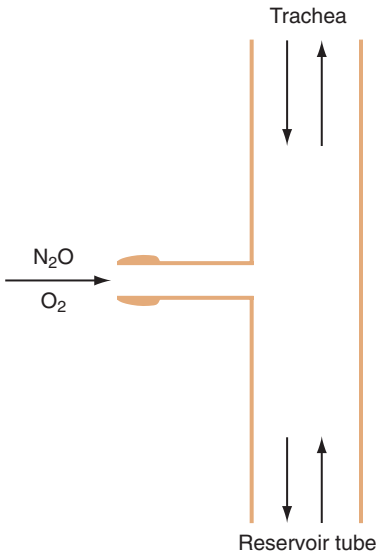

FIGURE 52.4 The T piece as described by Ayre. (From Ayre P. The T-piece technique. *Br J Anaesth.* 1956;28[11]:520–523.)

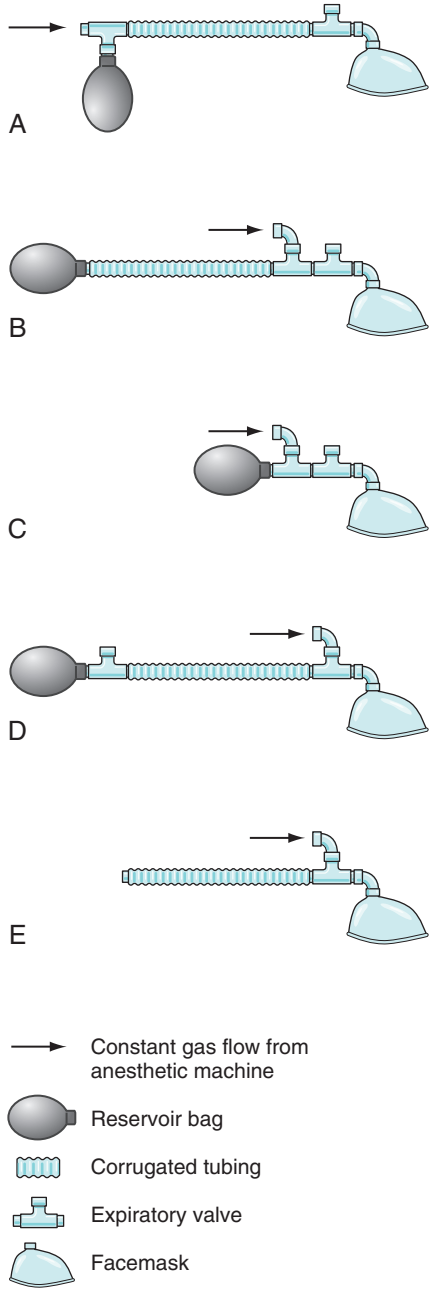

FIGURE 52.5 The Mapleson categories of breathing circuits. The most commonly used circuit for infants is the Mapleson D configuration. (From Mapleson WW. The elimination of rebreathing in various semi-closed anaesthetic systems. *Br J Anaesth*. 1954;26[5]:323–332.)

advantages and disadvantages of each are described elsewhere.[76] The Mapleson D configuration is frequently used to transport children in the hospital to and from the OR. The Mapleson D circuit is very lightweight and allows for easy adjustment of PEEP while the patient breathes spontaneously and peak inspiratory pressure when ventilation is controlled. The circuit requires three times the minute ventilation to prevent rebreathing of CO_2. The Mapleson D allows the child to breathe spontaneously without additional work to initiate gas flow; this contrasts with a self-inflating (e.g., Ambu bag, Ambu Inc., Columbia, MD) resuscitation bag that must be squeezed to initiate gas flow. However, in the absence of gas flow, a Mapleson D cannot facilitate ventilation as it is not self-inflating. Therefore for transport of children whose airways are intubated we recommend the Mapleson D but also suggest bringing a self-inflating resuscitation bag (e.g., Ambu bag) should the gas source fail.

Current anesthesia machines are unidirectional semi-closed circuits in which a fixed amount of fresh gas is added to the circle breathing circuit each minute and a means of removing CO_2 is present. These systems contaminate the environment with anesthetic gases less than the open systems, as well as retain the airway gas temperature and humidity better than the open systems. In the following text we describe the key components of the system with specific highlights to pediatrics when applicable including scavenging systems, CO_2 absorption, humidification, and mechanical ventilation.

SCAVENGING SYSTEMS

Scavenger systems are a necessary part of an anesthesia machine to prevent contamination of the OR with waste anesthesia gases. Scavenging systems are either open or closed and movement of waste gas can be either active or passive. An open system uses a reservoir to collect waste gas, which is then actively suctioned from the reservoir. The reservoir in these open systems communicates with the atmosphere, thereby avoiding either positive or negative pressure transmission to the airway. A closed system is not connected to the atmosphere of the OR but waste gas exits the machine and then the OR through a series of valves. In a closed system, scavenging can be either active via means of suction or passive, relying on heavier-than-air anesthesia gases and pressure to move waste gas to evacuation. These systems must have both positive- and negative-pressure relief valves to prevent pressure from being transmitted to the airway. Scavenger systems are necessary and helpful means to reduce the contamination of the OR.[77] In addition, anesthesiologists also contribute substantively to reducing OR contamination; fresh gas flows are not increased until the patient is ready for induction of anesthesia, a tight mask fit is preferred, the leak around the ETT should be minimal, and fresh gas flow rates should be reduced or turned off before disconnecting the anesthesia circuit to move or position the child.

CARBON DIOXIDE ABSORPTION

CO_2 absorption or the removal of CO_2 from the breathing circuit makes a circle system possible. This allows for the rebreathing of exhaled gases and inhalational agents, which reduces waste, pollution of the OR as well as the environment, and retention of heat and humidity within the circuit. All the materials that absorb CO_2 are chemicals that react with CO_2 converting it to stable compounds, hardeners to prevent obstruction of the canister, and dye indicators that identify when the absorption material is expended and should be changed. Soda lime, one typical CO_2 absorbent, contains approximately 80% calcium hydroxide ($Ca(OH)_2$), 15% water (H_2O), 4% sodium hydroxide (NaOH), and 1% potassium hydroxide (KOH). The chemical reactions can be described as a strong alkali with metal hydroxide functioning as a catalyst in the presence of water to convert CO_2 into calcium carbonate. The equations are as follows:

1. $CO_2 + H_2O \rightleftharpoons H_2CO_3$
2. $H_2CO_3 + 2NaOH$ (or KOH) $\rightleftharpoons Na_2CO_3$ (K_2CO_3) $+ 2H_2O +$ Heat
3. Na_2CO_3 (K_2CO_3) $+ Ca(OH)_2 \rightleftharpoons CaCO_3 + 2NaOH$ (KOH)

A number of sequelae occur when potent inhalational anesthetic interact with these absorbents; in the presence of desiccated soda lime, ether anesthetics can degrade to carbon monoxide and in

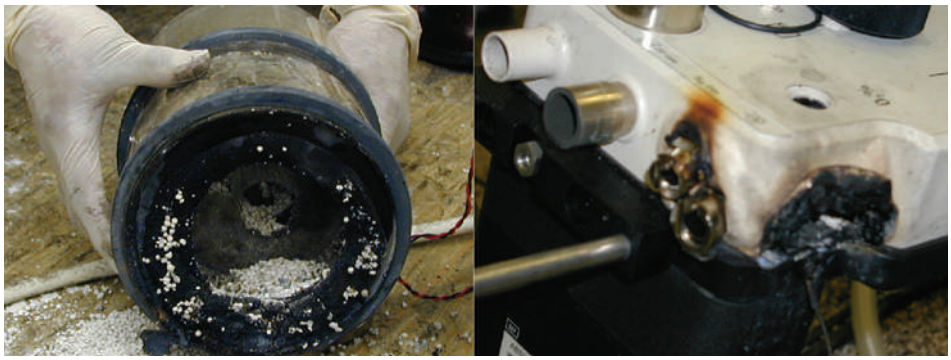

FIGURE 52.6 Sevoflurane/Baralyme interaction produced this fire in an anesthesia machine. (Courtesy Mr. A. Rich.)

the case of sevoflurane, to Compound A,[78–82] a vinyl compound known to cause renal injury in rats.[83,84] In the presence of favorable conditions, carbon monoxide production follows the order desflurane > isoflurane > sevoflurane > halothane.[85] Extreme heat and fire have been associated with the absorbent, Baralyme, which contained barium hydroxide. The reaction of sevoflurane with desiccated Baralyme created such a severe exothermic reaction that it has caused acute respiratory distress syndrome (ARDS),[86] fires[87] and explosions[88,89] in the OR (Fig. 52.6). Both carbon monoxide poisoning and fires typically occurred on a Monday morning after a weekend during which the fresh gas flow had been left running through the anesthesia machine without a reservoir bag, desiccating the absorbent. Baralyme was voluntarily withdrawn from the market in 2004 to prevent additional human injuries; further experiments showed that increased temperatures could occur with desiccated soda lime.[90] These events emphasize that we must remain vigilant and turn off the fresh gas flows between cases, ensure a reservoir bag is in place in the circuit and replace desiccated CO_2 absorbents with fresh absorbent. Concerns about degradation of inhaled anesthetics to carbon monoxide and compound A[91,92] led to the development of a number of CO_2 absorbents that do not contain the strong alkali agents NaOH or KOH and are inert to the ether anesthetics. These include Amsorb Plus (Armstrong Medical Limited, Coleraine, Northern Ireland), Lithely (Allied Healthcare Products, St. Louis, MO), Sodasorb LF (Smiths Medical), and Yabashi Lime-f (Yabashi Holdings Co., Akasaka, Japan). There are also absorbents that contain a reduced amount of NaOH, including Spherasorb (Intersurgical Ltd., Berkshire UK), and Drägersorb 800 Plus (Dräger). In addition, the risk of developing renal injury is related to the dose exposure of compound A and not just to sevoflurane.[93] However, this risk is far less likely than originally thought and now likely eliminated with the newer absorbents.[94–96] However, in a conservative fashion the US Food and Drug Administration in the January 2010 Prescribing Information for Ultane (sevoflurane) recommends: *"To minimize exposure to Compound A, sevoflurane exposure should not exceed 2 MAC·hours at flow rates of 1 to < 2 L/min. Fresh gas flow rates <1 L/min are not recommended"*; in the absence of any ill effects of compound A reported in humans, it is unclear if this recommendation is necessary (see also Chapter 7).

CO_2 absorbents must also include color indicators to identify when the capacity of the absorbent has been exhausted. Ethyl violet is one indicator, which changes from colorless to violet when the pH of the absorbent decreases. Exposure to fluorescent lights can decrease the concentration of functioning ethyl violet.[97] In addition, if consumed absorbent material is left unused for a period of time, it is possible for the color indicator to revert to white or colorless. This can occur when NaOH or KOH regenerates in the absorbent material with a subsequent increase in pH. This does not occur with absorbents that are NaOH- or KOH-free.

HUMIDIFICATION

Oxygen, N_2O, and air from tanks and connecting lines contain no humidity and are room temperature or cold compared with the patient. Warming and humidifying inspired gases help to maintain body temperature and prevent the drying of secretions, improve mucociliary function,[98,99] and reduce the inflammatory response.[100]

A small amount of heat is produced during the exothermic reaction that occurs when CO_2 is removed from the breathing circuit. However, the amount of heat produced is insufficient to maintain a child's temperature. The use of small fresh gas flows increases the humidity relative to high fresh gas flows.[101] However, small fresh gas flows do not increase the humidity sufficiently to preserve mucociliary function. Further, there was no difference in airway temperature between small and large fresh gas flows.[101] Clinicians may choose to use passive humidification with a heat and moisture exchanger (HME). The passive HMEs have a reflective filter or membrane that retains heat and moisture on the patient side of the circuit. HMEs increase the temperature and heat of the inspired gases to the point that they approach physiologic levels.[102] The best results are achieved when an HME is used in conjunction with small fresh gas flows. The downside to using HMEs is that they increase the dead space and can increase the partial pressure of CO_2 (PCO_2) if the minute ventilation is not increased.[103] Humidification of airway gases can also be active with systems that include heated wires within the breathing circuit or reservoirs for sterile water connected to the breathing circuit that can be heated. These systems are very effective at maintaining temperature and humidity but have some drawbacks. Active humidification systems are prone to condensation or "rain out" on the inside of the breathing circuit that can lead to obstruction of the airway, obstruction of the CO_2 gas sampling line, and inaccurate measurement of airway pressure and gas flow. Active humidification systems increase the resistance to gas flow and can alter the compliance and compression volume if they are not in line and warm when the machine check is performed. Finally, if active humidification systems are set incorrectly or malfunction, they can overheat and cause damage to the airway and trachea. The decision to use active or passive systems should be based on factors such as the size of the patient, duration of the case, and difficulty in maintaining an increased minute ventilation.

MECHANICAL VENTILATION

In addition to delivering anesthetic gases and oxygen and eliminating CO_2, one of the primary purposes of the anesthesia workstation is to ventilate the lungs. The complexity of this task is compounded in small infants and children in whom an inaccuracy of 20 mL might double the delivered tidal volume.[104] The determinants of the delivered tidal volume include the compliance of the anesthesia breathing circuit, the fresh gas inflow, the means of delivering the breath, the gas flows, and the dead space of airway circuit.[105] The newest generation of anesthesia machines uses internal electronics to address all of these components except dead space and to compensate for changes in these variables to estimate the minute ventilation.[106]

The electronics of modern anesthesia workstations can compensate for the compliance and compression volume of both the gases delivered and the tubing of the breathing circuit. Breathing circuits are either parallel or coaxial and can be smooth or, more commonly, corrugated. Corrugated breathing circuits come in a variety of sizes to accommodate the patient's size. Larger lumens have reduced resistance to air flow but a greater increase in volume when pressure is applied to the circuit. Compensation calibration can be performed with modern anesthesia workstations to accommodate for the change in volume as the circuit expands under pressure. Recent evidence demonstrated that the compliance of the corrugated circuit tubing is reduced, and therefore the compensation underestimated, if the tubing is not fully expanded before commencing the machine check.[107] The end of the breathing circuit should be occluded and the compensation test performed before use; the workstation increases the volume in the occluded circuit while pressure is being measured. The compliance factor of that breathing circuit is automatically entered into the ventilation system memory and used to compensate for the volume of expansion. This test is specific to the circuit in its current state. If the circuit size is changed or if the corrugated circuit's length is altered, the compliance factor will be inaccurate and therefore the delivered tidal volume will be inaccurate. If either of these changes occur, the compensation test should be repeated to ensure that the displayed respiratory indices are accurate.

One concern with the first generation of anesthesia ventilators was that changing the fresh gas flow could alter the tidal volume delivered to the lungs. The volume of gas set to be delivered entered the bellows mechanism of the ventilator during inspiration, augmenting or diminishing the intended tidal volume with the volume-controlled mode. The most recent generation of anesthesia ventilators does not have this limitation.[106] The mechanism by which this is accomplished varies among manufacturers. One design is to incorporate a valve that shuts off fresh gas flow during the delivery of the inspired breath. Another design is to measure the amount of fresh gas flow and adjust the volume in the bellows, piston, or turbine used to deliver the dialed tidal volume. The ability to measure gas flow very accurately throughout the anesthesia workstation allows for this type of adjustment as well as circuit compensation. Real-time monitoring extends to the ventilation system of the newest generation of anesthesia machines regardless of whether this is accomplished by pneumatics, piston, or turbine.

The latest generation of anesthesia machines also provides multiple modes of mechanical ventilation. These include pressure-controlled ventilation (PCV), volume-controlled ventilation (VCV), and volume-guaranteed ventilation (VGV). These modes can be set as intermittent mechanical ventilation (IMV), or synchronized intermittent mechanical ventilation (SIMV), in which the child's effort to breathe can trigger the ventilator to deliver a breath. Additionally, the ventilator can deliver pressure support (PS) above PEEP. We believe that PCV is the optimal mode for mechanical ventilation of most infants and children in routine practice. This preference may have developed from a time when the measurement of tidal volume with the ventilator was less accurate. At that time, however, pressure could be measured very accurately. For PCV, the clinician sets a positive inspiratory pressure (PIP) level, PEEP level, inspiratory:expiratory (I:E) ratio, and respiratory rate. The adequacy of ventilation is determined by observing the chest rise, auscultating breath sounds, monitoring the end-tidal CO_2 ($ETCO_2$), and intermittent blood gases as indicated. The ventilator delivers a breath with a very fast initial flow, which decreases as the target pressure is achieved. This is known as a decelerating flow pattern. The pressure in the airway is constant throughout the inspiratory breath and forms a square wave. In PCV mode, the tidal volume delivered depends on the compliance of the ventilator circuit and the respiratory system. One disadvantage of this mode of ventilation is that with a decrease in compliance (e.g., surgeon leaning on the infant's chest), the delivered tidal volume decreases. Alternatively, in a VCV mode, the clinician sets a tidal volume to be delivered, PEEP level, rate and I:E ratio. The adequacy of ventilation is determined in the same manner. The inspiratory pressure required to deliver the tidal volume depends on the compliance of the ventilator circuit and respiratory system as well as the time over which the breath is delivered. This inspiratory time is determined by the rate and the I:E ratio. In a VCV mode of ventilation, the rate of air flow is constant throughout the entire inspiratory cycle and forms a square wave. However, the pressure in the airway increases throughout the inspiratory time. Some clinicians argue that the constant air flow throughout the inspiratory breath prevents atelectasis; however, in our view it seems much easier to simply set a level of PEEP and apply an alveolar recruitment maneuver as necessary.

The practical differences between these two modes of ventilation are that if you set the peak pressure, you must monitor the tidal volume and adjust the peak pressure if the compliance changes. If you set the tidal volume, you must monitor pressure and adjust the flow, inspiratory time, and inspiratory waveform or tidal volume when compliance changes. For example, during laparoscopic surgery when the abdomen is inflated with CO_2, the tidal volume decreases and the pressure or rate increases in PCV mode to maintain the same minute ventilation. During the same case in a VCV mode, the ventilator pressure increases and the clinician will need to decide if the increase is tolerable or if the tidal volume needs to be decreased slightly. As a consequence of the differences in the air flow patterns between PCV and VCV modes, a greater pressure is required to achieve the same tidal volume as in the VCV mode. For most children with normally compliant lungs, this difference is negligible. VGV modes of ventilation have different names based on the manufacturer. Some clinicians believe that this mode is the quintessential ventilation strategy of both PCV and VCV. The clinician sets a required tidal volume while the ventilator measures the pressure in the airway over several breaths as it adjusts to deliver the desired tidal volume. Then, in an iterative manner, the ventilator uses pressure to achieve that set volume. The goal is to use the minimum pressure to deliver the prescribed tidal volume. The air flow pattern used is a decelerating waveform and the pressure is constant throughout the inspiratory breath. This would seem like the best of both worlds as this mode can be used for children who are receiving muscle relaxants or are deeply anesthetized. However, when the patient's lung compliance

changes rapidly, as in coughing or bucking on the ventilator, it is difficult to maintain the prescribed tidal volume.

The respiratory management of children with acute lung injury or ARDS requires specific barotrauma-sparing ventilator strategies. This newest generation of anesthesia machines ventilators can measure and deliver tidal volumes accurately enough to target 6 to 8 mL/kg. Compared with the overall population of patients, only a small number of children with ARDS come to the OR. Therefore with the current state of the art anesthesia ventilators, there may not be a significant benefit to bringing an ICU ventilator into the OR even for children with poor respiratory compliance. The current anesthesia machines include all the modes of ventilation that are generally used in an ICU setting. In addition, a significant advantage to using an anesthesia machine is the ability to rapidly deepen the depth of anesthesia with inhalational anesthetics. Further, if the APL valve is set to the same value as PEEP, the clinician can switch back and forth between mechanical and hand ventilation without altering PEEP. With an ICU ventilator, the patient is disconnected from the circuit to be hand ventilated; PEEP may be lost, potentially reducing lung recruitment.

Finally, with regard to mode of ventilation, newer anesthesia machines allow clinicians to set PS levels. PS provides additional airway pressure when the patient triggers a breath either by negative pressure on the ventilator circuit or altering the airflow. Sensitivity triggers can be adjusted such that most children are able to initiate PS. If the triggers are set very low, it is possible for "autocycling" to occur. Autocycling occurs when PS breaths are triggered by changes in pressure or flow within the ventilator circuit owing to leaking around an ETT or other non–patient-initiated mechanisms. This can generally be identified by a very rapid ventilator rate with very small tidal volumes.

There are a number of benefits to PS ventilation. For children who are not receiving neuromuscular blocks drugs (NMBDs), PS allows them to set their own ventilator rate. This allows the clinician to use respiratory rate as a measure for depth of anesthesia as well as for titration of opioid pain medications. PS may also provide increased minute ventilation at the end of the procedure compared with spontaneous ventilation, which might decrease the time for emergence. As stated earlier, the conducting portion or shaft of an LMA can substantively increase the mechanical dead space in infants and small children. At times, the patient's tidal volume can be small enough that dead space cannot be overcome. The use of PS and PEEP can assist the child to overcome this dead space and maintain a normal CO_2 level.

The latest generation of anesthesia ventilators can accurately deliver a set PEEP value. They typically have an interruption in fresh gas flow such that tidal volume is neither altered by nor dependent on the fresh gas flow. In earlier anesthesia machines, the constant fresh gas flow would generate small amounts of PEEP. With the current ventilators, it is possible to provide anesthetics with zero PEEP. We can think of very few circumstances (possibly increased intracranial pressure or single-lung ventilation) where even a small amount of PEEP is not beneficial. Even high levels of PEEP do not decrease cardiac output in children who have an adequate intravascular volume.[108,109] Rather than increasing the inspired fraction of oxygen (FIO_2) in response to decreasing saturations, the clinician should perform an alveolar recruitment maneuver followed by the addition of PEEP to keep the alveoli open.[110]

Anesthesia machines have the ability to monitor pressure and flow in the airway. Further, they monitor the inspired and expired concentration of gases from the elbow of the breathing circuit. These monitors increase patient safety and provide immediate feedback regarding the adequacy of ventilation and the depth of anesthesia. The anesthesia machine can detect increased airway pressure, indicating obstruction of the airway or bronchospasm, airway disconnection, apnea, high and low pressures, as well as minute ventilation, low inspired FIO_2, high anesthesia concentrations, increased inspired CO_2, and increased expired CO_2. Further, continuous CO_2 waveforms and pressure-flow and pressure-volume loops can provide a great deal of information about the respiratory system. The newest-generation anesthesia machines also permit the input of the child's age and weight, thereby enabling specific alarms to be set at initiation of anesthesia based on the child's age, weight, and other variables (see further).

One aspect of monitoring airway gases is that there must be a Luer connection to tightly connect the gas sampling line to the anesthesia machine. Mechanical dead space begins at the Y piece of the anesthesia breathing circuit and extends distally. This includes the elbow itself, HMEs, flexible airway connections or accordion, and the connecting area of the LMA. All of these items can increase the dead space significantly for small children; items with minimum internal volume should be used when possible, particularly in neonates and infants.

It should be noted that anesthesia machines can measure inspiratory and expiratory volumes accurately but have no means to increase the tidal volume to compensate for a leak around the ETT. With large tracheal leaks larger tidal volumes can be used to compensate for leaks. Clinical examination of chest rise, breath sounds, and expired CO_2 values must be used as well as the consideration for intermittent blood gases.

Equipment Cart

It is advantageous to use mobile, lockable, multidrawer carts to stock the wide range and sizes of items necessary to care for the full spectrum of infants and children. The drawers should be organized for ease of use: airway equipment, drugs, IV supplies, monitoring equipment, circuits, and suction catheters, separated into appropriately labeled drawers. To facilitate efficient and safe delivery of anesthesia, it is prudent to design and stock each cart identically. Because pediatric anesthesia is often administered outside the OR suite, these mobile carts simplify the safe practice of anesthesia and guarantee the availability of all necessary equipment in these remote locations for children of all sizes (Table 52.2).

