PULL-THROUGH FOR IMPERFORATE ANUS AND CLOACA

SURGICAL CONSIDERATIONS

Description

Imperforate anus anomalies are classified as **high** or **low**, depending on whether the distal rectum ends above or below the levator muscle. Usually, the rectum terminates as a "fistula" entering the perineum or pelvic structures anterior to the external anal sphincter. Rarely, the rectum ends blindly, often associated with trisomy 21. If the fistula terminates on the perineum, it is called a "perineal fistula" or "anterior anus." In girls, it often terminates inside the fourchette but outside the hymen, called a "vestibular" fistula. Fistulae to the vagina or uterus are rare; when they occur, they may be in conjunction with urethral anomalies. This combined structure—including the rectum, vagina, and urethra—is called a "cloaca." In boys, the fistula often ends in the urethra, occasionally the prostate, and rarely the bladder neck.

Surgical approach

At birth, associated conditions (e.g., VACTERL syndrome) are excluded while one waits 24 h for the appearance of meconium through a sometimes-hard-to-see perineal fistula. The operation is then performed according to the estimated site of the fistula. Low lesions are dilated or repaired; high lesions are treated with a divided RLQ or loop colostomy. Definitive repair of high lesions occurs after several months following contrast studies. This operation—called a **posterior sagittal anorectoplasty (PSARP)** or **Pena procedure**—is performed in the prone jackknife position. If the fistula is high, it occasionally will be necessary to turn the patient over for abdominal mobilization of the sigmoid colon.

Laparoscopic approaches are quickly replacing the PSARP, especially for high lesions. High lesions are also amenable to early **laparoscopic mobilization and pull-through**. This can be done with low fistulae as well, but dissection of the common wall between the urethra and fistula must be performed with care.

Usual preop diagnosis

Imperforate anus

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care and pain management options, and possible need for transfusion. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Low Lesions	High Lesions
Position	Supine, lithotomy	Prone, possible turn to spine or lithotomy

Incision	Midline perineal	Midline sacral, transverse abdominal
Special instrumentation	Muscle stimulator	⇐ + Urethral sound; vaginal pack
Unique considerations	None	Pressure points; prone position
Antibiotics	Preop: ampicillin 25 mg/kg iv + gentamicin 2.5 mg/kg iv	⇐
Surgical time	1–1.5 h	3–6 h
EBL	<5 mL/kg	5–10 mL/kg
Postop care	Apnea monitor if neonate	
Mortality	20%, due to associated anomalies	≤40%, due to associated anomalies
Morbidity	Anal stenosis: 5–10% Mucosal prolapse: 5%	⇐ Intestinal obstruction: 5–10% Neurogenic bladder: <5% Urethral stricture: 1–3%
Pain score	3–4	5–6

PATIENT POPULATION CHARACTERISTICS

Age range	Newborn–6 mo	12–18 mo
Male:Female	1.5:1	⇐
Incidence	1/5000	⇐
Etiology	Unknown	⇐
Associated conditions	CHD (common); esophageal atresia (15%); GU anomalies; sacral/spinal cord anomalies; VATER association	⇐

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Definitive repair is performed via the sacral and/or perineal route at ~12 mo. Children with rectal or anal agenesis without fistula will have had colostomies in newborn period. Other anomalies (e.g., VATER association VATER/VACTERL, vertebral anomalies, anal agenesis, cardiac defects, tracheoesophageal fistula [TEF]), esophageal atresia (EA) and/or renal or radial bone abnormalities may be present.

Respiratory	If VATER association is present, ✓ cervical spine. Avoid extreme head flexion. If prior TEF repair, concerns as previously noted in Anesthetic Considerations for Repair of Tracheoesophageal Fistula/Esophageal Atresia. **Tests:** CXR; cervical spine film
Cardiovascular	Patients with VATER association have a 20% incidence of CHD (e.g., VSD). Obtain echocardiogram and, if needed, cardiology consultation preop. **Tests**: Echo
Gastrointestinal	Colostomy may be present; thus, anesthesia records may be available for review.
Renal	Renal abnormalities may be present. **Tests:** BUN; Cr; electrolytes
Musculoskeletal	Radial bone deformities may be present.
Laboratory	Hct; T&C (✓ parental/directed donor blood availability.)
Premedication	If >9 mo, consider midazolam (0.5 mg/kg po) 30 min prior to arrival in OR. Consider 0.5 mg/kg po midazolam (maximum 20 mg) or 0.05–0.1 mg/kg iv midazolam (maximum 2 mg) for patients >9 mo.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Evaluate for concurrent disease. Discuss with surgeon possible epidural catheter.

INTRAOPERATIVE

Anesthetic technique

Combined epidural/GETA, warm OR to 75°F–80°F; heating pad on OR table.

Induction	Standard pediatric induction. Secure iv access and administer muscle relaxant (e.g., rocuronium 0.5–1 mg/kg or vecuronium 0.1 mg/kg) to facilitate ET intubation. Maintain air leak at >18–35 cm H_2O. Lumbar epidural catheter should be inserted after induction.	
ERAS	Verify preincision antibiotics. Assess volume status. Consider epidural or discuss with surgeon local wound infiltration at conclusion of procedure. Consider iv acetaminophen (10 mg/kg) for multimodal pain control and 0.1 mg/kg iv ondansetron for PONV prophylaxis.	
Maintenance	Volatile agent/air/O_2 with epidural analgesia (2 cc ropivacaine 0.2% or bupivacaine 0.25%), or morphine (0.1 mg/kg iv), hydromorphone (10–15 mcg/kg iv), or fentanyl (2–5 mcg/kg iv). Maintain neuromuscular blockade as surgically indicated.	
Emergence	Usually extubated at the end of the case. If NDMR was used, reverse neuromuscular blockade with sugammadex (2–4 mg/kg) or with a combination of neostigmine (0.07 mg/kg) and glycopyrrolate (0.01 mg/kg). Do not attempt reversal with neostigmine and glycopyrrolate until first twitch of TOF has returned. Ability to flex hips is a sign of adequate reversal.	
Blood and fluid requirements	Moderate blood/3rd-space losses IV: 20–22 ga × 2 BSS @ maintenance	Place ivs in the upper extremities because positioning of legs may impede venous flow. 3rd-space losses ~5

		mL/kg/h. Neonates should have supplemental glucose infusion.
Monitoring	Standard monitors Urinary catheter ± 24-ga radial arterial line	Maintain UO @ 0.5–1 mL/kg/h. Marked arterial waveform variation with ventilation is a sensitive indicator of hypovolemia. ABG/Hct/glucose prn.
Positioning	✓ and pad pressure points ✓ eyes	Patient may be turned during procedure.
Complications	Metabolic acidosis Hypovolemia →↓ BP Hypothermia	Mild metabolic acidosis may occur with significant bleeding or when 3rd-space losses are replaced with bicarbonate-deficient fluids (NS, albumin 5%, PRBCs).

POSTOPERATIVE

Complications	Subglottic edema Respiratory depression 2° to opiates	
Multimodal pain management	Continuous epidural analgesia Fentanyl (1–2 mg/kg iv q1h prn) Morphine (0.05–0.1 mg/kg iv q1–4h) Hydromorphone (0.002 mg/kg iv q1h) Acetaminophen 10	Aggressive pain management warranted

	mg/kg iv/po q6h
Tests	Hct, ABG, electrolytes
ERAS	Encourage early enteral nutrition and patient mobilization as appropriate. Assess for appropriate return of bowel function.

REPAIR OF INGUINAL AND UMBILICAL HERNIAS AND HYDROCELE

SURGICAL CONSIDERATIONS

Description

Inguinal hernia repair (**herniorrhaphy**) and its variant, **hydrocele repair**, are the most frequently performed operations in pediatric surgery. Most pediatric hernias are indirect; they occur when the processus vaginalis (a small pouch of peritoneum dragged down to the scrotum during gonadal descent) fails to obliterate. Infants, particularly the premature, are more likely than toddlers to develop bilateral and incarcerated hernias. Hydroceles are variants in abnormal obliteration of the processus vaginalis. Communicating hydroceles have a smaller neck and derive their name because this neck is so small that only intraperitoneal fluid, not bowel, can pass through it. Noncommunicating hydroceles have a completely obliterated proximal neck without communication to the peritoneal cavity. Noncommunicating hydroceles can resolve spontaneously during the first 2 yr of life; hydroceles that fail to resolve are typically communicating and repaired after 2 yr. Hydroceles can be diagnosed on physical exam as "communicating" when they empty/fill with postural change. Umbilical hernias have a tendency to close over the first 5 yr of life (~95%) and are repaired when large (>2 cm) or persistent. Complications of hernia/hydrocele repair include damage to the vas

deferens or testicular vessels, metachronous contralateral hernias (~10%) if just one side is repaired initially, and a very low incidence of infertility when bilateral repairs are undertaken. Bleeding, if any, is minor, recurrence uncommon (≤1%), and bowel resection is rarely necessary, even when a hernia is incarcerated. Overnight admission for apnea monitoring is suggested in premature children (≤54–60 wk corrected age). **Hydrocele repair** complications are similar to those of herniorrhaphy. **Umbilical hernia repairs** have very few complications. Acetaminophen pr or iv at the beginning of the procedure aids postop pain management.

Surgical approach

Inguinal hernias and hydroceles are repaired through a lower-lateral abdominal skin crease incision (more recently, laparoscopically), permitting separation of the sac from spermatic cord structures, followed by high ligation ± distal fenestration (in hydroceles). Umbilical hernia repair is performed through a transverse incision in the infraumbilical skinfold, through which the sac is resected from the undersurface of the skin and healthy fascial edges are closed.

Usual preop diagnosis

Inguinal hernia; umbilical hernia; hydrocele

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Inguinal	Umbilical
Position	Supine	⇐
Incision	Inguinal, bilateral	Infraumbilical
Unique considerations	Prematurity	Abdominal compression if hernia large
Antibiotics	None	⇐
Surgical time	40 min	⇐
Closing considerations	Nerve block, caudal	Umbilical block
EBL	5 mL/kg	⇐

Postop care	Apnea monitor; hospitalization for premature infants	None
Mortality	<1%	⇐
Morbidity	Apnea Recurrence	None
Pain score	3–5	3–5

PATIENT POPULATION CHARACTERISTICS		
Age range	Premature–adolescent	>2 yr
Male:Female	5:1	N/A
Incidence	1–2%	1%
Etiology	Patent processus vaginalis	Persistent umbilical defect
Associated conditions	Gonadal dysgenesis (rare)	None

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Hernia repair is most commonly performed in otherwise healthy infants in the first 2 yr of life, often on an outpatient basis. It is also performed on premature infants (<37-wk gestational age at birth). Premature infants are particularly prone to inguinal hernias. Postop apnea can occur in infants ≤60 wk postconceptual age, particularly if the infant was premature, has neurologic disease or anemia, or required intensive care in the early neonatal period. Infants ≤ 60-wk postconception usually require overnight admission for monitoring (postop apnea and ↓ HR).

Respiratory	Bronchopulmonary dysplasia (BPD), tracheomalacia, and subglottic stenosis are consequences of prolonged mechanical ventilation and immature lungs at birth. ✓ prior NICU Hx. ↓ FRC and ↑ PVR make infants with BPD more susceptible to hypoxia. They may require supplemental nasal O_2 on a chronic basis, have immature respiratory centers, and may exhibit paradoxical apneic/bradycardic episodes in

	response to hypoxemia. **Tests:** CXR
Cardiovascular	Prior PDA ligation is possible. These patients may be on diuretic therapy for intrinsic lung disease (e.g., BPD) with resultant decreased intravascular volume. **Tests:** CXR; electrolytes
Neurologic	Premature infants may be prone to seizure disorders. **Tests:** Anticonvulsant levels
Hematologic	Anemia is common at ~3 mo of age (physiologic nadir) and increases risk of postop apnea.
Tests	Hct; PT; PTT; Plt, as indicated from H&P
Laboratory	Other tests as indicated from H&P
Premedication	If appropriate (e.g., infants > 9 mo), midazolam (0.5 mg/kg po; maximum 20 mg) 30 min prior to arrival in OR or 0.05–0.1 mg/kg iv midazolam (maximum 2 mg).
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Evaluate for concurrent disease.

INTRAOPERATIVE

Anesthetic technique

Typically, GETA or LMA (± caudal [especially for bilateral repair] or ilioinguinal/iliohypogastric block [for single-sided repair]). An alternative in ex-preterm infants at high risk for postop apnea is spinal anesthesia without GA, though this is practiced more rarely. Warm OR to 75°F–80°F and use a forced-air warmer.

Induction	Mask induction in children with sevoflurane/N_2O/O_2. Secure iv. If appropriate, position the child for placement of caudal anesthetic: ropivacaine 0.2% or bupivacaine 0.25% ± epinephrine 1:200,000 @ 1 mL/kg (max 10 cc). If the child is otherwise healthy and >18 mo old, proceed with LMA; otherwise, tracheal intubation is preferred. If premature, consider

	atropine 0.02 mg/kg iv prior to intubation to prevent bradycardia. Intubation may be facilitated with rocuronium (0.6–1.2 mg/kg) or vecuronium (0.1 mg/kg).	
ERAS	Verify preincision antibiotics. Assess volume status. Consider caudal (bilateral surgery) or ilioinguinal/iliohypogastric block (unilateral surgery). Consider iv acetaminophen (10–15 mg/kg) for multimodal pain control and iv ondansetron (0.1 mg/kg) for PONV prophylaxis.	
Maintenance	Standard pediatric inhalational anesthetic is appropriate. With caudal anesthetic or nerve block, decrease the amount of volatile anesthetic and avoid or reduce opiates. If LMA and spontaneous ventilation are used, deepen anesthetic to 2 MAC of inhalational agents at incision to minimize risk of laryngospasm. Caudal onset time 10–15 min.	
Emergence	If NDMR was used, reverse neuromuscular blockade with sugammadex (2–4 mg/kg) or with a combination of neostigmine (0.07 mg/kg) and glycopyrrolate (0.01 mg/kg). Do not attempt reversal with neostigmine and glycopyrrolate until first twitch of TOF has returned. Extubate only when fully awake. LMA may be removed deep and oral airway is placed.	
Blood and fluid requirements	Negligible blood loss IV: 22–24 ga × 1 BSS @ maintenance	Infants receiving diuretics will require 10–20 mL/kg iv of BSS to avoid ↓ BP 2° volatile anesthetics. In children <1 mo old, use dextrose-containing iv solution (e.g., D10W for maintenance, LR for

		replacement fluids).
Monitoring	Standard monitors	Premature infants may become hypoglycemic. ✓ blood glucose during surgery.
Positioning	✓ and pad pressure points ✓ eyes	
Complications	Laryngospasm	
	Bronchospasm Local anesthetic toxicity Hypothermia Hypoglycemia	Rx bronchospasm: albuterol inhaler, mist, mask, deepen anesthesia

POSTOPERATIVE

Complications	Apnea/bradycardia Subglottic edema	Can ↓ incidence of apnea/bradycardia by administering caffeine (10 mg/kg iv) intraop or in NICU/PACU
Multimodal pain management	Field block Ketorolac 0.5 mg/kg iv q6h Acetaminophen (10 mg/kg po/iv q6h prn, 20 mg/kg pr q6h prn)	If no caudal is used, a field block (bupivacaine 0.25% 2–3 mL) at the end of surgery reduces pain in the immediate postop period. It is usually performed by the surgeon.
Tests/monitoring	Apnea monitor and pulse oximeter for 12–18 h for term infants ≤44 wk; premature infants ≤60 wk	Caffeine is no substitute for monitoring and attentive parents/nurses.
ERAS	Encourage early enteral nutrition and patient	

mobilization as appropriate.
Assess for appropriate return of bowel function.

SURGERY FOR THE UNDESCENDED TESTICLE

SURGICAL CONSIDERATIONS

Description

Also called "cryptorchidism," this occurs when a testicle fails to follow the usual pattern of descent. Testicles begin in fetal life just inferior to the kidney and, through differential growth, migrate to the base of the ipsilateral hemiscrotum, attached there by the gubernaculum. Problems occur when testicular descent does not occur, occurs partially, or occurs incorrectly. Testicles that are found in the abdomen, inguinal canal, perineum, thigh, suprapubic fat, or contralateral scrotum may be associated with subsequent problems, including infertility and malignant degeneration. Transposition and fixation of the testicles into their normal location (**orchidopexy**) does not eliminate these problems; rather, it places the testicle in a position where it can be more easily evaluated and may mitigate the progressive infertility thought to occur when testicles remain outside the scrotum. Because testicular descent can occur early in life, orchiopexy is usually performed around 9–12 mo of age.

Surgical approach

The operation begins in a similar fashion to a hernia repair, as 95% of cryptorchid testes have an associated hernia sac. One exception is if the testicle is thought to be **intra-abdominal**. In this circumstance, many surgeons will begin with a laparoscopic abdominal examination, using the vas deferens and testicular vessels to locate the testis. If it is high in the abdomen, it may be brought immediately to the perineum (difficult if the testicular vessels are short), or a two-step **Fowler-Stevens** approach is undertaken. In this approach, the gubernacular vessels supplying the inferior pole of the testis are encouraged to hypertrophy by division of the spermatic vessels, and the testicle is left in the abdomen near the internal ring. At a second operation ~6 mo later, the testicle is

brought down, much as in the primary operation following hernia repair. This involves creation of a passage down to the base of the ipsilateral hemiscrotum, through which the testicle is advanced as far as the vas deferens permits. The tough outer layer of the testicle—the tunica albuginea—is then attached to the scrotum in a subcutaneous pocket outside the dartos fascia to discourage migration back up to a high location. There is scant blood loss; however, there is a small risk to testicular viability. Small, high, abnormal testes with short vessels and vas associated with poor gubernacular vessels are deemed better removed than left in a high location where malignant degeneration might go undetected. A caudal block may be preferable to injection of local anesthesia at multiple sites.

Usual preop diagnosis

Undescended testicle; cryptorchidism

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Orchidopexy	First of a Two-Stage Repair
Position	Supine	⇐
Incision	Lower groin crease	Laparoscopic or open

RESECTION OF SACROCOCCYGEAL TERATOMA

SURGICAL CONSIDERATIONS

Description

Occasionally during gestation, a group of cells composing all three germ layers segregates and begins autonomous development as a teratoma. When this occurs just anterior to the coccyx, the tumor may remain small and local, or grow up into the abdomen or down into the peritoneum, attaining sizes as large as the child itself. Although a few centers attempt fetal surgery for very large lesions, in most hospitals, the child is delivered by the appropriate route (cesarean delivery for large external lesions), and the mass is addressed in the neonatal period or whenever it is diagnosed thereafter. Most (though not all) sacrococcygeal teratomas (SCTs) are initially benign; however, they may soon transform into malignancy beginning at 2 mo of age.

Surgical approach

Small teratomas are approached prone from the rectum; larger ones, with high blood flow, may first have an intra-abdominal procedure to ligate feeding vessels and mobilize the tumor. Once prone, a V-shaped incision is created down to the posterior aspect of the anteriorly displaced anus. Surgical principles of dissection include avoiding entry into the rectum (a colostomy is rarely necessary); meticulous hemostasis, including ligation of the median sacral artery; and removal of the coccyx, from which the tumor arises and may recur. At the end of the procedure, the levator muscles are brought together, and the anus is suspended from the presacral fascia. Bleeding can be massive, and adjacent structures (bowel, bladder, and presacral nerve plexus) are distorted and prone to injury.

Usual preop diagnosis

Sacrococcygeal teratoma

Differential diagnosis

May appear similar to meningomyelocele

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, pain management options, and possible need for transfusion. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE

Position	Prone, sometimes preceded by supine
Incision	Perineal chevron, sometimes preceded by transverse abdominal
Special instrumentation	Hegar dilators
Unique considerations	Intra-abdominal blood supply
Antibiotics	Ampicillin 25 mg/kg and gentamicin 2.5 mg/kg
Surgical time	2–5 h
Closing considerations	Extubation depends on duration and blood loss.
EBL	20–80 mL/kg
Postop care	NICU, prone
Mortality	Fetal, due to hydrops and high flow state; <10% neonatal
Morbidity	Bleeding Colostomy Pelvic nerve damage → bowel and bladder dysfunction Recurrence and/or malignant degeneration

PATIENT POPULATION CHARACTERISTICS

Age range	1–2 mo
Male:Female	1:1
Incidence	1/15,000 births
Etiology	Unknown
Associated conditions	Constipation; heart failure; Currarino triad (sacral agenesis abnormalities, anorectal malformations, presacral mass); malignant degeneration

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Sacrococcygeal teratoma is a rare tumor of infancy. Sometimes diagnosed prenatally, it also can present as late as 18–24 mo. Patients may present with urinary obstruction by the tumor mass; lower extremity pain, numbness, or weakness; or bowel obstruction. ~10% may have a sacral anomaly or myelomeningocele.

Respiratory	There may be respiratory compromise as a result of a large abdominal mass pushing up on the abdominal contents and the diaphragm. **Tests:** CXR, if indicated from H&P
Cardiovascular	Sacrococcygeal teratoma may be associated with high-output cardiac failure due to AV fistulae within the tumor. Consultation with a cardiologist may be appropriate. **Tests:** ECG; echo may be necessary.
Renal	Postrenal obstruction may compromise renal function. **Tests:** BUN; Cr
Gastrointestinal	Intestinal compression by the tumor may cause ↑ risk of gastric aspiration. **Tests:** Electrolytes
Hematologic	This tumor may be associated with coagulopathy. **Tests:** PT; PTT; INR
Laboratory	Other tests as indicated from H&P
Premedication	Patients >9 mo may benefit from midazolam (0.5 mg/kg) po 30 min before surgery. If iv is present, iv midazolam 0.05–0.1 mg/kg may be used (e.g., for 10 kg child, 0.5–1 mg midazolam). Consider 0.5 mg/kg po midazolam (maximum 20 mg) or 0.05–0.1 mg/kg iv midazolam (maximum 2 mg) for patients >9 mo.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Evaluate for concurrent disease.

INTRAOPERATIVE

Anesthetic technique

GETA, using a pediatric circuit; warm OR to 75°F–80°F; warm all iv fluids. Due t risk of coagulopathy and the possibility of spine malformations, epidural catheter usually is not considered.

Induction	Usually an inhalation induction. If an iv is present, then an iv induction is performed. A modified rapid-sequence induction is recommended in those patients with a large intra-abdominal mass compressing the GI tract. Otherwise, standard pediatric induction is appropriate. The appropriate size for the ETT is one that will allow a small leak around the tube when positive pressure is applied (18–35 cm H_2O).
ERAS	Verify preincision antibiotics. Assess volume status. Consider iv acetaminophen 10 mg/kg for multimodal pain control and ondansetron iv 0.1 mg/kg for PONV prophylaxis.
Maintenance	Standard maintenance. Muscle relaxation is appropriate.
Emergence	Depending on blood loss and fluid requirements, the patient may need to remain intubated at the end of the procedure. If extubation is elected, suction NG and confirm air leak around ETT before extubation. If there is no air leak, consider laryngeal edema and the need for continued intubation. If NDMR was used, reverse neuromuscular blockade with sugammadex (2–4 mg/kg) or with a combination of neostigmine (0.07 mg/kg) and glycopyrrolate (0.01 mg/kg). Do not attempt reversal with neostigmine and glycopyrrolate until first twitch of TOF has returned.
Blood and fluid	Potential for massive Tumor resection may be

requirements	blood loss. IV: Two large-bore iv catheters (e.g., 20–22 ga)	associated with massive blood loss, due to large pelvic venous bed, AV fistula, and coagulopathy. Close monitoring of Hct is necessary, along with correction of acidosis and Ca^{++} replacement.
Monitoring	Standard monitor ± Central line Arterial line (22 ga)	

POSTOPERATIVE

Complications	Bleeding Coagulopathy Hypoventilation Laryngeal edema	PICU is usually required. Maintain normothermia; correct metabolic acidosis. Postop ventilation is usually required due to potential risk of hypoventilation and laryngeal edema. Serial Hct may help detect postop hemorrhage.
Multimodal pain management	Fentanyl 1 mcg/kg/h iv Morphine (0.05–0.1 mg/kg iv q1–2h) Hydromorphone (0.005–0.01 mg/kg iv q1–2h) Acetaminophen (10 mg/kg iv/po q6h; 20 mg/kg pr q6h prn)	Approximate doses; titration required. Ketorolac likely not indicated due to risk of postop bleeding, possible compromise of renal function
Tests	ABG, Hct, PT/PTT	
ERAS	Encourage early enteral nutrition and patient mobilization as appropriate. Assess for appropriate	

return of bowel function.

ANESTHESIA FOR MINIMALLY INVASIVE SURGERY IN PEDIATRIC PATIENTS

Gregory B. Hammer

In recent years, there has been a significant increase in the practice of minimally invasive surgery in pediatric patients. Specific considerations for these surgeries (as in adult patients) include the effects of pneumoperitoneum on respiratory and cardiac function. ↑ abdominal pressure → ↓ diaphragmatic excursion, ↑ atelectasis, and V/Q mismatch. ↑ CO_2 levels can be difficult to control with mechanical ventilation; thus, manual ventilation may be necessary. There is risk of pneumothorax and pneumomediastinum. Use of Trendelenburg position further decreases FRC and lung compliance and increases the work of breathing. Cephalad movement of the carina may cause endobronchial intubation. Venous return may be impaired, causing ↓ CO. These effects are most pronounced in children <6 mo old. These children also may be at risk for reversal of L → R shunts through a patent foramen ovale (PFO) or ductus arteriosus.

Minimally invasive procedures that are frequently performed in pediatrics include appendectomy, pyloric stenosis, hernia repair, Nissen fundoplication, cholecystectomy, splenectomy, laparoscopically assisted bowel resection, thoracoscopy (VATS), and congenital diaphragmatic hernia repair. The general principles for anesthesia for minimally invasive surgery in pediatric patients are as follows:

PREOPERATIVE

1. Be vigilant about respiratory and cardiac function. Note baseline lung function (SaO_2, CXR, ABG); ✓ for any cardiac defects (e.g., L → R shunt, ↓ CO).
2. Epidural is usually not placed for laparoscopy or thoracoscopy, but it should be

considered at the end of the procedure if the decision is made to do open surgery or for large resections. Consider need for PT/PTT if significant bleeding or if preop health status indicates (e.g., oncology PT, malnutrition, renal/liver dysfunction).

3. Blood should be available for major cases including VATS for empyema. Although there usually is little blood loss with minimally invasive surgery, the potential for large-vessel disruption exists.
4. ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options.

Premedication	Consider 0.5 mg/kg po midazolam (maximum 20 mg) or 0.05–0.1 mg/kg iv midazolam (maximum 2 mg) for patients >9 mo.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Evaluate for concurrent disease.

INTRAOPERATIVE

Anesthetic technique

GETA; forced-air warmer; warm OR to 70°F–75°F; warm iv fluids.

Induction	Inhalation induction using sevoflurane, N_2O, followed by iv placement. If patient is at risk for aspiration, rapid-sequence induction is appropriate. For ET intubation in children, a cuffed tube may be used, with the cuff inflated to attain a leak at 18–30 cm H_2O. A cuffed tube is usually 1/2 size smaller than the corresponding uncuffed tube for age. If OLV is required, see Anesthetic Considerations for Pediatric Thoracic Surgery, for placement. Note the distance of the end of ETT from the carina. As abdominal girth is increased during CO_2 insufflation, it is common for the tube to advance to an endobronchial position.
ERAS	Verify preincision antibiotics. Assess volume status.

	Consider iv acetaminophen (10 for patients <1 yr old or 15 mg/kg for patients >1 yr old with maximum dose 650 mg) for multimodal pain control and 0.1 mg/kg iv ondansetron for PONV prophylaxis.	
Maintenance	Standard maintenance. Muscle relaxation is appropriate. An OG tube is placed to empty the stomach of any residual premedication and excess air introduced during PPV. Continued communication between the anesthesiologist and surgeon is essential. Pay attention to changes in positioning (e.g., Trendelenburg), intra-abdominal pressure (n1 = 15 cm H_2O), airway pressures, and BP. Recheck that BS = after insufflation, as cephalad movement of diaphragm may lead to endobronchial intubation.	
Emergence	In most cases, the patient can be extubated at the end of surgery. If NDMR was used, reverse neuromuscular blockade with sugammadex (2–4 mg/kg) or with a combination of neostigmine (0.07 mg/kg) and glycopyrrolate (0.01 mg/kg). Do not attempt reversal with neostigmine and glycopyrrolate until first twitch of TOF has returned.	
Blood and fluid requirements	IV: 22–20-ga catheter × 1 BSS maintenance fluids	Potential for 3rd space and blood loss, especially with VATS surgery for empyema
Monitoring	Standard monitors ± Arterial line Urinary catheter	Consider arterial line if patient has significant cardiac or respiratory compromise.
Positioning	✓ and pad pressure points ✓ eyes	
Complications	↑ CO_2 (40–50 mm Hg)	

	(common) ↑ PIP (common) Subcutaneous crepitus (moderately common)	
	Endobronchial intubation(common) Difficult ventilating (common) Hypovolemia	2° Trendelenburg position, ↑ abdominal girth. In thoracoscopy, if SLV is used, it may be necessary to raise the lung and ventilate transiently. → ↓ CO. Rx: crystalloid or albumin 10–20 mL/kg.
	Pneumothorax	CO_2 embolus (rare)
	Pneumomediastinum (rare)	
	Inadvertent cannulation of the vessel (rare)	

POSTOPERATIVE

Complications	Respiratory function impairment Bleeding Residual subcutaneous CO_2 Pneumothorax	Respiratory function may still be significantly impaired in the postop period and should be monitored closely.
Multimodal pain management	Ketorolac 0.5 mg/kg iv q6h, maximum 15 mg Morphine (0.05–0.1 mg/kg iv q1–2h) Hydromorphone (0.005–0.01 mg/kg iv q1–2h) Acetaminophen (10 mg/kg for patients <1 yr old or 15 mg/kg for	If there is significant intraop bleeding, avoid ketorolac for 24 h postop, and verify with surgical team before starting.

	patients >1 yr old po/iv q6h). Maximum acetaminophen dose of 650 mg q6h
ERAS	Encourage early enteral nutrition and patient mobilization as appropriate. Assess for appropriate return of bowel function.