Defibrillator and External Pacemakers

Every OR facility should be equipped with a direct-current defibrillator. It is not necessary to have a unit specifically for use with children provided the energy range may be adjusted to the appropriate levels (e.g., 2 joules/kg) and pediatric paddles are immediately available. Ideally, the design should incorporate all controls in the paddles, facilitating use without leaving the child's side. A sensing circuit that provides the capacity for synchronous defibrillation is desirable. External defibrillators with disposable pads applied to the front and back or right chest and left lateral chest of the child have improved the rapidity of response in some circumstances. These can be placed on high-risk children (e.g., cardiac surgery, cardiomyopathy, atrioventricular conduction defects) before induction of anesthesia.[64,111–115] Similar devices that allow for external cardiac pacing represent a major new advance for high-risk infants and children (see also Chapter 40).[116–118]

TABLE 52.2 Suggested Pediatric Equipment Cart Inventory

	DRAWER CONTENTS
Drawer 1	Laryngoscope handles (functioning) (2) Laryngoscope blades (functioning) Miller: 0 (2); 1 (2); 2 (2); 3 (2) Macintosh: 1 (2); 2 (2); 3 (2) Wis-Hipple: 1½ (2) Magill forceps: 1 pediatric, 1 adult 1-inch tape (4) ½-inch waterproof tape (4) Tourniquets of non-latex material: 4 each ¾-inch and ¼-inch Scissors Flashlight Extra batteries for laryngoscope handle
Drawer 2	Masks Neonate (3) Infant (3) Toddler (3) Child (3) Medium adult (3) Large adult (3) Airways 3.5 cm (5) 5.0 cm (5) 6.0 cm (5) 7.0 cm (5) 8.0 cm (5) 9.0 cm (5)
Drawer 3	Gauze sponges (sterile and nonsterile) Double-stick disks Rubber bands Adhesive bandages Alcohol swabs Antibiotic ointment Water-soluble surgical lubricant Lidocaine ointment 5% Bulldog clips Safety pins Corneal lubricant Pediatric blood tubes (blue, red, purple, and green) Eye patches
Drawer 4	Adult sodium bicarbonate (2) Pediatric sodium bicarbonate 8.4% (2) Infant sodium bicarbonate 4.2% (2) Cardiac lidocaine 100 mg (2) Dextrose 50% (1) Mannitol 25% (1) Diphenhydramine 50 mg (2) Calcium chloride 10% (4)
Drawer 4—cont'd	Calcium gluconate 10% (4) Sterile water Lidocaine 1% (5) Phenylephrine (5) Neostigmine 1:2000 (10) Ephedrine (5) Atropine (10) Isoproterenol (1) Furosemide (3) Epinephrine 1:1000 (10) Succinylcholine (1) Rocuronium (1) Dexamethasone 4 mg/mL (2) Dopamine (2) Ondansetron (10) Propofol (10)
Drawer 5	Pediatric uncuffed endotracheal tubes: 2.5 (6); 3.0 (6); 3.5 (6); 4.0 (6); 4.5 (6); 5.0 (6); 6.0 (6) Pediatric cuffed endotracheal tubes: 5.0 (3); 5.5 (3) Adult cuffed endotracheal tubes: 2 each of 6.0; 6.5; 7.0 Stylets in various appropriate sizes
Drawer 6	Pediatric and adult esophageal stethoscopes (6) Adult electrocardiography pads (10) Pediatric electrocardiography pads (10) 6.5F suction catheters (6); 10 of each size 8F and 14F Pediatric and adult Yankauer suction devices (10 each)
Drawer 7	Syringes: 60-mL (2); 20-mL (6); 12-mL (10); 6-mL (10); 3-mL (20); 3-mL (20); 1-mL with 27-gauge needle (20); a variety of needles to facilitate drug withdrawal (18-, 20-, 22-, 25-gauge)
Drawer 8	Intravenous catheters: 24-gauge; 22-gauge; 20-gauge; 18-gauge; 16-gauge; 14-gauge Pediatric intravenous boards: 2 sizes (4) T-connectors Three-way stopcocks, multiple stopcock manifolds, claves, Luer connectors, small volume (0.5–1 mL) drug administration tubing
Drawer 9	Pediatric and adult intravenous sets (6) Pediatric Buretrol (2) Intravenous extension sets (2) Lactated Ringer's solution 250 mL 0.9 normal saline solution (5) Air trap filters (6) Head strap Blood pressure cuffs (2 each size), 1 adult size with stethoscope Oximeter sensors for infants and children

NOTE: These are only suggested equipment cart materials. Each hospital should alter the order of drawers and their contents to suit its particular needs and for convenience.

Ultrasound for Regional Anesthesia and Vascular Cannulation

With the availability of ultrasound in the OR, it is reasonable to use ultrasound for certain procedures such as central venous cannulation and regional nerve blocks.[119–122] Improved success and safety have been reported with ultrasound for vascular access (see Chapter 49)[120,123–126] and for regional anesthesia if the practitioner is experienced (see Chapters 42 and 43).[119,127–129]

Most anesthesiologists can use ultrasound to obtain two-dimensional (2D) images but may not be aware of all the features

of their ultrasound machines. Newer machines allow the clinician to freeze the image, measure distances, zoom into an area, increase the gain of the image, interrogate a color Doppler signal, print, and possibly transmit images. Color Doppler is the use of a color-coded representation of velocity of the reflecting tissue put on top of the 2D image. Typically blood flow is depicted in red when the flow is directed away from the transducer and in blue when it is directed toward the transducer. The use of color Doppler can improve identification of arterial versus venous vessels, thus improving patient safety. The ability to print or transmit static images to the medical record will likely become important for medicolegal documentation of regional anesthesia in the future.

The physics of ultrasound in some ways favor the pediatric patient. Probes that operate at higher frequencies offer better spatial resolution but with a limited depth of penetration of the image, whereas those that operate at lower frequencies penetrate to identify deeper structures but have decreased resolution. Small children and infants, therefore, have excellent acoustic windows and structures that can easily be identified because the structures are more superficial than in adults (see Chapters 42 and 43). Needles can be difficult to visualize with ultrasound[130] because they do not enter the ultrasound field of view parallel to the transducer. The steeper the angle of the needle, the less reflection and therefore the less the ultrasound waveform. Further, soft tissue is a mix of fluid, fat, connective tissue, and muscle, each with different impedance, which creates difficulty distinguishing the needle from background material. Manufacturers have addressed this issue in two separate ways: by increasing the echogenicity of the needle and by electronically manipulating the ultrasound signal to enhance the needle tissue interface. Manufacturers such as Havel's Incorporated (Cincinnati, OH), Pajunk (Norcross, GA), B. Braun Medical (Bethlehem, PA) and others have insulated the sides of the needle to increase its echogenicity. There are multiple manufacturers of ultrasound equipment for anesthesia. These manufacturers have enhanced software to improve our ability to visualize the needle. BK Ultrasound (Peabody, MA) calls its feature "X-Shine"; GE Healthcare (Little Chalfont, UK) calls its feature LOGIQ-e; Mindray Zonare (Mountain View, CA) calls its feature "iNeedle"; Philips (Foster City, CA) calls its feature "Needle Visualization"; FujiFilm SonoSite (Bothell, WA) calls its feature "Advanced Needle Visualization (AVN)"; and Toshiba Medical Systems (Otawara, Tochigi Prefecture, Japan) calls its feature "Biopsy Enhancement Auto Mode (BEAM)." There are numerous ultrasound workshops each year at various medical society meetings to train practitioners to use ultrasound for vascular access and regional anesthesia.

Monitoring Equipment

THE ANESTHESIA RECORD AND BAR CODE DRUG ADMINISTRATION

Automated anesthesia recording-keeping systems are rapidly becoming ubiquitous in anesthesia practice and likely will replace paper records in all but the smallest anesthetizing sites in the very near future. These systems are also referred to as **A**nesthesia **I**nformation **M**anagement **S**ystems (AIMS). The issue for many practices is not whether to use an AIMS but which system to use and whether to switch to a newer version of the software or vendor. The decision to integrate AIMS into one's practice is beyond the scope of this chapter. These systems are expensive, requiring sizable hardware and software investments along with maintenance contracts that often must integrate efficiently with hospital-wide electronic health records (EHRs). As a result, hospital administrators usually decide which systems to purchase with advice from their Informatics and Anesthesiology departments.[131–133] An effective AIMS replaces the paper chart and reduces the workload of anesthesiologists, allowing them to focus on patient care. AIMS should ideally integrate information from the anesthesia machine, physiologic monitors, other equipment, and the EHR. Additional functions include automatically calculating cumulative totals for intakes, outputs, and drug infusions, documenting compliance with regulatory requirements such as "time-outs" and administering "antibiotics before surgical incision."[134,135] Whether these functions will reduce perioperative morbidity and mortality remains unclear.[136] The automatic recording of physiologic variables may improve accuracy of data but are not without errors.[137,138] For example, a pulse oximeter signal may be altered by the presence of a tourniquet at the time of IV cannulation, electrocautery may temporarily interfere with both electrocardiographic and temperature readings, and arterial BP readings will be interrupted by blood draws for periodic lab testing. These values can be annotated but most anesthesia providers either miss or disregard these erroneous or absent readings, leaving unusual or missing data in the electronic record. Such errors may have medicolegal implications as well as quality assurance questions.

There are many reasons to use the same manufacturer for AIMS and EHR. However, many of these systems were designed by engineers, not anesthesiologists, with clumsy user interfaces and workflow patterns. The workflow with many of these systems can initially be very taxing and quite different than using paper records. Before these systems are purchased, they should be evaluated under real-world conditions to determine their suitability. With regard to data, the accuracy of the information that one can extract from the AIMS is directly reflected by the accuracy of its input.[137] If data are easy to input and flows directly from the EHR and the OR monitors, the data may be more accurate. Unfortunately, the manufacturers of most AIMS are concerned with replacing a paper record, providing regulatory compliance, and integrating with the EHR and less focused on the need to extract data for research or quality improvement projects. We encourage the adoption of AIMS that record physiologic data such as heart rate, respiratory rate, expired and inspired gases, and CO_2 and oxygen saturation at 10-second intervals for research purposes and for medicolegal defense.

DRUG ERRORS, BAR CODING, AND INTEGRATION

Recent studies in adult patients[139] suggest that medication errors are common in the OR.[140,141] Medication errors are a major concern in pediatric practice and one of the focuses of the Wake Up Safe Quality Improvement campaign.[142] These include wrong drug, wrong dose, wrong route, and wrong patient errors. The process of labeling a medication syringe offers multiple opportunities for medication errors by the person drawing up the wrong drug, mislabeling the syringe, and mislabeling the concentration.[143] Medication errors that result in administration of the wrong drug may be reduced by color-coded labels (e.g., red for NMBDs, blue for opioids, yellow for induction drugs) but advanced technology allows us to consider implementing bar code confirmation of a particular drug. Such systems provide accurate labeling of syringes (date, time, concentration, and initials of provider) and have had great success in reducing medication errors both in and out of the OR.[140,144–148] It does not yet appear that there is significant integration of this technology in pediatric anesthesia. In a 2014 study,[149] none of 34 children's hospital across the United States

used bar code technology to identify medications. Bar code labeling can easily be integrated into the AIMS; they can be used to label individual syringes and verify that the correct drug is being administered. We encourage the adoption of this safety feature by all pediatric anesthesiologists, a change we expect will be implemented in the near future.

PRECORDIAL AND ESOPHAGEAL STETHOSCOPES

Precordial and esophageal stethoscopes offer the opportunity for an experienced practitioner to detect cardiac arrhythmias, obstruction of the endotracheal tube, wheezing, airway obstruction, laryngospasm, and decreases in BP compared with baseline (softening of heart tones), among other critical events. Unfortunately, the use of precordial stethoscopes to monitor children in the OR has decreased during the past few decades in a trend that appears to be continuing with each successive generation of anesthesiologists. This problem is underscored by the fact that if clinicians do not use precordial stethoscopes during their training, they are very unlikely to use them upon graduation and thereafter.

The precordial stethoscope is applied to the skin with a double-sided adhesive disk. It can be placed near the apex of the heart to best hear heart sounds, at the suprasternal notch to best hear the combination of heart and breath sounds, or in the left axilla if there is a chance of inadvertent right mainstem intubation (e.g., tetralogy of Fallot repair). Nonferrous versions may be available for use in MRI, but practically speaking, practitioners are more likely to monitor the exhaled CO_2 tension than use a precordial stethoscope.

Disposable esophageal stethoscopes, often combined with a temperature probe, have supplanted precordial stethoscopes as cardiothoracic monitors. The integrated probes are bigger than a simple temperature probe, so they are preferred in children 2 years of age and older. These probes are ideally positioned in a retrocardiac manner by passing the probes down the esophagus until the volume of the auscultated heart sounds is maximized.

Several technologic advances to both the precordial and esophageal stethoscopes have reached the commercial market. A wireless version of these monitors transforms the audio signal into digital data so the "sound" is transmitted wirelessly to a receiver worn by the anesthesiologist. This allows the anesthesiologist to move about in the OR and not be tethered to the short stethoscope tubing. An important advantage of both the precordial and esophageal stethoscopes rests with the fact that they transmit sound waves mechanically and equipment malfunctions are less likely. Even when combined with pulse oximetry and capnography, the stethoscope provides great reassurance that the patient has a BP and cardiac output. *If both the noninvasive blood pressure (NIBP) monitor and the oximeter fail, but the child has strong heart tones, a technical problem likely exists with the former two monitors. However, if the NIBP and pulse oximeter fail and the heart tones are very weak, then cardiac output may be compromised and attention should be immediately focused on resolving that problem rather than troubleshooting the monitors.*

NONINVASIVE BLOOD PRESSURE MONITORING

NIBP monitoring is a mainstay of clinical care. BP cuffs should be available in all age appropriate sizes. The BP cuff should cover approximately two-thirds of the upper arm length. Many practitioners recommend similar-sized BP cuffs on the calf of the lower leg and the upper arm, but there is little evidence to support this recommendation.[150,151] Some individuals may choose to use the thigh to measure BP when the arms are not available, but this is less common. As a result of the propagation of the arterial waveform throughout the body, a BP obtained on the calf may have a slightly greater systolic and lesser diastolic pressures compared with the same values in the upper arm.[150,152] Automatic NIBP units use an oscillatory means to detect the BP. These units are capable of frequent and accurate measurements. To prevent injury to the patient it is important that the NIBP units are set to the correct size (neonate, child, adult). The correct setting will ensure that the range of inflation pressures and deflation time do not cause venous stasis or nerve compression damage. Most devices have two sets of connecting tubing: one for children and adults and one for neonates. Neonatal tubing has different connectors and complementary BP cuffs; they are not interchangeable with adult tubing. Neonatal BP cuffs typically are sized 1 through 5 and fit approximately the same number as the infant's weight in kilograms. It should be noted that the monitor must be set to the correct patient and tubing size for the algorithms to produce accurate information. Backup equipment should be available to obtain BP by auscultation if needed. However, if the NIBP signal is lost, one should immediately attribute the loss of signal to hypotension and treat appropriately (with volume and/or vasopressors) until the equipment is assessed.

ELECTROCARDIOGRAM

The electrocardiogram (ECG) is a mainstay of clinical care. For general pediatric anesthesia, three-lead monitoring of the ECG is usually sufficient to detect arrhythmias and the basic heart rate. A monitor should display a single waveform (usually lead II) and usually does not require ST-segment analyses. The typical placement of leads is white lead to right shoulder, black lead to left shoulder, and red lead to the left flank. Placement of the red lead on the left lower extremity is usually not feasible. Further, lead placement often gets changed slightly based on the surgical field. For pediatric cardiac anesthesia five-lead monitoring of the ECG is used. Five-lead ECG improves the detection of ischemia and three waveforms are usually monitored. Lead placement for a five-lead ECG is the same as three with the addition of a green lead to right flank and a brown lead (V1) to the fourth intercostal space on the right side of the chest. Detection of the QRS is automatic. Signaling of the QRS tone can be set on the monitor to come from either ECG, pulse oximetry, or arterial waveform if present. The choice depends on the surgical type as electrocautery interferes with the ECG signal. Special nonferrous ECG leads and monitors are necessary for use in MRI. Most problems with ECG monitoring occur as a result of poor contact of the leads with the patient. This can sometimes be improved by cleaning the skin first with alcohol and placing new leads. Given the interference during electrocautery and during MRI imaging, the heart rate is best determined from the pulse oximeter.

OXYGEN MONITORS

Sensors that monitor the FIO_2 are built into every modern anesthesia machine. This is in addition to fail-safe devices that detect a decrease in the pressure in the oxygen line. Oxygen monitors with alarms are necessary to prevent the delivery of an hypoxic gas mixture, but they can also be set to alarm for a high FIO_2 as well. Low FIO_2 can be an unintentional consequence of very low flow anesthesia with air-oxygen blends in a closed circle system. However, there are several circumstances when a low FIO_2 is intentional and desirable: (1) a reduced FIO_2 may be necessary in some children with congenital heart disease to reduce the oxygen saturation to balance the pulmonary and systemic blood flows, (2) during airway surgery to reduce the risk of airway fires,

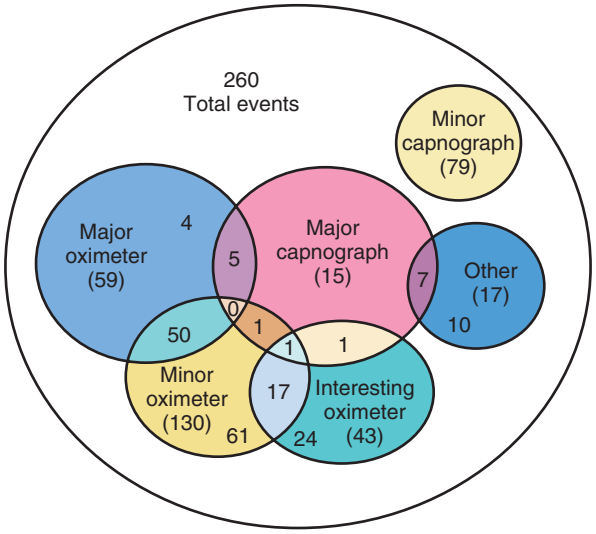
and (3) in infants and neonates to reduce the risk of retinopathy of prematurity (see Chapter 34).[153–155] It is not the FIO_2 but the child's arterial partial pressure of oxygen (PaO_2) that is important regarding retinopathy of prematurity. It is common practice to reduce the FIO_2, if otherwise safe for the neonate, to the point where the oxygen saturation measured by pulse oximetry (SpO_2) is between 91% and 95% to minimize the risk of oxygen toxicity without increasing perioperative mortality (see Chapter 37).

TEMPERATURE MONITORS

The child's temperature should be monitored throughout anesthesia to prevent hypothermia or hyperthermia. Hypothermia was a very common problem in pediatric anesthesia, particularly in neonates and infants, that has been resolved to a large extent with the adoption of forced air warmers. Hyperthermia most commonly occurs because of iatrogenic overheating and failure to decrease the temperature of the exogenous heat source in the face of an increasing body temperature. Other causes of hyperthermia include malignant hyperthermia, thyrotoxicosis, sepsis, drug overdose (cocaine, monoamine oxidase inhibitors and meperidine), and in children with arthrogryposis or osteogenesis imperfecta. In a child with malignant hyperthermia, fever is a late sign preceded by other factors, including an increase in end-tidal carbon dioxide tension ($PETCO_2$)$_2$, tachypnea, and tachycardia. Temperature can be monitored in the axilla, nasopharynx, esophagus, rectum, tympanic membrane, and the skin. Core temperature is most reliably measured on the tympanic membrane or in the esophagus. Rectal temperature is unpredictable as the tip of the probe may be lodged in stool and buffered from the true body temperature. Bladder temperature may be measured via a Foley catheter that has an integrated temperature monitor, but these catheters are sized only for older children. Skin temperature often slowly responds to changes in body temperature and is well known to underestimate the body temperature. The axillary temperature often underestimates the body temperature because the probe tip is not positioned within the axilla. In such a case, the probe measures the ambient temperature, which may be room air or the temperature from a forced air warmer (as great as 43°C). Axillary temperature may detect an increase in temperature that results from malignant hyperthermia because the deltopectoral triangle is the largest muscle group whose venous blood can be sensed with a probe in the axilla.

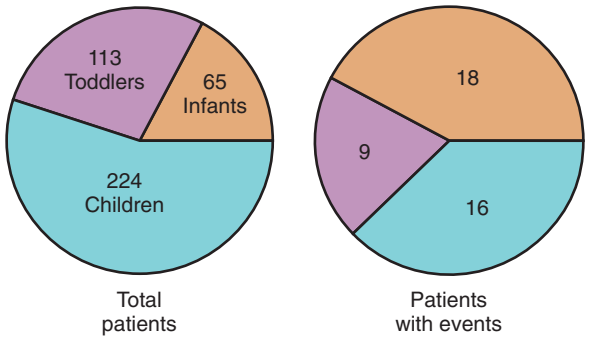
NONINVASIVE OXYGEN SATURATION MONITORS

Pulse Oximetry



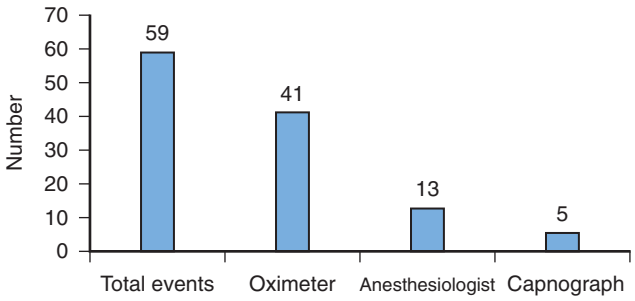
Pulse oximetry is a mainstay of clinical care in pediatric anesthesia, mandated for routine use in every anesthetic in most jurisdictions. Sensors are typically placed on the fingers and toes but can be applied to the ears or other body parts. When pulse oximeters were first introduced, clinicians needed proof that pulse oximetry was better than clinical judgment in detecting oxygen desaturations.[156,157] This notion is now uniformly accepted (E-Figs. 52.3, 52.4, and 52.5). Pulse oximeters determine the arterial oxygen saturation (SaO_2) of hemoglobin by using the absorbance of red (660 nm) and infrared light (930 nm) as it passes through tissue. The presence of two sensors allows the unit to identify blood that is moving (arterial) as opposed to the background oxygen saturation of the tissue. The wavelengths were also chosen to take advantage of the differences in the absorption of light between oxygenated and deoxygenated hemoglobin at these various frequencies. The sensors detect when the volume of the digit increases during systole by making the measurements only when the finger enlarges; the device can thus separate arterial from venous blood–hence the name "pulse oximeter." The ratio of absorbance of light is converted into an oxygen saturation using an algorithm that is proprietary to each of the manufacturers; that is, their combination of LED lights and detectors produces a certain ratio or signal and it is their own algorithm that produces the saturation value that is displayed. These algorithms are generated by producing various degrees of desaturation in adult volunteers while receiving a hypoxic gas mixture through a face mask. Arterial saturation values from 70% and greater with their paired pulse oximeter ratios are used to calibrate the algorithm. However, the algorithms were created with adult volunteers and then applied to children.

So how accurate are pulse oximeters? The largest study published comparing the SpO_2 values with SaO_2 values measured from arterial samples with co-oximetry in children had 225 subjects and 1980 samples.[158] The bias or the difference between SpO_2 and SaO_2 varied depending on the range of the saturations. SpO_2 values between 90% and 97% exceeded the SaO_2 by only 1%. However, SpO_2 values that were less than 90% exceeded the SaO_2 by 5% (with greater differences as the SpO_2 decreased). In children with some degree of lung injury, the ventilator management should be adjusted to maintain SpO_2 in excess of 90%. However, the accuracy of pulse oximeters in infants and children whose SpO_2 is less than 90% (e.g., in cyanotic heart disease, during laryngospasm) is of greater concern as palliative surgeries or the decision to intervene during an acute event is often based on the pulse oximeter saturation reading much less than 90%. Of the major manufacturers that were studied, no pulse oximeter yielded more accurate measurements than another.



A further technique used by some manufacturers to improve the accuracy of the pulse oximeter signal is to average the measurements over a period of 5 to 10 seconds. This allows the monitor to better characterize the signal produced and minimize the contribution of artifact. The significance of this averaging must be understood by the clinician during episodes of desaturation or hypoxia. For example, with difficult intubations or laryngospasm, the pulse oximeter signal will lag behind the desaturation event. This also means that an improvement in saturation will always take longer than anticipated after an open airway and ventilation have been reestablished. A study of continuous cardiac output in anesthetized children found that stroke index decreased with the severity of desaturation but this was accompanied by a compensatory increase in heart rate with maintained cardiac output; it appears that bradycardia is a relatively late sign of cardiac hypoxemia.[159]

Manufacturers are continually working to improve the algorithms and equipment to eliminate artifact that may be introduced by movement, darker skin color, poor perfusion, hypothermia, or increased ambient light. Improved algorithms and filtering have resulted in significant reductions in movement artifacts. Low perfusion and hypoxemic states provide ongoing challenges for pulse oximeter technology and some manufacturers have generated specific units and sensors to address these issues.



Pulse oximeter manufacturers have moved in two different directions to improve the accuracy of their devices. Masimo Corporation (Masimo Corporation, Irvine, CA) has developed pulse oximeters using multiple wavelength technology: the Masimo Rainbow Pulse Co-oximeters, which can provide much more information beyond oxygen saturation. The presence of additional wavelengths allows the oximeter to provide continuous readings for hemoglobin, carboxyhemoglobin, and methemoglobin. Validation of the hemoglobin measurements in various populations has been studied with varied success.[160–164] Although these devices

E-FIGURE 52.3 A total of 260 problems were observed in 153 of 402 patients studied. Major desaturation events (Spo_2 ≤85% for ≥30 seconds) and major capnograph events (esophageal intubation, kinked endotracheal tube, circuit disconnect, accidental extubation) are within the *bold circles*. Minor desaturation (Spo_2 ≤95% ≥60 seconds) and interesting events (Spo_2 ≤85 for <30 seconds) are also presented. Minor capnograph problems were simple hypercarbia ($PEco_2$ ≥60 mm Hg ≥60 seconds) or hypocarbia ($PEco_2$ ≤25 mm Hg ≥60 seconds). The total number of events that fulfilled the criteria for each category is listed in parentheses. Note that some events fulfilled criteria in two or more categories. *$PEco_2$*, expired carbon dioxide; *Spo_2*, oxygen saturation measured by pulse oximetry. (From Coté CJ, Rolf N, Liu LM, et al. A single-blind study of combined pulse oximetry and capnography in children. *Anesthesiology* 1991;74[6]:980–987.)

E-FIGURE 52.5 The pie chart on the left presents the age distribution of the 402 patients studied, and the pie chart on the right presents the number of patients in each category with a major desaturation event. Note that infants had a significantly higher incidence than did toddlers or children (P = 0.001). (Modified from Coté CJ, Rolf N, Liu LM, et al. A single-blind study of combined pulse oximetry and capnography in children. Anesthesiology 1994;74[6]:980–987.)

E-FIGURE 52.4 Fifty-nine major desaturation events were observed. Nearly 70% were first diagnosed by oximeter, 22% by the anesthesiologist, and only 8% by the capnograph. Pulse oximetry is by far the more sensitive monitor in providing an early warning of developing desaturation. (From Coté CJ, Rolf N, Liu LM, et al. A single-blind study of combined pulse oximetry and capnography in children. *Anesthesiology* 1991;74[6]:980–987.)

might not be absolutely accurate, the ability to follow them as a trend monitor during surgery offers promise. There is an additional manufacturer of a pulse oximeter that measures hemoglobin using an occlusion spectroscopy method (OrSense NBM 200 system, OrSense, Raleigh, NC). The accuracy of this device has been studied in adults, mostly for prescreening blood donors.[165–168] Unfortunately, the size of the reusable sensor may limit the use of this device in children. The ability to noninvasively measure carboxyhemoglobin and methemoglobin introduces the possibility of screening large numbers of patients as in an emergency department, bearing in mind some degree of possible inaccuracies. Further validation studies and improved algorithms continue.[163,164,169,170]

Any abnormal value as well as a suspected clinical scenario with a normal result (false negative) should be assessed with a confirmatory test. The presence of abnormal hemoglobin beyond carboxyhemoglobin and methemoglobin can, in theory, affect the accuracy of pulse oximeters,[171] although the most common types of abnormal hemoglobin (fetal and sickle cell) do not have an impact on pulse oximetry.[172–174] It should be further noted that these specialized oximeter probes are quite expensive (three to four times the cost of a normal probe) and thus have a limited role in routine pediatric care. Another advance relates to signal processing, or as Massimo termed it, Signal Extraction Technology (SET). For some manufacturers, the pulse oximeter waveform or plethysmography (commonly referred to as "pleth") is stylized and not an actual reflection of the strength of the arterial waveform. For other manufacturers, the pleth is reflective of the degree of perfusion. During inspiration, there is an increase in the venous return to the heart; during exhalation, there is a decrease in venous return. This periodic variation in venous return with respiration translates to subtle changes in the arterial pulse wave height. This effect (pulsus paradoxus) is more pronounced when there is a decrease in the central venous filling pressure (hypovolemia) or if there is a significant increase in the inspiratory force (upper airway obstruction). The newest generation of pulse oximeters has signal processing technology that can detect these variations. Hypovolemia, vasoconstriction, and decreased cardiac output can also lead to the loss of the pleth signal.[175,176] In addition to providing a visual representation of perfusion, the processing that identifies the pleth can be used to estimate respiratory rate. Taking this a step further with the Masimo SET, the Pleth Variability Index (PVI) is an algorithm used to predict patients whose cardiac output might benefit from fluid boluses. The PVI technology has been investigated and the results show promise in adults and children, although there remains some uncertainty in this regard.[177–179]

Covidien (Boulder, CO) has taken its Nellcor pulse oximeters in a different direction to improve the accuracy of their devices. Rather than producing multiple wavelengths of light, with its OxiMax technology Nellcor has embedded a digital memory chip onto the sensor. This chip contains the calibration and operating characteristics of that sensor that should in turn improve the accuracy. There is some variability in the wavelength of light produced by any light-emitting diode (LED). This chip allows the specific wavelength information to be stored and relayed to the device to use the most accurate algorithm. Nellcor pulse oximeters have respiratory rate monitoring, but they do not appear to yet have an algorithm to assess fluid responsiveness.

In addition, miniaturization and manufacturing of integrated circuits have reduced the size of pulse oximeters to fit on a finger. They have also been integrated into many watches and fitness devices. A number of manufacturers have rushed to market with these devices, although their accuracy has not been tested. Some clinicians are now using these devices for short-distance transports to the recovery room in place of no monitor at all. Whether this will improve clinical outcomes or whether these devices will replace those from the major manufacturers remains to be determined.

REFLECTANCE OXIMETRY

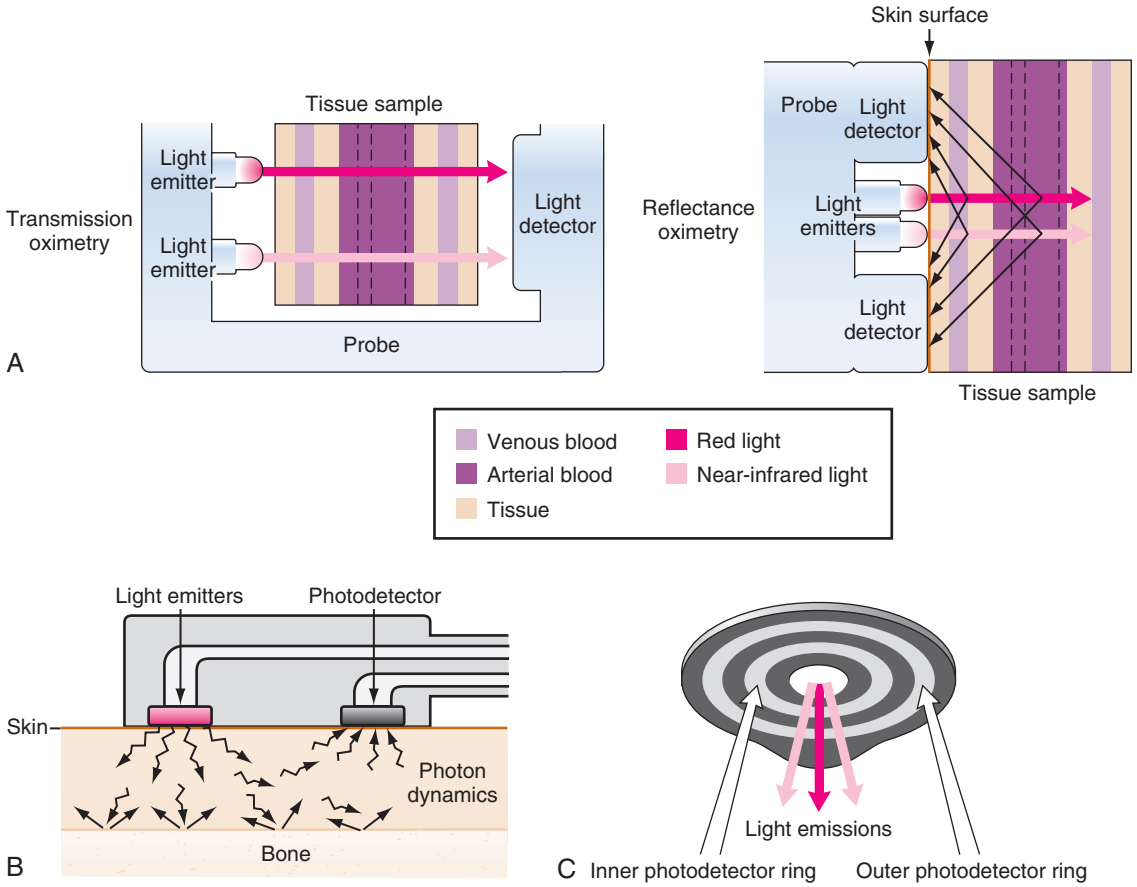
Reflectance oximetry was first created to improve oxygen saturation data in difficult clinical conditions, such as decreased perfusion, movement, and conditions in which optimal sites for standard transmission oximetry probes may not exist (e.g., burns). The technology behind reflectance oximetry involves the emission of multiple wavelengths of red and infrared light that are sensed in two or more photodetectors located a distance away from the diodes on the same probe sensor (Fig. 52.7). These devices measure reflected rather than transmitted light. The technology used to create these oximeter probes permits usage on a flat surface such as the forehead and on the fetal scalp. The forehead devices have had the largest use among pediatric anesthesiologists. Studies of reflectance oximeters in general demonstrate that these devices are more susceptible to erratic measurements when the probe is placed directly over an artery and vein.[180,181] Some potential advantages to using reflectance oximetry on the forehead include better signals during conditions of poor perfusion, lack of motion, and faster response time than conventional peripheral oximeter probes.[182,183] However, possible disadvantages include a high signal dropout rate (no measurable signal) and poor accuracy, often measuring lower than finger transmission oximetry, particularly in cases of venous congestion (e.g., Trendelenburg position or situations that impede venous return). Several studies report good correlation between concurrent measurements of oxygen saturation comparing reflectance oximetry on the forehead[184,185] and around the chest of premature infants[186] compared with extremity pulse oximetry and arterial co-oximetry measurements; these studies also report a clear dropout rate.

The Lifebox Monitoring Initiative

We have long recognized the improvement in patient safety with the use of pulse oximetry technology and its use is ubiquitous in developed nations. Unfortunately, in developing countries the availability of pulse oximetry during general anesthesia cannot be guaranteed (see Chapter 51). In fact, it is estimated that 5 billion people do not have access to safe surgery with approximately 70,000 ORs without basic anesthesia equipment and a shortage of 1 million surgeons, anesthesiologists, and obstetricians worldwide.[187,188] The anesthesia-related death rate is 100 to 1000 times greater than in developed countries.[189] Pulse oximetry is now part of the Safe Surgery Saves Lives project from the World Health Organization.[190,191] The Lifebox Foundation was formed in 2011 as a global patient safety initiative to provide pulse oximeters and education to developing countries.[192] The device has been shown to be accurate in healthy volunteers[193] and it has improved safety under anesthesia for thousands of individuals.[189,194,195] A donation of $250 USD to the Lifebox Foundation will purchase one device for donation, which includes a universal age probe, a pediatric probe for neonates, a multicountry charger, and multilanguage educational DVD; further information is available at www.lifebox.org.

NEAR-INFRARED SPECTROSCOPY

Near-infrared spectroscopy (NIRS) is a noninvasive, optical technology that bears similarities to pulse oximetry in that it uses



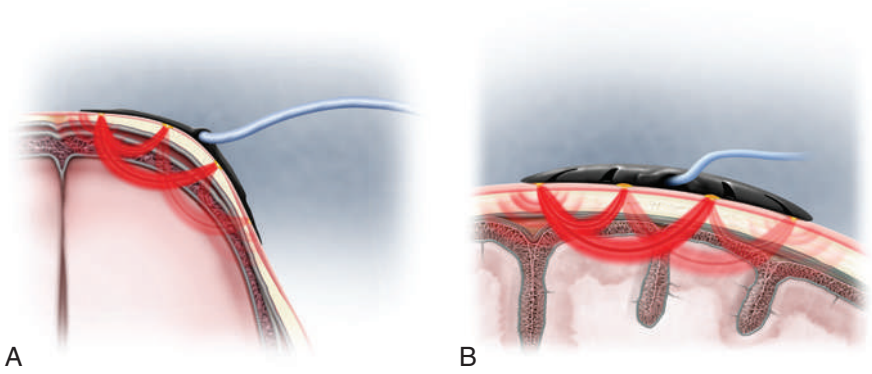


FIGURE 52.7 A, Comparison of conventional transmission pulse oximetry with reflectance oximetry. Note that with conventional oximetry the light detector is located directly opposite on the other side of a digit and detects light transmitted through the digit; with reflectance oximetry the light detector is located next to the light emitters and detects the light reflected back through and from the tissues. **B,** The typical configuration of a reflectance oximeter. **C,** Another configuration, in which several light detectors are located at different distances from the light emitters. In addition, reflectance oximeters may emit light in more than just 2 wavelengths, which is typical of conventional transmission pulse oximeters. (Modified from Kugelman A, Wasserman Y, Mor F, et al. Reflectance pulse oximetry from core body in neonates and infants: comparison to arterial blood oxygen saturation and to transmission pulse oximetry. *J Perinatol*. 2004;24[6]:366–371; and Keogh BF, Kopotic RJ. Recent findings in the use of reflectance oximetry: a critical review. *Curr Opin Anesth*. 2005;18[6]:649–654.)

the relative absorption of near-infrared light, 700 to 900 nm, through biologic tissues to determine tissue oxygenation (E-Fig. 52.6). Oxyhemoglobin and deoxyhemoglobin absorb light at different frequencies, and the use of a probe that emits and detects different frequencies of near-infrared light can be used to estimate tissue oxygenation. In pediatric anesthesia, this device has been widely used to measure "regional" cerebral oxygen saturation (rSO_2) for children undergoing and following congenital heart surgery.[196–199] It is also used in this same population to detect renal perfusion[200] and has been shown to predict the development of acute kidney injury.[201,202] NIRS has also been used to detect ischemia in neurosurgery,[203] spine surgery,[204] kidney transplant[205,206] as well as tissue free flaps.[207] NIRS may have applications in an ICU setting,[208] following brain injury[209] and during the use of therapeutic hypothermia.[210] Pulse oximetry requires the measurement of the pulsatile (arterial) component of the total light transmitted by the biologic tissue. Because NIRS does not require the subtraction of the pulsatile component, the signal is more than 100 times stronger and unaffected by poor perfusion compared with pulse oximetry. NIRS is susceptible to motion artifact and ambient light noise, although software algorithms have significantly decreased these sources of error. A probe placed on the child's forehead (or other tissue beds) measures the concentration of oxyhemoglobin and deoxyhemoglobin in the tissue underlying the probe. The NIRS device functionally measures the oxygenation of blood in the underlying tissues, including blood in the arterioles, capillaries, and venules. The majority (approximately 85%) of the signal originates from the venules; skin and bone and extracranial blood absorb only limited amounts of light, which is subtracted from the signal and does not have a significant impact of the measurement in infants and children. NIRS thus measures the oxygen saturation in venous and arterial blood and represents an average saturation across blood vessels and tissue. In cerebral oximetry, the oxygen saturation of the blood in the tissue (i.e., between the sending and emitting probe) depends on factors that affect oxygen transport, including cerebral blood flow (arterial partial pressure of carbon dioxide [$PaCO_2$]), hemoglobin saturation, hemoglobin–oxygen binding affinity, central venous pressure, and oxygen saturation in the arterial blood. Therapies aimed at improving oxygen delivery or

E-FIGURE 52.6 The pediatric clinical application of near-infrared spectroscopy relies on spatial resolution to extract surface tissue measurements, thereby isolating the target tissue in this image of the neonatal cerebral cortex. The depth of measurement is resolved by the spacing of the light-emitting and light-receiving elements. Spatial resolution is illustrated in this diagram as arcs of red light traveling between light emitters and light receivers. Note that the short path measurements **(A)** correspond to intervening tissues, and the long path measurements **(B)** correspond to the cerebral cortex. Light returned by the short path is deducted from total returned light, isolating the cerebral cortex. (Courtesy Nonin Medical, Plymouth, MT.)

decreasing oxygenation consumption by the brain will potentially increase cerebral oxygenation (rSO_2).[211]

There are a number of cerebral oximeters on the market: Equanox (Nonin Medical, Plymouth, MN); Fore-Sight (Casmed, Branford, CT); Invos (Covidien); and NIRO-200NX (Hamamatsu Photonics, Hamamatsu City, Japan). The performance of these NIRS devices has been reviewed[212]; they are able to detect episodes of desaturation but their accuracy may vary widely. In turn, they may be better suited to monitor trends in cerebral and tissue oxygenation. There have been a few new developments, one of which is Nonin Medical's release of their SenSmart, which incorporates both cerebral and reflectance pulse oximetry in the same device. All manufacturers now offer sensors for infants and children. Normal regional cerebral oxygen saturation (rSv_2) is believed to be between 60% and 80%.[213] The range of rSO_2 has been shown to vary in infants and children with congenital heart disease based on their anatomic lesion as well as their arterial saturations[214,215] and these values can be much less than those in healthy children. In controlled hypoxic-ischemic states in animals, electroencephalogram (EEG) slowing and increased tissue lactic acid levels occur at rSO_2 between 40% and 45%. The EEG becomes flat at rSO_2 between 30% and 35%, and if the cerebral ischemia is protracted, it may be associated with tissue infarction.[216] One other point that requires emphasis is that rSO_2 for cerebral oximetry can be greatly influenced by $PaCO_2$; thus emphasis should be on values during steady-state ventilation. These devices require a period of stabilization at a steady state to be accurate and cannot be considered as beat-to-beat monitors.

NIRS technology has important limitations. These monitors measure only the saturation in tissue below the probes, which reflects focal tissue oxygenation or ischemia. If the probe is placed on the forehead, it will reflect the state of the tissue in the frontal cortex and may not reflect other areas of the brain. The same would be true of renal oxygen saturations. While the kidney is the organ in the flank with the greatest oxygen extraction, all the tissue in that area contributes to the signal. We cannot therefore interpret all decreases in "renal" NIRS as reflecting a global acute kidney injury. One final issue remains with NIRS monitoring. We had hoped that NIRS would provide real-time guidance of regional tissue oxygenation and permit study of the effectiveness of interventions to improve the oxygenation. Research has shown a potential association between reduced saturations and outcomes.[197,198,200–202] However, there is limited information linking any interventions to outcomes. As suggested by recent review articles,[217,218] further research and improvements in NIRS technology are needed to clarify the role of regional tissue oximetry in pediatric patient management.

CARBON DIOXIDE ANALYZERS

Mainstream and Sidestream Analyzers

The most commonly used gas monitor is the infrared CO_2 monitor. This monitor is particularly useful in teaching about ventilation, CO_2 elimination from alveoli, as well as airway and ventilator management. Two configurations of infrared CO_2 monitors are available. They differ only in the location of the CO_2 analysis: (1) the sidestream analyzer, in which expired gas is aspirated from the anesthesia circuit and analyzed remotely; and (2) a mainstream analyzer, in which the gas is analyzed by an optical sensor within a cuvette just proximal to the elbow of the breathing circuit. Sidestream analyzers are lighter and less cumbersome than mainstream analyzers because the former involves no additional pieces to be inserted into the breathing circuit. Sidestream analyzers aspirate gas through a narrow-gauge flexible tube inserted into the breathing circuit at the elbow. The gas sampling line and water trap can become obstructed with water or secretions, requiring replacement of the parts. Mainstream gas analyzers are less often obstructed with secretions, but the analyzers are heavy, and if a small-ID tracheal tube is used, the analyzer may kink the tracheal tube, resulting in acute airway obstruction. Most OR monitors today use sidestream sampling whereas most ICU monitors use mainstream sampling. The current generation of sidestream monitors has improved precision that reduces the gas sampling rate to just 50 mL/minute and excellent accuracy even with small rapid tidal volumes.

The presence of CO_2 is the gold standard to ensure that the tracheal tube has been inserted within the trachea. In the OR this is generally achieved using capnography but during code situations, this is achieved using litmus color-changing devices (see E-Fig. 39.4). If no expired CO_2 is detected after a presumed tracheal intubation, one must assume that the tracheal tube is in the esophagus, or during a code it is presumed that there is inadequate CO_2 in the exhaled breath because of inadequate chest compressions. One should consider that the lack of CO_2 detected may be due to equipment malfunction such as obstruction of the sampling line[218] or severe bronchospasm. However, the prudent course of action is to first reexamine the glottis with a laryngoscope to determine whether the tube appears to pass through the cords and if it does, consider alternative explanations for the lack of CO_2. This would be particularly wise if the intubation had been difficult in the first place. Alternately, some remove the tracheal tube without reexamining the airway, mask ventilate the lungs, and reassess the situation. It is possible to have CO_2 present on capnography for one or two breaths if the tracheal tube was inserted into the esophagus. This can occur if the stomach had been distended by manual ventilation or crying before tracheal intubation, or if carbonated soft drinks were present in the stomach, CO_2 could be transiently detected immediately after an esophageal intubation.[219,220] This latter event should be very rare with appropriate nil per os (NPO) guidelines. If there is expired CO_2 detected after an esophageal intubation, the CO_2 peak tension will be very low and will decrease rapidly with successive breaths after placing the tracheal tube. Although it is beyond the scope of this chapter, it should be noted that the $ETCO_2$ value can be an indicator of effective cardiopulmonary resuscitation and correlates with outcome (see Chapters 39 and 40).[221–223]

Measurement of expired CO_2 tension is also helpful in detecting other clinical problems. Clinically important air embolism causes a transient but marked reduction in CO_2 excretion because the lungs are ventilated but not perfused; hence dead space is suddenly increased (see Chapter 26, Figs. 26.6 and 26.7). Quantitative measurement allows detection of the change in circuit flows, disconnections, tracheal tube kinking, or accidental extubations.[224] Capnography also signals the earliest clinical sign of an acute malignant hyperthermic reaction and the effectiveness of treatment (see Fig. 41.3).[224–226] The CO_2 waveform may also assist when diagnosing other types of respiratory difficulties (Fig. 52.8).[227] Bronchospasm and its response to treatment may be identified by changes in the CO_2 waveform; bronchospasm causes an increasing slope of the plateau during expiration, and resolution of the bronchospasm restores the plateau to the horizontal (see Fig. 13.9). A slow-speed recorder also allows trending, which we have found particularly useful in diagnosing small circuit leaks, partially kinked tracheal tubes, and rebreathing. In children free from pulmonary shunts, the arterial and alveolar CO_2 values

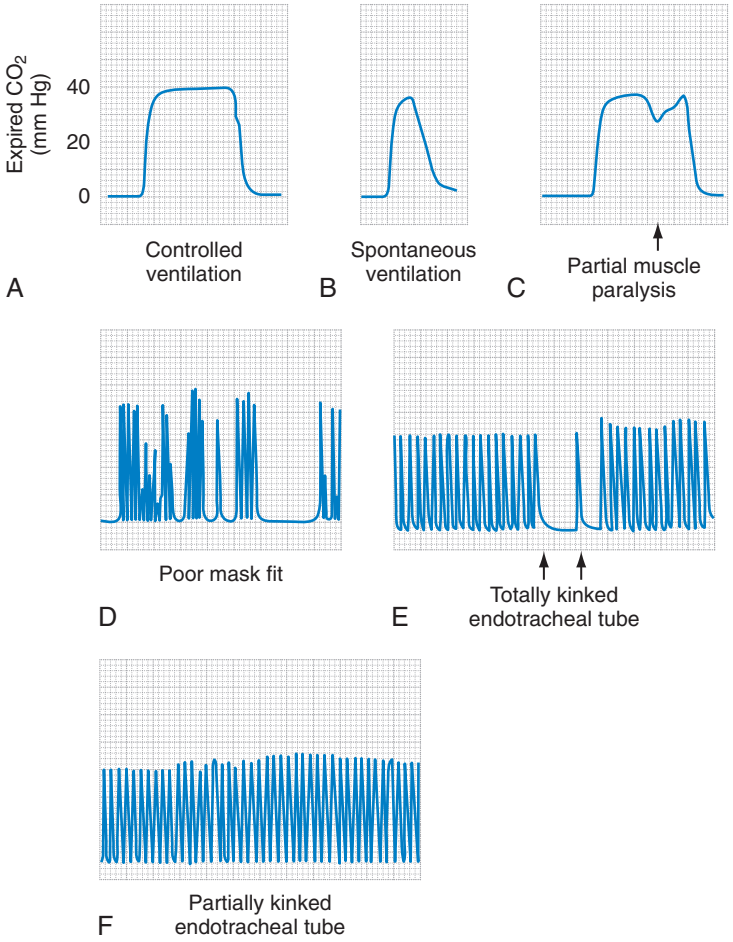

FIGURE 52.8 Expired carbon dioxide (CO_2) tracings (**A, B, C** = rapid recording; **D, E, F** = trend recording). **A,** Normal waveform with a long alveolar plateau indicating good alveolar gas sampling during controlled ventilation. **B,** Spontaneous ventilation with rapid respiratory rate; minimal alveolar plateau. **C,** Patient with partial muscle paralysis; note the change in the CO_2 waveform (*arrow*) during inspiration, which took place during the ventilator expiration. **D,** Poor mask fit with many periods when no CO_2 was detected; this also results in many false alarms. **E,** A totally kinked endotracheal tube was detected by the absence of a CO_2 waveform (*between arrows*); a similar trace could result in a circuit disconnect, esophageal intubation, or a simple pause in respiration. **F,** A partially kinked endotracheal tube may result in a slow change in peak expired CO_2; a similar change could be noted with an unrecognized endobronchial intubation, change in pulmonary compliance, circuit leak, or increase in metabolic rate. The reverse would occur with air embolism, hypothermia (decreased metabolic rate), improved compliance, or, increased fresh gas flow without compensatory change in ventilator settings. (From Coté CJ, Liu LM, Szyfelbein SK, et al. Intraoperative events diagnosed by expired carbon dioxide monitoring in children. *Can Anaesth Soc J.* 1986;33[3 Pt 1]:315–320.)