EX UTERO INTRAPARTUM TREATMENT (EXIT) PROCEDURE

SURGICAL CONSIDERATIONS

Description

The EXIT (ex utero intrapartum treatment) strategy was developed as a means of establishing an airway after iatrogenic occlusion of the fetal trachea to promote lung growth for fetuses with severe congenital diaphragmatic hernia (CDH). The EXIT strategy can be viewed as a "half" delivery in which a **hysterotomy** is performed, only the head and shoulders are "delivered," and uterine relaxation is maintained by high concentrations of an inhalational anesthetic and intravenous tocolytics, ensuring the maintenance of uteroplacental blood flow and gas exchange. Using this strategy, operations as long as 3 h on uteroplacental "bypass" have been performed without significant maternal bleeding and uterine contraction. It provides time to perform procedures such as direct laryngoscopy, bronchoscopy, tracheotomy, arterial and venous access, administration of surfactant, resection of neck or lung masses, and cannulation for ECMO (extracorporeal membrane oxygenation) support, thereby converting a potential emergent crisis into a controlled situation.

Surgical technique

A successful EXIT procedure is a carefully orchestrated event in which all members of the OR team have specific roles and responsibilities. The scrubbed personnel consist of two pediatric/fetal surgeons, a maternofetal medicine specialist/obstetrician, a pediatric anesthesiologist, a neonatologist, and other specialists as indicated, with appropriate nurses and techs as needed. Unlike the EXIT procedure, a conventional cesarean delivery makes no attempt to prevent bleeding from the hysterotomy because hemostasis is achieved by return of uterine tone following the relatively rapid delivery of the fetus. Because of the significant hemorrhage from a conventional hysterotomy, the EXIT procedure is carried out using a **hemostatic uterine stapling device** (US Surgical CS 57, US Surgical/Tyco, Norwalk, CT). First, a low transverse skin crease incision is used. The decision to use a Mallard versus Pfannenstiel fascial incision is determined by uterine size (e.g., presence/absence polyhydramnios) and placental position. If the operation is performed in the late third trimester and the placenta is posterior or fundic, the lower uterine segment can be opened and the uterus left in situ. An anterior or previa placenta often necessitates moving the uterus out of the abdomen/pelvis. The hysterotomy in this situation is not in the lower uterine segment. Intraop ultrasonography is critical to map placental position. If polyhydramnios is present, amnioreduction is performed to avoid underestimation of the proximity of the placental edge to the hysterotomy. Two applications of the uterine stapler are usually necessary for an adequate opening. Bleeding often occurs where staple lines fail to intersect and is easily controlled with suture ligation. Only the necessary fetal parts are delivered in order to maintain uterine volume and avoid vigorous contractions and placental separation. A **sterile pulse oximeter** is attached to the palm of the fetal hand. It is covered with foil and Tegaderm tape to prevent aberrant readings due to the operating room lights. The long oximeter cord is passed across the field to the anesthesiologist. The fetal eyes are covered with a warm wet laparotomy pad. The fetus is continuously bathed in warm saline. Care is taken not to manipulate or unnecessarily expose the umbilical cord to avoid spasm of the vessels. Sterile instruments that need to be available include a laryngoscope with at least two different sized blades and extra bulbs (batteries are not sterilized and are inserted separately), two sizes of a rigid bronchoscope, a light cord, various endotracheal (some with surfactant adapters) and tracheostomy tubes, endotracheal tube stylettes, a hand bag device with a manometer and sterile tubing that is passed off the field to an oxygen source, a sterile neonatal stethoscope, and a sterile syringe filled with surfactant (if necessary). IV access is obtained if possible. Alternatively, a mixture of fentanyl and an NMB agent such as rocuronium, vecuronium, or pancuronium can be administered im (deltoid) to the fetus immediately after the hysterotomy. After the airway is obtained and secured, the umbilical cord is clamped

and divided and the child taken to the resuscitation table by the neonatologist. The placenta is delivered and the uterus closed in the standard fashion. Oxytocin is administered immediately prior to clamping the umbilical cord to enhance uterine tone.

Indications

Clinical situations in which the fetal airway or cardiovascular well-being is significantly threatened by conventional cesarean or vaginal delivery are candidates for the EXIT strategy. Some examples are:

- Intrinsic laryngotracheal anomalies resulting in congenital high airway obstruction syndrome (CHAOS): laryngeal web/atresia/cyst/stenosis, and trachea stenosis/atresia
- Extrinsic airway compression: cervical teratoma/lymphangioma (may or may not result in CHAOS)
- Epignathus
- Severe hydrops from a cystic adenomatoid malformation of the lung after a 32-wk gestation
- EXIT to ECMO for severe CDH with congenital heart disease
- Delivery of thoraco-omphalopagus twins
- Delivery of twins discordant for a potentially obstructing neck lesion

ERAS: Preop counseling by the surgeon/anesthesiologist should include limiting maternal NPO duration, review of nutritional status, postop care, pain management options, and possible need for transfusion. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE	
Position	L uterine displacement
Incision	Low transverse
Special instructions	Fetal monitoring
Unique considerations	Need to maintain uterine relaxation
Child	Monitor for fetal hypoxia and bradycardia.
Antibiotics	Cefazolin 2 g iv
Surgical time	2 h
Closing	Extubation

considerations	
Postoperative care	Variable—moderate
Mortality	Rare
Morbidity	Risk of hemorrhage

STERILE EQUIPMENT (ON SURGICAL FIELD)	
ETT	3.0 cuffed; 2.5, 3.0, 3.5 uncuffed, and available stylets
Laryngoscopes and blades	Miller 0,1 Wis-Hipple 1,1.5
LMA	1, 1.5
Suction catheters	6 Fr, 8 Fr
Other	Mask, capnograph tubing, oral airways, umbilical tape, Steri-Strips, stethoscope

NONSTERILE EQUIPMENT READILY AVAILABLE	
Fiber-optic bronchoscope	Appropriate size for neonatal airway
Ambu bag	
Additional oxygen source	

Maternal risks and outcomes

The most serious and immediate maternal risk during the EXIT procedure is **intraop hemorrhage**. This may result from **uterine atony** and can be minimized by decreasing the concentration of the inhalational anesthetic and administering oxytocin before umbilical cord ligation. This, in combination with the hemostatic uterine stapling device, has kept the average maternal blood loss well within the accepted range for traditional cesarean delivery. In addition, **placental injury** may occur during hysterotomy, resulting in hemorrhage. This has occurred in the setting of polyhydramnios, in which the edge of the placenta was compressed, obscuring it from view by the ultrasonographer. It is advisable to perform intraop amnioreduction in cases with severe polyhydramnios with a potentially nearby placenta before performing an EXIT procedure to allow better placental visualization. In one study, the short-term

maternal outcomes after 34 EXIT procedures were compared to those from 52 nonlaboring patients who underwent nonemergent primary cesarean delivery of singleton fetuses. The rates of chorioamnionitis and endometritis and the postop hematocrit and hospital stays were similar between groups. The incidence of **wound infection** was increased in those undergoing EXIT procedure (15%) compared to controls (2%).

Lower uterine segment transverse hysterotomy is preferred for the EXIT procedure as it allows the possibility of future vaginal delivery. However, a low anterior placenta or an extremely large neck mass may make this incision impossible. In such cases, a classical hysterotomy is necessary, which would preclude future vaginal deliveries because of the risk of uterine rupture during labor. Thus, all pregnant women should be counseled that cesarean delivery may be required for all future pregnancies and that there is an increased risk of abnormal placentation with subsequent pregnancies.

ANESTHETIC CONSIDERATIONS

The features that distinguish the EXIT procedure from a conventional cesarean delivery are, in large part, due to the anesthetic management. Of paramount importance is the uterine relaxation achieved with an inhalational agent, most commonly isoflurane. Isoflurane has been administered in concentrations up to 2.5% to completely anesthetize the fetus to allow fetal laryngoscopy, bronchoscopy, tracheostomy, or tumor resection. Preservation of uteroplacental gas exchange with high concentrations of maternal isoflurane is well tolerated by the fetus for EXIT procedures lasting up to 180 min. Careful attention to the maintenance of maternal systemic blood pressure, often with the use of phenylephrine and ephedrine, is essential to safely use the high concentration of isoflurane required for uterine relaxation. Intraop fluid administration is kept to an absolute minimum 2° the postop predisposition to maternal pulmonary edema while on tocolytic agents. Occasionally, additional uterine relaxation is required, even when the end-tidal isoflurane concentration is ≥2.5%. This suggests that extensive manipulation of the uterus (e.g., forward displacement of the uterus to perform a posterior hysterotomy because of an anterior placenta) may stimulate the uterus to contract, even if high concentrations of isoflurane are used. For this situation, the intraop use of nitroglycerine provides excellent temporary uterine relaxation and is well tolerated. Pulmonary edema does not occur as a result of intraop intermittent dosing of nitroglycerine when it is used as an adjunct for uterine relaxation.

PREOPERATIVE

Conduct a rigorous preop evaluation of the mother, including CV history; evaluate all fetal anomalies in question. The most common indication for an EXIT procedure is the presence of a prenatally diagnosed neck mass, which is anticipated to result in severe airway obstruction following birth; severe micrognathia and mandibular hypoplasia may also require this approach. Preoperative consultation and coordination between treating providers are necessary.

Full-stomach precautions	Pretreatment with Bicitra® 30 mL po, ranitidine 50 mg iv
Positioning	Left uterine displacement
Premedication	Due to need for rapid-sequence induction and potential effects in the fetus, consider nonpharmacologic anxiolysis.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Evaluate for concurrent disease.

INTRAOPERATIVE

Anesthetic technique

GETA, rapid-sequence induction. The primary goal is to maintain complete uterine relaxation, to support maternofetal gas exchange, and to ensure fetal oxygenation. Uterine blood flow is not autoregulated, but directly related to MAP.

Maintain blood pressure with phenylephrine and ephedrine as necessary. Maintain fluid resuscitation to moderate due to propensity of pulmonary edema while on tocolytic agents. Use high concentration of isoflurane or sevoflurane to maintain uterine relaxation. Nitroglycerin can also be used to facilitate relaxation. Intrauterine infusion with normal saline may be necessary to preserve uterine volume and prevent separation of the placenta.

Induction	Rapid-sequence induction, with propofol and succinylcholine
ERAS	Verify preincision antibiotics. Assess volume status.
Maintenance	Volatile agent at high concentration to maintain uterine relaxation. Propofol (150–250

	mcg/kg/min) and remifentanil (0.2–0.5 mcg/kg/min) may help reduce uterine contractility in a dose-dependent manner and thereby reduce the need for large quantities of volatile anesthesia. With uterine exposure, reduce propofol to 50–75 mcg/kg/min.	
Special considerations	Coordination is necessary between maternal anesthesia team, surgical team, and pediatric anesthesia regarding cord clamping and delivery. The cord is clamped, volatile agent immediately discontinued, and N_2O continued, fentanyl and midazolam are given; oxytocin bolus and continuous infusion of oxytocin are titrated to uterine response. Once hemostasis is achieved, and uterine tone is restored, anesthetic agents are restarted.	
Care of fetus/neonate	Infant: delivery of the fetal head and upper extremity. Commence fetal monitoring with fetal scalp electrode, O_2 sat monitoring (normal SaO_2—65–75%). If possible, place iv catheter. Alternatively, additional anesthetic can be administered im via deltoid muscle (fentanyl 2–3 mcg/kg; rocuronium 0.5–1 mg/kg or vecuronium 0.1 mg/kg). After the airway is secured, the cord is clamped and delivery completed. Once the airway is secured, O_2 sat should increase to >90%. If unable to secure, consider surgical intervention. Secure ETT with umbilical tape, Steri-Strips. Secure iv access if not obtained previously. Hemodynamic management may include resuscitation with iv fluids and transfusion. Transfer to NICU unless further immediate surgical intervention is needed.	
Emergence	Usually extubated	
Blood and fluid requirements	Moderate blood loss IV: 16–18 ga × 1–2	Blood products available in the room due to potential for

		hemorrhage; cautious BSS administration due to potential for pulmonary edema related to the use of tocolytics
Monitoring	Standard monitors A-line	CVP to guide fluid resuscitation
Positioning	L uterine displacement	
Complications	Maternal hemorrhage Uterine atony	

POSTOPERATIVE

Complications (maternal)	Hemorrhage	✓ H/H regularly (e.g., 30 min for the 1st h); transfuse as necessary.
	Pulmonary edema	2° overly aggressive resuscitation, prolonged use of NTG
Complications (neonate)	Hypovolemia Respiratory compromise	2° fetal hemorrhage via the umbilical cord 2° aspiration, overresuscitation-ventilatory support as necessary
Tests	CXR to verify ETT position	
Multimodal pain management	Maternal Neonate	Patient-controlled analgesia Fentanyl 1–2 mcg/kg iv q1h prn Morphine (0.05–0.1 mg/kg iv q1–2h) Hydromorphone (0.005–0.01 mg/kg iv q1–2h)

	Acetaminophen 10 mg/kg iv q6h; 20 mg/kg pr q6h
ERAS	Encourage early enteral nutrition and patient mobilization as appropriate. Assess for appropriate return of bowel function.

PEDIATRIC BARIATRIC SURGERY

Description

Childhood obesity, defined by the U.S. Centers for Disease Control and Prevention as a BMI above the 95th percentile for age, is pandemic in the United States, with rates up to 18% for adolescents aged 12–19. Adolescent bariatric surgery has been shown to both improve the quality of life and significantly decrease the comorbidities of obesity including obstructive sleep apnea (OSA), hypertension, type 2 diabetes, nonalcoholic fatty liver disease, pseudotumor cerebri, joint disease, and depression. There are two fundamental strategies to accomplish weight loss through surgery. The first approach is **restriction** in which the stomach volume is reduced to physically limit the amount of food that can be consumed comfortably at a given time. The second approach is **malabsorption** in which a given amount of intestine is bypassed to decrease absorptive capacity for nutrients.

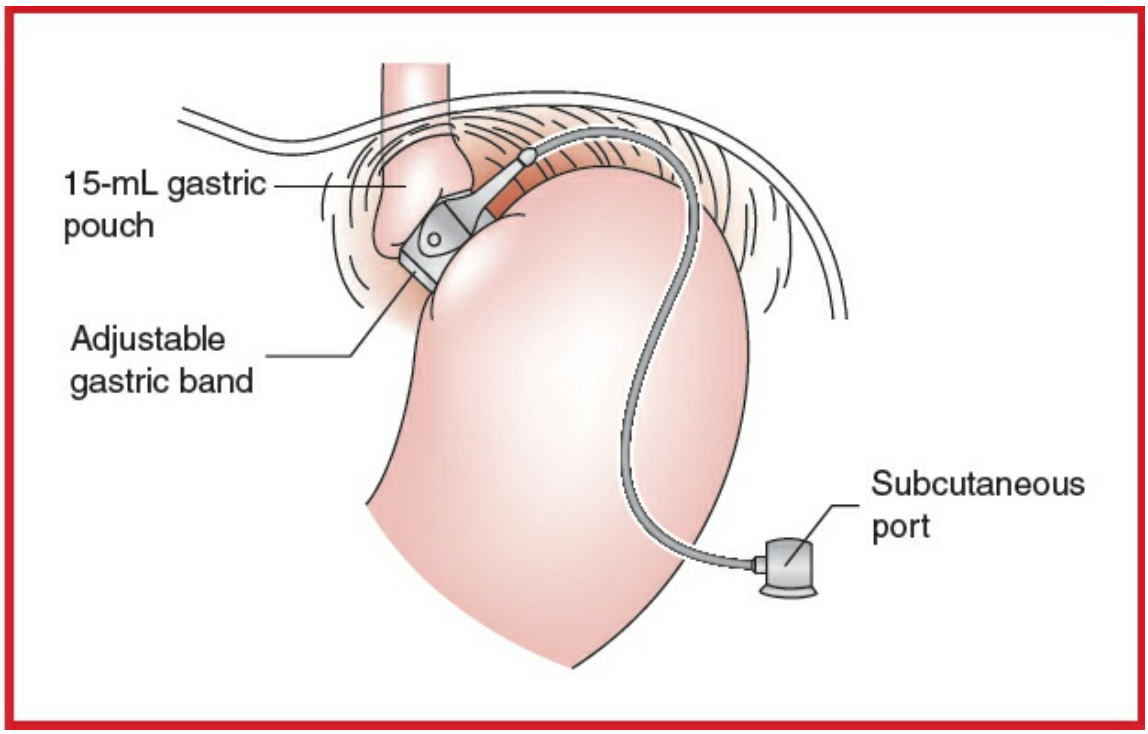

Figure 12.5-14 Gastric band approach.

Surgical approach

Prior to any consideration of surgical intervention, pediatric patients with obesity must be assessed by a multidisciplinary team including pediatricians, psychologists, social workers, physical therapists, and nutritionists. Nonsurgical weight loss options should be thoroughly investigated and exhausted prior to offering surgery.

The three most commonly performed procedures for obesity in the adolescent population are gastric band, sleeve gastrectomy, and Roux-en-Y gastric bypass. The **gastric band** (Fig. 12.5-14) is an adjustable device surgically placed around the stomach just distal to the GE junction. The procedure is generally done laparoscopically. An access port is placed in the subcutaneous tissue of the abdomen. The device variably compresses the stomach and restricts intake. **Sleeve gastrectomy** (Fig. 12.5-15) is performed by resecting the bulk of gastric tissue along the greater curvature leaving a small tubular stomach resulting in restriction and some malabsorption. The procedure is generally performed with laparoscopic staplers using a bougie (34–40 Fr) or endoscope in the stomach to guide the sizing of the resection. Finally, the **Roux-en-Y gastric bypass** (Fig. 12.5-16) involves division of the stomach leaving a small gastric pouch and creation of separate alimentary and pancreaticobiliary limbs of the intestine that delay the mixing of nutrients and pancreaticobiliary secretions, thus limiting absorption. Again, the preferred approach is laparoscopic. Perioperative complications associated with obesity must be considered in the

management of bariatric patients. Increased risk of thromboembolic disease and wound infection warrants prophylaxis. OSA and hypercapnia warrant postop monitoring.

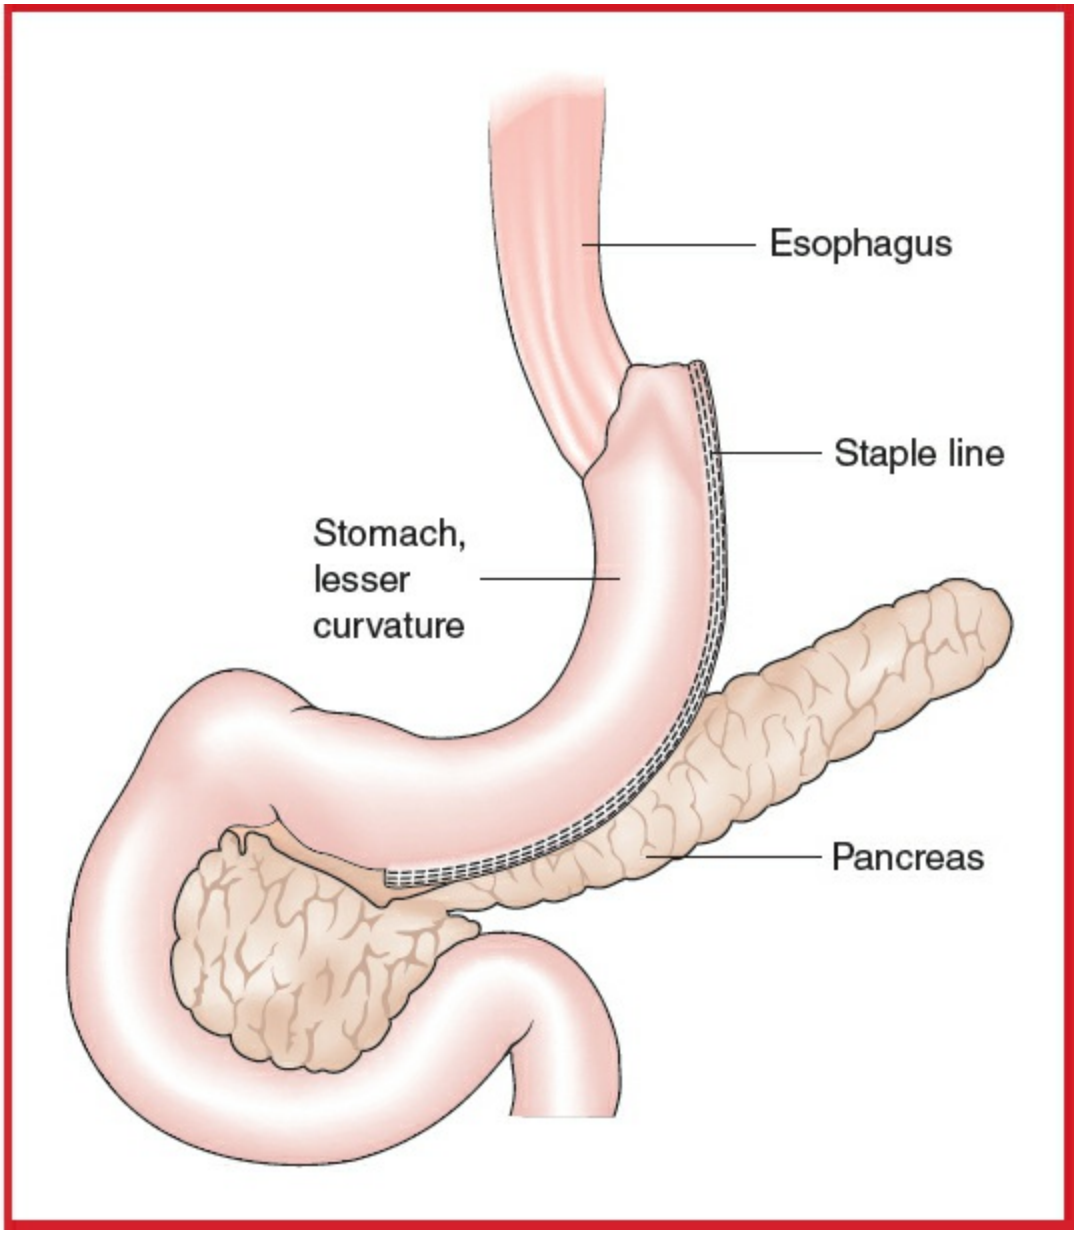

Figure 12.5-15 Sleeve gastrectomy.

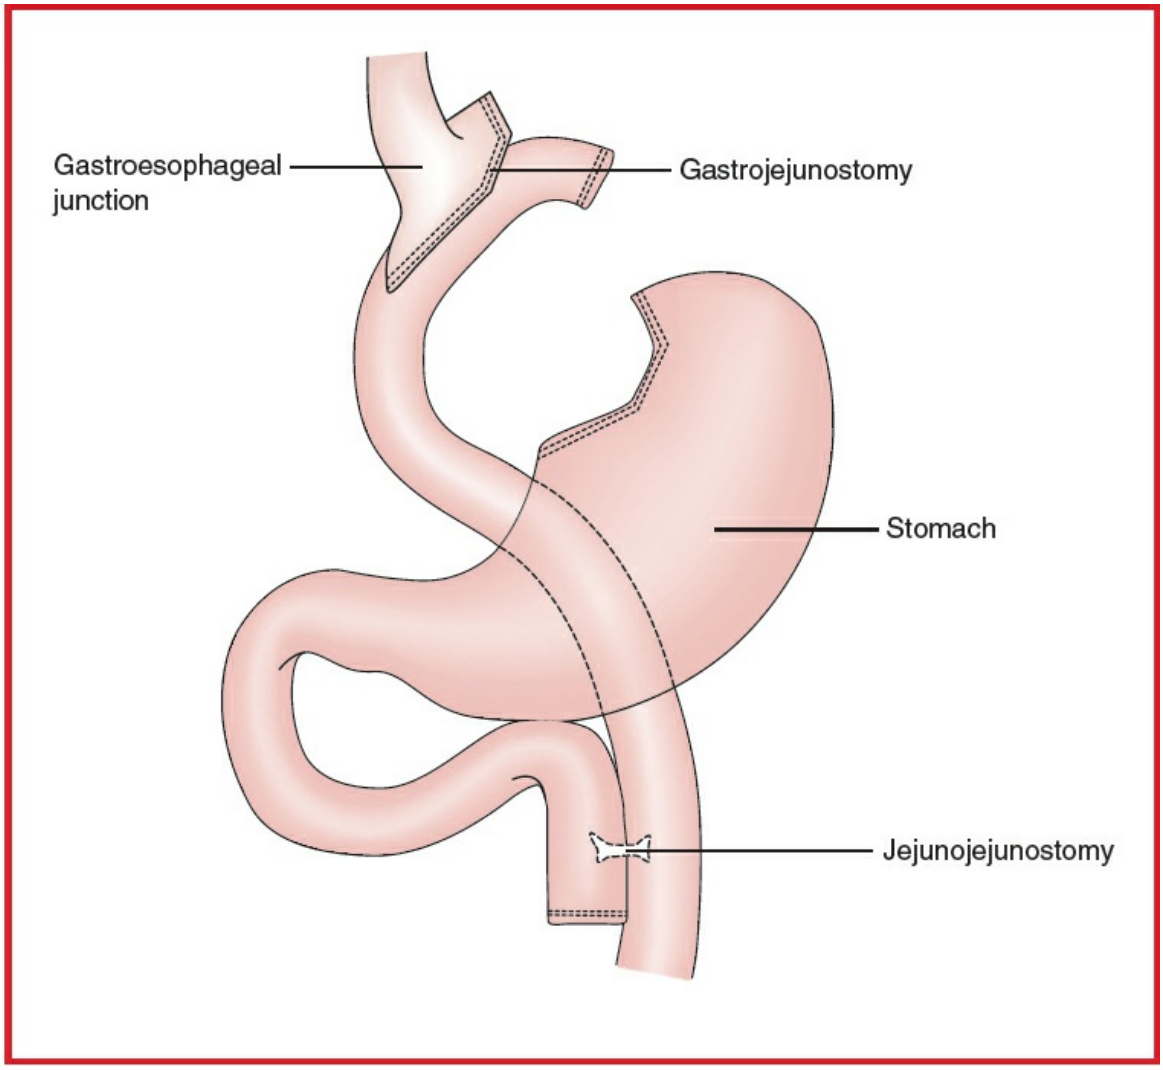

Figure 12.5-16 Roux-en-Y gastric bypass.

Variant procedures or approaches

A number of emerging endoscopic bariatric technologies aim to reduce the morbidity and mortality of existing techniques. Intragastric balloons and duodenal sleeves are promising but investigational at this time.

Usual preop diagnosis

Pediatric obesity (BMI > 50 or BMI > 45 with comorbid conditions). Majo comorbidities include OSA, type 2 diabetes, and pseudotumor cerebri.

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Roux-en-Y Gastric Bypass	Sleeve Gastrectomy/Gastric Band

Age range	Adolescents	
Male:Female	1:1	
Incidence	1:6	
Etiology	Diet and sedentary lifestyle	
Associated conditions	Obstructive sleep apnea, hypertension, diabetes, joint disease, depression	

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Morbid obesity, with a BMI > 40%, is associated with multiple comorbidities, including OSA, HTN, type 2 diabetes, fatty liver disease, and, in extreme cases pulmonary hypertension. A multidisciplinary evaluation must be performed prior to scheduling surgery, and a thorough preop evaluation is warranted, including review of medications, associated comorbidities, review of previous anesthetics, airway examination, and discussion of perioperative anesthesia plan. Also, include a review of any dieting strategies, especially medications taken for weight loss, as these may result in decreased response to vasopressors intraop. Patients with obesity may present challenges in iv placement and airway management. Postop pain management starts in the preop period with instruction in use of the incentive spirometer, visual analogue scale, and PCA if appropriate. A bariatric bed must be ordered preop.