($PaCO_2$ and $PACO_2$ [as reflected by a true end-expired sample]) should be within 2 to 3 mm Hg. The severity of a shunt or the diagnosis of a shunt may be made if this difference is greater than 5 mm Hg and if the CO_2 sensor is properly calibrated. Children with significant pulmonary problems such as inhalation injury may have larger differences between arterial and expired CO_2 values. In such cases, expired CO_2 monitoring may be used only for trending and as a disconnect alarm.[228] Expired CO_2 will be more accurate in assessing the adequacy of ventilation in children whose trachea is intubated compared with airway management with a facemask. However, even with a facemask the presence of bronchospasm and airway obstruction can be identified. During mechanical ventilation with an LMA the accuracy of $ETCO_2$ monitoring approaches that of an endotracheal tube.[229]

TRANSCUTANEOUS CARBON DIOXIDE MEASUREMENT

Transcutaneous partial pressure of CO_2 ($PtcCO_2$) monitoring has been available for many years for use in preterm and full-term neonates but never achieved widespread acceptance in pediatric anesthesia. The monitor includes a heating element and a variant of the Severinghaus-type CO_2 electrode. Heating the skin increases capillary blood flow as well as the PCO_2 and oxygen. The skin becomes more permeable to diffusion of gas, and the gas tensions are measured by the sensors. CO_2 is calculated using a change in the pH sensed by the electrode. In turn, pH is proportional to the logarithm of the change in CO_2. Previously transcutaneous monitoring was limited because of difficulties preparing and fixing the sensor, preparing the skin, needing to rotate the sensor to prevent burns, calibration time, and concerns for reliability. New

transcutaneous monitors have eliminated some of the earlier technical difficulties. These newer versions can limit the temperature so they are less likely to burn children's skin; they remain calibrated for greater intervals, and they appear to be more accurate. One study reported an acceptable correlation with arterial CO_2 among several models[230]: TINA TCM3 (Radiometer, Copenhagen, Denmark); TINA TCM3® (Radiometer, Copenhagen, Denmark), and SenTec (Therwil, Arlesheim, BL, Switzerland). Because the skin must be heated, the CO_2 values are greater than the local arterial values owing to increased local metabolic production; these systems correct for this increase.

The most common use for transcutaneous monitoring has been in intubated premature neonates and small infants because the dead space of a mainstream CO_2 cuvette greatly increases the dead space for these small infants. Another circumstance for which transcutaneous monitors are used is for those who require high-frequency oscillatory ventilation. In this case, it is not possible to monitor $ETCO_2$. There are also some clinical conditions in which $ETCO_2$ monitoring can be inaccurate and a transcutaneous monitor may be helpful. These include uncuffed tracheal tubes with a large gas leak, high respiratory rates, significant cardiopulmonary disease associated with increased dead space and/or right-to-left shunt, and conditions of frequent movement. One clear disadvantage of $PtcCO_2$ is the lack of breath-to-breath monitoring capability for apnea and disordered breathing provided by end-tidal capnography.[231] $PtcCO_2$ monitoring may have a role in anesthetized children with severe pulmonary disease or other pathology that prevents accurate $ETCO_2$ measurement. These devices work less well where there is thickened skin or significant subcutaneous edema. There may be a role for these devices in the monitoring of nonintubated patients who are receiving sedation. However, nasal cannula sidestream CO_2 monitoring will provide more immediate identification of apnea or obstruction.

BLOOD LOSS MONITORS

Close observation of the surgical field is the best single monitor of blood loss. A small-volume trap on the suction line before the major evacuation trap is particularly useful to quantify blood loss in small children. Surgical sponges are often weighed on a dietary scale immediately after they come off the surgical field, assuming that 1 g of weight is equivalent to 1 mL of blood, to assess the blood soaked up by the sponges. This minimizes the evaporative losses from the sponges. Point-of-care testing devices such as the HemoCue (HemoCue America, Brea, CA) and the i-STAT (Abbott Point of Care Inc., Princeton, NJ) rapidly assess hemoglobin values but each may underestimate the hematocrit at lower values. In addition to point-of-care testing, many ORs have blood gas analyzers such as the GEM Premier 3000 (Instrumentation Laboratory, Bedford, MA) that can provide hemoglobin measurements. The accuracy of all of these devices is likely sufficient to follow trends and make decisions about the need to transfuse blood,[232,233] certainly in the face of ongoing blood losses. Noninvasive hemoglobin measurements using multiwavelength pulse oximetry in general may be useful only for trend monitoring.[160–163] Overall, these noninvasive devices underestimate hemoglobin values and may err up to 1 g/dL, thus limiting their value during rapid blood loss where more accurate measurements are essential.

NEUROMUSCULAR TRANSMISSION MONITORS

Measuring the indirectly elicited twitch response is indicated when neuromuscular blocking agents are used (see Chapter 7). Residual or incomplete reversal of neuromuscular blockade is a common reason that adult patients are delayed in leaving the OR, may have prolonged postanesthesia care unit (PACU) recovery times, and develop respiratory complications in the early postoperative period.[234–236] Evidence confirms that even experienced anesthesiologists cannot assess the decrement in the train-of-four (TOF) accurately without some other monitor. Clinical signs (e.g., sustained head lift) are often difficult to perform in younger children but even if they are, they may fail to uncover significant residual blockade, introducing the potential for respiratory complications.[235,236] In neonates and infants, flexion of the hips is analogous to the clinical signs of recovery of neuromuscular blockade in adults.[237]

Two types of neuromuscular monitoring devices are available for clinical use: mechanomyography and acceleromyography. Mechanomyography models use constant current nerve stimulation. These devices self-calibrate and then deliver a constant stimulus (30-70 mA) to the skin regardless of other influences. Failure to deliver a supramaximal stimulus may result in overestimation of twitch suppression. The power should generally be left off between readings to avoid possible injury secondary to prolonged, repetitious exposure to electric current. Acceleromyography uses a piezoelectric sensor to quantify the acceleration (proportional to force) of the thumb and convert it to an electrical signal. There is considerable disagreement in the published literature as to which of these devices is most accurate.[238–240] Monitors based on acceleromyography are becoming more commonly available and some consider these to be more accurate than mechanomyography-based TOF monitors. However, these monitors are not user-friendly and difficult to use in infants because of the small arc of the displaced thumb. Others regard mechanomyography as more accurate because it is less influenced by external disturbances; that is, it does not go out of calibration.[241] Mechanomyography is currently the simplest and most useful clinical monitor to assess the degree of paralysis when using NMBDs in infants and children (see also E-Figs. 7.14, 7.15, and 7.17). The TOF does not require recording capability or baseline measurement because it compares only the fourth twitch with its own internal standard, the first twitch.[242] The unit may also be used with depolarizing NMBDs, monitoring only the first twitch amplitude. A significant decrement (>50%) between the first and fourth twitch in this context suggests phase II blockade (see E-Fig. 7.15).[243]

Needle electrodes should not be used in children because they may cause bleeding, infection, burns, or nerve injury; current density may be very high owing to the limited contact surface and the resistance of surrounding skin. Self-adhesive electrodes designed specifically for twitch monitors are available, but they are unnecessary, expensive, and tend to be too large for infants and small children. A reasonable alternative is a pair of infant-sized ECG electrodes. The choice of monitoring location depends on the nature of the surgery. It is preferable to select a site where a motor nerve is close to the body surface and its associated muscle group is available for observation. The most common site is the ulnar nerve in the forearm, observing the thumb movement (adductor pollicis brevis); this is the standard site for most research reports. Quantitating the response of other motor nerves is less reliable. Using the facial nerve may result in false-positive responses because the muscles may be directly stimulated, potentially leading to an overdose of NMBDs.

PROCESSED ELECTROENCEPHALOGRAM MONITORS

We anesthetize children daily, often with the use of regional anesthesia as a supplement to general anesthesia. It would be ideal

if we were able to monitor the effect of our anesthetic agents on the brain to ensure an adequate depth of anesthesia. Clinically, we have discrete endpoints such as loss of consciousness or limb movement under anesthesia, but we would prefer a monitor that examines awareness and other brain functionality. Therefore as anesthesiologists we may use the processed electroencephalogram (pEEG) in an attempt to provide this information.[244,245] We use a pEEG to reduce the amount of information displayed. A number of different devices are available to gather and present information from an EEG to the clinician. The most commonly used pEEG monitor is the Bispectral Index monitor (BIS Brain Monitoring System, Covidien, Boulder, CO). With the BIS monitor, a sensor is placed on the forehead that detects EEG signals from the frontal lobe of the brain as well as from the frontal motor cortex. The information received is converted into a dimensionless number between 0 and 100. The value of 100 represents a patient who is fully awake and value of 0 represents electroencephalographic silence or complete (isoelectric) suppression.

Like the algorithms for pulse oximeters, the algorithms generating the BIS values are proprietary and based on data from adult subjects, not infants and children. Furthermore, the algorithm was developed during isoflurane and propofol anesthesia, not sevoflurane, the latter having an EEG profile that differs from the former anesthetics. Although there are BIS sensors in pediatric sizes, the EEG changes with both age and development undermine the reliability of BIS values in children, particularly in infants younger than 1 year of age.[246–249] The BIS values in children are affected by several factors. Values are lower in children with developmental delay[250,251]; halothane yields different values from sevoflurane at equipotent MAC concentrations; the pEEG paradoxically increases with values of expired sevoflurane greater than 3%[252–254]; and adjuvant drugs such as opioids and benzodiazepines have variable effects.[255,256] N_2O does not change the BIS value,[257] although it is partially additive to the MAC of insoluble inhalation anesthetics in children; for some devices N_2O actually increases the reported number value. Loss of consciousness with dexmedetomidine as an adjunct to propofol is reported to occur at greater BIS values than propofol alone[258]; ketamine also paradoxically increases the BIS value.[259] Curiously, NMBDs directly interfere with the BIS readings in adults; that is, both succinylcholine and rocuronium decreased BIS readings immediately from values in the mid-90s to mid-80s and 70s and then after about 4 minutes to the 40s and 50s for seconds to longer than 10 minutes.[260] We suspect that the same holds true in children. Accordingly, pEEG signal profiles differ in children according to age and the anesthetics administered, rendering interpretation of the metric confusing and less reliable than it is in adults.

Several other pEEG monitors are clinically available.[261] The SedLine brain function monitor from Masimo refers to its pEEG as the Patient State Index (PSI). The SedLine EEG sensor has four active leads to collect information from both the left and right frontal lobes. The monitor displays a single dimensionless number, a density spectral array, or spectrograms of right and left brain activity and four channels of the bilateral EEG waveforms. The pEEG monitor from Narcotrend (Narcotrend-Gruppe Hannover, Germany) shows the raw EEG, a letter A-E indicating the stage of anesthesia, a dimensionless number, and a cerebrogram. The Response and State Entropy monitor from General Electric (GE Healthcare, Helsinki, Finland) integrates the frontal EEG and electromyography signals to produces its value. Entropy is the measure of irregularity in the EEG and electromyography signals. With anesthesia, the EEG and motor activity decrease and the entropy decreases in parallel.

To recommend the use of pEEG monitoring for most pediatric anesthetic cases, we must be able to demonstrate that such use is reliable, predictable, and associated with a significant benefit or a reduction in adverse events. A number of outcomes have been studied in children and adults. In theory, BIS monitoring might prevent too great of a depth of anesthesia during surgery; the tangible benefits are a reduction in the time to emergence, extubation, and PACU stay. In addition, such monitoring may decrease PONV as well as the amount of anesthetic agent used. Given the age-related differences in anesthetic outcomes, adult studies have also focused on the potential for reduction in delirium and cognitive decline.[262] Alternatively, the use of BIS monitoring would ensure a sufficient depth of anesthesia to prevent the possibility of intraoperative awareness. Thus on the one hand, an adequate depth of anesthesia is achieved, whereas on the other, a more rapid emergence may be established. BIS monitoring has been used to decrease the time to emergence in adults[263] and children,[264] although this has been refuted in another study.[265] In adults, BIS monitoring has decreased PONV[266]; no similar studies have been forthcoming in children. A meta-analysis showed a modest reduction in the consumption of anesthetic, PONV risk, and PACU time for adult ambulatory surgery but the cost savings were not greater than the electrodes and the monitors.[267] One additional issue that affects whether pEEG monitoring shows benefit is the type of anesthetic delivered; the only drug whereby pEEG provided consistent proven relationships with depth of anesthesia was propofol.[268–271] BIS monitoring may have its greatest value as a monitor of depth of anesthesia during TIVA, for which an end-tidal anesthetic concentration for propofol is not currently available, although this may change in the future.[272] It remains unclear if this is true in younger children but certainly it may provide value in teenagers undergoing spinal instrumentation when motor evoked potential monitoring is required.

The use of cerebral monitoring to prevent intraoperative awareness in adults has been studied in several trials. The B-AWARE Trial (2004) showed a decrease in awareness with BIS monitoring.[273] The B-Unaware Trial did not show a decrease in risk of awareness.[274] The BIS or Anesthesia Gas to Reduce Explicit Recall Clinical Trial (BAG-RECALL, 2008) failed to confirm the superiority of the BIS over end-tidal anesthetic concentrations to prevent awareness.[275] The Michigan Awareness Control Study (MACS) (2012) was stopped for futility.[276] The TIVA Trial (2011) was intended to demonstrate the differences between inhaled anesthetics and TIVA, wherein you can monitor depth of anesthesia reasonably well with end-tidal anesthetic gas concentrations. The TIVA Trial (2011) concluded that BIS monitoring prevents awareness during TIVA,[277] but a secondary analysis of the data showed that there was an effect of midazolam on the participants (amnesia of the operating room in the B-Unaware and BAG-RECALL trials).[278] In hospitals where patients receive midazolam in the holding area, the majority do not remember the OR.

A smaller body of literature regards the risk of awareness for children undergoing anesthesia. In 2011, a secondary analysis of five pediatric cohort studies[279] was published investigating awareness.[280–284] The multivariable regression analysis showed that maintenance of anesthesia with N_2O and the use of a tracheal tube were independently associated with awareness, both curious findings since the former confers amnesia and the latter implies use of an inhalational anesthetic (paralysis is infrequently used in pediatric anesthesia). Interestingly, the incidence of awareness

in these cohort studies averaged 0.74%, a frequency that exceeded the 0.1% to 0.2% reported in adults by severalfold.[285,286] In contrast to the adults who experienced awareness, none of the children in the earlier cohorts who had awareness reported distress, although 50% reported distress in the 5th National Audit Project (NAP5) recently.[280,287–289] To date, there is no evidence that pEEG devices decrease the frequency of awareness in children as 70% of the events in one report occurred at induction or emergence when the depth of anesthesia may not have stabilized.[289] The adult literature would indicate that there might still be a role for monitoring of pEEG in patients who are at high risk for recall (e.g., trauma patients and obstetric patients who require general anesthesia). A case could be made for their use in pediatrics—for example, for adolescents undergoing posterior spine fusion often with a TIVA anesthetic that the clinician must adjust during the case. In most instances, these patients are unparalyzed and monitored with motor evoked potentials, which requires deep levels of IV anesthesia to prevent movement. By the completion of surgery, recovery may be protracted because of the large amount of propofol infused, unless the dose was adjusted based on a pEEG monitor. Alternately, the anesthetic may need to be adjusted to perform a wake-up test and this too may be protracted if excess anesthesia had been administered. The use of pEEG monitoring or direct feedback from a skilled neurophysiologist who was monitoring the child can provide an indication of the depth of anesthesia. There are other potential cases for which we could consider the use of pEEG monitoring such as neuroanesthesia and otorhinolaryngologic procedures. In certain procedures, placement of the monitors on the forehead could interfere with the surgical site or sterile prep.

Several other issues raised in a recent editorial identified the need for more specific outcomes after pEEG monitoring to clarify potential benefits in children.[290] Currently, it appears that our outcomes focus on the times to removal of a tracheal tube, discharge from the PACU, or the frequency of adverse events. The numbers of patients needed to study or treat to prevent an adverse outcome that is extremely rare are exceedingly large, posing challenges in conducting such studies. Similarly, if we wish to monitor brain function during anesthesia, we may prefer to monitor an index of nociception.[291] The pEEG devices available today are limited to frontal EEG and motor movement and not to detect nociception. New devices under development will be able to monitor the entire brain but they remain experimental at this time.

CONTINUOUS CARDIAC OUTPUT MONITORING

Continuous cardiac output monitoring for anesthesia and critical care has great potential value in some patients. Multiple physiologic, pathophysiologic, and critical events and surgical interventions can affect preload, afterload, cardiac contractility, and heart rate and therefore decrease cardiac contractility and cardiac output (CO). Physicians have few monitors at their disposal to measure cardiac output or systemic vascular resistance non-invasively.[292–294] The next generation of monitors that could greatly advance the care of children may be devices that could accurately continuously assess CO and other indicators of cardiac function such as stroke index, cardiac index, and contractility. The ideal device would be accurate for both individual and trend measurements compared with a gold standard, would be minimally or non-invasive, cheap, portable, and independent of operator technique and experience. Ideally, the accuracy of the device should be unaffected by changes in patient age and size, developmental physiology, position or nature of the procedure (preterm infants to teenagers). Most current continuous cardiac output monitors do not fulfill all of these criteria.

Multiple different technologies that have been developed to improve CO measurement. These technologies are driven by the needs of the adult anesthesia and critical care market and are subsequently applied to children. In some instances, this has been easily accomplished, whereas in others the physiology and size varies so dramatically in children that they could not be applied. Several techniques may be used to measure CO: indicator dilution, evaluation of the arterial pressure waveform, ultrasound, direct or indirect Fick method, and variations of bioimpedance.[295–299] These devices must be developed with children in mind regarding their size, accuracy of measurements for values in the pediatric range, and integration in the OR for children.

The classic gold standard for the measurement of CO in humans is the direct Fick method. In this method, oxygen consumption ($\dot{V}O_2$) must be measured directly. The oxygen saturations of arterial and venous blood are measured to calculate arterial oxygen content (C_aO_2) and venous oxygen content (C_vO_2), respectively. Cardiac output is calculated using the formula:

$$CO = \dot{V}O_2/(C_aO_2 - C_vO_2)$$

Measurement of oxygen consumption at the bedside is exceedingly difficult. The patient's trachea must be intubated without an air leak around the ETT. A second gold standard for the measurement of CO is the pulmonary artery thermodilution (PAT) catheter. This method requires a catheter placed from a central venous location through the right atrium and ventricle into a pulmonary artery. Successful placement can be technically difficult, is associated with risks (embolism, pneumothorax, hemothorax, chylothorax, cardiac tamponade), and is infrequently used in the PICU. Pediatric use is now confined to limited cardiac surgical populations and during cardiac catheterization. This rare use limits the pediatric population that is available for comparison with data from new CO monitors and the information provided by PAT. Because of the limited use of Fick dilution in children, a number of studies have compared a new method to measure CO with another new technique, which is not a gold standard. Such comparisons limit the validity of the new technique. For devices that may be used for neonates, the accuracy of the CO monitors is usually confirmed in animal studies using ultrasonic flow probes placed around the pulmonary artery. These flow probes are very accurate and produce reproducible assessments. However, the applicability of data from animal models to humans is fraught with pitfalls. With these limitations, pediatric studies of new devices include small sample sizes and are often not tested in children in whom the data would be of greatest value (e.g., those in shock [septic, hypovolemic, cardiogenic]).

Indicator Dilution Method

This technique is based on the Stewart-Hamilton equation, which is the ratio of the amount of dye injected to the area under the concentration-time curve as the dye passes a detector. This is the principle used by PAT CO monitors to estimate CO. Cold saline solution may also be used as the indicator; it is injected into a proximal port of the catheter and then the temperature change is detected using a thermistor at the tip of the catheter. This is an invasive device as the catheter must be placed into the pulmonary artery. Furthermore, 5 to 10 mL of cold saline solution is used for each measurement, which is performed in triplicate. For repeated measurements, the fluid load can be substantial, particularly in neonates, infants, and critically ill patients who

require fluid restriction. One means to eliminate or reduce the cold saline solution boluses is by using a thermal filament rather than cold fluid. Edwards Lifescience (Edwards Lifescience, Irvine, CA) has created the Vigilance monitors and continuous CO catheters that have a thermal filament on the catheter. The saline injectate is replaced by thermal energy as an indicator as the filament intermittently heats and cools. The catheter is also able to perform PAT measurements in the usual manner. However, the smallest catheter size is 7.5F, thus limiting this device to adolescents or adults.

Another strategy to reduce the fluid boluses is to use another means of CO measurement between calibrations (that may use cold saline solution) as in both the PiCCO (Pulsion Medical Systems, Munich, Germany) and the LiDCO systems (LiDCO, London, United Kingdom). The PiCCO system uses a combination of central venous and arterial access. Cold saline solution is injected in the central venous line and the dilution curve is measured from the arterial line. This technique is also referred to as transpulmonary thermodilution (TPTD) as the cold injectate traverses the right heart, lungs, and left heart before being measured. The PiCCO devices also measure continuous CO using the arterial pressure-based continuous cardiac output technique (APCCO) (described later). The intermittent injections of cold saline solution are used to calibrate the APCCO measurements. TPTD systems are considered less invasive compared with PAT as they are typically performed with femoral central venous access and peripheral arterial access and do not require a catheter to transverse the heart. Furthermore, the arterial catheter can be used for normal BP monitoring and laboratory testing. However, the arterial catheter required is specific to the device manufacturer, which adds cost to the system. The TPTD technique has been validated in an animal model compared with perivascular flow probes as accurate and capable of tracking CO changes.[300] The TPTD technique using an earlier version of a Pulsion Medical System device (COLD Z-021, Pulsion Medical Systems) has been validated in children compared with the direct Fick method.[301,302] There is some evidence that TPTD can measure CO in subjects with left to right shunting. However, for the moment this appears to have been demonstrated only in animals.[303,304] In 2015, PiCCO catheters were recalled because the devices did not meet company internal standards; there were no patient-related events. However, at the time of this writing, online information regarding PiCCO from the manufacturer "is intended for an audience **outside the United States.**" There have been no updates regarding when these issues will be resolved. More relevant is the fact that this device requires both arterial and central venous access and therefore would be impractical for routine pediatric anesthesia cases.

The LiDCO system uses a bolus of a small amount of lithium chloride as an indicator for the intermittent CO measurements for calibration and also uses an APCCO system for continuous measurement (described later). The LiDCO device uses a peristaltic pump to pull arterial blood through a sensor that detects lithium. However, the measurements will be affected if the patient is already taking lithium for manic depression. In addition, NMBDs with a quaternary ammonia ion will be detected by the sensor. The manufacturer recommends waiting 15 to 30 minutes after a dose of NMBD before performing LiDCO measurements. More importantly, since the measurements are performed in triplicate during various portions of the respiratory cycle to improve accuracy (3 mL of blood per measurement), the volume of blood that may be removed in some infants and children is large (research permits up to 3% of the patient's blood volume). Thus this device is both invasive and requires a large amount of blood sampling. The LiDCO*plus* system is not recommended by the manufacturer for patients who weigh less than 40 kg, and the LiDCO*rapid* system is not approved for use in pediatric patients.

There is an additional CO monitoring device that uses an indicator dilution method but does not also incorporate APCCO. The COstatus monitor from Transonic (Transonic, Ithaca, NY) uses an ultrasound dilution method to measure CO. The system connects the patient's existing arterial and central venous lines with an extracorporeal customized tubing set. During measurement, a pump circulates blood through the arterial to venous tubing loop. Ultrasound measurements are taken of the arterial to venous tubing loop and a bolus of warmed saline solution is given to the patient. The saline solution bolus will dilute the blood in the arterial to venous tubing loop, changing the velocity of the ultrasound signal. The ultrasound velocity of blood is 1560 to 1590 m/second depending on blood protein concentration. The ultrasound velocity of saline solution is 1533 m/second. The difference between the two values creates a conventional indicator dilution curve. The saline solution bolus given is diluted as it transverses the right heart, lungs, and left heart in the same manner as a TPTD measurement. The benefits of this device are the use of a low volume of warmed saline solution, reducing the risk for temperature changes and volume overload. A further advantage is that this system uses normal central venous and arterial catheters that may already be in place. The accuracy of the device has been demonstrated in children.[305–307] This device has been shown to be accurate in the detection of intracardiac shunts as a result of the characteristic changes that occur in the ultrasound dilution curve.[152,304,307] The device is limited to children with central venous and arterial catheters limiting its utility to the PICU or limited children in the OR.

Arterial Pressure-Based Continuous Cardiac Output Monitors

These devices are also referred to as arterial pulse contour-based methods to measure CO. The device is based upon the work and formulas of the renowned physicist Karel H. Wesseling beginning in the mid-1970s.[308] The concept behind the device is that when the heart contracts, the arterial pressure wave of the stroke volume (SV) is transmitted through the arterial tree. It is then possible to use mathematical methods to convert the waveform from the arterial pressure back into a calculated SV. The formulas or equations involved must consider patient factors such as the dispensability and stiffness of the aorta and arteries. The aortic compliance changes not only with age but also with BP. There is also a change in the arterial pressure waveform as it is transmitted from the aorta to the periphery. As the waveform approaches peripheral arteries the systolic pressure increases, the diastolic pressure decreases, and the mean pressure remains about the same as the aorta. Non-patient factors that must be considered include the effect of vasoactive medications, patient temperature, and volume status on vascular tone. From a pediatric standpoint, we must consider that these formulas or algorithms were generated in adults and then applied to children. The specific physiologic changes as a child grows and develops will likely change their accuracy and therefore their validity. The PiCCO™ and LiDCO™ systems mentioned above use APCCO algorithms to calculate continuous cardiac output. For the PiCCO™ system there has been some support that the accuracy of the device is sufficient for use in children,[309,310] although other investigators reported a large interindividual variability in the measurements obtained.[311] These

conflicting results suggest that further studies are needed to validate the accuracy of this device in children. The LiDCO™ system refers to their APCCO method as PulseCO and the majority of validation studies have been in adults; only one pediatric study has demonstrated PulseCO to be accurate compared with pulmonary artery thermodilution (PAT).[312]

Edwards Lifesciences produces a FloTrac system that does not require an additional calibration. The system uses an algorithm that accounts for arterial compliance and vascular resistance based on patient characteristics such as gender, age, weight, and height. There have been multiple studies in adults that addressed the accuracy of this device. One study in children that compared FloTrac™ with PAT concluded that the former was inaccurate in children.[313] However, a second study demonstrated that it was able to identify increased SV variation during normovolemic hemodilution and that this resolved with fluid replacement[314]; the study was further limited by the fact that it was not carried out during surgery but rather at a steady state during hemodilution without surgical stimulation.

An additional method to calculate CO from the arterial pressure curve is referred to as pressure recording analytical method (PRAM). This method samples the pressure wave profile at a very high frequency (1000 Hz) and uses a beat-to-beat analysis of the waveform to calculate cardiac output. The MostCare device (Vytech Health, Padova, Italy), an example of this device, has been shown to be accurate in children.[315–317] The system analyzes the contour of the systolic and diastolic phases, the location of the dicrotic notch, and the area under the entire arterial pressure curve. This might be a promising method of minimally invasive CO monitoring as it only requires an arterial line.

ULTRASOUND DETERMINATION OF CARDIAC OUTPUT

Ultrasound determination of CO includes 2D transthoracic evaluation of the size and flow through the aortic valve to determine SV, transesophageal ultrasound of the descending aorta to determine blood velocity, and transthoracic continuous wave Doppler of the aortic or pulmonary valve determines velocity through the valve to determine SV. Transthoracic 2D echocardiography is frequently obtained for clinical needs. The cross-sectional area of the aortic valve is measured and the velocity of blood through the valve is recorded and then integrated as the velocity time integral (VTI). The area of the valve multiplied by VTI is the SV, and SV multiplied by heart rate is CO. Echocardiography as a technique to estimate CO has been extensively reviewed[318] and deemed to be sufficiently accurate that it is frequently used as the reference standard to compare with other methods of CO determination.[315,319–323] This technique requires considerable expertise and can only be applied intermittently. However, it does provide additional details of the structure and function of the heart, particularly in an ICU setting and cardiac OR.

The velocity of blood moving in the descending aorta can be measured with an ultrasound probe that is positioned in the mid-esophagus. Once in place, the probe is directed to produce the maximum Doppler signal. If the cross-sectional area of the descending aorta is obtained from a nomogram, then the SV of blood flow to the lower half of the body is known. Calculations are made to adjust for the percentage of blood flow to the upper and lower portions of the body and the entire SV and then CO can be measured. Alternatively, without using the cross section of the descending aorta the VTI alone can be used. One system, EDM+ (Deltex Medical, Greenville), has a pediatric probe for use in children who weigh 3 kg or more, are 50 cm or more in height, and younger than 16 years of age. The measurement of CO in children has been shown to be accurate[318,324,325] and predict fluid responsiveness.[326] Further studies have suggested that measuring the velocity of blood flow in the descending aorta to improve accuracy. It appears that small changes in the angle between the ultrasound probe head and the descending aorta substantively change the VTI, thus requiring frequent adjustments to improve the measurements. The large size of the probe prevents it from being left in small children for a prolonged period of time. In addition, the presence of a nasogastric tube in the esophagus may alter the measurement. When properly used, this technique does seem to be accurate, although it requires frequent repositioning and is limited to intubated children.

Velocity through the aortic or pulmonary valve can also be measured with a continuous-wave Doppler and then VTI calculated from the output. The Ultrasonic Cardiac Output Monitor (USCOM 1A model) (USCOM, Sydney, Australia) is a portable device that uses a small continuous-wave Doppler probe to measure VTI through either the aortic or pulmonary valve. The USCOM software uses the patient's height to determine the area of the aortic or pulmonary valve from a nomogram. The valve area is multiplied by the VTI to SV and SV multiplied by heart rate to give CO. The device was demonstrated to be accurate in animal studies compared with ultrasonic flow probes[327]; it also was inaccurate compared with PAT in children with intracardiac shunting.[326] Our experience differed in that we found that the device is accurate when compared with PAT in children without atrial or ventricular septal defects.[328,329] We found that the measurement technique was easy to learn with good interobserver variability. However, the measurements are intermittent and the clinician must have access to the neck or thorax. Further studies will be needed to demonstrate the response to changes in CO to determine whether the USCOM can be used as a trending device.

Direct and Indirect Fick Measurement of Cardiac Output

CO can be calculated directly using the Fick equation:

$$\text{CO} = \text{Oxygen consumption}/(\text{Arterial oxygen content} - \text{Venous oxygen content}).$$

$$\text{Oxygen content} = (\text{Saturation of oxygen} \times \text{Hemoglobin} \times 1.34) + (0.003 \times \text{PaO}_2).$$

During cardiac catheterization samples of blood are drawn for arterial and mixed venous saturations and can be used to measure direct Fick CO. However, most catheterization laboratories do not measure oxygen consumption. Rather, they use a nomogram or formula to estimate oxygen consumption.[330,331] Oxygen consumption can be measured with a respiratory mass spectrometer,[332] which can produce extremely precise results. These mass spectrometers are exceedingly expensive and not widely available. Oxygen can also be measured using a photoacoustic infrared gas analyzer such as the Innocor monitor from Innovision (Innovision ApS, Glamsbjerg, Denmark). Oxygen consumption can be calculated breath by breath by measuring the difference between inspired and exhaled oxygen. Further, this same device has a system for inert gas rebreathing as a means of determining CO. If a patient has both arterial and venous access to measure oxygen content, CO can be measured directly. If the patient does not have these catheters, CO can be measured indirectly. During an inert gas rebreathing test the patient breathes from a rebreathing bag for approximately 5 breaths or 15 seconds. In the rebreathing bag is a known, measured, starting concentration of N_2O and sulfur

hexafluoride. The N_2O is rapidly taken up by the blood and its rate of decrease in the bag is proportional to the blood flow to the lung. The blood flow to the lung is the effective pulmonary blood flow and in the absence of significant intrapulmonary shunt is equal to CO. The sulfur hexafluoride is not taken up in the blood and the change in its concentration in the bag is measured to determine the lung volume from which the N_2O was taken up. The oxygen consumption technique in the Innocor device yielded excellent correlations with the gold standard of measurement using a Douglas bag method[333] in children weighing more than 15 kg whose airways were intubated.[334] One author (PAR) has used the device and found the measurements of oxygen consumption are not difficult, although learning the inert gas rebreathing technique requires additional skill. Since the concentration of N_2O used is very small, the CO measured in this manner would be in error for any patient who recently received N_2O in the OR. Additionally, the dead space of the equipment is large for infants and small children, which could limit the ability to perform the test. Although it is a noninvasive technique, a further limitation is that the inert gas rebreathing technique is intermittent and it requires an intubated patient.

CO can be measured indirectly by using a modification of the Fick equation. In this case, partial rebreathing of CO_2 is used in place of oxygen consumption. One device that uses partial rebreathing is the Non-Invasive Cardiac Output (NICO) monitoring system, which was produced by Novametrix Medical Systems (Wallingford, CT) beginning in the late 1980s. Novametrix now is a subsidiary of Philips-Respironics and some of the technology has been incorporated into their NM3 device (Respironics NM3 Monitor, Philips Healthcare, Eindhoven, The Netherlands). In brief, the amount of oxygen entering the lungs is directly proportional to the pulmonary blood flow. In the same way, the amount of CO_2 leaving the lungs is proportional to pulmonary blood flow. If there is limited intrapulmonary shunting, then the amount of pulmonary blood flow equals CO. During a measurement with the NICO device the dead space of the breathing circuit is temporarily increased. During that time period, there is a change in the elimination of CO_2 ($\Delta\dot{V}CO_2$) and a rise in the P_{ETCO_2}. Pulmonary blood flow is calculated from the formula:

$$CO = \Delta\dot{V}CO_2 / \Delta P_{ETCO_2}$$

The original NICO monitor used a disposable sensor, which incorporated a CO_2 sensor and a differential pressure flow sensor. The CO_2 elimination rate, P_{ETCO_2}, and gas flow were closely tracked and the CO calculated. NICO devices are still present in many departments but are no longer commercially available. This is unfortunate as the technique did work for intubated mechanically ventilated older children.[319,335] The NM3 device measures volumetric capnography, which can be used to calculate CO. There are currently no papers describing the accuracy of this technique in children but it does hold scientific promise.

Bioimpedance, Electrical Cardiometry, and Bioreactance

Thoracic electrical bioimpedance (TEB) is a means of using the changes in electrical conductivity of the blood flow in the aortic arch to determine SV and in turn CO. A low-amplitude, high-frequency electrical current is passed through the thorax and the resistance is measured. There are small changes in the volume of the aorta within the thorax during the cardiac cycle, resulting in a change in the electrical resistance. The change in electrical resistance over time is converted through an algorithm into a measure of SV. The theory and technique is several decades old[336] and had many problems that led to inaccuracies. There have been marked improvements in bioimpedance measurements and are referred to as electrical cardiometry (or as electrical velocimetry). Electrical cardiometry also uses skin sensors to impart high-frequency current into the thorax and measure the change in impedance. This system takes advantage of the difference in thoracic impedance that occurs owing to the arrangement of red blood cells during the cardiac cycle. During diastole, the red blood cells in the heart and aorta are in a random orientation (chaotically oriented) and the electrical resistance is increased. During systole, the red blood cells are in motion and are therefore aligned (parallel oriented) and the electrical resistance is lower. The computer algorithms derive peak acceleration of blood in the aorta, the duration of left ventricular ejection, and then the velocity of blood flow, which then determines the SV. The Osypka Medical Company (Osypka Medical Inc., La Jolla, CA) has two products that measure CO through electrical cardiometry. The Icon model is a handheld, battery-operated, portable monitor. The Aesculon model incorporates the electrical cardiometry measurement but is a complete hemodynamic monitoring system; common settings are to record measurements at ten second intervals that average the prior 20 heart beats. The Aesculon incorporates pulse oximetry, noninvasive BP, and so on and provides data storage for research. In several studies using either the Icon or the Aesculon to measure CO, the latter was shown to be accurate compared with Fick determinations and PAT even in neonates.[320,337–339] In children after a Fontan palliation for congenital heart disease[340,341] and in a general OR setting,[159,342] the Aesculon provided valuable clinical information. The unique value of the device is that it requires application of only four standard ECG electrodes and no other special equipment (Figs. 52.9 and 52.10). This device is approved for use even in neonates.

Bioreactance is another noninvasive technology that measures CO. This device also passes an electrical current through the thorax, although it evaluates the phase shifts that occur as the resistance and reactance of the thorax change during the cardiac cycle. Phase shifts or time delays between the applied current and measured voltage occur as a result of the pulsatile blood flow in the larger arteries of the thorax. The phase shifts are used to estimate SV and therefore CO. Cheetah Medical produces the Nicom monitor (Cheetah Medical, Newton Center, MA). The accuracy of the Nicom model has been demonstrated in adults[343,344] and neonates,[322] but the pediatric trials have limitations. One study[345] showed that the CO measurements were in a range appropriate for the patients being studied, although no reference standard for CO was included. Studies have been conflicting regarding whether Nicom could predict fluid responsiveness.[346,347] This device is not approved for use in children, although studies are ongoing.

BEYOND CARDIAC OUTPUT MEASUREMENTS

Many other physiologic variables can be identified and measured with the previously discussed technology. One of the easiest to identify is the stroke volume variation (SVV). Almost all of the aforementioned technologies can either measure or calculate SV. The change in SV that occurs during the respiratory cycle is a good indicator of intravascular volume or fluid responsiveness. There is strong evidence that SVV is better at predicting fluid responsiveness compared with central venous pressure. In adult studies this has been demonstrated in sepsis,[348] major abdominal surgery,[349] kidney transplantation,[350,351] and major orthopedic surgery,[352] among others. In children, SVV has been shown to predict fluid responsiveness,[346] although, a systematic review

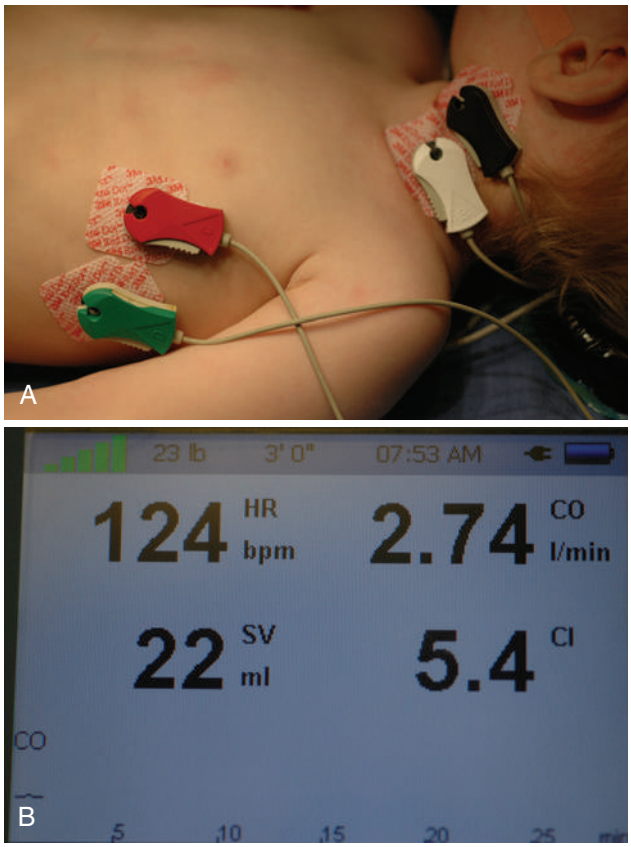

FIGURE 52.9 **A**, Cardiotronic Icon cardiac output device. The only additional equipment is four standard electrocardiogram (ECG) pads placed according to the manufacturer's instructions (Adult: two on left side at the level of xiphoid depression and two on the left neck over the carotid artery; Neonate: one on the left cheek or forehead, one over the left carotid artery, one on the left side at level of xiphoid depression, and the fourth on the left leg). **B**, Electrical cardiometry continuously estimates cardiac output, cardiac index, stroke volume, stroke index, and a variety of other parameters through quantitation of changes in impedance associated with changes in the orientation of red blood cells. During diastole, red blood cells are organized chaotically, but during systole they assume a position parallel to the direction of blood flow. Thus thoracic electrical bioimpedance relates to changes in thoracic aortic blood flow, and by using refined algorithms noninvasive measurement of continuous cardiac output with four ECG pads is achieved.

reported that only the variation in the aortic blood flow peak velocity with respiration predicted fluid responsiveness.[353]

For patients with acute respiratory failure, pulmonary edema can prolong intubation and recovery. Several of the devices that measure CO can be used to compute an extravascular lung water index (EVLWI), which is a measure of pulmonary edema.[354] One study in children[355] found that the increased EVLWI on admission to a PICU predicted both the duration of mechanical ventilation and survival.

Purchasing Anesthesia Equipment

With the increasing sophistication of monitoring and life support equipment, purchasing decisions are no longer intuitive. A complete grounding in the underlying engineering concepts would probably require an advanced degree in engineering, but a reasonable working knowledge of the operating principles, advantages, and special hazards of the various types of apparatus is relatively easy to obtain. Most hospitals now have a full-time biomedical professional staff, which often have considerable engineering and practical experience to assist in the purchasing, maintenance, and safety of all the equipment and systems used in the hospital setting. The biomedical professionals should be closely integrated into the purchasing, maintenance, and ongoing safety monitoring of all devices. Although vendors are pleased to promote a product, the manufacturer's information literature should be obtained from an unbiased source such as the equipment periodical *Health Devices,* published by ECRI (formerly Emergency Care Research Institute, Plymouth Meeting, PA). The biomedical or hospital safety office of each hospital usually subscribes to this periodical.

Another useful source of information is the specialty pediatric hospital. Whether through inquiry at medical meetings or by direct solicitation, practitioners at these unique resource institutions are often willing to share their special expertise.

The following are useful principles for any equipment purchase:

1. New purchases should interface with equipment that is already present. Considerable cost savings can occur if the same or compatible equipment is used in all the perioperative areas, including the OR, PACU, PICU, and NICU. Another issue to consider is how the equipment will interface with automated record-keeping systems and other hospital information systems if they are present. If an automated recording device is a possible plan for the future, the equipment should be evaluated for how well it will interface with systems that will possibly be purchased. Another compatibility issue to carefully review is the software required to use the equipment. Review the product information carefully to identify the need for software upgrades and compatibility, which can be important for safety and cost-effectiveness.
2. Recognize that the salesperson is inherently biased.
3. Always test proposed equipment in the environment in which it will be used, with the personnel who will be using it. What appears attractive in a display as presented by a salesperson may not function well in practice. It is also important to test the device in unusual circumstances to see how well it performs. The use of simulation is becoming an important modality to test devices under normal and unusual circumstances. Human factors must be considered, such as how easy it is to use the equipment clinically (i.e., the user interface), and equally important, the safety of the equipment or product. Evaluate systems issues that could lead to error or misuse. Software-driven products are harder to test for potential failures when they are connected to existing systems and products in your workstations; always test new equipment in the environment where it will be used.
4. Do not use equipment for any purpose other than that for which it has been designed.
5. Have your hospital biomedical staff be intimately involved with the safety issues of your systems, as described earlier, and periodically check for electrical leakage and other safety issues.
6. Decide explicitly how the product will be maintained. Will the biomedical professionals perform the necessary calibration, testing, and repair of the equipment, or will a member of your department assume this role? Spend the necessary resources to properly maintain the product; this is typically on the order of 10% of the cost of the device per year.

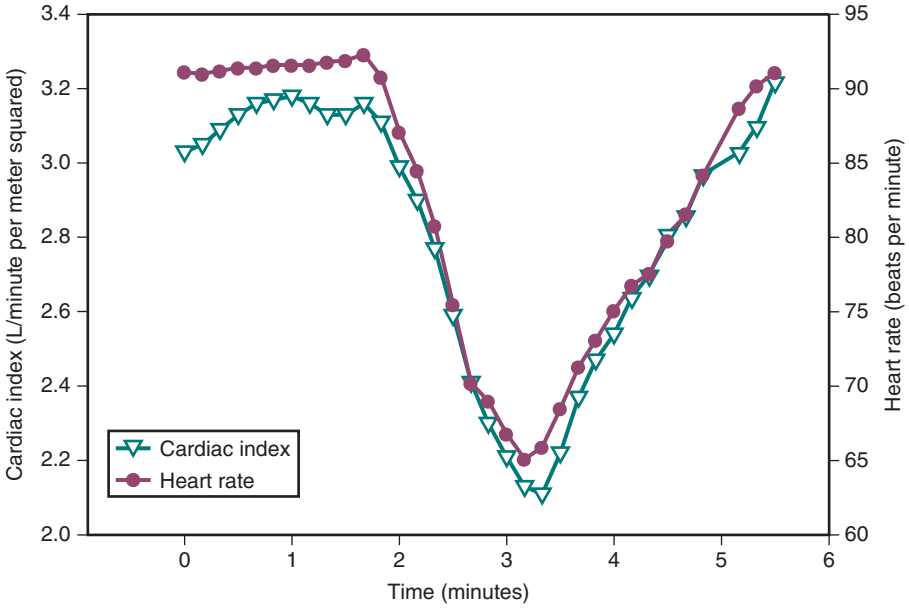

FIGURE 52.10 This graph plots the continuous cardiac index versus heart rate in a 6-year-old child undergoing a posterior fossa procedure. The bradycardia occurred with surgical brainstem irrigation with saline solution that was not adequately warmed. The Icon model averages data from the prior 20 heart beats and records this every 10 seconds. Data plotted here are the average for the six values during each minute of the event. In this case, we asked the surgeon to stop irrigating and administered atropine (0.02 mg/kg). Note how the Icon immediately tracked the improved cardiac index as the atropine took effect.

Consider a maintenance contract, if available. Ask the company to ensure the future availability of parts and the compatibility of subsequent modifications or design evolutions with your equipment.

7. Consider the cost and quality of disposable components of the equipment. This can also have an impact on the safety and cost of the product.
8. If two products are comparable but one has local service facilities, that one may be the better choice.
9. If areas of special needs have been recognized, be as detailed as possible with specifications. For example, if a monitor is to be used strictly in the OR, it may be reasonable to operate it from wall power. Conversely, if the monitor is to serve in the OR and for transport between the OR and the recovery room or ICU, it must have internal battery backup.

The more precisely needs can be defined, the more accurate the comparisons will be between the bids of rival vendors. Note that any given piece of equipment will occasionally be out of service, whether for regular preventive maintenance or for some unanticipated repair. Given this fact, in this era of cost containment it is often difficult to convince the hospital administration of a need for additional spare units.

Future of Simulation

THE FIELD OF PEDIATRIC anesthesia has become increasingly subspecialized, with unique challenges that demand high-quality teaching and training. Pediatric anesthesia is focused in detail, diverse in surgical and technical complexity, and tolerates an exceedingly small margin for error.[1] With the advancement of technology in radiology, the rise of procedural sedation and pediatric intensive care unit (ICU) requirements for bedside surgery, there is an increased challenge to provide safe, quality care in remote sites outside the traditional operating theater (see also Chapters 46 and 48). In many countries, tertiary pediatric services are becoming increasingly centralized and working hours of the individual medical professional have been reduced to address concerns of fatigue and burnout. An unintended consequence is a decline in exposure to difficult pediatric scenarios and emergencies for those who are not specialty trained in pediatrics.

There is an inverse correlation between the level of specialization and perioperative morbidity and mortality associated with pediatric anesthesia.[2] With the growth and increased sophistication of pediatric anesthesia, as well as the regionalization of specialty care, anesthesiologists are continually challenged to gain and maintain expertise in the safe and effective delivery of routine and emergency pediatric anesthesia. Early portions of a trainee's learning curve are inconsistent with the demands of safe and efficient patient care, thereby posing challenges for the medical education infrastructure.[3] Simulation education has provided an experiential learning paradigm for training and assessment for the past few decades, offering one solution to many of these challenges.[4–7] These advances provide opportunities to improve medical knowledge, communication, and decision-making skills for common as well as rare events.[8]

Traditionally, medical school education emphasized basic science knowledge and left most of the clinical practice to an apprenticeship model.[9] The focus of medical training had been on individuals gaining knowledge and skills rather than on clinical performance and team dynamics. Unfortunately, once a clinician had completed training, the required level of continued education declined in structure and formality. Within the past decade, there has been rapid progress and growth of simulation in health care training for purposes of improving patient safety and quality of care. Interest in simulation in health care derived from the historical utility of simulation for training purposes in nonmedical industries, such as commercial aviation, nuclear power production, and the military.[10] Similar to health care, these industries are known to be associated with hazards and complexities that benefit from simulation training. Many of the concepts in health care simulation education, including systematic training, rehearsals, performance assessment, situational awareness, and team interactions, have been adopted from the aviation industry and their work with flight simulators. Given that crises in pediatric anesthesia are relatively rare and unpredictable and that anesthesiologists, trainees, and experienced practitioners alike, are expected to be able to successfully manage these situations, simulation technology can fill these important knowledge gaps.[11] In this chapter, we review how simulation is applied in pediatric anesthesiology by describing its uses for learning and practicing basic and advanced skills and by defining key types of technologies and teaching approaches with illustrative videos.

Simulation-Based Training in Anesthesia

In a 1987 review of anesthesia training, gaps were identified in decision making and crisis management and diagnostic decisions were found to be relatively static.[12–14] Today, in the complex, rapidly changing, time-pressured environment of the operating room (OR), anesthesiologists are challenged beyond static decision making, especially when identifying and resolving crises and leading interdisciplinary teams. To reconcile this schism, the *anesthesia crisis resource management* (ACRM) program was developed based on the commercial aviation model: Crew Resource Management.[13,14] These investigators established a framework and curriculum to teach individual and team leadership skills, along with effective communication styles. ACRM provided anesthesia trainees with tools similar to those that made the complex dynamic world of aviation safer through decision making and crisis resource management. The development of anesthesia simulators and OR-simulated settings was critical in the implementation and growth of ACRM

as trainees and practitioners needed a safe venue to experience cases that challenged them in diagnostic problem solving, fixation errors, and poor teamwork in order to train and gain ACRM skills.

ACRM was an outgrowth of the patient safety movement that began in anesthesia in the early 1980s in America. In the late 1980s, research funding from the Anesthesia Patient Safety Foundation (APSF) supported the early development of several forms of human patient simulators (HPSs). Further publicity and advocacy from APSF propelled anesthesiology to the forefront of specialties in the application and adoption of simulators, with strong patient safety implications through education (residents attempting new skills for the first time on a mannequin), training (teamwork, critical event management, and situational awareness), and research (human performance).[15] Today, simulation in anesthesiology is global, with emphasis not only on medical knowledge and skills training, but also on ACRM, disaster training, debriefing, and patient safety. To maintain status as board-certified anesthesiologists, the American Board of Anesthesiology (ABA) requires candidates to complete the Maintenance of Certification in Anesthesiology (MOCA) program. One of the approved ways to achieve MOCA credit is to complete a simulation-based course at a simulation center endorsed by the American Society of Anesthesiologists.[5] In some institutions, such training is required as a condition of credentialing for practice and insurance coverage.