Respiratory

Adipose tissue is metabolically active, leading to ↑ O_2 consumption and increased work of breathing. Increased mass of the thoracic wall → ↑ resistance, ↓ compliance, and a restrictive breathing pattern. In addition, ↑ abdominal pressure → atelectasis and ↑ closing volume. Obese patients also frequently suffer from OSA. Adolescent patients may have an increased response to hypoxia and relatively decreased response to hypercapnia. With increasing age, sensitivity to increased levels of CO_2 is diminished, and $PaCO_2$ rises further. These changes predispose the obese patient to hypoventilation, hypoxemia, and hypercarbia. In addition, changes to the airway related to increased adiposity of the face and neck may make mask ventilation and intubation difficult. Closely review previous anesthetic records.

Nighttime hypoxemia and hypercarbia are frequently seen in obese patients. A sleep study helps to document severity of apneic episodes. Number and severity of apnea and hypopnea episodes (apnea, >10 sec of no airflow; hypopnea, >50% reduction of airflow, associated with ↓ O_2 sat > 4%). Symptoms include snoring, daytime sleepiness, headaches, and difficulty concentrating. Treatment is usually a BiPAP mask. Close monitoring is needed in the postop period, as administration of opioids may exacerbate symptoms, leading to further hypoxemia and hypercarbia.

Tests: CXR, baseline SaO_2, sleep study, documenting hypoxemia while asleep

Cardiovascular

Because cardiac output rises proportionately with weight, obesity in both children and adults is frequently associated with hypertension and possibly LVH. Even normotensive patients have increased preload and afterload, ↑ PAP, and elevated left and right heart stroke volume. Symptoms of pulmonary HTN (dyspnea on exertion, fatigue, syncope

baseline hypoxemia) should be elicited and ECG obtained in symptomatic patients.

Tests: ECG, echo if indicated

Gastrointestinal

Obese patients have higher intra-abdominal pressures and may be at increased risk of aspiration. Studies have shown that acidity and volume do not statistically differ from nonobese patients. The presence of diabetes or gastroparesis increases risk of aspiration. Fatty liver disease may be present, frequently indicated by a rise in ALT. Increased volume of distribution may necessitate higher initial doses of anesthetic induction agents, especially lipid-soluble agents such as propofol.

Tests: Chem 23

Renal

Increased RBF and GFR may necessitate increased doses of renally cleared medications.

Premedication

Premedication should be used with caution, as obese patients are at increased risk of hypoventilation and hypoxemia. Midazolam 1–2 mg iv may be given if needed, with constant monitoring. Preop medications are continued, with the exception of ACE inhibitors, which are held the night prior to surgery, to minimize risk of intraop hypotension.

INTRAOPERATIVE

Induction	Assuming a reassuring airway examination and history, a rapid-sequence induction with preoxygenation and cricoid pressure, followed by propofol 2–2.5 mg/kg (TBW) and succinylcholine 1 mg/kg TBW, is the safest way to secure the airway. If history of difficult intubation exits, or examination is suggestive of difficult airway, consider awake FOI, using topical anesthesia, midazolam iv, and remifentanil infusion (0.05–1 mcg/kg/min) or dexmedetomidine infusion (0.2–0.7 mcg/kg/h). Positioning should include the use of a ramp to facilitate neck extension. This allows alignment of

	laryngeal, pharyngeal, and oral axes and promotes optimal visualization of the airway with laryngoscopy.
ERAS	Verify preincision antibiotics. Assess volume status. Consider iv acetaminophen (10–15 mg/kg to a maximum of 650 mg) for multimodal pain control and 0.1 mg/kg (maximum of 4 mg) iv ondansetron for PONV prophylaxis.
Maintenance	Propofol 200 mcg/kg/min combined with low-dose sevoflurane or desflurane; rocuronium for NMB (after recovery of NM function following succinylcholine). Use opioids cautiously, as may lead to increased sedation on awakening. Suggest loading with hydromorphone 10 mcg/kg TBW, followed by remifentanil infusion 0.5–1 mcg/kg/min. Ketorolac 0.5 mg/kg iv may reduce opioid requirement.
Emergence	Extubate awake. NG tube suction prior to extubation. Caution in immediate postop period, as patient may have ↓ ventilatory drive with ↓ responsiveness to hypoxemia and hypercarbia. Cautiously titrate opioids. If NDMR was used, reverse neuromuscular blockade with sugammadex (2–4 mg/kg) or with a combination of neostigmine (0.07 mg/kg with a maximum of 5 mg) and glycopyrrolate (0.01 mg/kg with a maximum of 1 mg). Do not attempt reversal with neostigmine and glycopyrrolate until first twitch of TOF has returned.

POSTOPERATIVE

Complications	Hypoxia, hypercarbia, apnea, airway obstruction	Close monitoring, supplemental O_2 if needed, relatively small frequent opioid dosing
	Difficult postop ambulation	Assistance with ambulation, including physical, occupational therapy—

		additional doses of opioid should be utilized around ambulation sessions.
	DVT/PE	DVT and PE prevention—ambulation, compression stockings while in bed, subcutaneous heparin—discuss with surgical team.
Multimodal pain management	PCA may be used, with cautious dosing regimens (e.g., hydromorphone—no basal rate, 1–2 mcg/kg bolus dose with a maximum starting dose of 200 mcg q10min). Ketorolac 0.5 mg iv q6h may be used with caution, after checking renal function and coordinating with surgical team to ensure there are no concerns regarding possible postop bleeding. Acetaminophen 10–15 mg/kg iv q6h should be continued postop (maximum of 650 mg per dose). Postop monitoring is essential. Supplemental O_2 may be necessary via nasal cannula. Please see Appendix E: Multimodal Pediatric Postoperative Pain Management, p. E-1.	
ERAS	Encourage early enteral nutrition and patient mobilization as appropriate. Assess for appropriate return of bowel function.

KIDNEY AND UPPER URINARY TRACT OPERATIONS

SURGICAL CONSIDERATIONS

Description

With the increase in perinatal ultrasonographic detection of renal masses and hydronephrosis, pediatric kidney and upper urinary tract surgeries have become increasingly common. Children come to surgery at an earlier age, leading to a lower incidence of renal dysfunction.

Nephrectomy

Nephrectomy is most commonly performed to remove poorly or nonfunctioning kidneys secondary to congenital anomalies such as ureteropelvic junction (UPJ) obstruction or end-stage reflux nephropathy. Tumor nephrectomy is uncommon in children (with the exception of Wilms tumors). Multicystic dysplastic kidneys (MCDK) were removed in the past but currently are only removed if they become symptomatic or increase in size, as they have a benign course. Most often, a subcostal incision is used in children as it affords excellent renal exposure with less pain and risk of wound complications.

For benign processes, a flank/subcostal incision is commonly used, and careful

positioning of the patient is crucial. The ultimate goal is to have the patient in a 30°–45° flank up position on the respective side. However, failure to properly stabilize and secure the patient to the OR table can cause devastating consequences; therefore, efforts must be coordinated to properly position the patient. A rolled sheet or gel pad should be positioned beneath the dependent axilla, elevating the thorax to avoid brachial plexus neuropraxia. The dependent lower extremity is flexed at the hip and knee, while the overlying leg is kept straight. Padding is placed between the knees. In older children, in this lateral flank position, the kidney rest at the break of the table may be elevated to increase the distance between the rib and iliac crest, thus increasing exposure of the kidney. Attention is needed by the anesthesiologist during positioning, including care of the ETT, padding of pressure points, application of wide tape to secure patient safely, and repositioning of leads. After the patient is positioned, a transverse incision is made below the 11th or 12th rib. The peritoneum is reflected, and surgery remains retroperitoneal if possible. The ureter is dissected to the hilum, and the vessels are ligated. The kidney is excised, and the wound is closed.

A dorsal lumbotomy (incision parallel to the paraspinous muscle group) is an additional option for benign indications and is performed with the patient in the prone or lateral position. This has an advantage of being a muscle-splitting, rather than a muscle-cutting, incision and, as such, is associated with less postoperative pain. Abdominal padding may be added to raise the lumbodorsal area, and care should be taken to ensure complete pulmonary expansion in this position.

For Wilms tumor nephrectomies, a chevron incision is recommended as maximum exposure of the renal vessels, aorta, and vena cava is needed and retroperitoneal lymph nodes need to be dissected (Fig 12.6-1). In general, minimally invasive approaches are not recommended for Wilms tumor by the Children's Oncology Group.

Regardless of the position, a urethral catheter is usually placed and positioned for dependent drainage with care taken to avoid obstructing the tubing. In this way, the anesthesiologist may measure urinary output, though urinary extravasation may occur within the surgical site depending on the operation.

In routine open surgery of the kidney and renal pelvis, use of intraoperative local anesthesia (infiltration of local anesthetic in the surgical incision) and higher dosage of nonopioid pain medications (acetaminophen) appear to decrease pain intensity during the first postoperative day. Continuous epidural or caudal catheters can be effective for postoperative pain management but may result in urinary retention.

Usual preop diagnosis

MCDK; Wilms tumor; nonfunctioning kidney; dysplastic kidney; UPJ obstruction

Partial nephrectomy

Partial nephrectomies are usually performed for a poorly functioning or nonfunctioning upper pole of a duplicated system. Ectopic ureters and ureteroceles are frequently the cause of lost function. Again, these benign indications can be approached through either a lumbodorsal or a flank incision. If the upper pole is obstructed but functional, a **pyeloureterostomy** from the upper pole ureter to the pelvis of the lower pole may be performed to salvage as much functioning parenchyma as possible. Partial nephrectomies may be performed for bilateral Wilms tumor or other renal masses through a chevron incision as described above. Blood should be immediately available in these cases as there is a risk of significant blood loss. Urine output should be watched closely and the patient resuscitated as needed. Blood loss is attempted to be minimized by clamping of the renal vessels but comes at the risk of renal ischemia and free radical–mediated tissue injury upon reperfusion. For this reason, the surgeon will often apply an iced slush to the renal fossa to cool the kidney prior to clamping the renal vessels. Administration of 20% intravenous mannitol around this time is often done to help scavenge free radicals. An increasing number of partial nephrectomies are being done robotically for benign diagnoses.

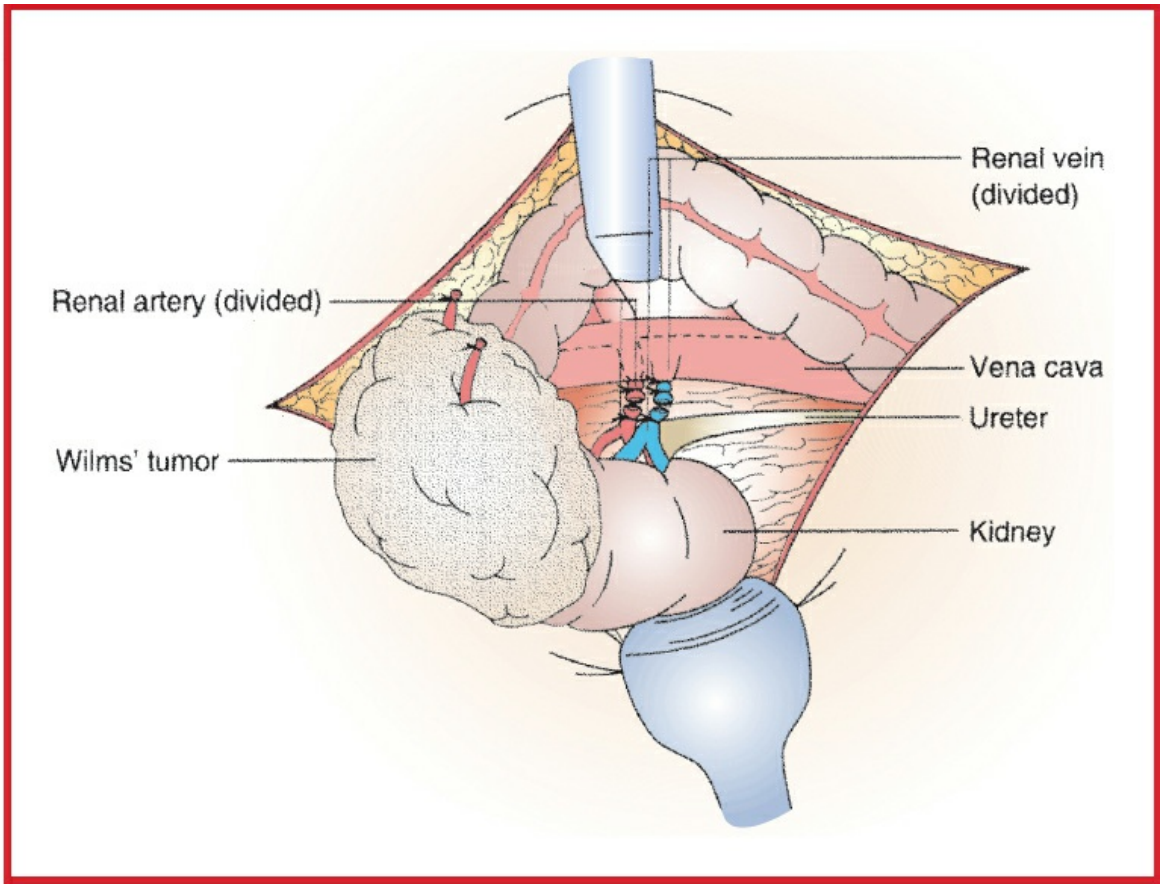

Figure 12.6-1 Anatomy for nephrectomy. (Reproduced with permission from Greenfield LJ, Mulholland MW, Oldham KT, et al. eds.: Surgery: Scientific Principles and Practice, 3rd edition. Lippincott Williams & Wilkins, Philadelphia: 2001.)

Usual preop diagnosis

Nonfunctioning pole of a duplex system; ureterocele; ectopic ureter; bilateral Wilms tumor; angiomyolipoma (common in patients with tuberous sclerosis)

Nephroureterectomy

Nephroureterectomy is performed for the upper pole of a duplex system that is obstructed due to an ureterocele or ectopic ureter. After the nephrectomy/partial nephrectomy is performed through one of the aforementioned approaches, the ureter is dissected as low as possible (usually to the level of the iliac vessels). The ureteral stump is left open if there is no vesicoureteral reflux and tied off if there is reflux. If indicated, distal ureterectomy can be performed via a second lower abdominal incision (typically a Pfannenstiel incision). If the initial incision was done in the prone position, the patient may need to be repositioned supine.

Usual preop diagnosis

Nonfunctioning upper pole of a duplex system; ureterocele; ectopic ureter

Pyeloplasty

Fetal hydronephrosis is detected in ~1 in every 300 pregnancies. Pyeloplasty to correct congenital obstruction of the UPJ is one of the most common pediatric upper urinary tract surgical procedures. The hydronephrotic kidney usually is exposed through either a dorsal lumbotomy or a subcostal flank incision. The patient may be in a prone or modified lateral decubitus position (see details related to subcostal or lumbodorsal incision previously described). In most instances, the operation is performed entirely retroperitoneally with exposure of the upper ureter and renal pelvis. The abnormal UPJ is excised, followed by an end-to-end anastomosis (**dismembered pyeloplasty** or **Anderson-Hynes pyeloplasty**). If the renal pelvis is intrarenal and dependent drainage is not possible via a conventional pyeloplasty, a **ureterocalicostomy** may be performed by removing an area of thin renal parenchyma and anastomosing the ureter to a lower pole calyx. At the conclusion of the procedure, a perirenal Penrose drain is often placed near the anastomosis, and, depending on surgeon preference, a ureteral stent or nephrostomy tube may be used. A urethral catheter is usually left after the procedure. An increasing proportion of these procedures are being performed using a robotic approach as detailed later. A major difference between these is that a robotic approach requires intraperitoneal access, while open approaches are usually extraperitoneal.

Usual preop diagnosis

Fetal hydronephrosis 2° UPJ obstruction; hydronephrosis with a decrease in kidney function and/or flank pain

Transureteroureterostomy (TUU)

This is a rare procedure, in which a ureter is anastomosed to the contralateral ureter. It is used when there is problematic drainage of a distal ureter into the bladder. It is sometimes required to salvage a failed reimplantation or to reroute a conduit-type diversion to an orthotopic neobladder or augmented native bladder. This technique can also be used to provide drainage in cases of distal ureteral trauma. A midline or Pfannenstiel incision is used, and the peritoneum is entered. The ureters are dissected, and the affected ureter is retroperitonealized and brought to the contralateral side anterior to the great vessels. It is anastomosed to the contralateral ureter end to side with absorbable suture. If required, the recipient ureter is then reimplanted into the neobladder or augmented bladder.

Usual preop diagnosis

Failed ureteral reimplant; modification of urinary diversion; distal ureteral trauma

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Nephrectomy/Pyeloplasty	Nephroureterectomy	TUU
Position	Supine/flank/prone	Supine/flank	Supine
Incision	Dorsal lumbotomy; subcostal; flank; chevron	Subcostal; flank; second incision: Pfannenstiel	Midline or Pfannenstiel
Antibiotics	1st- or 2nd-generation cephalosporin; aminoglycoside + clindamycin	⇐	⇐
Surgical time	2.5–4.5 h	3–4 h (repositioning may be required)	⇐
EBL	Minimal; if partial	Minimal	⇐

	nephrectomy, 300 mL		
Mortality	<1%	⇐	⇐

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

In infants and children, most upper urinary tract surgical procedures are performed to preserve or restore renal function. Patients may present with renal function that varies from minimally abnormal, requiring little or no modification of anesthetic plan, to end-stage renal disease (ESRD) with its associated abnormalities, including hypoproteinemia, chronic anemia, and serum electrolyte disturbances. A careful preop workup is required to determine the presence or absence of abnormal physiologic factors that will affect anesthesia management. For most cases, the workup will have been performed by the patient's physicians before surgery and will provide the rationale for the surgical procedure. Such nonspecific findings as anorexia, headache, nausea, fatigue, alterations in urine output, and the presence of edema will alert the clinician to the likelihood of renal failure.

Renal abnormalities often are present as one component of a congenital malformation syndrome (e.g., polycystic kidneys, cerebrohepatorenal syndrome). In formulating the anesthetic plan, drugs eliminated by the kidney (e.g., pancuronium, meperidine) should be avoided.

Respiratory	An evaluation of pulmonary function, including auscultation of the lungs, may indicate the presence of pulmonary edema (uremic lung) or a pleural effusion. **Tests:** ABG; CXR; SaO_2
Cardiovascular	HTN is commonly seen in these patients, who may be taking antihypertensive medications and diuretics. In severe cases, CHF or pulmonary edema may be present, necessitating the use of cardioactive drugs and diuretics to optimize the patient's clinical condition before surgery. Timing discontinuation of medication around the procedure is crucial. For example, ACE inhibitors need to be stopped at least 12–24 h before surgery under anesthesia. **Tests:** ABG; CXR; digitalis level; electrolytes
Renal	In cases requiring unilateral urinary tract surgery, the opposite kidney is usually normal. In the presence of renal insufficiency, a detailed evaluation of renal function is essential. Chronic metabolic acidosis may

	be present 2° poor kidney function, electrolyte abnormalities (↑ K^+, ↓ Ca^{++}, ↑ or ↓ Na), hypovolemia, hypervolemia, and/or poor tissue perfusion. Children with ESRD will have been dialyzed before surgery. Preop K^+ <6 mEq/L is usually safe. These patients may have an AV fistula, which must be protected during surgery (padded, no BP cuff). More commonly, a double-lumen central venous catheter will have been placed for hemodialysis (e.g., permacath). **Tests:** UA; UO; serum electrolytes; BUN; Cr; total protein; A/G ratio; ABG
Gastrointestinal	Renal failure is associated with increased incidence of delayed gastric emptying and gastroesophageal reflux. Modified rapid-sequence induction should be considered.
Hematologic	Anemia, bone marrow depression, and coagulopathies are common in patients with poor renal function, particularly platelet dysfunction. An Hct of 20–23% is not uncommon and is often well tolerated. Transfusion needs to be considered against the possibility of sensitization of immune system prior to possible renal transplant. **Tests:** Hb/Hct, PT/PTT; Plt count
Medications	Patients with ESRD will be taking many medications, which may influence the anesthetic plan. For example, chronic steroid therapy → Cushing facies and glycosuria; therefore, ✓ blood sugar and ✓ airway. Patients taking digitalis or diuretics → ↓ K^+→ arrhythmias. Aminoglycosides → prolongation of neuromuscular blockade. If possible, avoid renal toxic drugs in patients with renal insufficiency (e.g., NSAIDs, aminoglycosides).
Premedication	Standard preop medication if renal function is normal. Patients with ESRD may have increased sensitivity to sedatives; doses should be titrated carefully to effect. Avoid long-lasting sedative

ERAS	medications. Check compliance with presurgical ERAS recommendations (see above) including NPO status. Evaluate for concurrent disease, nutritional status, and hydration. Consider preop acetaminophen 10–15 mg/kg iv or po as an elixir.

INTRAOPERATIVE

Anesthetic technique

GETA ± epidural: (Platelet dysfunction should be assumed in ESRD and the risk/benefit of epidural placement carefully weighed.) Warm OR to 70°F–75°F; use warming pad on OR table and/or forced-air warming.

Induction	Mask induction is preferable, unless iv is already in place. If an indwelling permacath is to be accessed, heparin should be aspirated from the lumen before use. Routine use of dialysis catheters is discouraged due to the need for strict sterile technique in handling of the catheter to avoid line infection. Succinylcholine should not be used with renal failure patients due to risk of K^+ release in borderline hyperkalemic patients. In the presence of renal insufficiency, antibiotics (e.g., aminoglycosides) may interfere with the metabolism of muscle relaxants and prolong their effect and may further compromise renal function. Tracheal intubation, facilitated by an NMR (e.g., rocuronium 0.6–1 mg/kg or cisatracurium 0.2–0.3 mg/kg), is appropriate in patients with renal insufficiency. In appropriate patients (normal coags and no platelet dysfunction), epidural anesthesia with bupivacaine may reduce anesthetic requirements and provide postop analgesia (**NB:** local anesthetic clearance may be impaired in ESRD). Maintain muscle relaxation with rocuronium or cisatracurium.
ERAS	Verify preincision antibiotics. Assess volume status (see p. D-1). Maintain normovolemia and normothermia.
Maintenance	Standard pediatric maintenance. Moderate hyperventilation may be beneficial ($\rightarrow \downarrow K^+ + \uparrow$ pH).

Emergence	Reverse neuromuscular blockade with neostigmine and glycopyrrolate or atropine. Discuss with surgeon local wound infiltration. PONV prophylaxis should include dexamethasone (e.g., 30 mcg/kg) and ondansetron (0.1 mg/kg up to 4 mg iv).	
Blood and fluid requirements	IV × 1 in upper extremities BSS @ (maintenance): 4 mL/kg/h (1–10 kg) +2 mL/kg/h (11–20 kg) +1 mL/kg/h (>20 kg)	Usually minimal blood loss; however, renal surgery may be associated with ↑ blood loss. Transfuse with whole blood or PRBCs as needed to maintain an adequate Hct, based on physiologic response (usually 25–30%). If K^+ is high and patient has ESRD, use freshest PRBC or washed PRBC to minimize the K^+ load. Minimal iv flush should be administered in the presence of oliguric renal insufficiency. Fluids in excess can lead to pulmonary edema especially in an aneuric patient. Avoid K^+ containing crystalloid infusions. See Zero Balance Fluid Management, Appendix K, p. K-2.
Monitoring	Standard monitors ± Arterial line	Consider placing an arterial line in patients with significant renal failure particularly for those patients with poorly controlled HTN as they may exhibit marked hypotension or BP variability after induction; ✓ serum electrolytes and ABG frequently.

Positioning	✓ and pad pressure points ✓ eyes	✓ eyes frequently if prone or flank positions are used.
Complications	Peripheral nerve injury Eye trauma Hemorrhage Dysrhythmia Indigo carmine administration may lead to ↑ BP, ↓ HR, ↓ BP, and bronchospasm.	

POSTOPERATIVE

Complications	Hypovolemia Anemia Hypothermia Electrolyte abnormalities Coagulopathy Metabolic/respiratory acidosis	
Multimodal pain management	Acetaminophen	In renal failure, reduce analgesic doses by 50% to minimize cumulative effects. Use nonopioid analgesics. Back up with bolus opioid analgesics.
	Opioids via PCA/epidural catheter with mixture of local anesthetic—ropivacaine 0.1%, hydromorphone 3 mcg/mL, +/− clonidine 0.1–0.2 mcg/mL	Note: morphine metabolites morphine-6-glucuronide (analgesic) and morphine-3-glucuronide (antanalgesic) are renally excreted and accumulates in patients with renal failure. It is therefore preferred to use hydromorphone. For patients without renal failure, epidural or caudal catheters can be effective for postop pain management but may result

		in urinary retention. Peripheral nerve blockade (e.g., transversus abdominis plane block, TAP), quadratus lumborum plane block, and ilioinguinal and iliohypogastric blocks avoid this issue. Single-shot caudal may also be used for minor procedures. (See discussion in surgical section on p. 1521.)
ERAS	PONV protocol (see Appendix D, p. D-4)	Encourage early enteral nutrition, catheter removal, and ambulation as appropriate.
Tests	As indicated

PERCUTANEOUS STONE PROCEDURES

SURGICAL CONSIDERATIONS

Description

Whenever possible, the management of urologic stone disease is done endoscopically as procedures are shorter, patients have less pain, and potential complications tend to be less morbid. However, due to stone size, stone location, or patient anatomy, sometimes these modalities can fail. When this occurs and a stone must be treated, such

as in cases of infection or obstruction, percutaneous procedures are required. These include **percutaneous nephrolithotomy (PCNL)** and **open pyelolithotomy**.

Every child with renal calculi should undergo metabolic evaluation. Renal function should be checked preop. GA is usually required due to limited patient cooperation in the pediatric population and need for precise positioning. Moderate pain may be expected and should be treated with opioid therapy. Ketorolac should not be used due to potential renal effects.

Percutaneous nephrolithotomy (PCNL)

Patients undergoing PCNL can be admitted to the hospital the day before the procedure so that a nephrostomy tube can be placed by interventional radiology. Those who advocate prior nephrostomy placement feel that there is less bleeding when the stone procedure is done the following day. Some surgeons prefer to obtain their own access using a spinal needle and fluoroscopy during the case. Prior to starting the case, the anesthesiologist should ensure that blood is immediately available, as accessing the renal pelvis has the risk of disrupting intrarenal vasculature. After induction of general anesthesia, patients are placed in prone position with special care taken to ensure all extremities are secure and pressure points adequately padded. Access to the renal pelvis is obtained and the tract is dilated with a balloon. A sheath is then left in place to allow for placement of a nephroscope into the renal pelvis. The stone is then fragmented using either a laser or other device, and fragments extracted. In contrast to other endoscopic procedures, which tend to be short and without exposed vasculature, PCNL carries a risk of fluid absorption toxicity ("TUR syndrome"). Depending on the fluid used, there is a risk of hyponatremia in addition to volume overload. Both the surgical and anesthesia teams should be aware of the volume and type of fluid being used for the procedure. Related to this, it is imperative that fluids used are warmed to prevent hypothermia during the operation. After this operation, patients are often left with a nephrostomy tube and ureteral stent. Patients typically admitted to the hospital for 1–2 d postoperatively.

Usual preop diagnosis

Renal calculus

Open pyelolithotomy

The approach for an open pyelolithotomy is identical to that used for a pyeloplasty (described above). Once renal exposure has been obtained, a small incision is made in the renal pelvis and the stone manually removed. Postoperative considerations, including potential uses of a ureteral stent, nephrostomy tube, and Penrose drain, are

similar. Patients tend to be admitted for 2–3 d after this procedure.

Usual preop diagnosis

Renal calculus

TRANSURETHRAL PROCEDURES

SURGICAL CONSIDERATIONS

Description

Transurethral procedures are not as common in children as they are in adults; however, the instrumentation, general principles, and considerations are similar. The most common pediatric endoscopic procedures are **cystoscopy** and **vaginoscopy**, primarily as diagnostic procedures; **removal of** indwelling ureteral stents; transurethral incision of urethral stricture, for congenital lesions or complications of urethral surgery; **transurethral incision of posterior urethral valves** (PUV);**transurethral incision of ureterocele; subureteric injection for vesicoureteral reflux; endoscopic injections for urinary incontinence; placement of ureteral stents; and ureteroscopy (commonly with lithotripsy for treatment of stones)**. As described above, fluid absorption toxicity is rarely seen with these procedures in children.

The positioning and techniques are identical to those in the adult. Careful attention to positioning is required when the pediatric patient is placed in the lithotomy position. For smaller children, this involves the frog leg position at the distal end of the bed rather than stirrups. The patient can remain supine if a flexible cystoscope is used. The most frequent neurologic complication from lithotomy position may be injury to the common peroneal nerve → foot drop and sensory deficit. After the patient is positioned, a lubricated cystoscope or resectoscope (7–18 Fr) is introduced through the urethra. In infants, PUV may be resected using a small cutting electrode or a laser, whereas a resectoscope is used in older children. With the advent of prenatal ultrasonography, PUV (often seen with hydronephrosis and azotemia) are usually resected in the neonatal period.