What Is Simulation?

Simulation is a *technique* to replace or amplify real experiences with guided experiences that evoke or replicate aspects of the real world. Simulation is enabled by a diverse set of emerging *technologies*.[10] The application of simulation in the health care field is focused on education and training of clinicians. *Education* emphasizes knowledge, skills, and introduction to the actual work. *Training* emphasizes the actual tasks and work to be performed.[10] The term "simulator" is used in the health care field to refer to a device that represents a simulated patient and interacts appropriately in response to the actions of the simulation participant. In aviation, pilots are seated in the cockpit of a flight simulator, whereas in health care, clinicians are in a simulated OR, emergency ward, or patient floor in simulated clinical scenarios, caring for a simulated "patient" experiencing a critical or otherwise challenging event.

Participants in a simulation are "immersed" into a task or setting to the extent necessary to achieve the learning objectives. This may be conducted in a normal classroom or in an environment that extensively replicates the real world. In the latter case, participants and faculty enter into a "fiction contract" such that the instructor prepares an engaging simulation scenario and the participant attempts to care for the "patient" as if he or she were a real person.[15] Most importantly, it is incumbent on those who create and implement the simulation to create sufficient *realism* to enable the learner to feel the reality of the situation and respond accordingly.[16,17]

Participants in a simulation scenario experience *realism* in three distinct domains: *physical, conceptual, and emotional*.[16] Simulations that address all three domains are more likely to instill the intended learning objectives. A high degree of realism appropriate for the specific learning objectives is central to ensure that the learners become mentally and physically engaged. The *physical* properties of the simulator (the patient), such as weight, flexibility, tensile strength, and color, are important for developing kinesthetic awareness and muscle memory. For example, the weight of the head and force required to effectively perform laryngoscopy are important for teaching tracheal intubation, whereas the rubbery feel of the mannequin skin is not. *Conceptual realism* refers to the causal relationships observed in the scenario, such as a decrease in oxygen saturation during a period of apnea or the resolution of hypotension after an appropriate IV fluid bolus. High conceptual reality enhances clinical reasoning and decision making. Finally, *emotional* and *experiential* fidelity is achieved when participants experience familiar and authentic feelings, such as "emotional activation," anxiety, stress, fear, or excitement. Ultimately, realism in simulation is perceived as "an exciting simulation that captures the imagination, triggering physiologic responses and execution of ingrained clinical algorithms."[16] Although realism is important, it has been said that "when learning is the focus, the flawless recreation of the real world is less important."[17] It is necessary to find circumstances that help participants learn, rather than circumstances that exactly mimic a clinical situation.[17] The degree of realism desired for a successful simulation education program is an amount sufficient to achieve the intended learning outcomes.

Technologies Used in Simulation

PARTIAL TASK TRAINERS

Partial task trainers are mannequins or models (e.g., suturing board, intravenous [IV] arm, airway head) designed to allow participants to practice clinical skills and tasks (Fig. 53.1). They should be reliable, robust, and medically meaningful. Usually they represent a portion of a person rather than the whole. Although many are simple devices designed for learning or practicing a specific procedure (e.g., suturing, IV insertion, arterial line placement, laryngoscopy, cricothyrotomy, or intraosseous access), some are coupled with computers, robotic interphases, and digital graphics to provide sophisticated partial task simulators designed for learning or practicing more involved procedures (e.g., bronchoscopy and endoscopy, endovascular catheterization, or laparoscopic skills). These models are particularly useful for teaching invasive, risky, and rare procedures (e.g., emergency cricothyrotomy, transvenous pacing, or pericardiocentesis), complex psychomotor skills requiring repetitive training (e.g., ultrasound-guided central venous catheterization or awake fiberoptic intubation), or those that are safe but create increased anxiety for either the learner or the patient and his or her family (e.g., neonatal intubation,[18] urethral catheterization, IV insertion, or arterial puncture). The use of partial task trainers in a simulation environment is conducive for coaching and deliberate practice.[19] Curricula that use these types of devices focus on skills training at varying levels of skill-oriented goals, rather than a particular situation. For example, cricothyrotomy training on a partial task simulator aims to teach the procedure, regardless of the indication (e.g., angioedema, burns, obstructing mass, or hemorrhage). Specific partial task trainers used for simulating aspects of pediatric interventions include products to learn or practice lumbar puncture, peripheral IV insertion, intraosseous needle insertion, laryngoscopy and intubation, umbilical vein and artery catheterization, and cardiopulmonary resuscitation (see Video 53.1). In the context of skills training, there is strong evidence that simulation-based mastery learning can improve patient outcomes.[6] Although there are partial task trainers commercially available for many invasive procedures, simulation education faculty and operations specialists frequently design and produce "low-cost" models to teach practice procedures–for example, managing obstetric and neonatal emergencies in Mexico[20] and postpartum hemorrhage in rural Africa.[21]

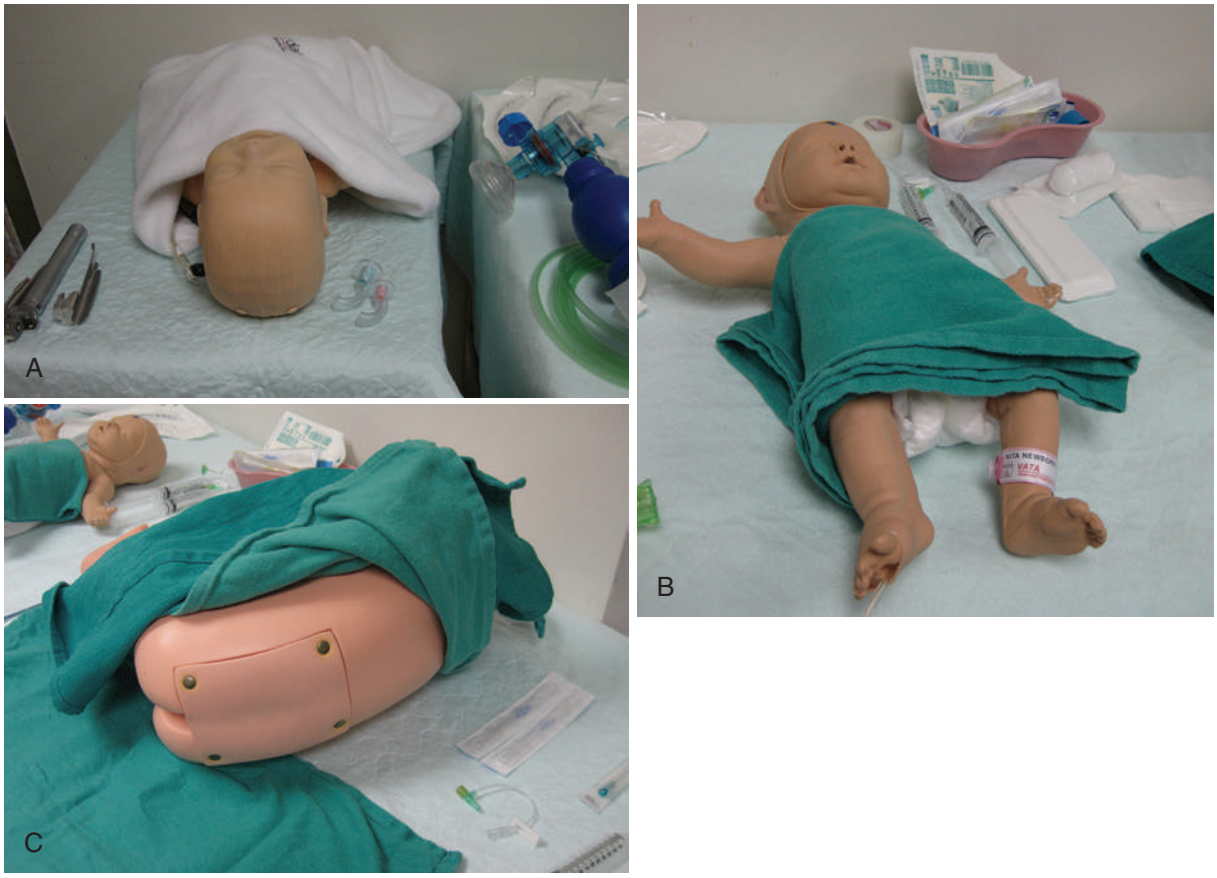

FIGURE 53.1 Examples of partial task trainers to practice **(A)** intubation in neonates (Laerdal SimNewB, Laerdal Medical, Stavanger, Norway); **(B)** peripheral intravenous placement (Nita Newborn Model #1800 Infant Venous Access Simulator, VATA, Canby, OR); and **(C)** central neuraxial techniques (M43C Pediatric Lumbar Puncture Simulator, Kyoto Kagaku, Kyoto, Japan).

HUMAN PATIENT SIMULATORS

An HPS is a representation of the human body constructed on a mannequin, typically made of plastic and metal, without a bony skeletal frame. Although popularized in the 1990s, the first mannequin-based simulator (SimOne) was developed at University of Southern California in the 1960s and was intended to facilitate medical education and training.[22] Adult HPSs became commercially available in the early 1990s; the first high-fidelity pediatric simulator was introduced in 1999. The METI PediaSIM (CAE Healthcare, Sarasota, FL) represented a child between 5 and 7 years of age. Two models of integrated infant HPSs became available in 2005: the METI BabySIM and the Laerdal SimBaby (Laerdal Medical, Stavanger, Norway) (Fig. 53.2). Both models exhibited standard vital signs and variable airway features (e.g., tongue swelling and laryngospasm), breathing patterns and sounds (e.g., retractions to illustrate upper airway obstruction, breath sounds [wheezing], and pneumothorax), cardiovascular features (e.g., heart sounds and peripheral pulses [diminished or absent]), and others (e.g., abdominal sounds and distention, and fontanel bulging). Both infant simulators produce a variety of monitor signals and allow extensive treatment interventions (e.g., intubation, laryngeal mask and nasogastric tube insertion, chest compressions, IV and

FIGURE 53.2 An infant human patient simulator (Laerdal SimBaby, Laerdal Medical, Stavanger, Norway) exhibits standard vital signs, variable airway features (tongue swelling, laryngospasm), breath sounds (retraction, wheezing), cardiovascular features (palpable pulses, heart sounds), and others (abdominal sounds, bulging fontanel).

intraosseous cannulation, and thoracocentesis) (see Video 53.1).[23] Incorporated into the clinical setting or in a simulation room outfitted with biomedical equipment and teams of health care providers, the HPSs can provide a high degree of clinical authenticity and realism to facilitate participants to fully engage in the care of the simulated patient. Typically, participants in simulation scenarios reflect on their performance during the simulation, for the purpose of sustaining and improving their practice with an instructor, in the process termed *debriefing*[24] (see Video 53.2).

STANDARDIZED PATIENTS

Standardized patients are actors who are trained to represent a patient's condition (e.g., symptoms or social situation) and may also be trained to provide informative feedback. It is common practice to use standardized patients when a simulation session focuses on interviewing, counseling, physical examination of a patient, or a situation that requires high emotional experiences such as giving bad news or de-escalating an upset family member. In pediatrics, actors are more likely to play the role of a parent (e.g., a standardized parent) and team members (e.g., a standardized nurse), although child actors have also been reported, in addition to the use of youthful-appearing actors who role-play adolescents.[25] Going beyond standardized patients, actors can be employed as standardized nurses, surgeons, even residents for the purpose of teaching supervision skills (see Video 53.1). Since 2005, a required portion of the U.S. medical licensing exam (USMLE Step II Clinical Skills) includes a series of standardized patient cases. Exams that use standardized patients and report data based on their ratings are termed objective structured clinical exams (OSCEs). These are common in many undergraduate and graduate medical education programs. OSCEs have also been incorporated into the national board certification exams for anesthesiology in Israel since 2003,[26] in the Royal College of Anaesthetists in the United Kingdom for nearly a decade,[27] and are planned to be introduced into the ABA certification process in the near future.[28]

HYBRID SIMULATION

Hybrid simulation refers to a technique of combining any of the above simulators into a single activity. For instance, in the OR, the simulation scenario may take shape using a combination of three elements: (1) an HPS, to provide the representation of the patient and clinical feedback in the form of the physiologic variables that can be measured and monitored; (2) a partial task simulator deployed to integrate a surgical skill that allows cutting and suturing of tissue; and (3) an actor trained to represent the patient's parent and enact family presence during resuscitation. Hybrids have been used successfully to assess professional, communication, and technical skills.[29]

Hybrid learning (otherwise known as *blended learning*) refers to the combination of web-based instruction incorporated with physical skills practice. As the field of simulation education has matured, it has become clearer that learning with simulation should not be isolated. Integration of simulation into course curricula has given way to hybrid learning techniques. For example, clinicians may complete online pre-course work to strengthen or activate prior knowledge in the days leading up to a simulation session. Subsequently, a simulation session can take place in the simulation-training environment, allowing for integration of new skills and attitudes. This model allows participants to obtain background knowledge to assist them with understanding the planned simulated procedural skills, which can save time and resources when conducting a training course for a large number of clinicians (e.g., central line maintenance for nursing staff) (see Video 53.1).

SCREEN-BASED SIMULATOR: VIRTUAL PATIENTS AND IMMERSIVE ENVIRONMENTS

Virtual patients are generally two-dimensional avatars on a computer display that serve to help learners maneuver through clinical situations or perform a task, such as the proper technique for taking a patient's medical history. They can also be incorporated into OSCE training when standardized patients are not available. For example, the American Heart Association uses a screen-based simulation to teach and assess knowledge from Advanced Cardiac Life Support (ACLS) and Pediatric Advanced Life Support (PALS) courses.[30]

Immersive environments, such as Second Life (Linden Lab, San Francisco, CA), Advanced Disaster Management Simulator (Environmental Tectonics Corp., Orlando) and multi-user virtual environments, have been used to teach disaster management using interactive virtual simulation systems.[31–33] Other examples include Gas Man (Med Man Simulations, Inc., Boston, MA) for teaching, simulating, and experimenting with the uptake and distribution of inhalational anesthetics,[34] and a virtual reality simulator for training in regional anesthesia.[35] Although virtual reality has been used in ACLS and PALS education,[30] the use of virtual reality simulators in anesthesia is novel and not yet widely incorporated into curricula (see Video 53.1). The American Society of Anesthesiologists recently began a commercial collaboration to develop a screen-based, virtual reality simulator as an adjunct to physical CRM and other skills training.[36]

Sites for Simulation

The number of simulation education centers has increased exponentially from the mid-1990s through the first decade of this century. While there is no exact count, there are at least 1000 centers worldwide incorporated within medical schools and residency training programs in hospital settings,[11] as well as nursing schools and allied health professions colleges.[37] Different settings of simulation education centers include hospital-based or medical school-based simulation centers, freestanding simulation facilities, and in situ simulation located within the actual clinical work environment (Fig. 53.3). Dedicated simulation facilities, either within an existing medical institution or a freestanding center, have been constructed throughout the industrialized world to house high-technology simulator equipment, such as mannequins, laparoscopic surgical equipment, robotics, and audiovisual laboratories. Although simulation education centers are expensive and require significant manpower to operate, they may serve to replace some traditional forms of clinical education for many of the reasons simulation is generally becoming more accepted (e.g., patient safety, clinical production efficiency, and lack of standardized curricula in the apprenticeship model). An in situ simulation location involves setting up the simulator equipment, trainers, and trainees within the actual work environment, such as the OR, emergency room, or ICU. The benefits of an in situ simulation include imitation of the work environment with equipment, personnel, and surroundings that are real and familiar to the trainee. Disadvantages of in situ simulation involve availability of the location, impromptu setup of equipment to operate in different locations, and increased manpower to help with setup and relocation (Table 53.1).

Applications of Simulation in Perioperative Pediatric Education

Perioperative pediatric cardiac arrest is a devastating event. When it occurs, the effects touch the lives of the family and countless health care providers involved. Pediatric cardiac arrest occurs more frequently in neonates than in older children and has a greater mortality.[38,39] The reported incidence of cardiac arrests ranges from 1.4 per 10,000 pediatric anesthetics performed to 3.3 to 4.6 cardiac arrests per 10,000 cases reported by single-institutions.[39–41] In the field of pediatrics, resuscitation skills are taught to pediatric residents using a simulated mock code scenario because perioperative cardiac arrests occur infrequently.[42–45] Furthermore, simulation-based training has been used for anesthesia training to evaluate the ability of anesthesia trainees to manage hyperkalemia after rapid blood transfusion[46] and ventricular fibrillation after hyperkalemia.[47] Newer infant simulators can generate a wide range of pediatric case scenarios and are mobile and wireless for in situ simulation in the OR and ICU. Some examples of simulation-based curricula developed for pediatric critical care medicine include post–congenital heart surgery (using a three-dimensional printed cardiac model),[48] cardiac pulmonary resuscitation skills,[49–52] neonatal resuscitation,[53] as well as specific critical care scenarios including mechanical ventilation of the critically ill patient.[54] Training and managing low-frequency, high-risk cases have been demonstrated in high-fidelity multi-institutional simulation "boot camps" in both pediatric ICU[55] and pediatric anesthesia fellowships.[56] Partial task trainers can be used to teach airway management skills such as difficult airway and neonatal intubation,[18] as well as regional anesthesia techniques.[57–59] High-fidelity simulations have been used in interprofessional health education to improve patient safety, surgical and anesthesia team communication, and patient handovers.[60]

FIGURE 53.3 Simulation in situ setup in an operating room. A human patient simulator (Laerdal SimBaby, Laerdal Medical, Stavanger, Norway) is used in this setting.

TABLE 53.1 Features of Simulation-Based Education by Location

	Distance	Features	Limitations	Operations
Hospital Simulation Center	*Pro:* Trainees available before, during, and after clinical duties. Other disciplines and professions available. *Con:* Interruptions may occur. Risk of simulation equipment or medication leakage back to clinical environment.	Multimodal education possible (human patient simulators, task trainer, standardized patients, hybrids). Hospital name, numbers, and infrastructure preserved.	Clinical environment may not be accurately represented (outdated equipment, medications not real).	Real estate might be at premium. Equipment and supplies must be ordered separately.
Freestanding Simulation Center	*Pro:* Greatest separation between working and learning environment. Psychological safety and confidentiality are easier to preserve *Con:* Environment and equipment may be significantly different from clinical practice.	Audio and video recording without compromising patient confidentiality. Ability to recreate different clinical environments.	Generic features required to represent multiple-hospital systems may lead to environments that are significantly different from the clinical environment.	Must fund and staff independent organization. May need to pay for transportation. Equipment and supply chain not readily available.
In situ Simulation	*Pro:* Shortest distance to travel. Participants present for work. *Con:* Interruptions are frequent. Family and other practitioners may be disturbed or bothered. Risk of simulation equipment or medication leakage back to clinical environment.	Ability to train in the intended environment enables evaluation of system-level safety features. Findings are readily applicable.	High acuity or census may lead to cancellation of sessions. Emergency equipment may go out of service (MH cart). Equipment may be used for clinical practice during the session (bronchoscope or GlideScope[a]). Difficult to obtain video recording and guarantee patient confidentiality.	Low facility cost (if not charged). Training at work requires no overtime. Disposable material and restocking, including medications, time, and effort to transport equipment to location.

[a]GlideScope (Verathon, Bothell, WA).
MH, malignant hyperthermia.

TABLE 53.2 Five Adult Learning Principles That Apply to the Medical Learner

1.	Adult learners need to know why they are learning.
2.	Adult learners are motivated by the need to solve problems.
3.	The previous experiences of adult learners must be respected and built upon.
4.	The educational approach should match the diversity and background of adult learners.
5.	Adult learners need to be involved actively in the process.

Modified from Okuda Y, Bryson E, DeMaria S Jr, et al. The utility of simulation in medical education: what is the evidence? *Mt Sinai J Med.* 2009;76(4):330–343, and Bryan R, Kreuter M, Brownson R. Integrating adult learning principles into training for public health practice. *Health Promot Pract.* 2009;10(4):557–563.

Comparing Traditional Learning With Simulation-Based Learning

The medical learner at each level of higher education (i.e., undergraduate, graduate, or postgraduate) is an adult learner. An adult learner is one who learns by several methods for different reasons at various stages in his or her education.[61] Adult learning theory teaches that active learning (with simulation) is an effective way to prepare for the dynamic clinical environment.[62] Five adult learning principles that help guide medical learners have been described[61–63] (Table 53.2).

Traditional medical education emphasizes learning and mastering cognitive skills based on textbook readings, lectures, and small group discussions. Evaluation of medical knowledge relies mainly on written or oral examinations. Training models are isolated and sometimes described as being within a "silo," in a static environment where nurses train with nurses, doctors with doctors, pharmacists with pharmacists, and so on. Retention and transfer is weak when passive learning models are employed. According to Kolb's experiential learning theory, simulation-based training allows for active learning, whereby participants are immersed into clinical scenarios and are able to experience how behaviors, interactions, and communication between multi-disciplines affect patient care and, potentially, patient outcomes.[64] The more realistic the case scenario, simulation environment, and actors are, the more those participating are able to become immersed in the task and engaged in the clinical scenario. This engagement with an authentic clinical problem and the need to resolve it as a team serves as the foundation for the debriefing that typically follows a simulation scenario.

Aspects of a High-Fidelity Simulation

High-fidelity simulation requires considerable manpower and preparation. A typical simulation consists of the following: a team leader, actors, high-fidelity mannequin, simulation room, audiovisual equipment, participants and learners, and a debriefer.[65] The team leader may be compared with a director of a film production. He or she is responsible for the smooth execution of the case scenario, from assigning and delegating roles to team members and directing the evolving scenario (usually from a control room), to handling unexpected problems and situations that may arise during the simulation. This position may be the same or different from an "operator," who is responsible for operating the mannequin behind the scenes in the console room. Actors or embedded simulation participants (ESPs; formerly known as "confederates") are responsible for creating the emotional realism of the case. They may assume roles, such as nurses, physicians, technicians, or administrative staff, to help guide the participants in a way that is clinically familiar. The challenge for actors is to maintain their simulated character and to interact with participants to guide them, but without overt interference with the clinical decisions and management. Communication between actors and the control room personnel using wireless audio devices is helpful in guiding the actors' responses in a manner that maintains conceptual fidelity and smooth flow of the scenario. The clinician caring for the patient or leading a clinical team within a simulated setting is frequently said to be "in the hot seat" because during the scenario the clinician preforms and makes critical decisions that influence the care of the patient. During the debriefing, a debriefer works with the team to aid in transforming a clinical experience into a learning opportunity.

The simulation room is ideally a flexible setting that can be converted into a range of patient care environments, such as the OR, emergency department, obstetric ward, a cafeteria, or other public place—anywhere an anesthesia team might be called to respond. Elaborate scenery, anesthesia, and surgical equipment used in everyday work and moulage (e.g., simulated blood and vomitus) may create very realistic scenarios. The rooms should be equipped with medical air, oxygen, and vacuum suction capabilities to run the high-fidelity mannequins and to provide for their use in the scenario.[65] Audiovisual equipment, such as cameras and microphones, are strategically placed so as to not be obvious to the participants, whose actions are followed in the simulation for debriefing and feedback. The debriefer is responsible for observing the simulation scenario and stimulating learning and discussion in a nonthreatening and organized way at the end of the event. The debriefer identifies elements of the simulation that possess educational value pertinent to the learning objectives of the course and facilitates the discussion of these learning nuggets (e.g., noting where communication broke down or situational awareness was lost) (Video 53.2).

What Is a Debriefing?

A debriefing is a "conversation between two or more people to review a real or simulated event in which participants analyze their actions and interactions, and reflect on the roles of thought processes, psychomotor skills, and emotional states, to improve or sustain performance in the future."[66] Debriefing is considered the most important component of simulation-based education, the time when learning is embedded.[67] As such, it has been exploited through different timing (during or after simulation), conversation facilitation techniques and conversation structure, and different process elements such as scripts, co-debriefers, and the use of video of the simulation session.[68] The debriefing usually follows each simulation, although there is a technique termed "pause-and-discuss," where the instructor interjects during pauses in a scenario.[69] Many simulation centers offer audio and video capture mechanisms, which can be used to review portions of the scenario during a debriefing. Debriefers can show trainees key moments, clarify recall discrepancies, and offer a global view of the room to participants who might have been focused on a task or fixated on a portion of the action. Although many instructors use video during debriefing and students ambivalently appreciate the opportunity to see what they could not appreciate while within the simulation to bridge the gap between experiencing an event

and making sense of it, there are limited published data on the specific value of this technique.[70]

There are numerous styles and methods of debriefing in health care simulation. Some of the published debriefing methods are Structured and Supported Debriefing,[71] TeamGAINS,[72] PEARLS,[73] the SAiL Diamond,[74] and Debriefing with Good Judgment.[75]

We describe here the method used at our home institutions: Debriefing with Good Judgment. Like most debriefing methods, we include three phases: *reactions*, *understanding*, and *summary*.[24,66,76] The *reactions phase* invites participants to share how they felt, allowing the participants to vent and deactivate from the heightened emotional state provoked by participating in a simulation. The debriefer leads the group through a description of the facts of the case to ensure that everyone understands the clinical scenario before tackling the learning objectives. The *understanding phase* is the richest and longest phase, intended to help participants analyze and apply what happened and explore deeper meaning of the interactions. Discussion and teachings are involved in this phase to help simulation participants gain new perspectives and insights into group dynamics and communication. Lessons learned during the simulation can be generalized and applied to the real world, preparing participants to transfer new knowledge into their clinical practice. In the *summary phase*, participants share lessons learned, including individual and group behaviors (both positive and negative), skills, and thinking patterns that they wish to improve, as well as those that were productive and they wish to retain for future performance.[24,66,76]

An effective debriefer requires training and practice to acquire unique skills that are not taught in traditional health care educational programs. Instructors and facilitators are encouraged to learn about the principles of effective debriefing via the literature, formal courses, and mentoring. The Debriefing Assessment for Simulation in Healthcare (DASH) is an example of a testing instrument developed to assess and improve debriefing skills.[77]

Using Simulation for Evaluation

Although patient simulators are well accepted as a core component of CRM and other clinical training, their acceptance and validity as assessment tools for clinical performance have not yet been widely established or validated. In particular, a number of senior professionals are reluctant to be assessed in a simulator environment (e.g., in the process of their recertification). However, some scoring systems for simulator-based performance assessments have been developed, such as the Anaesthetists' Non-Technical Skills (ANTS) system.[23,78] Although validity is not yet rigorous (e.g., based on correlation of training with consistent transfer of skills into clinical use or improvement of patient care), recent studies have shown that simulation-based assessment can be done with sufficient reliability to be used for testing (e.g., reproducible scenarios can be created and implemented, raters can be trained to assign reproducible scores of performance, and critical clinical skills can be simulated).[79] For instance, the Harvard Assessment of Anesthesia Resident Performance Research Group created a validated simulation-based assessment tool to identify critical gaps in safe anesthesia resident performance early in training.[80] Multiscenario, simulation-based assessment has the potential to assess performance of pediatric anesthesia skills in anesthesia residents and pediatric anesthesia fellows; however, further measures of validity, including correlations with direct measures of clinical performance, are needed to establish the true utility and validity of these simulations as assessment tools.[81]

Simulation is widely considered effective in improving clinical skills in a way that is safer than the traditional apprentice model of training. Although there is a dearth of evidence regarding the effectiveness of simulation or the cost relative to its benefit, there is substantial literature that documents its utility. A meta-analysis has established the overall effectiveness of simulation-based training.[4] Furthermore, simulation-based training showed improved outcomes, specifically in survival of children after cardiopulmonary resuscitation.[82]

Challenges Using Simulation

Although simulation centers are increasingly popular worldwide, there are many challenges for establishing and maintaining a simulation program. Trained educators in simulation are few and apprenticeship models require extensive time and effort. Furthermore, availability of faculty members to develop curricula and routinely run simulation case scenarios has been a challenge owing to operational costs and the high demands of clinical practice and patient care.[83] In some institutions where a freestanding simulation center is not feasible, establishing in situ simulations using existing hospital facilities, remodeling old facilities into a simulation room, or having mobile units that contain simulation equipment have been successfully implemented. In the United Kingdom and Canada, the Managing Emergencies in Paediatric Anaesthesia (MEPA) course was developed whereby international centers can share over 60 case scenarios through simulation and telemedicine to train residents.[84] In countries where lack of funding, poor infrastructure, and limited manpower may impede structuring local simulation centers, this "telesimulation" model promotes sharing of knowledge and opportunities for simulation education worldwide[84] (for more details, visit https://mepa.org.uk/about-mepa/mepa-t/).

Future of Simulation

Simulation-based education provides many opportunities for curriculum development in anesthesia residency training, with creative strategies to enhance clinical experiences to practice caring for rare cases and to improve mass-casualty training. Although the apprenticeship model and patient care experience are unlikely to be replaced, incorporation of simulation-based training can help provide solutions to systems-based problems, improve interdisciplinary team training, ease relocation into facilities, and help adapt to new equipment and technology. Since 2004, the Society for Simulation in Healthcare has represented a growing community of educators and researchers who use simulation techniques for education, testing, and research for health care. This consistently growing international society (>3000 members in 2016) is a broad-based, multidisciplinary, multispecialty network that ties together physicians, nurses, and allied health professionals with educators and other social scientists, as well as with industry.[15] Societies such as the Society for Simulation in Healthcare in America and the Society in Europe for Simulation Applied to Medicine, provide technical and political leadership for the simulation community. There are numerous local and profession-specific simulation organizations. The International Pediatric Simulation Society has been meeting for more than eight years (http://ipssglobal.org/).

The long-term impact of simulation on health care still remains to be determined. What is certain is that a large part of anesthesiology and other specialty residency training and maintenance of

skills will incorporate simulation-based techniques for education, training, testing, and research. In Israel and the United Kingdom, simulation-based stations are included in the National Anesthesia Board exams and OSCEs in anesthesia, respectively.[26,27] The American Board of Anesthesiology is currently planning to introduce OSCEs into its licensing exam by 2018.[28] Future research must nonetheless focus on addressing questions of how best to use simulation to improve real-life quality of care, patient safety, and long-term outcomes of health care.

ANNOTATED REFERENCES

Andreatta P, Saxton E, Thompson M, Annich G. Simulation-based mock codes significantly correlate with improved pediatric patient cardiopulmonary arrest survival rates. *Pediatr Crit Care Med*. 2011;12(1):33-38.

This is a longitudinal, mixed-method research design to evaluate the viability and effectiveness of a simulation-based mock code program on patient outcomes as well as residents' confidence in performing resuscitations. The study suggests that a simulation-based mock code program may significantly benefit pediatric patient outcome as well as improve learner perceived value and increase learner confidence.

Blum RH, Boulet JR, Cooper JB, et al. Simulation-based assessment to identify critical gaps in safe anesthesia resident performance. *Anesthesiology*. 2014;120(1):129-141.

Valid methods are needed to identify anesthesia residents' performance gaps early in training. However, many assessment tools in medicine have not been properly validated. The authors designed and tested a behaviorally anchored scale used in simulation-based assessment, to identify high- and low-performing residents with regard to domains of concern to expert anesthesiology faculty. The study provides initial evidence to support the validity of a simulation-based performance assessment tool.

Fehr JJ, Boulet JR, Waldrop WB, et al. Simulation-based assessment of pediatric anesthesia skills. *Anesthesiology*. 2011;115(6):1308-1315.

The purpose of this study was to develop a set of relevant simulated pediatric perioperative scenarios and to determine their effectiveness in the assessment of anesthesia residents and fellows. The study showed that the simulation content was relevant and raters could reliably score the scenarios. This study has the potential to contribute to pediatric anesthesia performance assessment, but measures of validity are needed to establish the utility of this approach.

MaGaghie WC, Issenberg SB, Petrusa ER, Scalese RJ. A critical review of simulation-based medical education research: 2003-2009. *Med Educ*. 2010;44(1):50-63.

This review article presents a qualitative synthesis of historical and contemporary research on simulation-based medical education from 2003 to 2009.

Rudolph JW, Simon R, Dufresne RL, Raemer D. There's no such thing as "non-judgmental" debriefing: a theory and method for debriefing with good judgment. *Simul Healthc*. 2009;1:49-55.

The authors describe an approach to debriefing known as "debriefing with good judgment," which emphasizes disclosing instructors' judgment and eliciting trainees' assumptions about the situation and their reasoning for acting as they did. This approach draws on theory and empirical findings from a 35-year research program in the behavioral sciences on how to improve professional effectiveness through "reflective practice."

Weinstock PH, Kappus LJ, Kleinman ME, et al. Toward a new paradigm in hospital-based pediatric education: the development of an onsite simulator program. *Pediatr Crit Care Med*. 2005;6(6):635-641.

This is a descriptive study looking at how an onsite, comprehensive pediatric simulation program in the pediatric intensive care unit can serve as a cost-effective method to enhance the frequency and breadth of critical incident training and education.

indications for, 1131
internal jugular vein and, 1134–1136, 1135*f*
during massive blood transfusion, 274
in neurosurgery, 608–609
Seldinger technique in, 1131, 1132*f*
subclavian vein and, 1136–1137
in trauma patient, 898
in urologic surgery, 673
Central venous line, 702
Central venous pressure, 208, 258, 510, 1130, 1131*f*, 1131*t*
Centrifugal pump, 506–507, 506*f*
CentriMag centrifugal pump, 506–507
Cephalosporins, 1158–1159
Cerebellar astrocytoma, 566, 567*t*, 619
Cerebellar herniation, 605
Cerebral aneurysms, 552
Cerebral angiogram, 1090
Cerebral blood flow, 581, 606
dexmedetomidine effects on, 172
fetal, 875
increased intracranial pressure and, 604–605, 605*f*
inhaled anesthetics and, 126
Cerebral blood volume, 606
Cerebral cortex malformations, 566
Cerebral edema, 660–661, 699, 823
Cerebral ischemia, 604–605
Cerebral metabolic rate for oxygen controlled hypotension and, 276–277
inhaled anesthetics and, 126
Cerebral metabolic rate for oxygen consumption, 606
Cerebral near-infrared spectroscopy, 463–464, 475–477
Cerebral oxygen saturation, 677
Cerebral palsy, 22, 562–563
comorbidities in, 562–563
epidural analgesia in, 1061
minimum alveolar concentration affected by, 125–126
musculoskeletal pain in, 1069
orthopedic surgery in, 749
pain in, 1029–1030, 1069, 1070*t*
scoliosis in, 734–735
Cerebral perfusion, overventilation for, 5
Cerebral perfusion pressure
description of, 581, 606, 699, 899
increased intracranial pressure and, 604–605, 605*f*
Cerebral salt wasting, 216, 810
Cerebral State Monitor, 1112
Cerebrospinal fluid, 581, 604, 605*f*
daily production rate for, 604
pathogens in, 1148*t*
reabsorption of, 604
volume of, 950.*e*1
Cerebrovascular autoregulation, 606–607, 607*f*
Cervical burn contractures, 321–322
Cervical spine
anomalies of, 321*t*
evaluation of, 899*f*–900*f*, 900–901
immobilization of, 317, 900–901
injury of, 618, 898, 900–901
instability of, 793–794
pseudosubluxation of, 900
teratoma of, 887, 887*f*
Chain of communication, 1079
Chain of infection, 1147*f*
Charcoal filters in malignant hyperthermia, 124, 925, 927.*e*1*f*
Charcot-Marie-Tooth disease, 570
CHARGE association, 368, 410, 856
CHD7 gene, 368
Chemoreceptor, 281–282
Chemotherapy, 241, 245, 241.*e*1*t*–241.*e*2*t*
Cherubism, 307.*e*1*t*–307.*e*4*t*
Chest
anatomic relationship with neck, 1135*f*
circumferential burn of, 828
Chest compressions, 910*t*, 1102
Chest-encircling method for cardiac compressions, 910, 910*f*
Chest radiography
in heart disease, 383, 383*f*
in noncardiac surgery in congenital heart disease, 536–537
Chest wall
breathing mechanics and, 15
compliance of, 282
fentanyl, 155*t*, 157–159, 158*f*
rigidity of, 1041, 1125
Chest wall impedance, 1047
Chewing gum, preoperative fasting and, 36
Chiari malformation, 564–565, 565*t*, 625–627, 626*t*, 627*f*
Child
autistic, 57–58
circulating blood volume of, 202*t*
growth and development of, 8–24
airway dynamics in, 17–18
blood pressure, 18, 18*t*
cardiac output, 18–19
chest wall and respiratory muscles, 15
closing capacity, 17
elastic properties of lung, 15
face, 14
functional residual capacity, 16–17, 17*f*
gastrointestinal tract, 20–21
gestational age assessment and, 9–14, 9*t*
head circumference and, 13, 13*f*
heart rate and, 18, 18*t*
hematopoietic and immunologic system, 21–22
Child *(Continued)*
hepatic system, 19–20, 20*t*
infant's transition to air breathing and, 14–15
neurologic and cognitive issues, 22–24, 23*t*
normal and abnormal, 8–9, 9*t*
normal ECG findings, 19
pancreas, 21
regulation of breathing and, 17–18
renal system, 19
respiratory system, 14–18
static lung volumes and, 15, 16*t*
teeth, 14
total lung capacity, 15–16, 16*f*
upper airway, 14, 15*f*
weight and length assessment, 9–13, 12*f*, 12*t*
in informed consent, 69, 70*t*
perioperative behavioral stress in, 25–34
attachment issues and, 25–26
behavioral versus pharmacologic interventions for, 31
cognitive development and understanding of illness and, 25
health care provider intervention in, 30–31
intraoperative clinical outcomes and, 33
parental presence during induction of anesthesia and, 28–29, 29*f*
pharmacologic interventions for, 31, 31*f*
postoperative outcomes and, 32–33, 32*f*
preoperative anxiety and, 26–31, 27*f*, 28*t*
preoperative interview and, 29–30
temperament and, 26
surgical lesions of chest in, 352–353, 353*f*
thoracic lesions in, 352–353, 353*f*
Child abuse, 80
Childhood Adenotonsillectomy Trial, 758
Child-life specialists, 1, 27, 39, 51
Child maltreatment, 80
Children's Hospital of Eastern Ontario Pain Scale, 1025*t*, 1027, 1027*t*
Children's Hospital of Wisconsin Sedation Scale, 116
Child soldiers, 1162
Child-Turcotte-Pugh score, 697
Chin lift technique, 306
Chloral hydrate, 172–173
neurotoxicity of, 589–590, 583.*e*1*t*–583.*e*10*t*
preoperative, 44
sedation outside operating room using, 1113, 1113*f*, 1122, 1122*t*–1123*t*
Chloramphenicol, 86
Chlorhexidine, 1134
Chloride
in body fluids, 209*t*
neurotoxicity of anesthetics and, 587–588
Chloroprocaine, 1049, 1053–1055, 1055*t*
Chloroprocaine test, 1058, 1060*f*
Chlorpromazine, 471
Choanal atresia, 811–812, 856
Cholecystectomy, 227
Cholestatic liver disease, 697
Cholinesterase deficiency, 82, 146–147
Chordee, 679–680
Choreoathetoid cerebral palsy, 563*t*
Choroidal blood volume, 791–792
Choroid plexus papillomas, 604, 620
Christmas disease, 230–231
Chromaffin tumors, 652

Chromatin immunoprecipitation, 82–83
Chromosomal syndromes, 365–366
Chromosome 22q11.2 deletion syndrome, 367
  DiGeorge syndrome and, 367, 850
Chronic hemolytic anemia, 223
Chronic inflammatory demyelinating polyneuropathy, 571
Chronic kidney disease, 661
Chronic pain, 1063–1075
  abdominal, 1066, 1066*t*
  ancillary data in, 1065
  complementary therapies for, 1074, 1074*f*
  in complex regional pain syndrome, 1067–1068, 1067*f*–1068*f*, 1068*t*
  genetics of, 94–95
  headache, 1066–1067, 1067*t*
  history in, 1064–1065, 1065*t*
  multidisciplinary approach to, 1063–1064
  musculoskeletal and rheumatologic, 1068–1069, 1069*t*–1070*t*
  pharmacotherapy for, 1070–1074
    anticonvulsants in, 1072–1073
    antidepressants in, 1073
    local anesthetics in, 1074
    muscle relaxants in, 1073–1074
    nonsteroidal antiinflammatory drugs and cyclooxygenase-2 inhibitors in, 1070–1071
    opioids in, 1071–1072, 1071*t*
  physical examination in, 1065
  in sickle cell disease, trait, and variants, 1069–1070, 1070*t*
Chronic renal failure, 661–663, 662*t*
  cardiovascular complications in, 663
  causes of, 663, 664*t*
  hematologic problems in, 662–663
  urologic surgery in, 672–673
Chronic renal insufficiency, 661
Cidofovir, 657
Cimetidine, 173
  preoperative, 49–50, 50*t*
Cineangiography, 387
Ciprofloxacin, 1158*t*
Circuit filters, 1155
Circuits for anesthesia machine, 1184*f*
Circulating blood volume, 201–202
  estimation of, in transfusion therapy, 257–265, 258*t*
  in extremely low-birth-weight infant, 845, 845*t*
  fluid management and, 201–202, 202*t*
Circulation
  after burn injuries, 827–828, 827*t*
  cardiopulmonary resuscitation and, 910–911, 910*f*–911*f*
  fetal
    description of, 424–426, 425*f*–426*f*, 871, 872*f*, 426.*e*1*t*
    neonatal circulation transition from, 845
  uteroplacental, 872–873
Circulatory arrest, deep hypothermic, 406, 422, 473–474, 473*f*, 477
Circulatory support, 500–519
  anesthetic considerations in, 512–515, 513*t*
  contraindications for, 500–504
  devices for, 502*t*, 504–510, 506*f*
    centrifugal pump, 506*f*
    continuous flow pump, 509–510
    extracorporeal membrane oxygenation, 504–506
    outcomes of, 515–517
    pulsatile pump, 507–509, 507*f*–508*f*
  future directions in, 518
  indications for, 500–504
  initiation of, 500–504, 501*t*
  perioperative management of, 510–515
    anesthetic considerations in, 512–515, 513*t*
Circulatory support *(Continued)*
    hematologic considerations in, 511–512
    hemodynamics and, 510–511
    prevention of infection in, 512

AAGBI Safety Guideline

Management of Severe Local Anaesthetic Toxicity

1 Recognition

Signs of severe toxicity:

- Sudden alteration in mental status, severe agitation or loss of consciousness, with or without tonic-clonic convulsions
- Cardiovascular collapse: sinus bradycardia, conduction blocks, asystole and ventricular tachyarrhythmias may all occur
- Local anaesthetic (LA) toxicity may occur some time after an initial injection

2 Immediate management

- Stop injecting the LA
- Call for help
- Maintain the airway and, if necessary, secure it with a tracheal tube
- Give 100% oxygen and ensure adequate lung ventilation (hyperventilation may help by increasing plasma pH in the presence of metabolic acidosis)
- Confirm or establish intravenous access
- Control seizures: give a benzodiazepine, thiopental or propofol in small incremental doses
- Assess cardiovascular status throughout
- Consider drawing blood for analysis, but do not delay definitive treatment to do this

3 Treatment

IN CIRCULATORY ARREST

- Start cardiopulmonary resuscitation (CPR) using standard protocols
- Manage arrhythmias using the same protocols, recognising that arrhythmias may be very refractory to treatment
- Consider the use of cardiopulmonary bypass if available

GIVE INTRAVENOUS LIPID EMULSION
(following the regimen overleaf)

- Continue CPR throughout treatment with lipid emulsion
- Recovery from LA-induced cardiac arrest may take >1 h
- Propofol is not a suitable substitute for lipid emulsion
- Lidocaine should not be used as an anti-arrhythmic therapy

WITHOUT CIRCULATORY ARREST

Use conventional therapies to treat:

- hypotension,
- bradycardia,
- tachyarrhythmia

CONSIDER INTRAVENOUS LIPID EMULSION
(following the regimen overleaf)

- Propofol is not a suitable substitute for lipid emulsion
- Lidocaine should not be used as an anti-arrhythmic therapy

4 Follow-up

- Arrange safe transfer to a clinical area with appropriate equipment and suitable staff until sustained recovery is achieved
- Exclude pancreatitis by regular clinical review, including daily amylase or lipase assays for two days
- Report cases as follows:
  - in the United Kingdom to the National Patient Safety Agency (via **www.npsa.nhs.uk**)
  - in the Republic of Ireland to the Irish Medicines Board (via **www.imb.ie**)

If Lipid has been given, please also report its use to the international registry at **www.lipidregistry.org**. Details may also be posted at **www.lipidrescue.org**

Your nearest bag of Lipid Emulsion is kept .....

This guideline is not a standard of medical care. The ultimate judgement with regard to a particular clinical procedure or treatment plan must be made by the clinician in the light of the clinical data presented and the diagnostic and treatment options available.

© The Association of Anaesthetists of Great Britain & Ireland 2010

IMMEDIATELY

Give an initial intravenous bolus injection of 20% lipid emulsion **1.5 ml.kg^{-1}** over 1 min

AND

Start an intravenous infusion of 20% lipid emulsion at **15 ml.kg^{-1}.h^{-1}**

AFTER 5 MIN

Give **a maximum of two** repeat boluses (same dose) if:

- cardiovascular stability has not been restored **or**
- an adequate circulation deteriorates

Leave **5 min** between boluses

A maximum of **three** boluses can be given (including the initial bolus)

AND

Continue infusion at same rate, but:

Double the rate to **30 ml.kg^{-1}.h^{-1}** at any time after 5 min, if:

- cardiovascular stability has not been restored or
- an adequate circulation deteriorates

Continue infusion until stable and adequate circulation restored or maximum dose of lipid emulsion given

Do not exceed a maximum cumulative dose of 12 ml.kg^{-1}

An approximate dose regimen for a 70-kg patient would be as follows:

IMMEDIATELY

Give an initial intravenous bolus injection of 20% lipid emulsion 100 ml over 1 min

AND

Start an intravenous infusion of 20% lipid emulsion at 1000 ml.h^{-1}

AFTER 5 MIN

Give a **maximum of two** repeat boluses of 100 ml

AND

Continue infusion at same rate but **double** rate to 2000 ml.h^{-1} if indicated at any time

Do not exceed a maximum cumulative dose of 840 ml

This AAGBI Safety Guideline was produced by a Working Party that comprised:
Grant Cave, Will Harrop-Griffiths (Chair), Martyn Harvey, Tim Meek, John Picard, Tim Short and Guy Weinberg.

This Safety Guideline is endorsed by the Australian and New Zealand College of Anaesthetists (ANZCA).

MHAUS — Malignant Hyperthermia Association of the United States

Dedicated to Patient Safety

MH Hotline: 1-800-644-9737 • Outside the US: 001-209-417-3722

Emergency Therapy for MALIGNANT HYPERTHERMIA

CAUTION! This protocol may not apply to all patients; alter for specific needs. Effective February 2015

DIAGNOSIS

Signs of MH:

- Increasing $ETCO_2$ *(despite hyperventilation)*
- Trunk or total body rigidity
- Masseter spasm or trismus
- Tachycardia/tachypnea
- Mixed respiratory and metabolic acidosis *(MH can occur without significant metabolic acidosis)*
- Increased temperature *(may be an early or a late sign)*
- Myoglobinuria

Sudden/Unexpected Cardiac Arrest in Young Male Patients:

- Presume hyperkalemia and initiate treatment *(see #6)*
- Measure blood gases and electrolytes
- Measure CK, myoglobin, ABGs, until normalized
- Usually secondary to occult myopathy *(e.g., muscular dystrophy)*
- Resuscitation may be difficult and prolonged
- Myoglobinuria is common

Trismus or Masseter Spasm with Succinylcholine

- Early sign of MH in many patients
- If limb muscle rigidity, begin treatment with dantrolene.
- For emergency procedures, continue with non-triggering agents, evaluate and monitor the patient, and consider dantrolene treatment.
- Check CK immediately and at 6-8 hr intervals until returning to normal. Observe for dark- or cola-colored urine. If present, liberalize fluid intake and test for serum and urine myoglobin. *(see D below)*
- Observe in PACU or ICU for at least 24 hours if metabolic signs of MH were present.

ACUTE PHASE TREATMENT

1 GET HELP. GET DANTROLENE. Notify Surgeon. Call MH Hotline.

- Discontinue volatile agents and succinylcholine.
- Hyperventilate with 100% oxygen at flows of 10 L/min. to flush volatile anesthetics and lower $ETCO_2$. If available insert activated charcoal filters into the inspiratory and expiratory limbs of the breathing circuit. The Vapor-Clean™ filter may become saturated after one hour; therefore, a replacement set of filters should be substituted after each hour of use.
- Halt the procedure as soon as possible; if it is not possible to stop surgery, continue with non-triggering anesthetic technique.
- Don't waste time changing the circle system and CO_2 absorbent.

2 Dantrium®/Revonto®/Ryanodex®

2.5 mg/kg rapidly IV, if possible through large-bore IV

To convert kg to lbs for amount of dantrolene, give patients 1 mg/lb (2.5 mg/kg approximates 1 mg/lb).

- Dantrium/Revonto – Each 20 mg vial should be reconstituted with at least 60 mL sterile water for injection, USP (without a bacteriostatic agent). There are 3 grams of mannitol in each 20 mg vial of Dantrium and Revonto.
- Ryanodex – Each 250 mg vial should be reconstituted with 5 mL sterile water for injection, USP (without a bacteriostatic agent) and shaken to ensure an orange-colored uniform, opaque suspension. There are 125 mg of mannitol in each 250 mg vial of Ryanodex.
- Repeat until signs of MH are reversed.
- Sometimes more than 10 mg/kg (up to 30 mg/kg) of dantrolene is necessary.

3 Bicarbonate for metabolic acidosis

- 1-2 mEq/kg if blood gas values are not yet available

4 Cool the patient

- If core temperature > 39° C Apply ice to surface.
- Infuse cold saline intravenously.
- Lavage open body cavities.
- Other cooling techniques may be applied at clinician's discretion.
- Stop cooling if temperature < 38° C and falling to prevent hypothermia.

5 Dysrhythmias

Usually responds to treatment of acidosis and hyperkalemia.

- Use standard drug therapy

EXCEPT avoid calcium channel blockers—

(may cause hyperkalemia or cardiac arrest in the presence of dantrolene).

6 Hyperkalemia

Treat with hyperventilation, bicarbonate, glucose/insulin, calcium.

- Bicarbonate 1-2 mEq/kg IV
- For pediatric, 0.1 units regular insulin/kg and 2 mL/kg 25% dextrose or for adult,10 units regular insulin IV and 50 mL 50% dextrose
- Calcium chloride 10 mg/kg IV or calcium gluconate 10-50 mg/kg IV for life-threatening hyperkalemia
- Check glucose levels hourly.