Ureteral stents or bladder stones are removed using forceps or other tools, after crushing or pulverization with a laser if necessary. Eye protection may be worn by operating room staff if a laser is used. Occasionally, when ureteral stents are placed/removed, an intraoperative retrograde pyelogram is performed to evaluate the upper tract collection system. During cystoscopy, localization of the ureteral orifices may be difficult due to inflammation, prior bladder surgery, or congenital ectopia. The anesthesiologist may be asked to administer intravenous fluorescein, methylene blue, or indigo carmine, which will filter through the kidneys and produce colored urine to assist with locating the ureteral orifices. Indigo carmine specifically has potential effects of ↑ BP by increasing afterload and causing reflex bradycardia. Fluorescein carries a risk of bronchospasm/pulmonary edema in patients with allergies or asthma and can rarely cause hypotension. Methylene blue may cause CNS depression, methemoglobinemia in patients with G6PD-deficiency, and serotonin syndrome in patients taking antidepressants.

As noted before, stone surgical procedures are typically done using the most minimally invasive technique, such as extracorporeal shock wave lithotripsy (ESWL)**and ureteroscopy**. Often, these procedures require fluoroscopy, which may bring with it both equipment considerations (fluorocompatible moving tables) and positioning requirements to allow C-arm placement.

For pain control, aside from opioids in the immediate postoperative period, lidocaine gel may be injected transurethrally at the completion of the transurethral procedure to avoid postoperative urethral irritation. Some surgeons administer phenazopyridine (Pyridium) to decrease catheter irritation. Finally, if a catheter is left, an antimuscarinic may be given to decrease bladder spasms (oxybutynin).

Cystoscopy/Cystolitholapaxy

Positioning for these procedures is typically done in lithotomy position. After induction of general anesthesia, a cystoscope is inserted and the urethra/bladder visualized. Depending on the procedure, a range of instruments may be used to biopsy, remove, or obliterate lesions, foreign bodies, or stones. If lasers are used, eye protection may be used by operating room staff. Most lasers have a very short working distance so the risk of ocular injury is small. Pure cystoscopic procedures tend to be fairly short, with the majority requiring <1 h. Paralysis is not always required. Depending on the procedure performed, a Foley catheter may or may not be left at the end of the procedure.

Usual preop diagnosis

Intravesical foreign body (ureteral stent); bladder calculus; bladder outlet obstruction;

urethral stricture; ureterocele; hematuria; urethral/vaginal mass; posterior urethral valves, urogenital sinus

ESWL (extracorporeal shock wave lithotripsy)

This procedure utilizes ultrasound to break the stone from outside the body. The child is placed in a supine position on a special bed. The need for general anesthesia or sedation is still required to reduce movement as this procedure requires aiming the burst in three dimensions but may depend on the child's age, the extent of stone burden, and the kind of extracorporeal lithotripter being used. Usually general anesthesia with endotracheal intubation in young children is required.

Usual preop diagnosis

Nephrolithiasis, ureterolithiasis

Ureteroscopy and laser lithotripsy

Positioning for this procedure requires lithotomy. Paralysis is needed for upper tract instrumentation as patient movement such as a cough could cause ureteral perforation, especially when using the semirigid ureteroscope. Lasers are frequently used for these procedures. After the stone is fragmented and removed, a stent is often left to prevent obstruction from ureteral edema or fragments. In some cases, the stent may be left with a string attached that will exit the urethra and be visible outside of the body. These strings should be not manipulated except to allow for stent removal at a later date. It is important to know that ureteral access in children is tenuous, and it is not uncommon (especially for untreated ureteroscopy patients) that the scope or access sheath will not be accommodated by the ureter. In these cases, only a ureteral stent will be placed and remain in place to allow the ureter to passively dilate up in size, with plan for another attempt at ureteroscopy 1–2 wk later. Thus, large doses of paralytics should not be given until ureteral access is established, as, if only a stent is placed, the procedure will be quite short.

Usual preop diagnosis

Nephrolithiasis, ureterolithiasis

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Cystourethroscopy,

	Cystolitholapaxy	ESWL	Ureteroscopy
Position	Lithotomy	Supine	Lithotomy
Incision	None	None	⇐
Antibiotics	Aminoglycoside ± ampicillin; 1st- or 2nd-generation cephalosporin; amoxicillin/clavulanate	None	Aminoglycoside ± ampicillin; 1st- or 2nd-generation cephalosporin; amoxicillin/clavulana
Surgical time	Cystoscopy: 10 min Transurethral procedure: 0.5–1 h	1 h	1–2 h
EBL	Minimal	None	⇐

SIMPLE OPEN BLADDER OPERATIONS

SURGICAL CONSIDERATIONS

Description

Open bladder operations commonly performed on children include **ureteral reimplantation** for correction of vesicoureteral reflux, obstructive megaureters, or ureterocele; **vesicostomy creation or closure (Blocksom)**; and **bladder neck reconstruction**.

Ureteral reimplantation

Vesicoureteral reflux (VUR) is one of the most common abnormalities of the urinary tract in children and is present in about 25–50% of children who get UTIs. Although VUR resolves spontaneously in many children, there are a number of indications for correction of VUR. These include high-grade VUR, progressive VUR and renal scarring, failure to resolve within several years, other bladder surgery, breakthrough UTIs, and poor medical compliance.

Ureteral reimplantations can be performed using different approaches to the bladder (e.g., extravesical, intravesical, or a combined approach); however, these different approaches require a similar exposure and abdominal incision. In general, these are extraperitoneal rather than intraperitoneal operations. Initially, cystoscopy may be performed to plan a potentially complex reimplantation (e.g., duplex systems, ectopia, or periureteral diverticula). A suprapubic (Pfannenstiel) incision (Fig. 12.6-2) is usually made, the fascia is opened (may either be muscle cutting or splitting incision; in the latter, the fascia may be opened vertically), and the bladder is exposed. Sufficient muscle relaxation is required to enable the surgeon to place a self-retaining retractor to expose the bladder. The anesthesiologist also may be asked to limit N_2O to decrease the amount of peritoneal contents bulging toward the bladder and surgical field. The bladder is then opened (intravesical approach), and the ureteral reimplantation(s) is

performed. Alternatively, the bladder is mobilized to expose the posterolateral ureter, which is then reimplanted (extravesical approach). When required, ureteral stents are placed in the bladder and removed cystoscopically 1 mo later. A Penrose drain may be left in place, which is either brought through the incision or through a separate skin puncture.

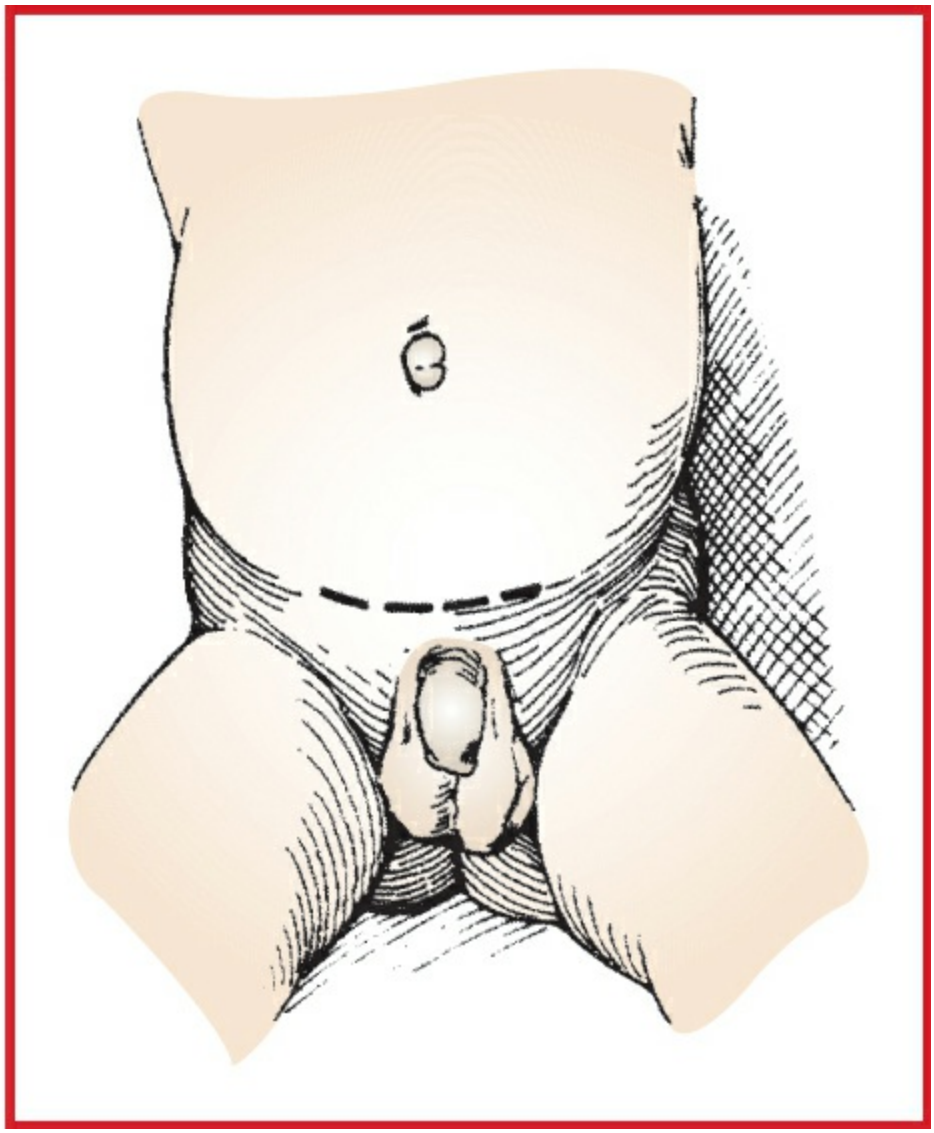

Figure 12.6-2 A Pfannenstiel incision in Langer lines is a low transverse incision that provides good access to the bladder and other pelvic organs and good cosmesis. (Reprinted from Hinman F:Atlas of Pediatric Urologic Surgery, 2nd edition. WB Saunders, Philadelphia: 2009. Copyright © 2009 Elsevier. With permission.)

Obstructive megaureters and ureteroceles are other conditions that may require ureteral reimplantation. The abdominal exposure and indications do not differ significantly from ureteral reimplantation for VUR; however, tailoring of the ureter by reducing its caliber by excising redundant tissue or plication may be necessary. Reconstruction of the bladder neck also may be required if an ureterocele extends distally through the bladder

outlet.

Regional anesthesia techniques—specifically caudal or epidural analgesia—have gained popularity for these procedures. They have been shown to decrease postoperative pain medication requirements. However, as the patient usually leaves the hospital within 48 h, long-term epidural or caudal anesthesia is usually not required. As there may be increased risk of urinary retention following neuraxial anesthesia, a urethral catheter is usually left in place postoperatively. The diagnosis of urinary retention may be difficult to make following bladder surgery, and catheterization trauma may occur. However, an indwelling catheter may cause increased discomfort from bladder spasms and irritation. Intravesical lidocaine gel may alleviate some bladder irritation, though oral oxybutynin and Pyridium may be considered as well. Without a catheter, children usually void spontaneously within 6–9 h after surgery. For these reasons, the surgeon's preference on whether an indwelling urethral catheter will be left at the conclusion of the procedure should be elicited at the beginning of the case and considered in the selection of a regional block.

Usual preop diagnosis

VUR; obstructive megaureter; ureterocele

Vesicostomy

Infants and very young children may require reliable bladder drainage and decompression until definitive bladder or urethral surgery (e.g., spina bifida failing intermittent catheterization). A vesicostomy accomplishes this by allowing urine to flow continuously from a small, lower abdominal vesicocutaneous fistula. In this procedure, the patient is placed supine, and a 2-cm transverse incision is made halfway between the umbilicus and the pubis, and the bladder is dissected extraperitoneally to expose the dome. The bladder is opened at the dome (urachus) and is anastomosed to the abdominal skin with absorbable sutures, creating a small fistula. Closure of a vesicostomy is likewise done in a supine position and involves excision of the fistula tract and subsequent closure of the bladder and skin.

Usual preop diagnosis

Posterior urethral valves; severe VUR; neurovesicular dysfunction (as seen in spina bifida); prune belly syndrome

Bladder neck operations

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options.

See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Reimplantation	Vesicostomy
Position	Supine	⇐
Incision	Pfannenstiel or low midline extraperitoneal	⇐
Unique considerations	None	⇐
Antibiotics	1st- or 2nd-generation cephalosporin; aminoglycoside + clindamycin	⇐
Surgical time	1.5 h	45 min
EBL	Minimal	⇐
Postop care	PACU; ± urethral catheter ± stents. Anticholinergics for bladder spasms. Older children may benefit from epidural anesthesia.	PACU; ± vesicostomy catheter
Mortality	<1%	⇐
Morbidity	Infection: <3%	⇐
	Bleeding: <3%	⇐

COMPLEX OPEN BLADDER OPERATIONS

SURGICAL CONSIDERATIONS

Description

A variety of pathologies may be associated with a need for complex bladder reconstruction or augmentation. These include conditions associated with severe congenital malformations, such as epispadias and bladder exstrophy, and those associated with neurogenic bladder, such as spina bifida, cerebral palsy, and spinal cord injury. In regard to severe congenital malformations, these often require multiple-staged procedures with the ultimate goal being a continent bladder of adequate capacity. Specific procedures are highly patient dependent and may involve work on the bladder neck, urethra, and ureters. In regard to neurogenic bladders, a main concern is the failure of bladder storage and/or compliance, leading to urinary incontinence, high voiding pressures, and upper tract deterioration. In these cases and also when infectious or fibrotic processes have caused a reduction in bladder capacity, the patient may be a candidate for **bladder augmentation** with the native intestine, colon, stomach, or ureter (in the case of significant ureteral dilation). A **continent catheterizable stoma** may be performed at the same time due to the frequent need for catheterization subsequent to the procedure. Patients with limited mobility who require urethral catheterization can also

opt for the placement of a continent catheterizable stoma using the appendix or ileum. This may be done as a separate procedure with or without augmentation. In both groups, patients have often had many operations, and the operative team needs to consider possible latex sensitivity (see Appendix G: Special Considerations for Latex Allergy, p. G-1).

In some cases of severe malformations that cannot be corrected or severe urinary incontinence, bladder augmentation and stoma formation are combined with closure of the bladder neck or insertion of an **artificial urethral sphincter**.

Patients with neurogenic bowel may become dehydrated more easily during bowel preparation prior to surgery. Although traditionally mechanical and antibiotic bowel preparation for 1–2 d prior to surgery was recommended, growing evidence in the general surgery literature suggests that bowel preparation does not reduce wound infections or anastomotic leaks and may actually increase ileus rates. Ultimately, the use of bowel preparation is surgeon dependent. Anesthesiologists should be aware of the length and extent of preop bowel preparation in case the patient has become dehydrated or suffered electrolyte imbalances due to this process. Special consideration should be made for patients who have ventriculoperitoneal (VP) shunts. Typically care is made to sequester the shunt in sterile fashion, keeping it away from any spillage from bowel segments.

Bladder neck reconstruction

These procedures usually are required in patients with severe anomalies, such as exstrophy, or severe incontinence due to an incompetent bladder neck. These are complex procedures, with dissection often difficult. The approach to the bladder is similar to that of ureteral reimplantation, using a lower abdominal (Pfannenstiel) incision (Fig. 12.6-2). The space of Retzius is dissected bluntly and the anterior bladder wall and pubic bone are exposed. The bladder is opened and the bladder neck dissected and reconstructed. Various techniques to tubularize the anterior bladder wall, elongate the urethra, and increase outlet resistance may be used. Bilateral ureteral reimplantation and bladder neck suspension can be performed at the same time. These procedures are variable in length but tend to be quite long given their complexity and may require more than 4 h to complete. One special consideration is latex allergy (see Appendix G).

Usual preop diagnosis

Exstrophy/epispadias complex; spina bifida; neurogenic bladder; incontinence; bladder neck malformation

Bladder augmentation

Bladder augmentation is usually performed on children with a small capacity bladder, resulting from congenital abnormalities or fibrosis with poor compliance. Cystoscopy may or may not be performed at the same time. The patient is usually in supine position, and the operation may be performed through a lower midline due to the need to harvest a bowel segment. If laparoscopic bowel harvest is planned, then a Pfannenstiel incision can be used for the augmentation. The bowel and bladder are mobilized, with wide intraperitoneal exposure, leading to potentially large insensible losses in children. The relevant bowel segment is harvested, and the remaining native bowel is reanastomosed across the defect in the standard stapled or hand-sewn fashion. The "patch" of bowel segment is then sewn onto the bladder using running absorbable suture to minimize risk of future bladder calculi. At the end of the procedure, a suprapubic tube is placed to decompress the bladder and allow irrigation of mucus produced by the bowel segments. In the past, nasogastric decompression was maintained until return of bowel function. Some surgeons will ask for the tube to be removed at the end of the procedure. Perioperative antibiotics are usually continued for a minimum of 3 d.

As a special consideration, with larger numbers of patients undergoing bladder augmentation, perforation is not uncommon. Extraperitoneal bladder perforation of a normal bladder may be managed with drainage alone, but perforation of an augmented bladder is almost always managed operatively because the perforation is considered to be intraperitoneal and involves a higher risk of subsequent infection or abscess.

Usual preop diagnosis

Spinal cord injury, spina bifida, exstrophy, cerebral palsy; urinary incontinence; bladder tuberculosis, schistosomiasis, interstitial cystitis

Continent catheterizable stoma (Mitrofanoff appendicovesicostomy or Monti tube)

In the case of a child who needs lifetime catheterization, a continent catheterizable abdominal stoma is often preferred due to its greater ease of catheterization, particularly for children with motor impairment. Use of the appendix as a flap-valve conduit between the bladder and the abdominal wall was first described by Mitrofanoff in 1980. Operative setup is similar to that of a bladder augmentation. After amputation of the appendix, the base is brought through the abdominal wall to form a stoma at the umbilicus. The tip of the appendix is amputated to create a tube, and a small submucosal trough is made in the posterolateral bladder. An indwelling catheter is placed in the channel to maintain patency immediately postoperatively. Other catheterizable continent stomas may be constructed from short segments of the reconfigured ileum (Monti).

Usual preop diagnosis

Spina bifida, spinal cord injury, or cerebral palsy with neurogenic bladder; urinary retention or urinary incontinence, limited mobility

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Bladder Augmentation	Continent Catheterizable Stoma	Bladder Neck Reconstruction
Position	Supine	⇐	⇐
Incision	Lower midline incision, intraperitoneal	⇐	Pfannenstiel or low midline, extraperitoneal
Special instrumentation	Catheter in bladder/suprapubic tube, possibly NG tube	Catheter in bladder/suprapubic tube, possibly NG tube, catheter in stoma	Dependent on procedure
Unique considerations	Spina bifida pts may have latex allergy.	Pts with chronic catheterization may have infected urine; treat with preop antibacterial irrigation and culture-specific antibiotics.	Spina bifida pts may have latex allergy.

PENILE SURGERY

SURGICAL CONSIDERATIONS

Description

Pediatric penile operations usually correct congenital urethral abnormalities or involve circumcision. The most common surgical operation performed in the United States, **circumcision**, consists of the excision of the preputial skin to expose the glans. It can be performed for religious, ethnic, social, or medical reasons (e.g., phimosis or recurrent balanitis).

Circumcision

Freehand circumcision involves using two incisions to remove a sleeve of penile skin to fully expose the glans. Various clamps (Gomco, Mogen, etc.) can be used to circumcise in the newborn period. Most circumcisions performed in the operating room on older children or those with penile skin anomalies will be freehand excisions. Regarding analgesia, even in the neonate, a penile block is recommended for this procedure. In older children being circumcised, both caudal and penile blocks can offer a similar duration of anesthesia (4–8 h). However, school-aged children may be bothered more by leg numbness and inability to void from the caudal block.

Usual preop diagnosis

Phimosis, balanitis, family preference for circumcision

Hypospadias

Hypospadias is an abnormal opening of the urethral meatus, resulting from incomplete development of the urethra. The defect can be located anywhere from the corona of the glans to the perineum. Accordingly, surgical correction can require limited reconstruction as in the **meatal advancement glanuloplasty (MAGPI)** procedure or extensive dissection and reconstruction requiring 3–4 h of surgery. Although most pediatric urologists perform a one-stage reconstruction for the majority of hypospadias, some more extensive cases may require a two-staged repair. Options for single-staged repairs include a **tubularized incised plate (TIP)**, an **onlay flap** using the preputial skin, and rarely an **onlay graft** using harvested tissue from another location. An artificial erection is obtained by infusion of normal saline into the corpora to judge need for and adequacy of repair. This may cause significant fluid absorption in a small child.

The surgeon may choose not to use a urethral catheter in distal hypospadias repairs and some midshaft repairs. In such cases, caudal anesthesia should be avoided due to risk of urinary retention and risks of surgical complications relating to the need for postoperative catheterization. A **penile nerve block** may be helpful in such cases, with care given to avoid a penile hematoma, disruption of penile anatomy, or disruption of blood flow to the dorsal penis. Should a penile nerve block be performed, the use of

1% lidocaine with 1:100,000 epinephrine is done at the discretion of the surgeon. In all cases, postoperative urethral instrumentation should be avoided, as catheterization of the newly formed urethra could disrupt the repair. Catheters, when placed, are usually secured by stitching to the glans penis. Often at the conclusion of the surgery, the surgeon may require an additional 3–5 min of anesthesia to properly apply dressings to protect the hypospadias repair.

If repair of postop fistulae or other complication is done, buccal mucosa may be needed to create a new urethra, which would require access to the patient's mouth for harvesting of the buccal mucosa.

Of special concern to anesthesiologists, an association between use of caudal blocks and hypospadias repair complications (i.e., fistula formation) has been described. Several series have documented this association, but did not control for the severity of the hypospadias itself, which is known to be an independent risk factor for complications. Indeed, the only retrospective study controlling for this found that only hypospadias severity, and not the type of anesthetic block, was a risk factor for complications after repair. It is possible that caudal blocks are utilized more frequently in more complex repairs, as operative times are longer, most patients are left with a urethral catheter, and more pain is anticipated. Further, the biologic mechanism for how a caudal block would impact hypospadias complications remains unclear. While awaiting further well-designed prospective RCT studies to clarify the causality of the observed association in the retrospective studies, we continue to believe that caudal blocks are appropriate for hypospadias repairs.

Usual preop diagnosis

Hypospadias ± chordee; fistula repair; epispadias repair; penile torsion; concealed penis

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Circumcision	Hypospadias
Position	Supine	⇐
Incision	Circumferential penile	⇐ + ventral penis

Special instrumentation	None	Optical magnification, possibly microscope
Unique considerations	1% lidocaine ±1:100,000 epinephrine for hemostasis	Tourniquet; injectable NS for artificial erection; 1% lidocaine ± 1:100,000 epinephrine. If a catheter is placed, liberal iv fluids may be given.
Antibiotics	None	Surgeon dependent
Surgical time	30 min	1.5–4 h
EBL	Minimal	<50 mL
Postop care	Outpatient	Outpatient or ward ± urethral catheter
Mortality	<1%	⇐
Morbidity	Infection: 2%	⇐
	Hematoma: 2%	⇐
		Urethrocutaneous fistula (5–20%), urethral stricture, urethral diverticulum
Pain score	2	5

PATIENT POPULATION CHARACTERISTICS		
Age range	Neonates–children	>4 mo
Incidence	61%	1:300
Etiology	Acquired	Congenital
Associated conditions	Infection	Cryptorchidism; inguinal hernia; bifid scrotum

GENITAL PROCEDURES (CLITOROPLASTY, VAGINOPLASTY, URETHROPLASTY)

SURGICAL CONSIDERATIONS

Description

Masses of the introitus include urethral prolapse, prolapsed ectopic ureterocele, and rhabdomyosarcoma. Genitoplasty is usually performed in female patients with abnormal genitalia, such as ambiguous genitalia resulting from abnormal steroidogenesis (congenital adrenal hyperplasia [CAH], danazol exposure), a urogenital sinus, or cloacal anomalies.

Urethral prolapse repair

With the patient in lithotomy position, a simple circumferential incision is made at the junction between the prolapsed mucosa and the urethral meatus. The prolapsed tissue is excised, and an end-to-end anastomosis is performed with absorbable suture. Introital rhabdomyosarcoma often requires open or transurethral biopsy of the mass and is subsequently treated with chemotherapy in most cases.

Usual preop diagnosis

Urethral prolapse, urethral mass (e.g., introital rhabdomyosarcoma)

Vaginoplasty/clitoroplasty

These procedures are performed in patients with ambiguous genitalia and are usually associated with hormonal imbalance (CAH). In the past, this surgery was performed urgently in neonates for gender assignment reasons. However, there is controversy regarding the medical necessity for early surgery versus waiting for puberty to allow the child to decide. It is imperative that stress dose mineralocorticoid and glucocorticoid (steroid) replacement is given prior to the start of any procedure. The initial procedure usually requires reduction of the enlarged clitoris and reconstruction of the labioscrotal folds. With the patient in a lithotomy position, skin incisions are made to allow partial resection of the corporal bodies and glans with nerve sparing. Periclitoral skin flaps are used to reconstruct the clitoris and labial folds. Vaginoplasty is performed through a perineal approach by creating an urethrovaginal septum. The vagina usually can be pulled into its normal position between the urethra and rectum and anastomosed to perineal skin flaps using absorbable sutures. Vaginoplasty can be performed with clitoroplasty in an infant. If performed later in life (puberty), a vaginoplasty with complex flaps and bowel interposition is necessary. If a long, complicated intra-abdominal procedure is anticipated, an abdominoperineal approach is used. During some of these procedures, a loop of sigmoid colon or ileum is isolated, along with its mesentery, and is brought through the perineal incision. It is then anastomosed proximally to the vagina and distally to skin flaps. Additionally, these procedures may be used for **gender reassignment** if masculinization of the ambiguous genitalia in a genotypic male is not possible.

Usual preop diagnosis

Ambiguous genitalia; CAH; cloacal exstrophy; urogenital sinus persistence; danazol exposure

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE	
Position	Lithotomy
Incision	Perineal or abdominoperineal
Special instrumentation	Loupes (magnification)

Position	Lithotomy
Unique considerations	Steroid replacement may be necessary (CAH)
Antibiotics	1st- or 2nd-generation cephalosporin; aminoglycoside + clindamycin
Surgical time	2–4 h
EBL	10–15 mL
Postop care	± Urethral catheter
Mortality	<1%
Morbidity	Infection: <5% Bleeding: <5% Flap necrosis: <5%
Pain score	6

PATIENT POPULATION CHARACTERISTICS	
Age range	Clitoroplasty, 3–6 mo; vaginoplasty, puberty
Incidence	1:30,000 births (ambiguous genitalia)
Etiology	Congenital
Associated conditions	Hypothalamic-pituitary axis suppression; adrenal hyperplasia; steroid replacement therapy

ANESTHETIC CONSIDERATIONS FOR TRANSURETHRAL PROCEDURES, OPEN BLADDER PROCEDURES, PENILE SURGERY, AND GENITAL PROCEDURES

PREOPERATIVE

Typically, infants and children presenting for these procedures are otherwise healthy, with some notable exceptions. **Vesicoureteral reflux** may be associated with renal dysplasia and HTN. The**prune belly (Eagle-Barrett) syndrome** includes dystrophic abdominal musculature, requiring an evaluation of pulmonary function. **Bladder and cloacal exstrophy** may be accompanied by a spinal cord abnormality (e.g., tethered cord, spina bifida). Congenital cardiac anomalies may be present, and an evaluation should be performed prior to surgery.

Pediatric urology patients with lower urinary tract dysfunction and underlying neurologic disorders (e.g., myelomeningocele) and exstrophy are at risk for developing latex allergy as a result of repeated urethral catheterizations or surgical procedures.

Circumcision and hypospadias repair are most commonly performed in the first 2 yr of life in otherwise healthy children.

Respiratory	Prune belly syndrome: pulmonary function may be decreased. ✓ for Hx of respiratory compromise. Postop ventilatory support may be necessary. ✓ adequate reversal of NMB and force of cough. **Tests:** CXR; others as indicated from H&P
Renal	Renal anomalies may be present as part of a congenital malformation complex. **Tests:** As indicated from H&P
Endocrine	Surgeries for genital disorders usually are performed to reshape anatomic abnormalities 2° congenital endocrine disorders. Ambiguous genitalia are associated with congenital adrenal abnormalities. They are usually detected in the 1st mo of life and may lead to severe salt-losing crises with ↑ Na^+ and ↓ K^+. The electrolyte status of these patients must be evaluated in the preop period. Treatment consists of steroid replacement. **Tests:** Electrolytes; blood sugar
Premedication	If >7–9 mo of age, consider midazolam premedication (0.5 mg/kg) po or 0.1–0.2 mg/kg iv. Avoid long-lasting sedative medications.

ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Evaluate for concurrent disease, nutritional status, and hydration. Consider preop acetaminophen 10–15 mg/kg iv or po as an elixir.

INTRAOPERATIVE

Anesthetic technique

GA (ETT or LMA) using a pediatric circle. A combined technique with epidural or caudal anesthesia is often used. For small children, warm OR to 70°F–75°F. Use warming pad and/or forced air warming on OR table.

Induction	For patients <5–10 yr, standard mask induction with sevoflurane/N_2O/O_2. Older patients may agree to standard iv induction, facilitated by the use of topical local anesthetic cream or patch. For open-bladder and complex genital procedures, an indwelling epidural catheter for intraop and postop pain relief is recommended.
ERAS	Verify preincision antibiotics. Assess volume status. Discuss with surgeon local wound infiltration at conclusion of procedure. Consider iv acetaminophen (10 mg/kg for patients <1 yr old or 15 mg/kg for older patients with maximum dose of 650 mg). Consider PONV prophylaxis with iv ondansetron (0.1 mg/kg) Maintain normovolemia and normothermia.
Maintenance	Standard pediatric maintenance. With epidural anesthesia, volatile and/or iv anesthetic requirements are reduced.
Emergence	Typically, no special considerations. Carefully evaluate patient for adequate ventilation prior to extubation in those with prune belly syndrome. Discuss with surgeon local wound infiltration. PONV prophylaxis should include dexamethasone (e.g., 30 mcg/kg) and ondansetron (0.1 mg/kg up to 4 mg iv).

Blood and fluid requirements	Minimal blood loss IV: 22 or 24 ga × 1 BSS @ (maintenance): 4 mL/kg/h (1–10 kg) +2 mL/kg/h (11–20 kg) +1 mL/kg/h (>20 kg)	Complex cases may be associated with significant blood loss and require transfusion with whole blood or PRBC. See Zero Balance Fluid Management, Appendix K, p. K-2.
Monitoring	Standard monitors ± Arterial line	Place arterial line for measurement of arterial gases or to ✓ Hct and blood glucose if significant blood loss or long case is anticipated, in patients with concurrent renal dysfunction.
Positioning	✓ and pad pressure points ✓ eyes	
Complications	Nerve damage	In lower extremities, ✓ if padding is insufficient with lithotomy position.

POSTOPERATIVE

Complications	Prune belly: hypoventilation Adrenogenital syndrome: adrenal insufficiency	Assisted ventilation may be required.
Multimodal pain management	Acetaminophen Epidural or PCA analgesia IV opioids	Use nonopioid analgesics. Back up with bolus opioid analgesics. Ditropan or ketorolac will ↓ bladder spasm. Ketorolac → renal insufficiency. Do not use if renal function is abnormal.
ERAS	PONV protocol (see p. D-1)	Encourage early enteral nutrition, catheter removal,

and mobilization as appropriate.

INGUINOSCROTAL PROCEDURES

SURGICAL CONSIDERATIONS

Description

Undescended testis (cryptorchidism), hydrocele, and inguinal hernia are common in pediatric urology, and surgery is usually performed on an outpatient basis. Testicular torsion is one of the few true pediatric urologic emergencies because testicular infarction will occur within hours of the torsion. Testicular tumors in children, accounting for 1–2% of all pediatric solid tumors, are more frequently benign than those in adults and represent the main indication for **radical or simple orchiectomy** in children.

Orchiopexy

A nonpalpable testis may warrant diagnostic laparoscopy as the initial procedure, with subsequent laparoscopic or open abdominal orchiopexy versus orchiectomy if the testicle is found to be intra-abdominal (detailed under Laparoscopic and Robotic Procedures). 20% of nonpalpable testes become palpable after induction of anesthesia. Orchiopexy for a palpable undescended testis is performed through a small inguinal incision. Here, the external oblique fascia is opened, exposing the inguinal canal. The testis is localized, and the cord is dissected to gain adequate length for scrotal fixation, without torsion or tension. If the testicle is high and adequate inguinal mobilization is not possible, dissection into the retroperitoneum may be required. The scrotal pouch is created by making a skin incision two-thirds the way down the scrotum and then by

blunt dissection between the skin and dartos muscle. The testis is fixed into this pouch with suture.

Both ilioinguinal nerve block and caudal analgesia appear to be equally effective in management of postorchiopexy pain, but parents should be counseled on the risk of postoperative urinary retention with a caudal block. When a preoperative inguinal block is considered, this should be discussed with the surgeon. Alternatively, the block may be performed at the end of the procedure or the wound irrigated with 0.25% bupivacaine. The total dose of bupivacaine to be used for irrigation should be discussed with the anesthesiologist and should not exceed 3 mg/kg. Both of the above methods provide excellent postoperative analgesia and facilitate early discharge from the surgical recovery unit.

Usual preop diagnosis

Cryptorchidism; nonpalpable testis

Testicular torsion

Testicular torsion is a pediatric urologic emergency. There is no definitive diagnostic imaging study and the diagnosis is primarily clinical, although ultrasound with Doppler scans of the testis can be useful. At times, symptoms of testicular torsion may be indistinguishable from epididymitis or torsion of the testicular appendages (embryonic remnants). Once in the operating room, the testis is delivered through a scrotal incision, examined, detorsed, and assessed for viability. If the testis is nonviable, a **simple scrotal orchiectomy** is performed. If the testicle is viable, it is fixed in a **scrotal dartos pouch**, often using a three-point suture fixation. The contralateral testis is fixed in a similar fashion, usually through a second scrotal incision. A torsion of a testicular appendage usually is treated medically with pain control and anti-inflammatory agents. If this condition is discovered at surgical exploration, the diseased tissue is excised, the testis is reinserted into the scrotum, and the wound is closed. It should be noted that neonatal (antenatal) or perinatal torsion may require an orchiopexy in the newborn period. If the diagnosis is unclear, if there is concern for a testicular mass, and/or if there is an associated hydrocele or hernia, this operation may be performed through an inguinal incision.

Usual preop diagnosis

Testicular torsion; torsion of the testicular appendage

Hydrocelectomy–inguinal hernia repair

This procedure is performed through an inguinal incision, with subsequent dissection of the inguinal canal. The patent processus vaginalis is carefully dissected from the cord

structures, the peritoneal sac is ligated at the level of the internal inguinal ring, and the wound is closed after evacuation of the hydrocele liquid. (Also see Repair of Inguinal and Umbilical Hernias, Hydrocele.)

Usual preop diagnosis

Hydrocele; inguinal hernia

Radical orchiectomy

Although simple orchiectomy is performed through a scrotal incision, radical orchiectomy (used when testicular cancer is suspected) is performed through an inguinal incision. The external oblique fascia is opened, and the spermatic cord is isolated and clamped at the level of the internal ring. The testis is delivered through the incision and examined. If the testis is felt to contain malignancy, the cord is ligated and divided at the level of the internal inguinal ring. If there is uncertainty in the diagnosis, a biopsy can be performed.

Usual preop diagnosis

Testicular mass

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Orchiopexy, orchiectomy, hydrocelectomy, and hernia repair are performed most commonly in otherwise healthy children.

Renal	With phimosis, there may be Hx of UTIs. Possible pyelonephritis. Hematuria requires GU workup. **Tests:** UA; renal function (BUN, Cr), as clinically indicated
Laboratory	Hct; others as indicated from H&P
Premedication	If >7–9 mo of age, consider midazolam (0.5 mg/kg po) before induction. Avoid long-lasting sedative medications.
ERAS	Check compliance with presurgical ERAS

	recommendations (see above) including NPO status. Evaluate for concurrent disease, nutritional status, and hydration. Consider preop acetaminophen 10–15 mg/kg iv or po as an elixir.

INTRAOPERATIVE

Anesthetic technique

GETA or LMA/mask anesthetic, using a pediatric circle (consider using humidified and warmed gases for infants). A combined technique with caudal anesthesia often is used for nonendoscopic procedures. For small children, warm OR to 70°F–75°F. Use warming pad and/or forced-air warming on OR table.

Induction	In younger patients, mask induction is customary before iv placement. If the surgical procedure will be >30 min, tracheal intubation or LMA is preferred. Intermediate-acting NMR (e.g., rocuronium, 0.6 mg/kg iv) is administered to facilitate tracheal intubation. If appropriate, caudal anesthesia can be obtained using ropivacaine 0.2% and bupivacaine 0.125 or 0.25% ± epinephrine 1: 200,000, 1 mL/kg up to 10 mL total. Test dose of 0.1 mL/kg for maximum of 3 mL should be given after a negative aspiration through the catheter or needle. If a catheter is used, and additional 0.8 mL should be injected to account for the dead space of the catheter. A positive test dose, in contrast to adults epidural test dose, could be indicated by an increase in HR, a decrease in HR, a decrease in BP, or ST-T wave changes. The caudal local anesthetic dose should be fractionated with frequent aspirations. The addition of clonidine (1–2 mcg/kg) to the caudal block intensifies and prolongs the analgesia, with minimal sedation. Acetaminophen 30–40 mg/kg PR or 10 mg/kg iv over 30 min may be given following intubation.
ERAS	Verify preincision antibiotics. Assess volume status. Discuss with surgeon local wound infiltration at conclusion of procedure. Consider iv acetaminophen (10 mg/kg for patients <1 yr

	old or 15 mg/kg for older patients with maximum dose of 650 mg). Consider PONV prophylaxis with iv ondansetron (0.1 mg/kg). Maintain normovolemia and normothermia.	
Maintenance	Standard pediatric maintenance. If no regional block is performed, at least 2 MAC anesthesia is required prior to skin incision to prevent laryngospasm in nonintubated patients. Caudal anesthesia can be used to provide the majority of analgesia in nonendoscopic procedures.	
Emergence	If neuromuscular blockade is used, reverse with neostigmine (0.07 mg/kg iv) and atropine (0.02 mg/kg iv) or glycopyrrolate (0.01 mg/kg iv). Extubate when patient is fully awake or deep. Discuss with surgeon local wound infiltration. PONV prophylaxis should include dexamethasone (e.g., 30 mcg/kg) and ondansetron (0.1 mg/kg up to 4 mg iv).	
Blood and fluid requirements	Negligible blood loss IV: 20–22 ga × 1 BSS @ maintenance	Pediatric maintenance: 4 mL/kg/h (0–10 kg) +2 mL/kg/h (11–20 kg) +1 mL/kg/h (>20 kg) See Zero Balance Fluid Management, Appendix K, p. K-2.
Monitoring	Standard monitors	
Positioning	✓ and pad pressure points ✓ eyes	Ocular compression/corneal abrasion may occur with oversized mask.
Complications	Laryngospasm	Rx: 100% O_2, jaw thrust, positive pressure. If iv is present, first deepen the level of anesthesia with propofol. If necessary, administer succinylcholine (1–2 mg/kg iv) in addition to atropine (0.02 mg/kg iv). If no iv, give succinylcholine 3 mg/kg im and atropine 0.02 mg/kg im.

	Intravascular local anesthetic administration	Epinephrine in caudal anesthetic (to detect intravascular administration) does not significantly prolong analgesia.

POSTOPERATIVE

Complications	Bleeding	
Multimodal pain management	Caudal or regional block Acetaminophen (10–20 mg po/iv and 10 mg q6h prn; alternatively 30–40 mg pr on first dose, followed by 20 mg pr q6h prn)	Optimal analgesia and presence of parents in PACU will minimize child's agitation/movement/crying. Use nonopioid analgesics. Back up with bolus opioid analgesics.
ERAS	PONV protocol (see p. D-1)	Encourage early enteral nutrition, catheter removal, and mobilization as appropriate.

LAPAROSCOPIC AND ROBOTIC PROCEDURES

SURGICAL CONSIDERATIONS

Description

Laparoscopy and robot-assisted laparoscopic techniques are used more frequently by pediatric urologists. Complexity and duration of procedures range from basic laparoscopy to locate an impalpable testis (**diagnostic laparoscopy** with subsequent **laparoscopic orchiopexy**) to robotic-assisted **partial nephrectomy** for a nonfunctional renal moiety. Additional procedures that have gained popularity using a minimally invasive approach include **nephrectomy, nephroureterectomy, adrenalectomy, pyeloplasty**, and **varicocelectomy**.

In both basic laparoscopy and robot-assisted laparoscopy, pneumoperitoneum is created by insufflating CO_2 (to a pressure of 12–16 mm Hg) either through the Veress needle technique or after trocar insertion in the peritoneal cavity through a small, 1-cm periumbilical incision under direct vision **(Hasson technique)**. Respiratory pressures on the ventilator must be watched closely, as insufflation can be released quickly should the need arise. Urine output should be monitored, as pneumoperitoneum may depress renal blood flow and function. Other trocars (sizes range from 2 to 15 mm) are then inserted as necessary, under direct laparoscopic vision whenever possible, avoiding abdominal wall vessels and internal organs. The specific placement of ports and patient position (typically supine or flank) is dependent on the procedure.

Advantages to the use of the robot include improved 3D visualization and instrument control compared to traditional laparoscopy. Though the data are limited, there is increasing evidence that robotic surgery may afford decreased postop pain, shorter hospital stays, and decreased blood loss. However, ~20–45 min of robot setup time should be calculated into the time under anesthesia. Additionally, issues with port placement, difficulty anatomy due to smaller patient size, and positioning of the robot itself all contribute to a highly variable operative time. It is important for there to be regular communication between the surgical and anesthesia teams about the expected duration, as this may change throughout the procedure. Adequate leg padding and securing of the patient to the bed during these procedures is of paramount importance,

for both ease of the surgery as well as patient safety during the procedure. A test roll of the table should occur prior to the start of the procedure to ensure the patient is secure. Once docked, the robot takes up a significant amount of space in the operating room and may make access to the patient during the case difficult. Lines should be checked and confirmed to be working well prior to the start of the procedure.

Diagnostic laparoscopy with potential orchiopexy or orchiectomy

Performed for an impalpable testis, if diagnostic laparoscopy reveals blind ending vessels, confirming the absence of a testis, the procedure is terminated relatively quickly, and no further incisions are made. **Large doses of paralytics should not be given until it is confirmed with the surgical team that the procedure will need to proceed beyond the initial diagnostic laparoscopy**. An inguinal testis remnant usually indicates either antenatal testicular ischemia or torsion. If the vessels are seen to enter the inguinal ring, laparoscopy is concluded and inguinal exploration is performed. If the testis is located intra-abdominally, it is evaluated for size and location to determine whether to proceed to **orchiectomy** versus a one- or two-stage (**Fowler Stevens**) **orchiopexy**. Laparoscopic orchiectomy or **gonadectomy** may be performed in intersex situations for a dysgenetic (streak) gonad, for a nonviable gonad, or for a gonad in which minimal cord length exists. If adequate cord length permits, laparoscopic ligation of the gonadal vessels is done, and the testis is placed into a scrotal pouch (**dartos pouch**) in one stage. If there is inadequate cord length, the gonadal vessels are still ligated, but the patient will require a future second-stage Fowler Stevens operation to bring the testicle into the scrotum once adequate collateral vasculature has been allowed to develop intra-abdominally. In other situations, **laparoscopic or open dissection** of testicular vessels on a peritoneal pedicle in the retroperitoneum may be performed. It should be noted that the robot is not typically used in this procedure.

Usual preop diagnosis

Nonpalpable testis; cryptorchidism

Varicocele ligation

Using a transperitoneal approach, identical to that of the approach for diagnostic laparoscopy, the spermatic veins are isolated from the abdominal wall and are ligated with metallic clips to reduce the varicocele. Use of a robot is typically not required for this procedure. The primary complications from this procedure are hydrocele and varicocele recurrence.

Usual preop diagnosis

Varicocele

Renal surgery (nephrectomy [including partial], nephroureterectomy, pyeloplasty)

Patients are typically placed in the lateral-decubitus position with the target kidney up, though partial lateral-decubitus, prone, or supine positioning may be used in some cases. Flexion of the operating table may be requested to help facilitate access to the kidney. Initial and subsequent port placement is variable but is performed using the aforementioned principles. If used, the robot will typically approach the side of the table the patient's back is facing (if in the lateral-decubitus position). For supine and prone cases, the robot will be at the foot of the bed. The approach to the kidney is typically transperitoneal, though purely retroperitoneal approaches have been described. After sufficient insufflation, mobilization of the colon is done (if required) and the kidney dissection is performed.

In a nephrectomy, the hilar vessels are ligated with metallic clips. The kidney is then retrieved through the 10-mm port by morcellating it or the incision can be dilated or elongated. Nephroureterectomy is performed in a similar manner, except that the ureter is dissected down to its insertion into the bladder where it is excised with a small cuff of bladder tissue. The resulting incision in the bladder is closed using two layers of suture. For partial nephrectomies, blood should be immediately available in these as there is a risk of significant blood loss. Blood loss is attempted to be minimized by clamping of the renal vessels but comes at the risk of renal ischemia and free radical–mediated tissue injury upon reperfusion. Administration of 20% intravenous mannitol around this time is often done to help scavenge free radicals, as ice slush cannot be used in a laparoscopic approach. Urine output should be watched closely and the patient resuscitated as needed. Once the affected area of the kidney is removed, it is placed in a bag and retrieved through the 10-mm port.

Prior to a pyeloplasty, some surgeons will place a ureteral stent at the start of the case, which may require the patient to start in lithotomy and later be repositioned. The stent assists with ureteral identification during the case. After initial entry, port placement, and kidney dissection, the pyeloplasty is carried out using the same principles as open pyeloplasty. This includes dismembering the ureter from the renal pelvis, spatulation of the ureter, and careful reassembly of the ureteropelvic unit. The patient is usually left with a ureteral stent at the end of the case. Whether surgery is performed intra- or extraperitoneal, laparoscopic/robotic surgery with CO_2 insufflation is associated with potentially significant systemic hemodynamic changes in children, as previously described.

Usual preop diagnosis

UPJ obstruction; infected or nonfunctioning kidney; HTN; multicystic or dysplastic kidney; protein-losing nephropathy in ESRD; renal mass

Vesicoureteral reimplantation

This procedure is typically done using robotic assistance. After initial cystoscopy to determine that there is adequate bladder size for a robotic procedure, the patient is placed in a supine position with legs splayed. This procedure may be performed intravesically but more commonly is done extravesically/intraperitoneal (**Lich-Gregoir**). In both cases, a urethral catheter and at times ureteral stent(s) are left in place postoperatively. If an extravesical approach is selected, the initial port is placed in the umbilicus and two robotic working ports are placed laterally. The robot is then docked, coming in from the direction of the patient's feet, and the patient is dropped into the Trendelenburg position, to improve exposure of the pelvic organs. The ureter is then dissected down to where it meets the bladder and a detrusorrhaphy is performed. If an intravesical approach is selected, an initial port is placed through a midline incision one-third of the way from the umbilicus to the pubis. The bladder is entered, and a balloon trocar is placed through a cystotomy into the bladder, followed by two robotic working ports. The ureteral reimplantation is then performed. Primary complications following robotic ureteral reimplant include urine leak, transient ureteral obstruction, and persistent reflux.

Usual preop diagnosis

Vesicoureteral reflux

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Undescended Testis/Varicocele	Renal Surgery	Ureteral Reimplant
Position	Supine; 15° Trendelenburg	Lateral decubitus	Supine, legs splayed, Trendelenburg
Incision	5–10-mm umbilical port + one or two additional ports	Four ports usually necessary	12-mm umbilical port and 5–8-mm working ports

			× 2
Special instrumentation	Bladder catheterization, NG tube	⇐	Cystoscopy, bladder catheterization
Unique considerations	Secure child firmly to avoid movement with table tilting. Intra-abdominal pressure = 14–16 mm Hg. Lower pressure may be needed if pulmonary mechanics are compromised. Urethral catheter commonly placed.	⇐	
Antibiotics	Cefazolin 30 mg/kg q4h	1st- or 2nd-generation cephalosporin; aminoglycoside + clindamycin	As necessary per preop urine culture
Surgical time	30 min–1 h	2.5 h (nephrectomy) to 4 h (pyeloplasty)	3–5 h
EBL	Minimal	⇐	⇐
Postop care	PACU → home	PACU → ward	PACU → ward
Mortality	<1%	⇐	⇐
Morbidity	Overall: 0.6–5%	⇐	⇐
	Trocar misplacement: bowel perforation	⇐	⇐
	Vascular/organ thermal injury from electrocautery	⇐	⇐
	CO_2 embolus	⇐	⇐

	Grounding pad thermal injury	⇐	⇐
	Trocar site bleeding, trocar hernia	⇐	⇐
	Varicocele only: recurrent varicocele (1–11%), hydrocele (1–5%)	Bleeding = 5%	Recurrent reflux, transient ureteral obstruction, urine leak
Pain score	2	4	4

PATIENT POPULATION CHARACTERISTICS	
Age range	10 mo–18 yr
Male:Female	Male (cryptorchidism)
Incidence	3% of newborn boys
Etiology	Congenital
Associated conditions	Renal insufficiency

ANESTHETIC CONSIDERATIONS

(See also Anesthetic Considerations, p. 1528.)

During mask induction, care should be taken to avoid excessive positive pressure with consequent insufflation of the stomach. An OGT should be placed immediately after induction and intubation to remove air from the stomach, decreasing the risk of gastric puncture with placement of trocars and improving surgical view during procedure. Creation of a pneumoperitoneum as part of a laparoscopic procedure impairs ventilation and can restrict venous return. The use of Trendelenburg and lithotomy positions can further compromise respiratory function. Anesthetic considerations for pediatric patients undergoing laparoscopic procedures are further considered in Chapter 12.5. Severely limited patient access in robotic-assisted surgery makes it difficult to respond to the patient. A practice trial maneuvering the cumbersome robotic equipment should be performed to ensure rapid access to the patient in case of emergency. Care should be taken not to move the operating room table after the robotic arm/instruments are placed to avoid patient injury.

PERCUTANEOUS PINNING OF DISPLACED SUPRACONDYLAR HUMERUS FRACTURE

SURGICAL CONSIDERATIONS

Description

Supracondylar fractures of the **distal humerus** are the most common elbow fractures in children and the most common pediatric fractures requiring reduction under general anesthesia (GA). They have a justifiable reputation for complications because of the close proximity to neurovascular structures with a reported incidence of 2–11% for brachial artery injury and 12–20% for nerve injury (anterior interosseous branch of the median nerve, ulnar nerve, or radial nerve palsies). The most serious potential complication is a compartment syndrome of the forearm, which **requires emergent surgery** for reduction and fasciotomy.

The vast majority of these injuries result from falling on an outstretched arm (FOOSH) with the elbow **extended**—an extremely common childhood event. The Gartland

classification is used to guide treatment with type 1 fractures being minimally displaced and usually stable. They can be managed with a splint alone. Most supracondylar fractures are either type 2, **partially displaced**, or type 3, completely displaced fractures, and require GA for **closed reduction and percutaneous pinning (CRPP)**. They can also be classified based on the direction of displacement of the distal fragment into flexion and extension types. Extension-type supracondylar fractures are significantly more common, but flexion-type fractures are more likely to require open reduction.

Documentation of the neurovascular examination is mandatory upon initial evaluation, immediately before anesthesia and upon awakening postop. When a patient presents to the emergency department, if the neurovascular status is normal, and if the patient has eaten recently, it may be safe to wait for 6–12 h with continued monitoring of the neurovascular status. Reduction is obtained by a combination of traction and manipulation. Complete muscular relaxation is essential during the reduction maneuver. Usually, two 0.062-inch smooth Kirschner wires are inserted across the fracture site using intraoperative fluoroscopy. Many surgeons prefer to use the intensifier screen as a platform, thus requiring the patient to be at the edge of the OR table. Occasionally, the fracture cannot be reduced closed, and an open reduction is necessary. In that case, the arm is reprepped, and an incision is made to openly visualize and reduce the fracture. The same type of smooth pin fixation is then used (Fig. 12.7-1). Following the pinning, either a splint or well-padded bivalve cast is applied before the patient is awakened.

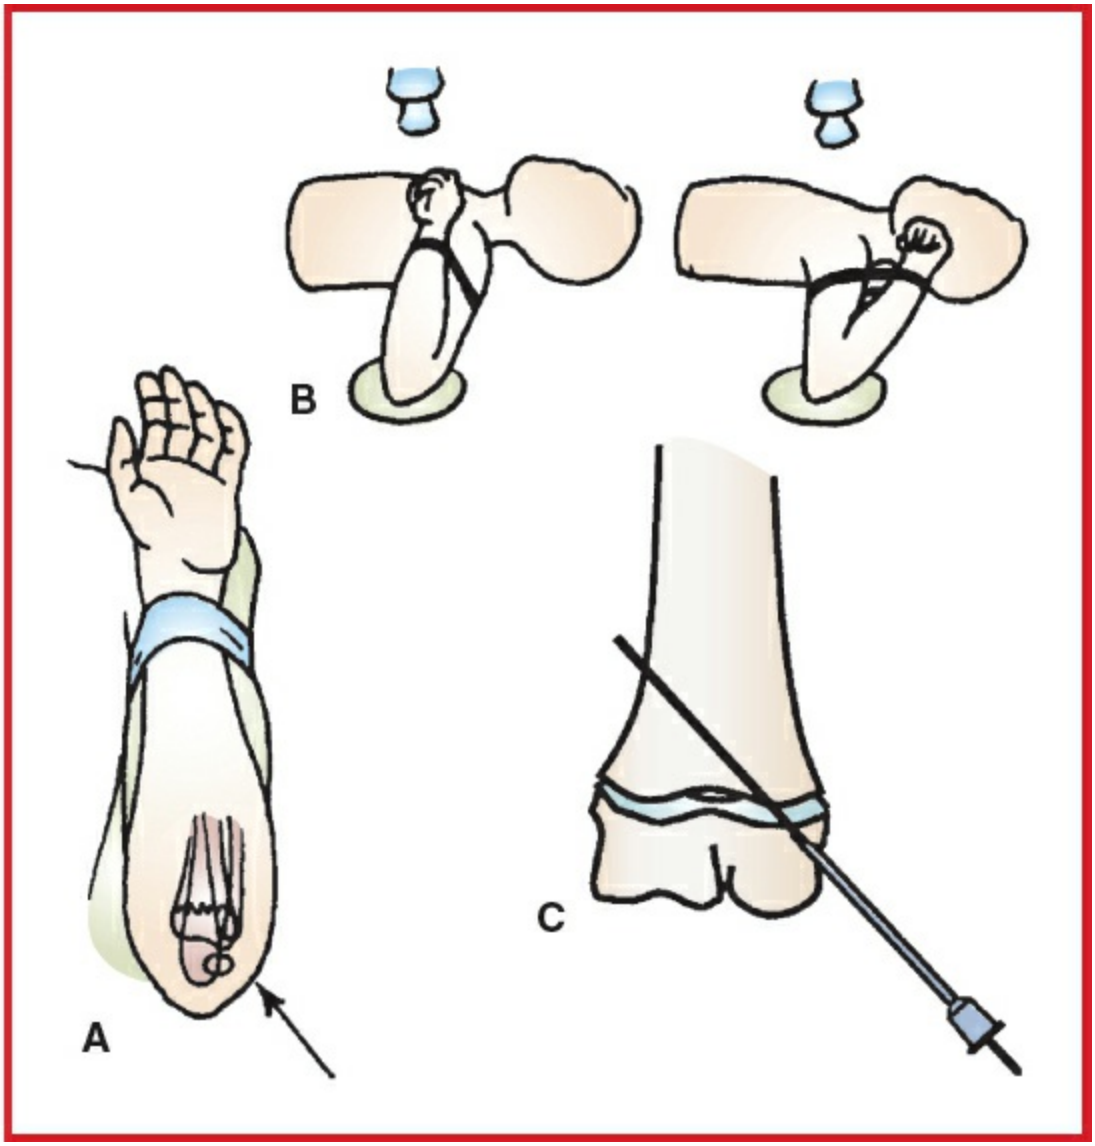

Figure 12.7-1 Percutaneous pinning of supracondylar humerus fracture. **A:** The fracture is manually reduced and held with elbow flexed. **B:** Fracture reduction is assessed with I.I. **C:** The fracture is stabilized with percutaneous K-wires. (Reproduced with permission from Chapman MW:Chapman's Orthopaedic Surgery, 3rd edition. Lippincott Williams & Wilkins, Philadelphia: 2001.)