7 Follow...

$ETCO_2$, minute ventilation electrolytes, blood gases, CK, core temperature, urine output and color, coagulation studies. If CK and/or K+ rise more than transiently or urine output falls to less than 0.5 mL/kg/hr, induce diuresis to >1 mL/kg/hr and give bicarbonate to alkalinize urine and prevent myoglobinuria-induced renal failure *(see D below)*.

- Venous blood gas (e.g., femoral vein) values may document hypermetabolism earlier than arterial values.
- Central venous or PA monitoring as needed.
- Place Foley catheter and monitor urine output.

POST ACUTE PHASE

A Watch for MH relapse by continuously evaluating the patient for at least 24 hours following cessation of signs of MH. 25% of MH events relapse, which can be fatal. Treat immediately if relapse occurs. Signs of MH relapse include:

- Increasing muscular rigidity in the absence of shivering
- Inappropriate hypercarbia with respiratory acidosis
- Metabolic acidosis without other cause
- Inappropriate temperature rise

B Give dantrolene, 1mg/kg IV q 4-6h or 0.25mg/kg/hr by infusion and continue for at least 24 hr and sometimes longer as clinically indicated.

Dantrolene can be stopped, or the interval between doses increased to q8h or q12h if all of the following criteria are met:

- Metabolic stability for 24 hours
- Core temp is less that 38°C
- CK is decreasing
- No evidence of myoglobinuria
- Muscle is no longer rigid

C Follow vital signs and labs as above (see #7)

- Frequent blood gases as per clinical signs
- CK every 6 hours; less often as the values trend downward

D Follow urine myoglobin and institute therapy to prevent myoglobin and the subsequent development of acute renal failure. CK levels above 10,000 IU/L is a presumptive sign of rhabdomyolysis and myoglobinuria. Follow standard intensive care therapy for acute rhabdomyolysis and myoglobinuria by hydration and diuretics (urine output >2 mL/kg/hr along with alkalinization of urine with Na-bicarbonate infusion and careful attention to both urine and serum pH values).

E Counsel the patient and family regarding MH and further precautions; refer them to MHAUS. Fill out and send in the Adverse Metabolic Reaction to Anesthesia (AMRA) form (www.mhreg.org/registry) and send a letter to the patient and her/his physician. Refer patient to the North American MH Registry and the nearest Biopsy Center for follow-up.

This Protocol is for reference, guidance, and informational purposes only, and does not represent mandatory standards or requirements. Medical Facilities should conduct their activities based on independent medical judgment. A Practice of Anesthesia for Infants and Children

CJ Coté MD, J Lerman MD, BJ Anderson MB ChB

Pocket Reference Guide

Note that the drug doses and management decisions presented are those that are commonly recommended; each child's care must be individualized according to the child's underlying medical and surgical conditions. All drug doses should be double checked before administration so as to avoid errors.

RESUSCITATION

Oxygen	Ventilate with 100% oxygen
Epinephrine (Adrenaline)	1 µg/kg to treat hypotension IV; 10 µg/kg IV for cardiac arrest; repeat every 3-5 minutes as needed
Atropine	20 µg/kg IV (for symptomatic bradycardia); maximum dose 1 mg for child and 2 mg for adolescent
Bicarbonate	1-2 mEq/kg IV to be guided by blood gas analysis for <5 kg, base excess × Wt/4; for child, base excess × Wt/6; for adult, base excess x Wt/10
Calcium Chloride	10-20 mg/kg IV (0.1-0.2 mL/kg of a 10% solution)
Calcium Gluconate	30-60 mg/kg IV (0.3-0.6 mL/kg of a 10% solution)
Adenosine (Adenocard)	100 µg/kg rapid IV bolus and flush (maximum 6 mg); second dose 200 µg/kg (maximum 12 mg)*
Lidocaine	1 mg/kg IV then followed by 20-50 µg/kg/min by infusion pump
Amiodarone (Cordarone)	5 mg/kg IV, maximum 300 mg for ventricular fibrillation and/or ventricular tachycardia
Procainamide (Pronestyl)	5-15 mg/kg IV loading dose over 30-60 minutes, then 20-80 µg/kg/min by infusion pump. ECG monitoring required. Caution: hypotension and prolonged QT interval may occur particularly when combined with amiodarone
Magnesium	25-50 mg/kg IV for Torsades de Pointes (maximum dose 2 g)
Glucose	For hypoglycemia, IV glucose 0.5 mL/kg of D50W or 2.5 mL/kg of D10W. Add maintenance infusion to 4-12 mg/kg/min

*Reduce by half if administering through a central line or for patients who have had a heart transplant.

VASOACTIVE DRUGS

Note that all are administered by IV infusion pump; consider invasive arterial pressure monitoring

Dopamine	1-20 µg/kg/min; titrate to effect
Dobutamine	1-20 µg/kg/min; titrate to effect
Epinephrine (Adrenaline)	0.05-1 µg/kg/min; titrate to effect, 1-10 µg/kg bolus
Isoproterenol (Isuprel)	0.05-1 µg/kg/min; titrate to effect
Norepinephrine (Levophed)	0.05-1 µg/kg/min; titrate to effect
Phenylephrine (Neo-Synephrine)	0.5-10 µg/kg/min; titrate to effect, 0.5-10 µg/kg bolus
Milrinone (Primacor)	50-100 µg/kg loading dose followed by 0.25-1 µg/kg/min infusion
Nitroprusside (Nipride)	0.5-10 µg/kg/min; titrate to effect; observe for signs of cyanide toxicity
Nitroglycerine (NitroQuick)	1-10 µg/kg/min; titrate to effect
Prostaglandin E_1	0.01-0.1 µg/kg/min (Note that apnea may occur and intubation is often required with doses >0.05 µg/kg/min)
Vasopressin (Pitressin)	0.0001-0.001 units/kg/min

CARDIOVERSION/DEFIBRILLATION (EXTERNAL)

Cardioversion	For supraventricular/ventricular tachycardia 0.5 joules/kg **SYNCHRONOUS**; repeat up to 2 joules/kg
Defibrillation	For ventricular fibrillation/ventricular tachycardia 2 joules/kg **ASYNCHRONOUS**; repeat up to 4 joules/kg

RULE OF SIXES

0.1 µg/kg/min = 0.6 mg/100 mL administered as body weight (kg) **in mL/h**

1 µg/kg/min = 6 mg/100 mL administered as body weight (kg) **in mL/h**

10 µg/kg/min = 60 mg/100 mL administered as body weight (kg) **in mL/h**

20 µg/kg/min = 120 mg/100 mL administered as body weight (kg) **in mL/h**

ANAPHYLAXIS

Search for cause, especially latex allergy; remove source if possible

Oxygen	Ventilate with 100% oxygen
Epinephrine (Adrenaline)	1 µg/kg IV to treat hypotension/bronchospasm; repeat with increasing doses every 3-5 minutes as needed; may need continuous infusion
Fluid bolus	20 mL/kg balanced salt solution; repeat as necessary
Phenylephrine (Neo-Synephrine)	0.1 µg/kg/min IV; titrate to effect if inadequate response to epinephrine
Hydrocortisone	2-3 mg/kg IV
Diphenhydramine	1-2 mg/kg IV
Ranitidine (Zantac)	1.5 mg/kg IV
Vasopressin	0.5-1 U/kg IV

HYPERKALEMIA TREATMENT

Intervention	Dose
Calcium chloride	5-10 mg/kg/dose IV; repeat until normal sinus rhythm
Calcium gluconate	15-30 mg/kg/dose IV; repeat until normal sinus rhythm
Hyperventilation	
Albuterol (Ventolin, Proventil)	By inhalation administered with a spacer
Salbutamol	5 µg/kg IV over 15 min
Glucose + insulin	Glucose (0.5-1 g/kg) with insulin (0.1 U/kg) given IV over 30-60 min
Kayexalate	1 g/kg (up to 40 g) q4h (PO, PR, per gastric tube)

LARYNGEAL MASK AIRWAY (CLASSIC)

Weight (kg)	Size	Cuff volume (mL)	Largest ETT that will fit through LMA
<5	1	4	3.5 uncuffed
5-10	1.5	7	4 uncuffed
10-20	2	10	4.5 uncuffed
20-30	2.5	14	5 uncuffed
30-50	3	20	6 cuffed
50-70	4	30	6 cuffed
70-100	5	40	7 cuffed
>100	6	50	7 cuffed

ETT SIZE (mm ID)

	Uncuffed	Cuffed
Preterm (<1.5 kg)	2.5	
Preterm (1.5-3 kg)	3	
Full-term neonate	3	
1 year	4	3-3.5
2 years	5	4-4.5
>2 years	Age/4 + 4 (or 4.5)	0.5-1.0 mm smaller than uncuffed ETT*

*Assure leak with deflated cuff at 20-40 cm H_2O PIP.

DISTANCE OF INSERTION (cm) EVEN WITH GUMS

Preterm (<1000 grams)	6-7
Preterm (<2000 grams)	7-9
Full-term neonate	~10
1 year	~11
2 years	~12
16 years	~18
≥20 years	~20-21

LARYNGOSCOPE BLADES (APPROXIMATE SIZE)

Age	Miller	Wis-Hipple	Macintosh
Preterm	0		
Full-term neonate	0		
Term-2 years	1	1	
2-6 years		1.5	1-2
6-10 years	2	NA	2
>10 years	2 or 3	NA	2 or 3

INDUCTION AGENTS

	IV (mg/kg)	IM (mg/kg)	Rectal (mg/kg)
Propofol (Diprivan)	2-3 mg/kg IV		
Ketamine (Ketalar)	1-2	3-12	5-10
Etomidate (Amidate)	0.2-0.3		
Thiopental	4-6		20-30
Methohexital	1-3		20-30

DURATION OF E-CYLINDER OXYGEN SUPPLY

Non-SI units	SI units
Time (in minutes) = 1/3 × tank pressure (pounds/square inch)/oxygen flow rate (L/min)	Time (in minutes) = tank pressure (kPa)/(23 × oxygen flow rate [L/min])

NEUROMUSCULAR BLOCKING DRUGS

Succinylcholine (Anectine)*	2-3 IV for <1 year; 1-2 IV; 4-5 IM or 1-3 intralingual (submental) for >1 year
Rocuronium (Zemuron)	0.3 in neonates lasts ~30-45 min, 0.6 in children lasts ~30-45 min, 1.2 in children for rapid sequence intubation lasts ~75 min
Vecuronium (Norcuron)	0.1 IV
Pancuronium (Pavulon)	0.05-0.1 IV
Cisatracurium (Nimbex)	0.1 IV neonates; 0.1-0.2 older children
Atracurium (Tracrium)	0.5 IV

Doses are IV mg/kg unless otherwise stated.
*Pretreatment with anticholinergic recommended.

DANTROLENE

Containers/70 kg	Drug	Dantrolene concentration
36	Dantrium or Revonto	20 mg/vial in 60 mL of sterile water (0.33 mg/mL)
3	Ryanodex	250 mg/vial in 5 mL of sterile water (50 mg/mL)

ANTAGONISTS (IV)

Neostigmine (Prostigmin)	0.02-0.05 mg/kg + atropine 0.02 mg/kg or glycopyrrolate 0.01 mg/kg
Edrophonium (Enlon)	0.3-1 mg/kg + atropine 0.02 mg/kg or glycopyrrolate 0.01 mg/kg
Sugammadex (Bridion)	2 mg/kg for reversal of rocuronium or vecuronium
Physostigmine (Antilirium)	0.01-0.03 mg/kg followed by infusion 0.03 mg/kg/hr to treat cholinergic syndrome
Naloxone (Narcan)	0.25-0.5 µg/kg, additional doses titrated to effect; up to 100 µg/kg (maximum 2 mg) may be needed for respiratory arrest; must observe child for recrudescence. May also give the effective dose IM to prevent recrudescence
Flumazenil (Romazicon)	10 µg/kg/dose, titrate to effect; must observe child for minimum of 2 hours after antagonism

ANALGESICS

Non-opioids	
Acetaminophen oral/rectal (Tylenol) **Acetaminophen IV**	Non-IV routes (Tylenol): 10-15 mg/kg PO every 4-6 hours or 30-40 mg/kg PR loading dose, then 20 mg/kg PR every 6 hours ***(maximum 75 mg/kg/24 hr)*** IV routes: 15 mg/kg **paracetamol** IV every 6 hours (NB: only 7.5 mg/kg in neonates)
Ibuprofen (Advil)	10 mg/kg PO every 6 hours (max 800 mg)
Ketorolac (Toradol)	0.5 mg/kg up to 15 mg <50 kg; 0.5 mg/kg up to 30 mg >50 kg, IV, IM, PO every 6 hours
Ketamine (Ketalar)	0.25-1 mg/kg every 8-10 minutes IV as needed
Opioids	
Fentanyl (Sublimaze)	0.5-2 µg/kg; greater doses up to 100 µg/kg for cardiac or other major cases
Hydromorphone (Dilaudid)	0.015 mg/kg IV every 3-4 hours
Morphine	0.05-0.1 mg/kg IV every 3-4 hours (postoperative analgesia infusion 5-20 µg/kg/h)
Remifentanil (Ultiva)	0.05-0.15 µg/kg/min (may need larger doses for brief periods); continuous infusion may cause hypotension and bradycardia
Tramadol	1-2 mg/kg q6h (max. 100 mg) children 4-16 years
Methadone	0.1 mg/kg q8h

OPIOID CONVERSION APPROXIMATIONS

Morphine (1 mg) is equivalent to:

	IV (mg)	PO (mg)
Fentanyl (Sublimaze)	~0.01 (10 µg)	~0.02 (20 µg)
Hydromorphone (Dilaudid)	~0.15	~0.75
Oxycodone (OxyContin)		~2-3
Methadone	~1	~1.5
Tramadol (Ultram)	~10	~15

ANTIHISTAMINES

	IV (mg/kg)	PO (mg/kg)
Diphenhydramine (Benadryl)	1-1.25	1-1.5
Ranitidine (Zantac)	1.5	2-5
Famotidine (Pepcid)	0.5	0.5

ANTIEMETICS

	IV (mg/kg)	PO (mg/kg)
Dexamethasone	0.0625-0.15 (max 10-15 mg)	
Metoclopramide (Reglan)	0.15	0.15
Ondansetron (Zofran)	0.05-0.1 up to a maximum total dose of 4 mg	0.1 up to 4 mg
Tropisetron (Navoban)	0.1-0.2	
Palonosetron (Aloxi)	1.5-20 µg/kg (max 1.5 mg) (limited data in children)	
Aprepitant		3 (max 125 mg) for 6 mo to <12 yr

ANTICHOLINERGICS

	IV (mg/kg)	PO (mg/kg)
Atropine	0.02 (20 µg/kg)	0.02-0.03
Scopolamine	0.01 (10 µg/kg)	
Glycopyrrolate	0.01 (10 µg/kg)	

DIURETICS

Chlorothiazide (Diuril)	10-15 mg/kg PO every 12 hours
Furosemide (Lasix)	1-2 mg/kg/dose PO/IM/IV
Spironolactone (Aldactone)	1 mg/kg PO every 8-12 hours
Mannitol	0.25-0.5 g/kg IV (slowly to avoid hypotension)

ANTIHYPERTENSIVES

	Adrenergic receptor	Dose
Captopril (Capoten)		0.05-0.25 mg/kg q6h PO or NG
Hydralazine		0.1-0.2 mg/kg IM/IV q4-6h
Esmolol (Brevibloc)	β 1	100-500 µg/kg IV over 1-5 min; 50-100 µg/kg by infusion pump up to 300 µg/kg/min
Labetalol (Trandate)	α 1, β 1, and β 2	0.1-0.4 mg/kg IV every 5-10 min until desired effect
Atenolol (Tenormin)	β 1	1-2 mg/kg/day PO up to 3 mg/kg in single or divided doses until desired effect
Propranolol (Inderal)	β 1 and β 2	0.05-0.1 mg/kg/dose IV every 10 min; titrate to effect; max single dose 10 mg; hypotension may occur in infants; (1-2 mg/kg PO q6h)
Nitroprusside (Nipride) & Nitroglycerin (NitroQuick) (See above)		0.5-10 µg/kg/min by infusion pump; titrate to effect; may cause precipitous decrease in blood pressure; arterial line recommended

LOCAL ANESTHETICS (VOLUME ADJUSTED FOR NERVE BLOCKS)

Conversion from percent to mg/mL: concentration (percent) × 10 = mg/mL

Maximum doses	Plain mg/kg	With epinephrine (1:200,000) mg/kg
Lidocaine	5	7
Bupivacaine	2.5	3
Levobupivacaine	2.5	3
Ropivacaine	2.5	3

MIDAZOLAM DOSING ACCORDING TO ROUTE OF ADMINISTRATION (APPROXIMATE EQUIVALENCE)

MIDAZOLAM

Route	mg/kg	Onset (min)	Peak effect (min)
Intravenous	0.05-0.15	Immediate	3-5
Intramuscular	0.1-0.2	3-5	10-20
Orogastric	0.25-0.75	5-15	10-30
Nasal	0.1-0.2	3-5	10-15
Rectal	0.75-1	5-10	10-30

KETAMINE DOSING ACCORDING TO ROUTE OF ADMINISTRATION

Route	mg/kg
Intravenous	1-2
Intramuscular	2-10
Oral	3-6
Nasal	2-4
Rectal	5-10

FLUID AND BLOOD

Maintenance Fluids (balanced salt solution)

For neonates and infants <6 months: 4 mL/kg/h first 10 kg, 2 mL/kg/h 10-20 kg, 1 mL/h for each kg above 20 (consider adding glucose to infusion)

Perioperatively for infants and children >6 months: 10-40 mL/kg over 1-4 hours

SEDATIVES

Chloral hydrate	50-100 mg/kg maximum 2 g in divided doses (PO or PR)
Dexmedetomidine (Precedex)	0-2 µg/kg loading dose infused over 10 minutes followed by **0.7-1 µg/kg/h**
Pentobarbital	2 mg/kg IV every 10 minutes up to 6 mg/kg

ANTIBIOTICS

Antibiotic#	AGE: 1st wk (>2 kg) (mg/kg)	AGE: 1-4 wk (mg/kg)	AGE: >4 wk (mg/kg)	Repeat intraoperative dosing (h)
Ampicillin/ Sulbactam	#	50 (ampicillin)	50 (ampicillin) max 3g	2
Ampicillin	50 q8h	25-50 q6h	50 q6h max 2g	2
Aztreonam	30 q12h	30 q8-12h	30 q8h max 2g	4
Cefazolin	20 q24h	20 q8h	30 q8h max 2g (>120 kg, 3g)	4
Cefuroxime	25-50 q12h	25-50 q12h	25-50 q8h max 1.5g	4
Cefotaxime	50 q8-12h	50 q6-8h	50 q6-8h max 1g	3
Cefoxitin	30 q8h	30-33 q8h	40 q8h max 2g	2
Cefotetan	#	30 q12h	40 q12h max 2g	6
Ceftriaxone	50 q24h	50-75 q24h	50-75 q12-24h max 2g	NA
Cefuroxime	25-50 q12h	25-50 q12h	25-50 q8h max 1g	4
Ciprofloxacin	10 q12h	10 q12h	10 q8h max 0.4g	NA
Clindamycin	5 q12h	5 q8h	10 q6-8h max 900 mg	6
Ertapenem	#	15 q12h	15 q12h max 1g	NA
Fluconazole	3 q72h	3 q24h	6-12 max 0.4g	NA
Gentamicin (over 60 min)	4 q24h	3.5 q24h	2-2.5 q8h Single dose 5 mg/kg	NA
Levofloxacin	#	#	10 q12h max 0.5g	NA
Metronidazole	7.5 q12h	15 q12h	7.5-15 q6h max 0.5g	NA
Moxifloxacin	5 q24h	10 q24h	10 q24h max 0.4g	NA
Nafcillin	25 q8h	25 q6h	25-50 q4-6h max 12g/day	NA
Piperacillin/ Tazobactam	100 (piperacillin) q12h	100 (piperacillin) q8h	Infants 2-9 mon (piperacillin) 80 mg/kg; > 9 mon and ≤40 kg (piperacillin) 100 mg/kg; >40 kg (piperacillin) max 3.375g	2
Ticarcillin	75 q12h	50-75 q8h	33-50 q4-6h max 3.1g	NA
Vancomycin (over 60 min)	15 q12h	15 q8h	10-15 q8h max 2g	NA

#Consult pharmacy for preterm or low birth weight infants and children with renal failure
Current American Society of Hospital Pharmacists recommendations for surgical IV antibiotic prophylaxis weight-normalized. https://www.ashp.org/-/media/assets/policy-guidelines/docs/therapeutic-guidelines-antimicrobial-prophylaxis-surgery.ashx?la=en&hash=8387AA6F0FE4BAA7B661A1634C467E872B3DAF0A [accessed October 22, 2017] and Lexicomp Online: http://www.wolterskluwercdi.com/lexicomp-online/

TRANSFUSION SHORT CUTS

Whole blood	6 mL/kg	Increases hemoglobin 1 g/dL
PRBCs	4 mL/kg	Increases hemoglobin by 1 g/dL
Platelets	5-10 mL/kg	increases platelet count by 50,000-100,000/mm^3
Fresh frozen plasma	10-15 mL/kg	Factor levels increase by ~15-20 percent
Cryoprecipitate	1-2 units/kg	Increases fibrinogen by ~ 60-100 mg/dL

SPECIAL PROBLEMS

Diabetes insipidus

Dilute polyuria (urine osmolality <250 mOsm/L, >2 mL/kg/h), hypernatremia (sodium >145 mEq/L) with serum hyperosmolality (>300 mOsm/L)

DDAVP (desmopressin) 1-10 mU/kg/h (0.0025-0.025 µg/kg/h), titrate to effect (4 µg = 16 IU)

von Willebrand Disease (VWD) (Treatment depends on the type)

Desmopressin (DDAVP) 0.3 µg/kg IV once 30 minutes preoperatively (avoid in Type 2B)

Amicar 100 mg/kg IV or PO 1 hour preoperatively, then q4-6h depending on the type of VWD

SBE REGIMEN FOR DENTAL SURGERY

Route	Antibiotic dose
Oral	Amoxicillin 50 mg/kg PO
IV (unable to take oral medication)	Ampicillin, Cefazolin, or Ceftriaxone 50 mg/kg IV
Oral (allergy to penicillins)	Cephalexin 50 mg/kg or Clindamycin 20 mg/kg or Azithromycin 15 mg/kg PO
IV (allergy to penicillins and unable to take oral medication)	Cefazolin or ceftriaxone 50 mg/kg or clindamycin 20 mg/kg IV

For complete listing of SBE indications for other surgeries/procedures, see http://www.heart.org/idc/groups/heart-public/@wcm/@hcm/documents/downloadable/ucm_307644.pdf.

NORMAL HEMODYNAMIC INDICES AND WEIGHT

Mean systolic blood pressure (mm Hg) in preterm and term infants

Gestational age at birth	Day 1 of life	Day 10 of life
24	41	52
28	44	62
32	50	69
36	56	76
40	63	83

Age	Normal blood pressure (mm Hg): Mean systolic	Normal blood pressure (mm Hg): Mean diastolic	Mean heart rate (beats/min)	Weight range 10th-90th percentile
Preterm	55-75	35-45	120-170	
0-3 months	65-85	45-55	100-150	2.5-7.5
3-6 months	70-90	50-65	90-120	4.8-9.5
6-12 months	80-100	55-65	80-120	6.5-12.5
1-3 years	90-105	55-70	70-110	8.75-17
3-6 years	95-110	60-75	65-110	15.5-25
6-12 years	100-120	60-75	60-95	17-55
12-20 years	110-135	60-75	55-85	30-86

Simple formula to predict weight from age:
Infants 1-11 mo: Wt (kg) = (Age [months] + 9)/2
Children 1-4 yr: Wt (kg) = 2 × (Age [yr] + 5)
Children 5-14: Wt (kg) = 4 × Age (yr)

BLOOD PRODUCTS

$$\text{MABL} = \frac{\text{EBV} \times (\text{child's hematocrit} - \text{minimum accepted hematocrit})}{\text{child's hematocrit}}$$

e.g., 10-kg child with a hematocrit of 42% who could be hemodiluted to a hematocrit of ~25% (assuming EBV = ~70 mL/kg)

$$\text{MABL} = \frac{700 \times (42-25)}{42} = \frac{700 \times 17}{42} = 285\ \text{mL}$$

EBV, Estimated blood volume; *MABL,* maximum allowable blood loss.

PRBC TRANSFUSION

$$\text{Volume of PRBCs} = \frac{(\text{desired Hct} - \text{present Hct}) \times \text{estimated blood volume (70 mL/kg} \times 10\text{ kg)}}{\text{Hematocrit of PRCBs}}$$

$$= \frac{(35-23) \times (70 \times 10)}{60}$$

$$= 140\ \text{mL PRBCs}$$

$$\text{Volume of PRBCs to be transfused} = \frac{(35-23) \times (70 \times 10)}{60} = \frac{12 \times 700}{60}$$

$$= \sim 140\ \text{mL PRBCs}$$

e.g., a 10-kg child with a hematocrit of 23 who you wish to transfuse to a hematocrit of 35