Usual preop diagnosis

Supracondylar fracture of the elbow

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

Percutaneous Pinning	Open Reduction

Position	Usually supine, occasionally prone or lateral	⇐
Incision	None	1″ lateral
Special instrumentation	Power drill, intraop fluoroscopy	⇐
Unique considerations	Full stomach; impending compartment syndrome	⇐
Antibiotics	Usually none	Cefazolin 25 mg/kg
Surgical time	30–60 min	30–90 min
Closing considerations	Cast or splint	⇐
EBL	Minimal	⇐
Postop care	PACU → room; close neurovascular monitoring	⇐
Mortality	Rare	⇐
Morbidity	Late angular deformity, especially cubitus varus: 10%	⇐
	Nerve palsy (typically anterior interosseous [median], ulnar or radial nerve) from the fracture itself: 7–12%	⇐
	Compartment syndrome (Volkmann contracture): <0.5% (some degree of vascular spasm or loss of radial pulse much more common)	⇐
	Stiffness, myositis ossificans	⇐
	Vascular injury	⇐
	Ipsilateral fracture	⇐
Pain score	3–5	3–6

PATIENT POPULATION CHARACTERISTICS

Age range	3–10 yr with peak age range of 5–8 yr
Male:Female	1.6:1
Incidence	Frequent
Etiology	Trauma, usually a fall
Associated conditions	Usually normal, healthy child

CLOSED OR OPEN REDUCTION OF DISPLACED LATERAL CONDYLE HUMERUS FRACTURE

SURGICAL CONSIDERATIONS

Description

Lateral condylar fractures of the distal humerus are second only to supracondylar fractures in frequency. Initial radiographs of lateral condyle fractures can look deceptively normal; however, because these fractures cross the physis (growth plate) and enter the articular surface, they require anatomic reduction to restore joint surface congruity and to avoid a premature physeal arrest. In addition, the elbow may be unstable and dislocate if the fracture extends into the trochlea of the humerus. Accurate and stable reduction minimizes the risk of nonunion, a well-known complication resulting from unsuspected rotation of the fracture fragment and by traction forces of the extensor muscles attaching to this condyle. Unlike supracondylar fractures, neurovascular complications are rare with lateral condyle fractures.

Although minimally displaced fractures can be treated with a cast, 60% of lateral condyle fractures are displaced and require manipulation and pinning. Casting without manipulation, and thus requiring no anesthesia, is indicated for stable fractures that are displaced <2 mm. Nonoperative treatment is associated with a high risk (up to 15%) of subsequent displacement despite immobilization. More significant displacement (>2 mm) is an indication for operative treatment, which requires GA. Stable fractures with 2–4-mm displacement can be treated with **CRPP** under fluoroscopic control. **Open reduction and pinning** is necessary for fractures that are unstable, rotated, or displaced more than 4 mm. Screw fixation is gaining popularity, but pinning remains the gold standard. Muscular relaxation is advantageous when performing either a closed or open reduction of the fracture. A sterile tourniquet is used for cases requiring open reduction.

Usual preop diagnosis

Displaced lateral condyle humerus fracture

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, postop care, and pain management options. **See Appendix K: Pediatric ERAS, p. K-6 to K-8.**

ASPIRATION AND INJECTION OF UNICAMERAL BONE CYST

SURGICAL CONSIDERATIONS

Description

Unicameral bone cysts (UBCs) are benign lesions typically located centrally in the metaphyseal regions of long bones, in skeletally immature patients, and most commonly in the proximal humerus. The cyst is rarely a source of pain until presentation (typically after a fracture). The benign radiographic appearance allows clinicians to follow most lesions without the need for surgical biopsy. Surgical care is indicated when the UBC is of sufficient size and location to cause mechanical weakening of the bone and predispose to a pathologic fracture. The goals of surgical care are to confirm the diagnosis of UBC and to reestablish the mechanical integrity of the bone. Diagnosis of a UBC is made by percutaneous aspiration of the lesion, using a standard 16- to 18-gauge spinal needle under GA. Fluoroscopic guidance facilitates needle placement. The presence of clear, straw-colored fluid confirms diagnosis of UBC. An alternative diagnosis, such as aneurysmal bone cyst, is more likely if frank blood is aspirated. If the lesion contains no fluid, it may be a nonossifying fibroma. Open biopsy may be necessary if the diagnosis is unclear.

Multiple treatment options are described in the literature, but most cases can be treated

adequately with percutaneous aspiration and injection of the cavity with a substance to promote new bone formation. **The surgeon may inject radiopaque dye to verify that the entire cavity is contiguous.** If the cystic cavity is loculated by bony trabecula, a **curette** or **percutaneous Kirschner** wire is used to convert the lesion into a unicompartmental space, so the subsequent injection will easily access the entire lesion. Scraping the inner cyst walls also helps to disrupt the cyst lining and is thought to improve the chance of filling in the cavity. The final surgical step is to introduce a second "venting" needle into the cyst to allow lavage with sterile saline, followed by injection of the cavity. Historically, methylprednisolone has been used, but more recent evidence suggests a higher success rate when autologous bone marrow is injected. Injectable allograft bone preparations also can supplement the bone marrow injection. Care must be taken to avoid aspirating from the first needle after the second has been placed, to avoid intraosseous air embolism.

Usual preop diagnosis

Unicameral bone cyst

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, postop care, and pain management options. **See Appendix K: Pediatric ERAS, p. K-6 to K-8.**

SUMMARY OF PROCEDURES

	Percutaneous	Open
Position	Supine	⇐
Incision	None	Length of cyst
Instrumentation	Spinal needles, Kirschner wires, intraoperative fluoroscopy	Curettes
Unique considerations	Risk of air embolus	Additional time for intraop pathology evaluation
Antibiotics	Usually none	Cefazolin 25 mg/kg
Surgical time	30–60 min	60–90 min
Closing considerations	None	Cast or splint
EBL	Minimal	⇐

Postop care	PACU → room	PACU → room/home
Mortality	Rare	⇐
Morbidity	Infection	⇐
	Iatrogenic fracture	⇐
	Growth arrest: rare	⇐
Pain score	0–2	3–6

PATIENT POPULATION CHARACTERISTICS

Age range	3–14 yr; rarely found in adults (<15%)
Male:Female	1:3
Incidence	20% of benign bone lesions; most common location is the proximal humerus (67%), followed by the proximal femur (15%).
Etiology	Unknown. Venous obstruction → fluid transudate containing high levels of interleukin-1 and interleukin-6, which stimulate osteoclasts
Associated conditions	Usually normal, healthy child. Initial presentation typically follows a pathologic fracture.

RELEASE FOR TORTICOLLIS

SURGICAL CONSIDERATIONS

Description

Congenital muscular torticollis is a painless tilting of the head due to unilateral contracture of the sternocleidomastoid muscle. The head tilts toward the involved side and rotates toward the opposite side (a "cock-robin" posture such that the chin points to the opposite side). It is associated with breech and difficult deliveries, as well as other musculoskeletal disorders, such as metatarsus adductus, hip dysplasia, and talipes equinovarus. Multiple theories regarding the etiology of congenital muscular torticollis have been proposed, including fibrosis of the sternocleidomastoid muscle following a peripartum intramuscular bleed, fibrosis resulting from a compartment syndrome of the sternocleidomastoid muscle, intrauterine crowding, and a primary myopathy of the sternocleidomastoid muscle. Eighty percent of cases of torticollis are a result of this congenital contracture of the sternocleidomastoid muscle. Less common etiologies—such as congenital cervical spine malformations (e.g., Klippel-Feil syndrome), neurologic disorders, a cranial or cervical neoplasm, inflammatory conditions (e.g., Grisel syndrome), or an ocular dysfunction—should also be excluded. Congenital muscular torticollis is seen more frequently on the right side (i.e., tilting to the right and turned to the left). The majority (50–70%) will resolve spontaneously within the first year of life with minimal residual deficit. However, in the remainder, persistent torticollis will lead to skull and facial deformities (plagiocephaly). If the child sleeps prone, he or she will usually lie with the affected side down, resulting in flattening of the face on that side. If the child sleeps supine, flattening of the contralateral skull occurs. This plagiocephaly will become permanent if the torticollis persists and is left untreated.

Initial treatment includes physical therapy with stretching of the sternocleidomastoid muscle. For children <1 yr of age, a program of stretching is recommended and will resolve 90% of cases. After 2 yr of age, nonoperative treatment is not likely to be effective. Children with persistent torticollis and an unacceptable amount of facial asymmetry should be treated surgically before 3 yr of age. However, some improvement in facial asymmetry has been reported in children treated surgically up to 8 yr of age.

Surgical options include a unipolar release, a bipolar release, a middle-third transection, or a complete resection. Unipolar release involves division of the distal insertion of the sternocleidomastoid muscle and usually is performed for a mild deformity. For more extensive involvement, bipolar release is usually performed. This

procedure entails division of both the insertion and origin of the sternocleidomastoid muscle. Z-plasty of the clavicular head or transfer of the clavicular head to the sternal head may be done to maintain a more normal cosmetic contour of the neck. Potential surgical complications include injury to the spinal accessory nerve, jugular veins, carotid vessels, and the facial nerve. Postop, patients are encouraged to perform simple stretching exercises, but they will often require bracing to maintain the corrected alignment.

Usual preop diagnosis

Congenital muscular torticollis

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Unipolar	Bipolar
Position	Supine	⇐
Incision	Transverse, 1.5 cm superior to the sternum and clavicle over muscle insertion	⇐ + 1 cm distal to mastoid process behind the ear at muscle origin
Unique considerations	Plagiocephaly	⇐
Antibiotics	Cefazolin 25 mg/kg	⇐
Surgical time	30 min	45 min
EBL	Minimal	⇐
Postoperative care	PACU → room/home	⇐
Mortality	Rare	⇐
Morbidity	Hypertrophic scar	⇐
	Loss of normal muscle contour	⇐
		Spinal accessory nerve injury

Pain score	3–5	3–5

PATIENT POPULATION CHARACTERISTICS	
Age range	Onset at birth, surgery after age 1 yr
Male:Female	1:1
Incidence	1/500
Etiology	Fibrosis of the sternocleidomastoid; possible intrauterine or perinatal muscle compartment syndrome
Associated conditions	Usually normal, healthy child; hip dysplasia in 20%

ANESTHETIC CONSIDERATIONS

POLLICIZATION OF A FINGER

SURGICAL CONSIDERATIONS

Description

Pollicization is indicated in the infant with congenital absence or hypoplasia of the thumb. It is a technically demanding procedure that involves conversion of an adjacent functional finger (usually the index finger) into a useful thumb. The components of the

donor finger, including the bones, tendons, nerves, and vascular supply, are used to form a functional thumb and thenar mass (Fig. 12.7-2). Tendon transfers are performed to substitute for the absent or hypoplastic thenar muscles. These patients often have other associated congenital malformations, which should be ruled out prior to surgery. The organs that are commonly involved include the vertebrae, anus, heart, trachea, esophagus, kidneys, hematopoietic system, and lower limbs. Commonly associated genetic syndromes include Holt-Oram syndrome (cardiac septal defects and radial deficiency), TAR syndrome (thrombocytopenia with absent radius), and Fanconi anemia (aplastic anemia).

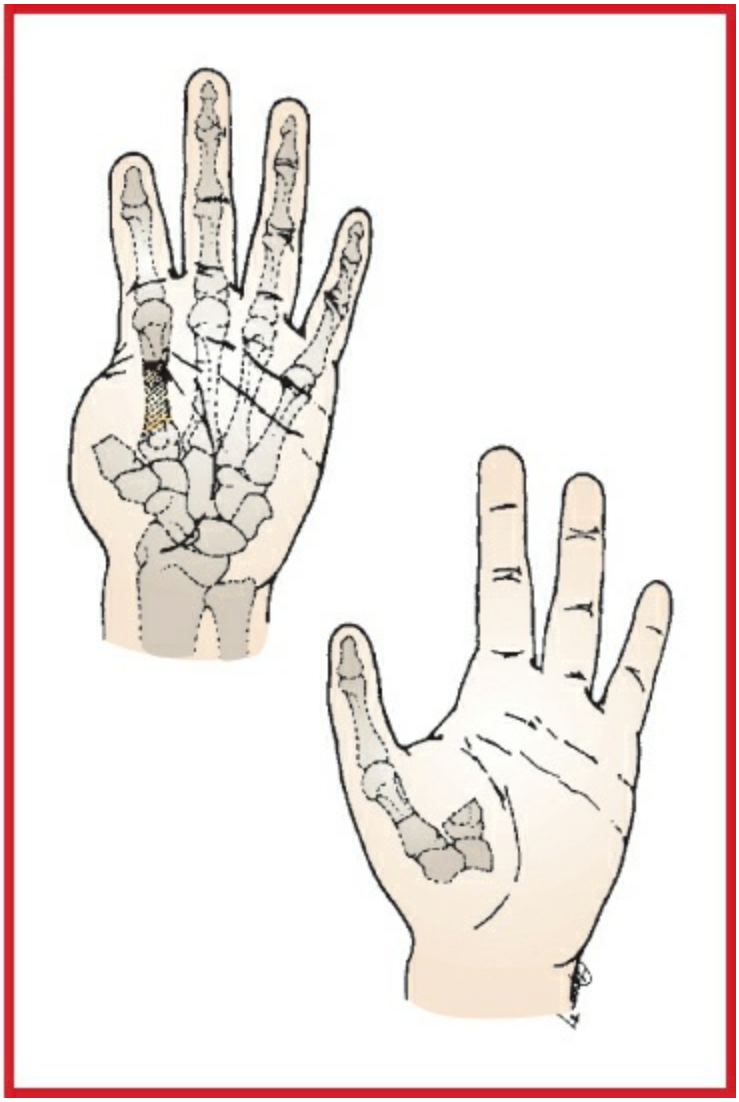

Figure 12.7-2 Pollicization of a finger. (Reproduced with permission from Chapman MW:Chapman's Orthopaedic Surgery, 3rd edition. Lippincott Williams & Wilkins, Philadelphia: 2001.)

Variant procedure or approaches

There are several different surgical techniques, which share the basic transposition and

rotation of the finger to the thumb position.

Usual preop diagnosis

Aplastic thumb; hypoplastic thumb; radial club hand; radial longitudinal deficiency

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE	
Position	Supine, with arm extended on hand surgery table
Incision	Multiple incisions on the hand
Special instrumentation	Pneumatic tourniquet; magnification loupes
Antibiotics	Cefazolin 25 mg/kg (children)
Surgical time	3–4 h
Tourniquet	100 mm Hg above systolic; max time = 120 min
Closing considerations	Complex skin flaps are necessary. A plaster splint is placed while the patient is still anesthetized.
EBL	Minimal; performed under tourniquet control
Postop care	PACU → overnight admission for observation or perfusion to the transposed finger
Mortality	Minimal
Morbidity	Ischemia (loss of digit): Rare Skin flap necrosis: Moderately common
Pain score	1–2

PATIENT POPULATION CHARACTERISTICS	
Age range	1–2 yr is ideal time for surgery. Procedure should be done before patient begins school.
Male:Female	1:1
Incidence	Overall, about 1/20,000 live births require a variant of

	this procedure.
Etiology	Unknown; also associated with thalidomide ingestion
Associated conditions	Associated with congenital anomalies of the upper extremity, esophagus, spine, and lower extremities Absence of radius (radial club hand), common Various forms of syndactylies, common Abnormalities of the hematopoietic system (Fanconi syndrome), cardiovascular system (ASDs in Holt-Oram syndrome), spine, and GI system, along with hypothyroidism, are frequently associated.

SYNDACTYLY REPAIR

SURGICAL CONSIDERATIONS

Description

Syndactyly refers to congenital failure of separation of two or more fingers. If the connection extends to the end of the digits, it is defined as “complete” syndactyly. Otherwise, it is defined as “incomplete” syndactyly. It can also be broken down into “simple” or “complex” based on whether the connection involves soft tissue alone or soft tissue and bone, respectively. Complex syndactyly often includes fusion of adjacent phalanges or interposition of accessory phalanges, with frequent abnormalities of the neurovascular structures. Surgical treatment is typically recommended to allow independent digital function as well as for aesthetic reasons. The timing of surgery is determined on an individual patient basis, but is usually recommended prior to 18 mo of age to prevent detriments in hand development.

Syndactyly release and reconstruction involves creation of a dorsal, proximally based skin flap to recreate the web. Zigzag dorsal and palmar incisions are created by starting distally and moving proximally. The digital nerve and arteries are dissected proximally as far as possible. Due to concern for vascular insufficiency, both sides of a digit at the same time are not released at the same time. Primary closure is almost never possible, and supplemental full-thickness skin grafts harvested from the groin are often required to complete the closure. It is not always possible to save all the bony elements. Patients with conditions such as Apert syndrome must undergo careful preoperative evaluation of their airway.

Usual preop diagnosis

Syndactyly of fingers; bifid finger, thumb/finger

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, postop care, and pain management options. **See Appendix K: Pediatric ERAS, p. K-6 to K-8.**

SUMMARY OF PROCEDURE	
Position	Supine
Incision	Zigzag between digits; skin graft donor site from groin
Special instrumentation	Magnification loupes are always necessary. Tourniquet is mandatory.
Unique considerations	Groin skin often taken for graft closure
Antibiotics	Usually none
Surgical time	2–4 h
Closing considerations	Above-the-elbow cast or splint to keep incision away from the mouth and other hand of the infant or child
EBL	20 mL
Postop care	PACU → home, if simple syndactyly
Mortality	None associated with procedure
Position	Supine
Morbidity	Digital necrosis Partial slough of flaps or skin graft requiring revision

	Scarring and some stiffness of fingers "Web creep" (distal migration of the webspace) Angulatory deformities late, occasionally depending on degree of involvement of the skeleton and joint
Pain score	1–3

PATIENT POPULATION CHARACTERISTICS	
Age range	6 mo–5 yr
Male:Female	2:1
Incidence	1/2000 births (the most common significant congenital hand anomaly)
Etiology	Family Hx (10–40%); failure of differentiation in the 6th–8th wk of intrauterine life
Associated conditions	Polydactyly, accessory phalanges; Apert syndrome; Poland syndrome

ANESTHETIC CONSIDERATIONS

See Anesthetic Considerations for Upper-Extremity Procedures.

ANESTHETIC CONSIDERATIONS FOR UPPER-EXTREMITY PROCEDURES

(Procedures covered: percutaneous pinning; displaced supracondylar humerus fracture; closed/open reduction; displaced lateral condylar humerus fracture; aspiration/injection unicameral/bone cyst; torticollis release; pollicization of the finger; syndactyly release)

PREOPERATIVE

The majority of children presenting for repair of upper-extremity fractures are otherwise healthy. Most of these patients present for repair of a traumatic injury; thus, the preop workup is routine. Some arm procedures, such as repair of a compound fracture, require immediate attention and necessitate emergency surgery and full-stomach considerations. Some upper-extremity procedures such as pollicization of a finger may be needed in patients suffering from other congenital anomalies or syndromes; thus, a detailed preoperative evaluation is needed.

Laboratory	Tests as indicated from H&P
Premedication	Standard premedication. Avoid long-lasting sedative medications.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Consider preop acetaminophen 10–15 mg/kg iv or po as an elixir.

INTRAOPERATIVE

Anesthetic technique

GETA or LMA because children rarely tolerate regional anesthesia alone. In the older patient, regional anesthesia may be appropriate and can reduce the risk of aspiration pneumonitis associated with GA in the patient with a full stomach. A combined technique offers the advantages of reduced anesthetic requirements and postop pain relief; however, regional anesthesia is relatively contraindicated in patients with neurovascular compromise.

General anesthesia

Induction	Standard induction except in acute trauma patients, where rapid-sequence induction is appropriate
ERAS	Verify preincision antibiotics. Assess volume status (see p. K-6). Maintain normovolemia and normothermia.
Maintenance	Standard maintenance
Emergence	Management of emergence and extubation should be

	routine, except in difficult airway cases, which require awake extubation. Skin closure is frequently followed by application of a splint; patient should remain anesthetized during splinting procedure. Discuss with surgeon local wound infiltration. PONV prophylaxis may include dexamethasone (e.g., 30 mcg/kg) and ondansetron (0.1 mg/kg up to 4 mg iv).

Regional anesthesia

Ultrasound guidance

Ultrasound-guided nerve block techniques are increasingly used in pediatric anesthesia. The use of ultrasonography increases the ability to position the needle as close to the nerve as possible avoiding inadvertent trauma to the adjacent structures. Direct visualization also helps in optimizing the volume and distribution of the local anesthetic, thus improving the safety and efficacy of the block.

Anesthetics and doses	See Table 12.7-1.
Interscalene block	Performed at level of C6 to minimize risk of pneumothorax. The phrenic nerve lies anterior to the brachial plexus and is frequently blocked by anterior spread of LA, leading to hemidiaphragm paralysis. This is usually well tolerated; however, care must be taken in patients with respiratory compromise. Temporary Horner syndrome may result from LA migration to sympathetic chain. Major complications (e.g., total spinal or pneumothorax) resulting from interscalene block are very rare; therefore, this technique is suitable for outpatients. Interscalene block is contraindicated in patients with contralateral recurrent laryngeal nerve palsy.
Supraclavicular block	Ultrasound guidance has enhanced the safety of supraclavicular approach to supraclavicular block. The trunks and divisions of the brachial plexus run very close to the subclavian artery as it travels over the first rib. This block ensures complete anesthesia of the upper extremity with the exception of the upper medial aspect

	of the axilla, which is supplied by the intercostobrachial nerves. Complications such as hemothorax and pneumothorax can be reduced by careful in-plane approach under ultrasound.
Infraclavicular block	The infraclavicular approach to brachial plexus block has the advantage of blocking the axillary and musculocutaneous nerves. The coracoid approach is shown to be safer than the classical approach. Use of ultrasonography increases the efficacy and safety of this block.
Axillary block	The medial aspect of the upper arm is innervated by the intercostobrachial nerve (T2) and requires a separate subcutaneous field block in the axilla, especially when a tourniquet is used. The musculocutaneous nerve, which takes off from the brachial plexus high up in the axilla, can also be missed by the traditional axillary block. This nerve can easily be identified in the upper part of the arm in the belly of coracobrachialis muscle, under ultrasound guidance. This block is needed to prevent tourniquet pain and to provide analgesia in the distribution of lateral cutaneous nerve of forearm, a branch of musculocutaneous nerve.
Supplemental sedation	Supplemental sedation may be accomplished with use of propofol by continuous infusion (50–150 mcg/kg/min).
Blood and fluid requirements	Minimal blood loss IV: 22 ga × 1 BSS @ 4-2-1 rule maintenance IV catheter should be placed in the nonoperated extremity.
Monitoring	Standard monitors.
Positioning	✓ and pad pressure points ✓ eyes
Interscalene block complications	Total spinal Epidural anesthesia IV injection (Sz/dysrhythmias) Resuscitative equipment, including airway management tools, and intralipid should be immediately available. Dose

	Stellate ganglion block (Horner syndrome) Laryngeal nerve block Phrenic nerve block Pneumothorax	of 20% intralipid: 1.5 mL/kg repeat × 2 max 3 mL/kg; infusion rate 0.25 mL/kg/min.
Supraclavicular block complications	Hematoma, hemothorax, pneumothorax, phrenic nerve block	In-plane ultrasound guidance has improved the safety of this block.
Infraclavicular block complications	Hematoma Pneumothorax Inadvertent intravascular injection	The coracoid approach has reduced risk of complications.
Axillary block complications	Inadequate block Intravascular injection Peripheral nerve damage Axillary hematoma Axillary artery thrombosis Pneumothorax	Very small doses of local anesthetic can cause CNS toxicity if reverse flow occurs during an intra-arterial injection. Axillary thrombosis and pneumothorax are extremely rare.

Table 12.7-1 Maximum Recommended Doses of Anesthetics for Regional Anesthesia

Drug	mg/kg (*with Epinephrine)	Duration (min)
Lidocaine	5 (*7)	45–180
Bupivacaine	2.5 (*3)	180–600
Ropivacaine	3	180–600
Tetracaine	1.5	180–600
2-Chloroprocaine	8 (*10)	30–60
Procaine	8 (*10)	60–90

POSTOPERATIVE

Multimodal pain management	PCA. Regional block	Combined regional-GA provides excellent postop

		pain management. Emphasize nonopioid analgesics. Back up with bolus opioid analgesics.
ERAS	PONV protocol (see p. D-1)	Encourage early enteral nutrition and mobilization.
Tests	None routinely indicated

POSTERIOR SPINAL INSTRUMENTATION AND FUSION

SURGICAL CONSIDERATIONS

Description

Posterior spinal instrumentation refers to implanted metal rods affixed to the spine to correct and internally splint the deformed spine. Originally designed for scoliosis, posterior spinal instrumentation is commonly performed simultaneously with **spinal fusion** for a variety of diagnoses, including fracture, tumor, degenerative changes, and developmental spinal deformity. Hook-rod systems became popular in the mid-1980s and are still used by spine surgeons. Today, the most common form of spine fixation involves pedicle screws (introduced in the 1990s) that allow greater control of the vertebra for improved stability and, if needed, improved correction of deformity.

Regardless of the surgeon's choice of instrumentation, the spine is most commonly

approached by an extensive midline posterior incision (although anterior and lateral approaches are described), in which a subperiosteal exposure (typically T2-T5 down to L1-L4) is used to elevate all the paraspinous muscles as far laterally as the tips of the transverse processes. Instrumentation (pedicle screws and/or hooks) is placed on both the concave and convex sides of the spine (Fig. 12.7-3). These points of fixation are joined to two contoured rods running parallel to the spine on either side. With linked fixation in place, the correction can begin (in the case of scoliosis or spinal deformity) by compressing along the convex surfaces and distracting along the concave surfaces. Postoperatively, some spine surgeons advise the use of a TLSO brace for the initial months following surgery.

Sublaminar wire loops (Fig. 12.7-4) are commonly used instead of the hook-rod method of spinal instrumentation when treating neuromuscular spinal deformity (e.g., cerebral palsy, muscular dystrophy, myelomeningocele, or spinal muscular atrophy). This alternative construct provides more points of fixation to the spine and eliminates the need for postop bracing. When a large degree of pelvic obliquity is a component of the patient's deformity, the instrumentation often is extended into the iliac wings (Fig. 12.7-5).

One of the most prominent fears in the minds of patients and their parents undergoing elective spine surgery are neurologic deficits. Intraoperative neuromonitoring is designed for early detection of impending spinal cord damage. **Somatosensory evoked potentials** (SSEPs) and **motor evoked potentials** (MEPs) are used routinely in high-volume spinal deformity correction centers. MEPs may offer more utility as they monitor the motor tracts in the anterior spinal cord, which is at higher risk of ischemia during spine surgery (especially during deformity correction). Close coordination among the surgeon, spinal cord monitoring personnel, and anesthesiologist is necessary to properly recognize adverse intraop spinal events and to minimize the occurrence of false-positive findings. Many spine surgeons also request that an intraop wake-up test be performed to further verify spinal cord function.

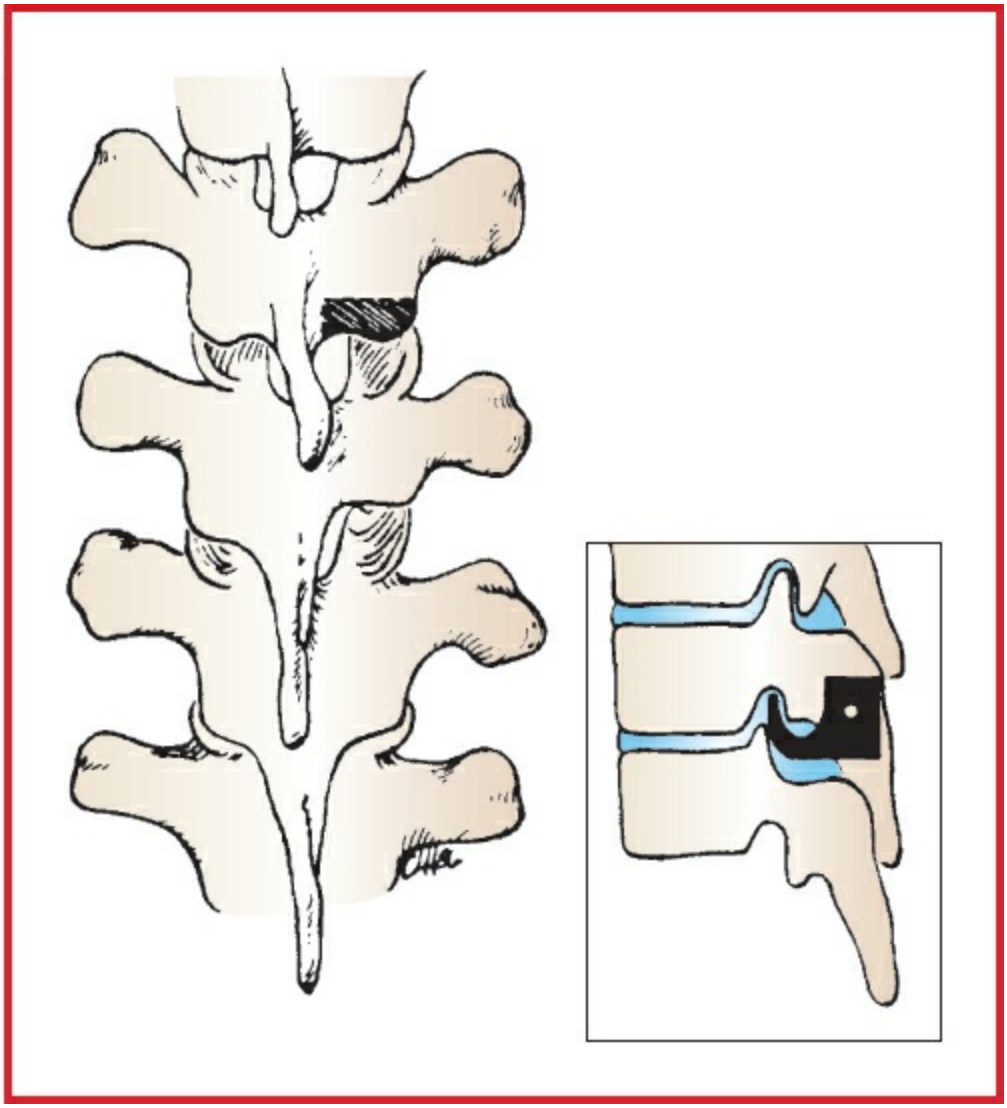

Figure 12.7-3 Placement of a standard pedicle hook, in a hood-rod device. (Reproduced with permission from Chapman MW:Operative Orthopaedics, 3rd edition. Lippincott Williams & Wilkins, Philadelphia: 2001.)

Usual preop diagnosis

Scoliosis (usually idiopathic or neuromuscular); kyphosis (increased round back); reconstruction for tumor, trauma, or other

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

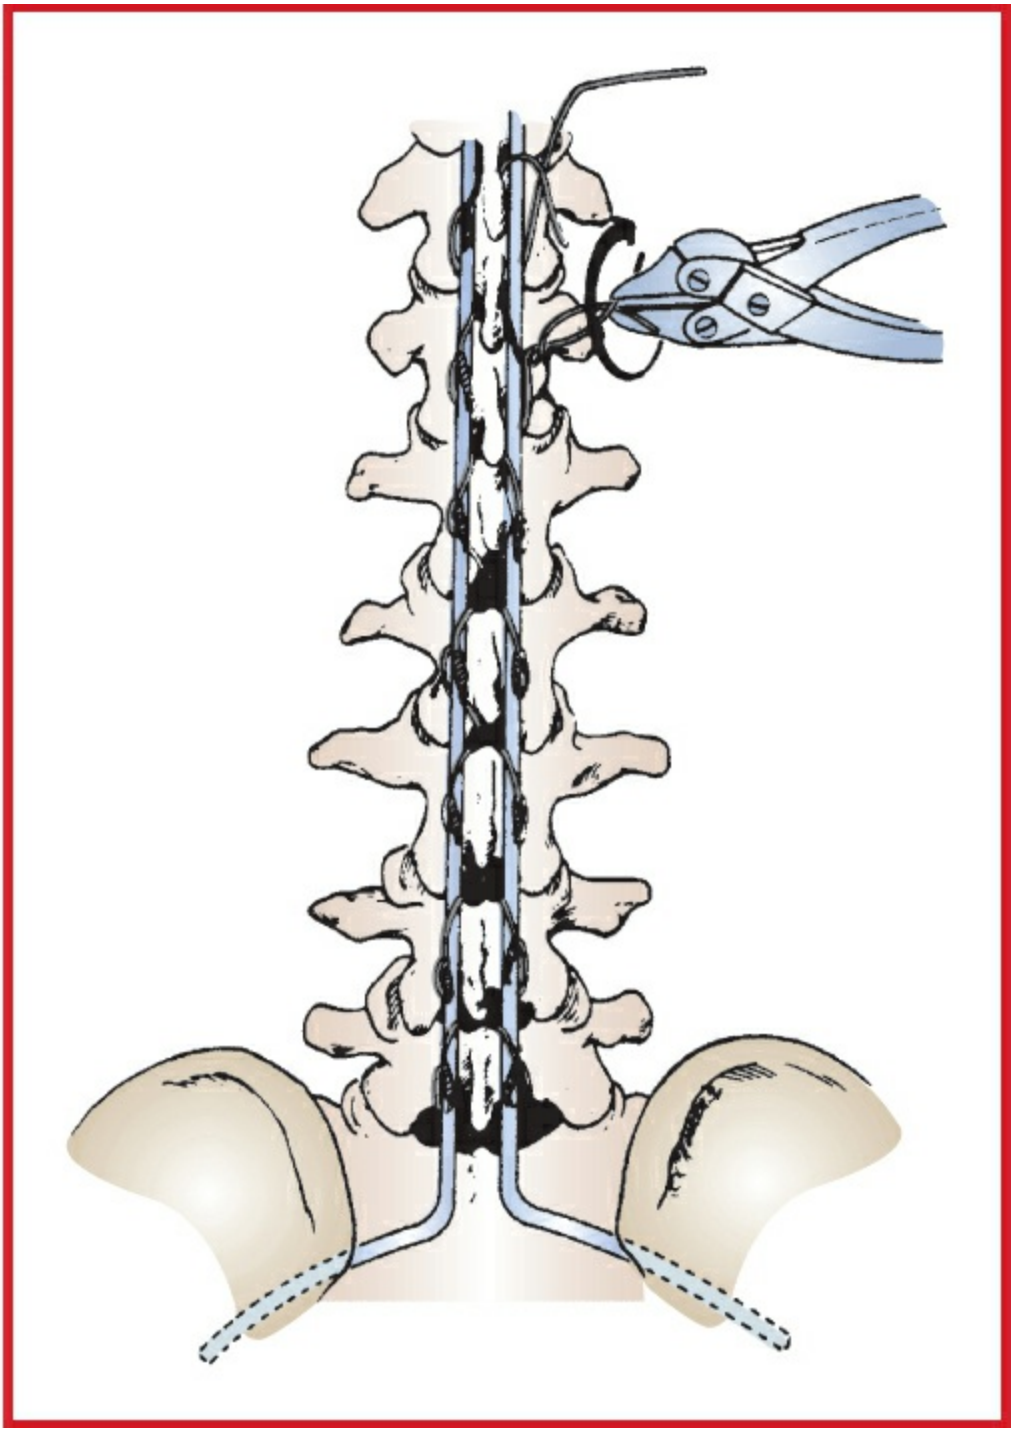

Figure 12.7-5 Positioning rods in the pelvis; sublaminar wires being tightened. (Reproduced with permission from Chapman MW:Operative Orthopaedics, 3rd edition. Lippincott Williams & Wilkins, Philadelphia: 2001.)

SUMMARY OF PROCEDURE

Position	Prone (on spinal frame or bolsters); avoid abdominal, elbow, and ocular compression.
Incision	Posterior midline; optional separate iliac crest bone graft

Special instrumentation	Rods, hooks, pedicle screws, wires
Unique considerations	"Wake-up" test and/or SSEPs; induced ↓ BP is often requested; prolonged prone positioning places brachial plexus and ulnar nerve at risk.
Antibiotics	Cefazolin 25 mg/kg iv
Surgical time	2–6 h
Closing considerations	Greatest blood loss typically toward the end of procedure. Avoid hypotension after instrumentation is implanted.
EBL	1200–3000 mL
Postop care	ICU: 1–2 d
Mortality	0–0.5%
Morbidity	Acute ileus: very common Genitourinary infection: 5–7% Hematoma, massive bleeding: 1–5% Pneumothorax, pneumonia, atelectasis: 1–5% Hook dislodgement requiring reoperation: 0–2% Wound infection: 0–2% Superior mesenteric artery syndrome: 0–1% Thromboembolism: <1% Spinal cord injury and/or root injury: 0.6% Delayed: Pseudarthrosis: 0–5% Late rod fracture: 0–5% Progression of spinal deformity: 0–2%
Pain score	7–9

PATIENT POPULATION CHARACTERISTICS

Age range	Usually 8–40 yr
Male:Female	1:5
Incidence	1–2/10,000

Etiology	Idiopathic (50–75%); neuromuscular (20–30%); associated with syndromes such as osteochondral dystrophies, osteogenesis imperfecta, etc. (5%); congenital scoliosis (2–5%)
Associated conditions	Neuromuscular: Friedreich ataxia (myocarditis and other cardiovascular anomalies; sudden death) Myelomeningocele (latex allergy, chronic UTI, hydrocephalus) Muscular dystrophy (muscle weakness, cardiomyopathy, dysrhythmias, succinylcholine → prolonged muscle contraction, ↑ sensitivity to respiratory depressant effect of barbiturates, opiates, and benzodiazepines) Cerebral palsy (GERD, ↓ airway protective reflexes, ↑ postop pulmonary complications, malnourishment, Sz, medication may interfere with Plt function) Higher incidence of MH Connective tissue disease: Ehlers-Danlos and Marfan syndromes (avoid ↑ BP → aortic dissection; ↑ risk of pneumothorax). Osteogenesis imperfecta (position and intubate with great care) Congenital osteochondral dystrophies

ANTERIOR SPINAL FUSION FOR SCOLIOSIS

SURGICAL CONSIDERATIONS

Description

Anterior spinal fusion is performed through a transthoracic and/or retroperitoneal approach to the vertebral bodies, in which the intervertebral discs are removed and a bone graft is placed between the vertebral bodies. The disc removal ("release") loosens the spine and allows greater deformity correction than posterior-only procedures. Often, no instrumentation is used anteriorly when the anterior fusion is performed as a first stage to a "front-and-back" fusion. (In such cases, posterior spinal instrumentation is subsequently implanted to correct the spinal deformity.) Anterior spinal instrumentation is performed when a posterior spinal fusion is not needed (e.g., idiopathic thoracolumbar or lumbar scoliosis).

When **instrumentation of the anterior spine** is performed, the surgical approach is through a flank incision and then through a rib bed on the convex side of the curve (usually the 10th rib). The retroperitoneal plane is entered and developed by blunt dissection behind the transversus abdominis muscle. The pleural cavity is entered, and the diaphragm usually must be divided circumferentially near its costal origin and around posteriorly to the spine. The prevertebral areolar plane is then entered, and the segmental vessels to each vertebral body are clipped or cauterized in the midline. The psoas muscle is elevated off the lateral aspects of the vertebral bodies. Each disc in the fusion area (usually 3–5 discs) is excised back to the posterior longitudinal ligament.

Next, vertebral screws are inserted transversely across the appropriate bodies and joined at their heads by a rod (Figs. 12.7-6 and 12.7-7). Bone graft (typically from the rib harvested during the surgical approach) is placed within each discectomy level. A chest tube is placed before closure of the thoracic cavity.

Usual preop diagnosis

Idiopathic or neuromuscular scoliosis

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Fusion with Instrumentation	Release (No Instrumentation)
Position	Full lateral decubitus (Fig. 12.7-8)	⇐
Incision	Flank: over the rib at top vertebra in the curve (usually T9-T11)	⇐
Special instrumentation	Screws, staples, rods	None
Unique considerations	Flex OR table at thoracolumbar junction until disc removal and deformity correction. Procedure often followed by posterior spinal fusion. Proximity of great vessels → potential for major bleeding. Patients with neuromuscular scoliosis often have poor generalized nutrition. SSEP/MEP is often used to monitor spinal cord function.	⇐ Uninstrumented release is always followed by posterior spinal fusion with instrumentation.
Antibiotics	Cefazolin 25 mg/kg iv	⇐
Surgical time	3–4 h	2–3 h
Closing considerations	Chest tube always used; hypotension, if used electively, must be reversed before closure.	⇐
EBL	500–2000 mL	250–2000 mL
Postop care	ICU 1–2 d	⇐
Mortality	0–2%, depending on underlying	⇐

	conditions	
Morbidity	Overall: 30%, depending on underlying condition	20%
	Ileus and atelectasis: ~50%	⇐
	UTI: 10–25% (common in spina bifida)	⇐
	Minor transient root weakness or paresthesia: 10–20%	1–5%
	Partial sympathectomy: common	⇐
	Late kyphosis above instrumentation: 5–10%	—
	Nonunion and hardware failure: 5%	—
	Massive blood loss: 2–5%	⇐
	Respiratory failure: 1–2%	⇐
	Pneumonia: 1%	⇐
	Paraplegia (acute anterior spinal artery syndrome): <1%	⇐
	Thromboembolism: rare (<5% in children)	⇐
Pain score	5–8	4–7

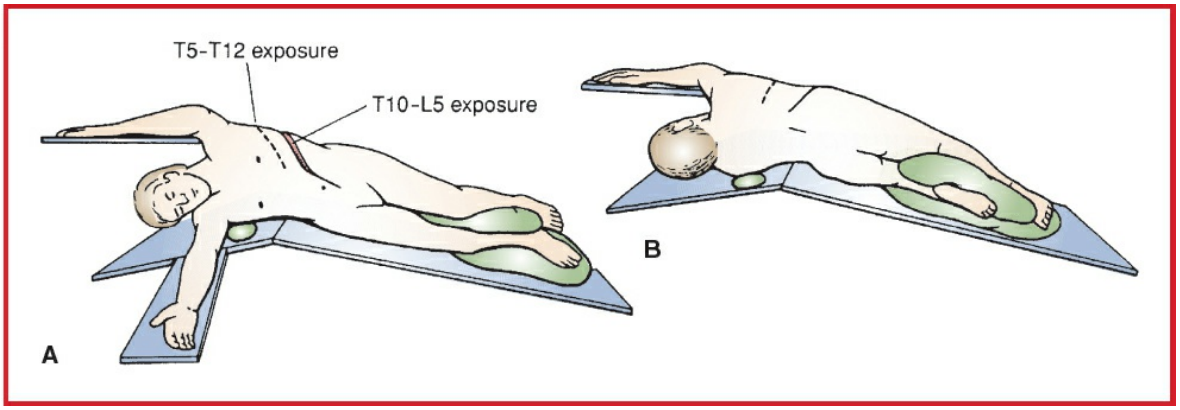

Figure 12.7-8 Lateral decubitus position (diagrammatic) for anterior spinal procedures: **(A)** anterior view; **(B)** posterior view. Roll is placed under axilla to minimize axillary artery compression. Skin incision for exposure of T5-T12 is shown with the dotted line. PELVIC OSTEOTOMY

SURGICAL CONSIDERATIONS

Description

Pelvic osteotomy is used to improve coverage of the femoral head in cases of developmental hip dysplasia. Besides immediately increasing coverage, the osteotomy can stimulate the growth of a shallow acetabulum. It is frequently performed in

conjunction with open reduction and occasionally with femoral osteotomy. The surgical approach is made along the iliac crest, exposing the external (gluteal) surface of the iliac bone and sometimes the internal (iliac) surface as well. The pelvic osteotomy is performed just above the acetabulum and sometimes through the pubis and ischium, depending on the direction of rotation and reorientation desired. Pelvic osteotomies either reorient an intact acetabular hyaline cartilage surface or are designed as salvage procedures to enlarge the acetabulum by fibrocartilage metaplasia (see next section, Acetabular Augmentation and Chiari). **Salter innominate osteotomy** is the classic reorientation osteotomy, in which a complete cut of the supra-acetabular iliac bone allows rotation through the symphysis pubis. **Pemberton operation** is a slightly more difficult incomplete iliac osteotomy, rotating on the triradius cartilage (Fig. 12.7-9), which is at the center of the acetabulum in young children. The **Steel, "Dial,"** or **Eppright osteotomies** are the most difficult reorientation procedures. In each, the acetabulum is freed totally from any bony contact with the remainder of the pelvis and rotated into better position.

ACETABULAR AUGMENTATION (SHELF) AND CHIARI OSTEOTOMY

SURGICAL CONSIDERATIONS

Description

Acetabular augmentation is a “salvage” procedure used to deepen the hip socket when a realignment osteotomy of the pelvis and/or femur would not adequately cover the femoral head. This is accomplished by securing strips of cortical cancellous bone graft onto the proximal surface of the hip capsule. The surgical approach is anterior to the hip, elevating the gluteal muscles subperiosteally from the outer surface of the ilium. The reflected head of the rectus femoris tendon is elevated, and a domed-shaped slot is created just above the capsular attachment to the ilium. Abundant cortical cancellous strips of bone graft are then harvested from the upper two-thirds of the outer wall of the ilium. These bone grafts have a natural curve and lie on the convexity of the hip capsule. No internal fixation, other than suture repair, is used to hold the bone graft in place. This creates a large bony augmentation (shelf) over the uncovered femoral capsule.

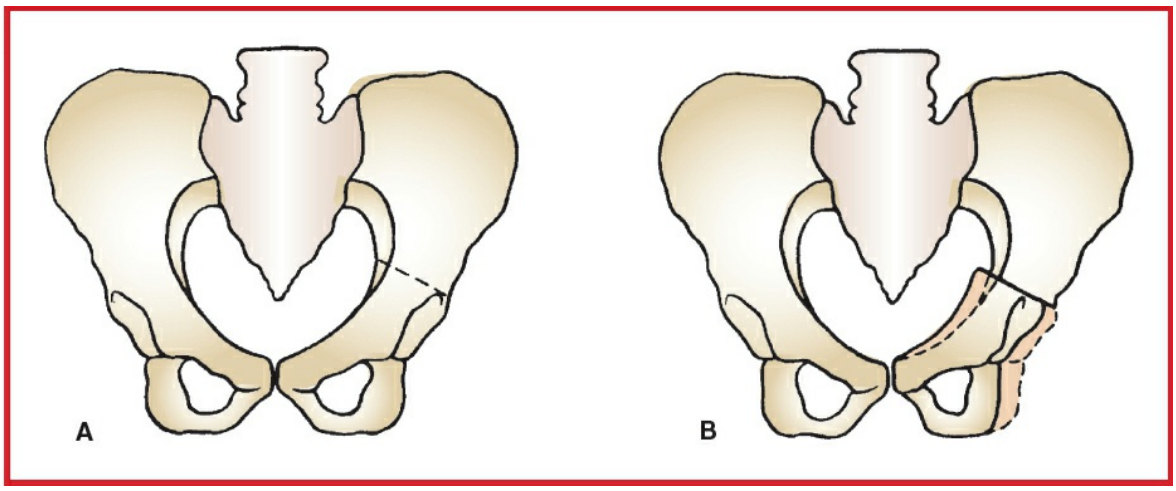

Figure 12.7-10 Chiari osteotomy. **A:** Line of osteotomy. **B:** Completed osteotomy. (Reprinted from Crenshaw AH, ed: Campbell's Operative Orthopaedics, 8th edition. Mosby-Year Book, St. Louis: 1992. Copyright © 1992 Elsevier. With permission.)

Variant procedure or approaches

The bone graft may be taken as a large, sculpted, solitary, cortical cancellous strut or wedge, or more commonly, as curved "shavings" anchored in a dome-shaped slot just above the hip capsule. In the **Chiari procedure**, a complete dome-shaped osteotomy allows lateral displacement of the ilium just above the proximal hip capsule (Fig. 12.7-10). The line of the osteotomy corresponds more or less with the slot of the shelf procedure. In either case, the result is abundant bony coverage over the hip capsule, which undergoes metaplasia into fibrocartilage.

Usual preop diagnosis

Acetabular dysplasia (shallow socket) due to congenital hip dislocation or developmental neurologic subluxation

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Acetabular Augmentation	Chiari Osteotomy
Position	Supine or slightly tilted up (reverse Trendelenburg's)	⇐ or lateral decubitus
Incision	Oblique or longitudinal; anterior hip region	⇐

Special instrumentation	Usually no internal fixation; I.I. or intraop x-ray	Two large screws or pins; I.I. or intraop x-ray
Antibiotics	Cefazolin 25 mg/kg iv	⇐
Surgical time	1.5–3 h	⇐
Closing considerations	Unilateral or 1.5 spica cast mandatory	Spica cast (optional)
EBL	100–500 mL	200–800 mL
Postop care	PACU → room. Care as necessary for cast	⇐
Mortality	Minimal	⇐
Morbidity	Lateral-femoral cutaneous nerve dysfunction: 30–50% Infection: 1%	Sciatic or peroneal palsy: 2% Possible need for later C-section: Rare
Pain score	4–6	4–6

PATIENT POPULATION CHARACTERISTICS

Age range	6–35 yr
Male:Female	1:1.5
Incidence	<1/10,000 in general population; in neuromuscular population (e.g., cerebral palsy, poliomyelitis residuals): 5–10%
Etiology	Neuromuscular hip subluxation with shallow acetabulum; residual shallow acetabulum (poor coverage from congenitally dislocated hip)
Associated conditions	Cerebral palsy; polio; spina bifida; myopathy; congenital atrophies; Charcot-Marie-Tooth disease

OBER FASCIOTOMY AND YOUNT-OBER RELEASE

SURGICAL CONSIDERATIONS

Description

Ober fasciotomy is performed to release flexion, abduction, and external rotation contracture at the hip. This contracture usually occurs as a result of profound flaccid paralysis and prolonged positioning in a so-called frog position of 90° flexion, abduction, and lateral rotation at the hips. This results in tightening of the iliotibial (IT) band (the greatly thickened lateral aspect of the fascia lata) and related structures. The operation is performed through an anterolateral incision just distal to the iliac crest. All of the fascial investments of the tensor, sartorius, and, at times, the rectus femoris and gluteus medius and minimus are divided while preserving any normal-appearing muscle fibers. The limb is stretched into progressively more adduction and extension, until a neutral position can be obtained. The **Yount procedure** is added when the knee also is contracted in a flexed mode due to tightness of the IT band. The Yount procedure consists of further resection of a segment of the IT band and a lateral intermuscular septum through a separate distal midlateral longitudinal incision just above the knee. An oblique segment of the IT band and septum are removed and not repaired.

Usual preop diagnosis

Flaccid paralysis and "frog"-type contracture due to poliomyelitis, myelomeningocele, or myopathy

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Ober Fasciotomy	Yount-Ober Release
Position	Supine; both legs must be prepped and draped to well above the iliac crest area for intraop stretching.	⇐
Incision	Oblique iliac crest	Midlateral longitudinal above knee joint, ~10 cm
Unique considerations	Patients with sensory and motor loss have a tendency to get pressure sores.	⇐
Antibiotics	Usually none	⇐
Surgical time	1 h/side	30 min/side
Closing considerations	Bilateral above-knee casts	⇐
EBL	<150 mL	<50 mL
Postop care	PACU → room; extensive physical therapy program of stretching exercises. Myopathic patients are at risk for postop respiratory compromise.	⇐
Mortality	Minimal	⇐
Morbidity	Hematoma: ~1%	⇐
	Fracture of atrophied bone postop: <1%	⇐
	Infection <1%	⇐
	Pressure sores from positioning or casts: <1%	⇐
Pain score	3–4	3–4

PATIENT POPULATION CHARACTERISTICS

Age range	2–15 yr
Male:Female	1:1
Incidence	Extremely rare in children born in the United States; however, polio is seen commonly in southeast Asian and Latin American immigrants.
Etiology	Polio; myelomeningocele; myopathy or dystrophy
Associated conditions	Other contractures; incontinence; pressure sores in myelomeningocele

HIP, OPEN REDUCTION, AND FEMORAL SHORTENING

SURGICAL CONSIDERATIONS

Description

Open reduction of the hip replaces a dislocated femoral head into the anatomic acetabulum, at times after an unsuccessful attempt to reduce the hip by closed means. A developmental dislocation presents with a more normal acetabulum and occurs around birth or later. A teratologic congenital dislocation of the hip occurs early in utero and, as a result, has a high-riding dislocation with a poorly developed acetabulum, presenting much more difficulty in obtaining and maintaining reduction. The most common surgical approach is through an extended anterior incision. The hip capsule is exposed circumferentially, after division and tagging of the origins of the rectus, femoris, and sartorius muscles and retraction of the tensor and gluteal muscles. The iliopsoas tendon is either lengthened or divided. The capsule is opened in an oblique

fashion, the ligamentum teres is excised, and any obstacle to reduction is removed. The femoral head is replaced in the socket, and the capsule is repaired in a "vest-over-pants" imbrication, with the hip reduced under direct visualization (Fig. 12.7-11). A medial approach through the adductor region can be used in very young children (<18 mo) but does not allow a capsular repair. If femoral shortening is necessary, the surgical excision is either extended anterolaterally or a separate lateral incision is made longitudinally over the proximal femur.

Variant procedure or approaches

Most children <2 yr old can simply have the hip repositioned (back into the socket)—closed or open—and subsequently have normal hip development. In older children, especially with a high dislocation, a segment of the femur is removed subtrochanterically to allow reduction without pressure (thus allowing "descent" of the femoral head). If the acetabulum is very shallow, a pelvic osteotomy may be added (see Pelvic Osteotomy).

Usual preop diagnosis

Developmental dislocation of the hip; teratologic congenital dislocation of the hip

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

ADDUCTOR RELEASE OR TRANSFER AND PSOAS RELEASE

SURGICAL CONSIDERATIONS

Description

Neuromuscular diseases (most often cerebral palsy) can cause spasticity throughout the body. At the hip, long-term spasticity can lead to adduction (adductors) and flexion (iliopsoas) contractures. The goal of surgical intervention varies based on the functional demands of the child (i.e., whether they are ambulatory or whether they need help with hygiene), but the general goal is to slightly weaken the hip adductors/flexors to allow greater motion. The same releases performed in cerebral palsy are often utilized in the treatment of other causes of hip contracture due to developmental hip dislocation, juvenile arthritis, etc.

The patient is positioned supine and the hip is abducted and externally rotated. Using a medial groin incision, the adductor tendons (adductor longus, adductor brevis, and gracilis) are isolated and divided with electrocautery. Using the same incision and in nonambulatory patients, the iliopsoas (hip flexor) tendon is located and divided at its

insertion onto the lesser trochanter. If less flexor lengthening is desired (i.e., ambulatory patients), the iliopsoas can be fractionally lengthened close to the pelvic brim. Variations of these procedures exist. In the classic **Banks** and **Green** procedure, the anterior branch of the obturator nerve is divided on the surface of the adductor brevis leading to more permanent adductor weakness. This procedure has lost popularity as the denervated muscles can undergo denervation fibrosis resulting in recurrent contracture. Some surgeons transfer the now released adductor longus and gracilis muscles to the ischium (posterior/lateral to the former origin) to convert the hip adductors into hip extensors by altering their direction of pull. At the end of the procedure, a long leg and/or spica cast is applied under anesthesia.

Usual preop diagnosis

Adduction and flexion contracture of the hip with subluxation due to cerebral palsy, acquired encephalopathy, or progressive neurologic disorder

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Adductor Release	Adductor Transfer	Psoas Release
Position	Supine	Supine or lithotomy	⇐
Incision	Medial proximal groin, longitudinal or transverse	Transverse medial groin	Anterior groin
Unique considerations	Frequently bilateral; often poor hygiene, especially if severe contracture; proximity to the perineum	⇐	⇐
Antibiotics	± cefazolin 25 mg/kg iv	⇐	⇐
Surgical time	1 h	1.5 h	1 h
Closing considerations	Bilateral leg casts or double spica cast	⇐	⇐

EBL	<100 mL	⇐	⇐
Postop care	PACU → room; care as necessary for spica cast	⇐	⇐
Mortality	Minimal	⇐	⇐
Morbidity	Hematoma, drainage	—	—
	Infection: <1%	⇐	⇐
	Recurrence of adduction deformity		
Pain score	2–4	2–4	2–4

PATIENT POPULATION CHARACTERISTICS	
Age range	2–20 yr
Male:Female	1:1
Incidence	0 in general population; 30% of cerebral palsy patients (0.6–5.9/1000)
Etiology	Cerebral palsy (90%); slowly progressive degenerative neurologic conditions (8–10%); head injury and drowning (1–2%)
Associated conditions	Multiple other contractures; GERD; poor general nutrition; developmental delay

PINNING OF SLIPPED CAPITAL FEMORAL EPIPHYSIS

SURGICAL CONSIDERATIONS

Description

During rapid growth period, the shearing stress of the body weight on the hip joint may cause the femoral head (capital epiphysis) to gradually (over weeks to months) slide posteriorly and inferiorly relative to the femoral neck by shearing through the "physis" or growth plate—termed **slipped capital femoral epiphysis (SCFE)**. Although most SCFE present with chronic symptoms (85%), patients can also present after mild trauma (fracture through the growth plate). This can occur unilaterally or bilaterally. The most common treatments are percutaneous **in situ pinning** (without reduction) or **modified Dunn procedure** (with open reduction), which are used to prevent further slipping of the epiphysis on the growth plate. Using intraop fluoroscopy for guidance, usually one (occasionally two) cannulated screw is placed percutaneously through the anterolateral aspect of the femoral neck into the femoral head epiphysis. Historically, pins (rather than screws) were used for fixation, but there was a high rate of pin complications (i.e., migration to be intra-articular with chondral damage).

Variant procedure or approaches

After the physis is closed, if there is severe residual deformity, a corrective osteotomy is performed in the trochanteric region (see Proximal Femoral Osteotomy, Southwick Procedure). If the surgeon believes that it is not possible to place a screw from the neck to the head (i.e., slip is too severe), **open epiphysiodesis with bone grafting** is an option. This is performed through an anterolateral groin incision, where the hip capsule is opened widely, and the growth plate is curetted before placing bone graft (usually harvested from the iliac crest) across it (linking the femoral head/neck). A body spica cast is frequently needed.

Usual preop diagnosis

Acute or chronic SCFE

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Pinning of SCFE	Variant Open Epiphysiodesis
Position	Supine	⇐
Incision	Short, proximal thigh or stab incision	Anterolateral groin
Special instrumentation	Guide wires; cannulated screws; I.I.; fracture table	I.I. (recommended)
Unique considerations	Frequently bilateral (≤20%); often obese	⇐
Antibiotics	Cefazolin 25 mg/kg up to 1–2 g iv	⇐
Surgical time	0.5–2 h	1–3 h
Closing considerations	None	Frequently needs spica cast
EBL	Negligible	200–500 mL
Postop care	PACU → room	Body spica cast, occasionally
Mortality	Minimal	⇐
Morbidity	Unsuspected pin penetration: ≤37%	⇐
	Avascular necrosis: ≤33% (in acute slip cases)	⇐
	Chondrolysis, hip stiffness: 1–28%	⇐
	Fracture after pin removal: <1%	⇐
	Infection: <1%	
Pain score	2–3	2–3

PATIENT POPULATION CHARACTERISTICS

Age range	10–16 yr
Male:Female	2–3:1
Incidence	1–3/100,000 (higher in African Americans)

Etiology	Excessive loading of the growth plate (obesity or increased angle of inclination of the physis) Insufficient tensile strength of collagen and proteoglycans around the femoral neck Increased thickness of the physis as from excessive growth hormone, hypogonadism, hypothyroidism, hyperparathyroidism, renal osteodystrophy, almost any other significant endocrinopathy Radiation therapy
Associated conditions	Obesity; endocrinopathies; renal osteodystrophy

FLEXIBLE INTRAMEDULLARY NAILING OF LONG-BONE FRACTURES

SURGICAL CONSIDERATIONS

Description

Stabilization of long-bone fractures with flexible nails is used in both the upper and lower extremities. These implants can be placed through small incisions and allow the surgeon to take advantage of its elastic memory to exert balanced dynamic force to hold

the reduction. As a result, immobilization (splinting or casting) and prolonged immobility are often unnecessary. For femur fractures, in comparison to standard rigid nails used in older children and adults for the femur, the entry site for flexible nails is distal to the femoral neck and does not risk the blood supply to the femoral head.

This technique can be utilized for femur, tibia, radius, ulna, and humerus fractures. The child is placed supine on either a radiolucent operating table (or fracture table for the lower extremity) to allow intraoperative fluoroscopy. Closed reduction is attempted, but with the surgeon proceeding with an open reduction if it fails. After the fracture is aligned, a small incision is made and dissection is carried down to the periosteum where a small hole is made in the cortex. This hole allows the flexible nail to enter the medullary canal and be passed either retrograde or anterograde across the fracture site while being contoured by the surgeon. No intramedullary reaming is performed before nail insertion. Intraop imaging is used to assess for rotational and angular stability and for possible rare need for cast application.

Usual preop diagnosis

Fracture

ERAS: Family preop counseling by the surgeon/anesthesiologist should include: limiting NPO duration, review of nutritional status, postop care, and pain management options (Fig. 12.7-12). See Appendix K: Pediatric ERAS, p. K-6 to K-8.

PROXIMAL FEMORAL OSTEOTOMY

SURGICAL CONSIDERATIONS

Description

Femoral osteotomies are performed in the inter- or subtrochanteric region to redirect the femoral head more superiorly (valgus) or inferiorly (varus) and/or for rotational correction of excessive rotational deformities (anteversion or retroversion). The usual surgical approach is direct lateral over the proximal femoral shaft (just distal of the greater trochanter). The deep fascia is split, and the underlying vastus muscle is elevated subperiosteally to expose the femoral shaft. The osteotomy site is confirmed with fluoroscopy before being cut using a power saw. This creates two free fragments that are realigned prior to applying fixation, which is commonly achieved with plate/screws.

Variant procedure or approaches

Different named plates (e.g., AO blade, Coventry screw, Richards screw, Wagner) may be used to affix the proximal to the distal femoral segments. In the case of a chronic

superior hip dislocation (i.e., developmental dysplasia of the hip), a 1- to 4-cm segment of femur may be removed to allow soft tissue relaxation and descent of the femoral head into the socket. Most proximal femoral osteotomies are performed in the subtrochanteric area, but some are performed in the intertrochanteric or base of the neck (**Kramer compensating**). The **Southwick osteotomy** is an example of a more complicated subtrochanteric osteotomy, which allows correction in three directions (varus, lateral rotation, and extension).

Usual preop diagnosis

Developmental hip subluxation; excessive hip anteversion; residual deformity from Perthes disease; coxa vara; SCFE; residual deformity

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

EPIPHYSIODESIS

SURGICAL CONSIDERATIONS

Description

Epiphysiodesis is performed in skeletally immature adolescents with a significant leg-length discrepancy (anisomelia) to modify the growth in either the ipsilateral or contralateral lower extremity. The timing of the procedure is critical and is based on the child's bone age (growth remaining) and the amount of length discrepancy (between the two lower extremities).

At the precise age determined by these methods, the epiphysiodesis procedure can be completed (most commonly at the distal femoral and proximal tibial physes) using multiple available options for modulating growth at the physis, including bone blocks, drilling, staples, and small two-hole plates ("eight plates"). The original techniques described by **Phemister** (Fig. 12.7-13), **White**, and **Stubbins** involved removing a ¾″–1¼″ square or rectangular block of bone from the center of the physis using a box chisel, which was rotated 90° or 180° and reinserted to create a bone bridge across the physis. Another option for permanent closure is **physeal drilling**, which can be accomplished percutaneously using fluoroscopic guidance. **Blount** described the use of stout, reinforced staples bridging over the physis (using a tension band–type mechanism) inserted medially and laterally at the knee through small incisions (1″). This procedure causes compression of the physis to prevent growth. Another similar technique that has become popular recently is the use of small two-hole plates ("eight plates"). Both of these techniques provide the theoretical advantage of being reversible (i.e., resumption of growth after hardware removal) if overcorrection is found with follow-up.

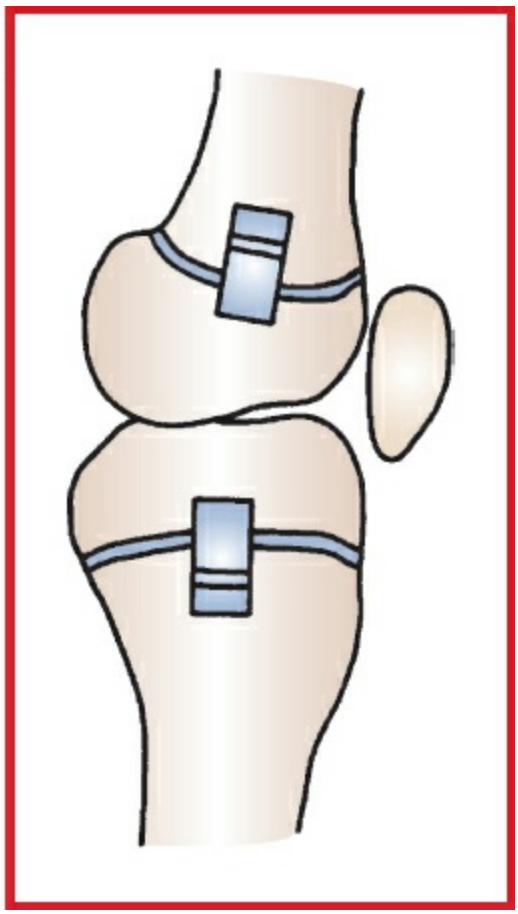

Figure 12.7-13 Phemister method of epiphysiodesis (block of bone reversed and then reinserted to form osseous bar). (Reproduced with permission from Chapman MW:Chapman's Orthopaedic Surgery, 3rd edition. Lippincott Williams & Wilkins, Philadelphia: 2001.)

Usual preop diagnosis

Limb-length discrepancies of 2–5 cm in adolescents (willing to accept a slight diminution in adult stature)

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SOFIELD PROCEDURE

SURGICAL CONSIDERATIONS

Description

Long-bone deformities are common in certain conditions, such as osteogenesis imperfecta. These can be corrected using a **Sofield procedure** (fragmentation rodding) in an attempt to reduce recurrent fractures, to allow bracing, and/or to aid ambulation. These types of procedures are needed less frequently in the upper extremities.

The procedure involves exposure of at least one end of the long bone (to insert fixation) and exposure of a varying amount of the long bone shaft (to allow multiple osteotomies to be created). If the deformity is severe, the entire shaft is exposed via a longitudinal incision, usually laterally. By creating multiple osteotomies (usually 2–4), a curved/deformed bone can be manipulated piecemeal (similar to a "shish kebab") to allow a straight intramedullary rod to traverse all of the segments.

Variant procedure or approaches

As these surgeries are done on children with growing bone, the bone can continue to elongate beyond the end of the intramedullary rod in some cases. The unsupported portion of the bone will be liable to fracture and to developing a new deformity—often requiring revision surgery. To address this, **Bailey** and **Dubow** developed an elongating (or growing) rod system that telescopes (similar to a car radio antenna) within the bone to allow for some growth. The surgical technique for insertion of the rod is, however, identical to any fragmentation rodding, except that both ends of the bone must be exposed. Similar elongation can be accomplished with a **Fassier-Duval** rod without requiring exposure of both bone ends.

Usual preop diagnosis

Osteogenesis imperfecta; fibrous dysplasia (occasionally); rickets; congenital pseudarthrosis of the tibia

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE

Position	Supine

Incision	Lateral for femur; anterolateral for tibia
Special instrumentation	± fluoroscopy (I.I.) table
Unique considerations	Tendency to hyperthermia; other bones may fracture in more severe cases, even as a result of a BP cuff. If dentinogenesis imperfecta is present, extreme care should be taken during intubation to prevent tooth trauma. In these patients, neck motion is often limited.
Antibiotics	Cefazolin 25 mg/kg iv
Surgical time	1–1.5 h/tibia; 1.5–2.5 h/femur (often done sequentially on the same day)
Closing considerations	Double spica cast if the femur is rodded.
EBL	Depending on patient age and size, as well as use of a tourniquet for the femur, 50–250 mL; for the tibia, 50–100 mL
Postop care	PACU → room; avoid trauma to the mouth or other bones in PACU.
Mortality	<1% (usually related to severe restrictive lung disease, in the most severely involved cases)
Morbidity	Intraop hyperthermia: common Intraop fracture of other bones Late rod migration: common Late refracture: common Nonunion: rare Exuberant callus simulating osteosarcoma: rare Infection: <1% of rodding Radial nerve palsy (in cases of the humerus or radius rodding)
Pain score	2–3 (It is surprising how little discomfort these children have, especially the 2nd or 3rd time a bone is rodded.)

PATIENT POPULATION CHARACTERISTICS

Age range	2–25 yr
Male:Female	1:1
Incidence	1/20,000 (osteogenesis imperfecta); other etiologies much less common
Etiology	Congenital (hereditary deficit in collagen synthesis), most commonly as autosomal dominant or spontaneous mutation: all cases
Associated conditions	Dentinogenesis imperfecta; diminished vital capacity due to associated kyphoscoliosis ↓ hearing due to otosclerosis and impingement of the 8th cranial nerve; pelvic distortion causing chronic constipation; basilar impression and other C-spine abnormalities causing brainstem compression or even hydrocephalus (rare)

LIMB LENGTHENING

SURGICAL CONSIDERATIONS

Description

Limb lengthening usually is performed in the lower extremity for congenital or acquired

leg-length discrepancies of at least 5 cm. Lesser discrepancies are dealt with by bone shortening or epiphysiodesis of the longer extremity. The basic principles include (a) application of an adjustable, external fixator; (b) "low-energy," transverse bone cut (osteotomy without the use of a power saw) through a small, longitudinal incision over the involved bone; (c) preservation of the periosteal sleeve; (d) gradual lengthening, usually 1 mm/d in fractional adjustments; and (e) when the desired limb length is obtained, either using bone graft and plate acutely or leaving until the bone gap fills in and stabilizes (average 38 d/cm gained).

Limb lengthening dates back to the early 1900s, but it fell into disfavor because of the high rate of major complications. **Wagner** improved the technique by introducing a simplified, unilateral, large-pin fixator, but performed the osteotomy in the midshaft and began lengthening immediately (Fig. 12.7-14). The patient is followed radiographically to allow modification of the lengthening speed (mm/d), pin care and/or exchange, and revision of the external fixator alignment if needed. This technique usually requires a bone graft and later plating as a second operation to obtain healing. **DeBastiani** used a similar large-pin fixator (**Orthofix**) but performed the osteotomy more toward the end of the bone in the metaphysis and waited 1 wk before beginning lengthening. Spontaneous healing was commonly achieved without bone grafting. **Ilizarov** introduced a more complex, but more adaptable (i.e., changing translation, angulation, and/or rotation during treatment), small-pin transfixation system with a circular fixator. This alternate fixator is used in a similar fashion with an osteotomy within the metaphysis to create a site of healing callus, which is stretched (callotasis) to gain length. When the desired additional length is reached (usually between 4 and 10 cm), the distraction is stopped and the callus is allowed to consolidate (heal) into the bone. Recently, some authors have shown good results with the addition of an intramedullary nail as an internal guide while the distraction is produced with an external fixator.

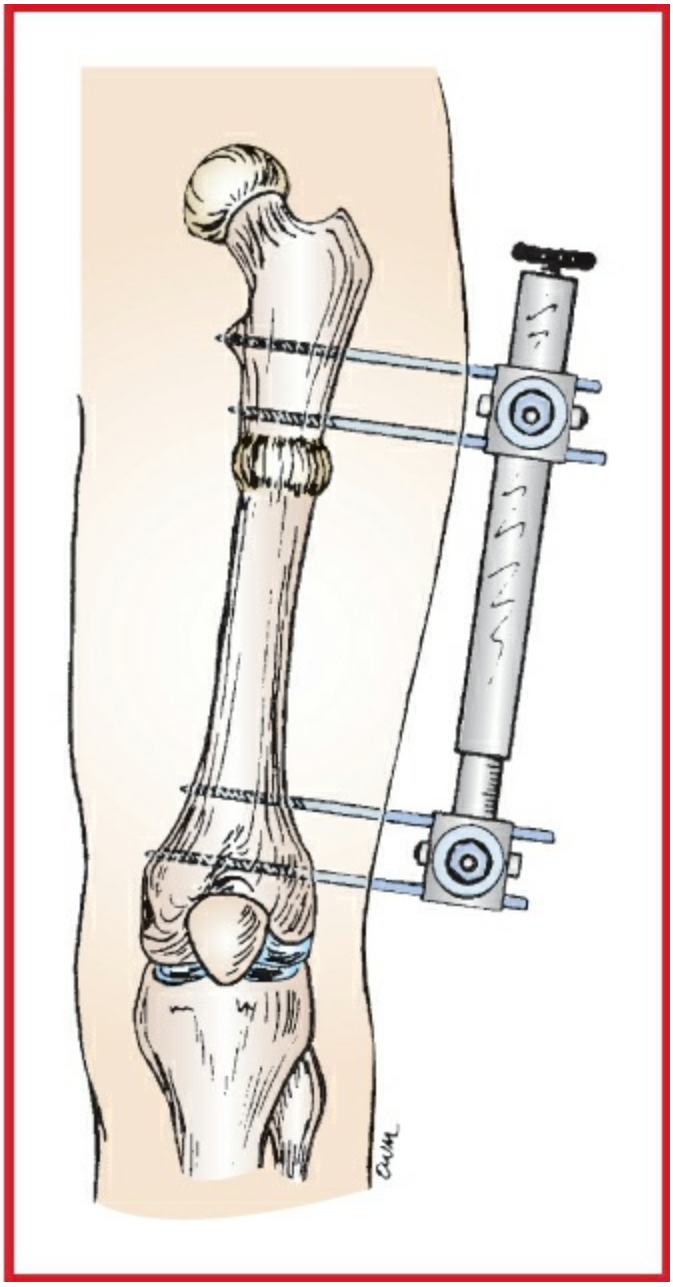

Figure 12.7-14 Wagner apparatus for leg lengthening. (Reproduced with permission from Chapman MW, ed: Operative Orthopaedics, 2nd edition. J. B. Lippincott, Philadelphia: 1993.)

Usual preop diagnosis

Congenital or acquired anisomelia (limb-length discrepancy) due to overgrowth or growth retardation >5 cm

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

PATELLAR REALIGNMENT

SURGICAL CONSIDERATIONS

Description

Patellar realignment encompasses over 100 procedures designed to prevent lateral subluxation and dislocation of the patella. These disorders include a spectrum of malalignments of the patella, ranging from simple excess lateral tilt, recurrent partial subluxation, and recurrent episodic dislocation to irreducible chronic dislocation. As such, the surgical procedures also encompass a spectrum of complexities, depending on the degree of instability. Nowadays, an arthroscopic inspection often is performed first. The basic principles of the repair include both proximal and distal realignments. **Proximal realignment** includes (a) lateral release, which is the division of the

contracted lateral patellar retinacular joint capsule and other tight lateral tissue, the first step in all surgical repair; (b) medial tightening, including reefing and/or advancement of the medial capsule and vastus medialis muscle insertion; and (c) distal realignment, consisting of redirection of the patellar tendon more medially (and sometimes more anteriorly).

Variant procedure or approaches

Arthroscopic or open lateral release is the simplest and first-step procedure. It may be sufficient when there is only subluxation and not true dislocation, and it has the advantage of being an outpatient procedure. For frank dislocation, an open "proximal realignment" also includes the medial tautening. If this is not sufficient to hold the patella centralized and if the patient has open epiphyses (<16 yr), the lateral half of the patellar tendon may be released (distal realignment) and reattached medially (**Roux-Goldthwait**), or the patella may be held medially by tenodesing the semitendinosus tendon to it. In skeletally mature patients, the bony insertion of the patellar tendon is osteotomized and transferred medially (**Trillat**) or anteromedially (**Maquet**). The **Hauser procedure** of distal and medial transfer of the tibial tubercle has had a very poor long-term outcome and is seldom performed.

Usual preop diagnosis

Lateral patellar subluxation; recurrent dislocation; congenital or chronic lateral patellar dislocation

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, postop care, and pain management options. **See Appendix K: Pediatric ERAS, p. K-6 to K-8.**

SUMMARY OF PROCEDURES

	Proximal Realignment	Trillat	Maquet

TENDON TRANSFER, LENGTHENING (POSTERIOR TIBIAL)

SURGICAL CONSIDERATIONS

Description

Extremity tendons may be lengthened (for contracture) or transferred to change the muscle force vector and compensate for paralysis or paresis of other muscle groups. Originally used for the treatment of poliomyelitis sequelae, these lengthenings and transfers are now used for a variety of deformities due to more common neuromuscular disorders, such as cerebral palsy, muscular dystrophies, Charcot-Marie-Tooth disease, and traumatic nerve palsies. Basic principles are that the muscles to be transferred should be at least grade 4/5 strength and that the loss of normal function should be well compensated. The posterior tibial muscle (PTM) is a representative example, but many extremity muscles have one or more described lengthenings or transfers. Tendon transfer procedures frequently are combined with other transfers or fusions.

For moderate spastic ankle varus, the simplest procedure, **PTM lengthening**, is accomplished by an intramuscular myotendinous "slide." This refers to simply cutting the tendinous fibers well within the distal muscle belly and leaving a small gap in the tendon while the surrounding muscle fibers remain intact. An alternative for spastic varus is the **split posterior tibial transfer** of the PTM. Four short, 2- to 3-cm incisions are used to expose and dissect half of the posterior tibia tendon at its insertion on the navicular. Then, half of the tendon is passed proximally up its sheath to a second incision just posterior to the distal tibial shaft medially. The freed half tendon is passed laterally to the peroneal tendon sheath just distal to the lateral malleolus, where, through a final incision, the tendon is anastomosed to the peroneus brevis.

For complete flaccid foot drop (e.g., peroneal nerve palsy), the entire posterior tibial tendon is transferred. First, it is detached at its medial insertion, delivered proximally at the distal tibia posteriorly, passed **anteriorly** through a window in the interosseous membrane, and then subcutaneously passed to the middorsal surface of the foot, where it is fixed into the middle cuneiform by a pullout stitch.

Usual preop diagnosis

Flaccid or spastic developmental deformity, such as varus or valgus foot neuromuscular disease

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Lengthening	Split Transfer	Anterior Transfer
Position	Supine	⇐	⇐
Incision	Longitudinal posteromedial calf	Medial foot; posteromedial calf; lateral ankle; lateral foot	Medial foot; posteromedial calf; anterior ankle; dorsal foot
Special instrumentation	None	Tendon passer	Pullout suture; buttons
Unique considerations	Underlying neurologic disease Usually added to other procedures (e.g., Achilles tendon lengthenings)	⇐	⇐
Antibiotics	Usually none	⇐	⇐
Surgical time	30 min	1 h	⇐
Closing considerations	Below-knee cast	⇐	⇐
EBL	<20 mL	<50 mL	⇐
Postop care	PACU or room	⇐	⇐
Mortality	Rare	⇐	⇐

TRIPLE ARTHRODESIS AND GRICE PROCEDURE (EXTRA-ARTICULAR SUBTALAR ARTHRODESIS)

SURGICAL CONSIDERATIONS

Description

Triple arthrodesis is used to realign the hind foot of skeletally mature patients with significant fixed or flexible deformities of multiple etiologies. The technique involves denuding three cartilaginous surfaces of the hindfoot (talonavicular, talocalcaneal (subtalar), and calcaneocuboid joints) to expose the underlying bone. This is mainly performed through an oblique incision over the lateral side of the sinus tarsi incision, but an additional short medial incision over the talonavicular joint can be added. Supple (passively correctable) deformities can be easily corrected prior to arthrodesis, but correction of fixed deformities is more difficult and often requires resection of bone wedges based on the alignment (valgus, varus, planus, cavus, etc.). After correction of the deformity (and preparation of the surfaces), internal fixation (screws or staples) is placed to maintain the reduction and allow arthrodesis. Postoperative immobilization is required with a short leg cast.

Variant procedure or approaches

Because the triple arthrodesis removes growth cartilage, it is unsuitable in growing children (<12–14 yr). **Grice** developed an **extra-articular subtalar fusion** (initially for postpoliomyelitis deformity) that can be performed as early as age 2–3 to improve planovalgus foot alignment. This procedure is accomplished through the same lateral sinus tarsi incision and involves placing a block of autologous bone graft (harvested from the tibia, fibula, or iliac crest) between the talus and calcaneus to push the alignment away from a valgus hindfoot without violating the cartilage.

Usual preop diagnosis

Varus or cavovarus foot deformities; severe valgus or equinovalgus

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURES

	Triple Arthrodesis	Grice Procedure
Position	Supine, slightly tilted up on the operative side	⇐
Incision	2" oblique over the sinus tarsi; optional medial incision	⇐
Special instrumentation	Pins, screws, or rods	Pin or screw
Unique considerations	Intraop x-ray to confirm pin position	Iliac or tibial autologous graft
Antibiotics	Usually, cefazolin 25 mg/kg iv up to 2 g	Cefazolin 25 mg/kg iv up to 2 g
Surgical time	1–2 h	1–5 h
Closing considerations	Above-the-knee cast	⇐
EBL	<100 mL	<50 mL
Postop care	PACU → room	⇐
Mortality	Rare	⇐

Morbidity	Superficial skin slough	⇐
	Superficial infection	⇐
	Nonunion of at least one arthrodesis site (usually talonavicular)	⇐
	Aseptic necrosis of the talus: rare	⇐
Pain score	6–8	4–5

PATIENT POPULATION CHARACTERISTICS

Age range	>12 yr (triple arthrodesis); 3–10 yr (Grice)
Male:Female	1:1
Incidence	<1% (depends on diagnosis and severity of deformity)
Etiology	Neuromuscular imbalance (most cases); congenital malformations (e.g., coalitions, severe pes planus); incompletely treated or overcorrected clubfoot; postfracture of calcaneus or talus
Associated conditions	Poliomyelitis; cerebral palsy (↑ GERD, ↓ airway protective reflexes, ↑ postop pulmonary complications); myelomeningocele; Charcot-Marie-Tooth disease (↑ sensitivity to muscle relaxants); congenital tarsal coalition

SURGICAL CORRECTION OF CLUBFOOT

SURGICAL CONSIDERATIONS

Description

Due to the success of the manipulation/casting followed by an Achilles tenotomy (**Ponseti technique**), surgery for clubfoot has been less commonly performed. However, resistance to nonsurgical management is an indication for open release. The orthopedic literature is replete with reports of varying techniques for surgical correction of resistant clubfoot. Turco popularized the one-stage surgical correction of resistant (uncorrected by casting) clubfoot (talipes equinovarus) in 1971. The four components of the deformity are (a) hindfoot equinus (back of the heel is up), (b) hindfoot varus (rolled inwardly), (c) midfoot cavus, and (d) forefoot adductus (medial deviation). Beyond this, however, there exists considerable disagreement as to the pathologic anatomy, ideal skin incision, position, and which structures to release. Most surgeons vary the degree of release in proportion to the degree of deformity, often performing release of the same deep structures through totally different skin incisions. The most important structures released include the entire posterior capsule of the ankle and subtalar joint; capsule of the subtalar, talonavicular, and calcaneocuboid joints; Achilles tendon, posterior tibial tendon, and usually the toe flexors; and origin of the abductor, halluces, and plantar fascia. The navicular is repositioned on the talus and usually held with a small pin.

Variant procedure or approaches

Turco procedure is essentially a posteromedial procedure only and is performed through one incision on the medial aspect of the foot. Crawford described a much more extensile approach through an incision (**Cincinnati**) that runs from anteromedial, around the back of the tendo Achilles, and then anterolateral to the calcaneocuboid joint. This approach is also used by McKay, Simons, and others for a more complete release. I there is severe equinus deformity, however, the incision is difficult to close posteriorly after correction of the equinus (stretching the posterior skin). **Carroll** accomplishes much the same correction using a separate medial and posterolateral incision.

Usual preop diagnosis

Resistant idiopathic clubfoot; secondary clubfoot due to paralysis

ERAS: **Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, postop care, physical therapy, and pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.**

SUMMARY OF PROCEDURES

	Turco	Cincinnati/McKay/Simons	Carroll
Position	Supine	Prone or supine	Supine
Incision	Straight medial foot	Transverse from the navicular bone medially posteriorly across the heel cord and then laterally to the cuboid	Medial zigza and posterolater longitudinal
Special instrumentation	Usually loupe magnification; small K-wires to hold reduction	⇐	⇐
Unique considerations	Tourniquet mandatory and often bilateral	⇐	⇐
Antibiotics	Cefazolin 25 mg/kg iv	⇐	⇐
Surgical time	1–2 h/foot	⇐	⇐
Closing considerations	Well-padded, loose-fitting, above-the-knee cast × 10–14 d	⇐	⇐
EBL	<30 mL	⇐	⇐

ANESTHETIC CONSIDERATIONS FOR PEDIATRIC ORTHOPEDIC SURGERY OF THE PELVIS AND LOWER EXTREMITIES

(Procedures covered: pelvic osteotomy; acetabular augmentation and Chiari osteotomy; Ober fasciotomy; Yount Ober release; hip, open reduction; adductor release and/or transfer; psoas release; pinning of SCFE; femoral osteotomy; epiphysiodesis; Sofield procedure; limb lengthening; tendon transfer or lengthening; triple arthrodesis, Grice procedure; correction of clubfoot)

PREOPERATIVE

Children undergoing orthopedic procedures of the lower extremities typically fall into two groups: (a) posttrauma but otherwise healthy and (b) those with a variety of chronic medical problems, including cerebral palsy, congenital hip dislocation, limb deformities, osteogenesis imperfecta, juvenile rheumatoid arthritis, epidermolysis bullosa (EB), and various myopathies and muscular dystrophies. The anesthesiologist should review the anesthetic implications of these various syndromes or diseases (see Table 12.7-2). Many of these patients will have cardiac, respiratory, endocrine, and metabolic derangements, as well as airway abnormalities that may affect anesthetic management. In addition, the surgical procedures may run the gamut from a simple syndactyly repair of the toes with little blood loss to pelvic osteotomies (in small

children) with blood loss approaching the patients' blood volume. Many patients with SCFE are obese and require anesthetic techniques that minimize the risk of aspiration.

Table 12.7-2 Preop Anesthesia Considerations for Pediatric Orthopedic Diseases

Condition	Special Anesthetic Considerations
Achondroplasia	± Unstable spine: preop neuro and ortho exams are critical. Careful positioning is necessary; prevent compression of cervicomedullary junction by placing a bolster under the shoulders. Difficult iv access. ± GERD 2° obesity. Anticipate difficult mask fit and intubation. Possible choanal stenosis/narrow nasopharynx; may preclude nasal airway/nasal intubation and placement of NG tube. Smaller ETTs are needed. ± Restrictive lung disease and chronic respiratory infections common.
Apert syndrome	C-spine fusion and small nasopharynx. Hypoplastic maxilla, prominent mandible/cleft palate. Difficult laryngoscopy and ET intubation. ± Tracheal stenosis/abnormal tracheal cartilage. Possible choanal stenosis/atresia; may preclude nasal airway, nasal ETT, and NG tube placement. Difficult vascular access. ± Craniosynostosis → ↑ ICP. ± CHD.
Arthrogryposis	Poor cervical mobility; TMJ ankylosis; possibility of difficult intubation. iv access and positioning difficult 2° flexion or contracture deformity. 10% incidence of CHD
Cerebral palsy	Communication difficulties. Scoliosis → restrictive lung disease. ± GERD. ↑ sensitivity to succinylcholine. ↑ resistance to NMRs. MAC decreased. Contractures → restricted access for examination and positioning. ± Latex allergy. Difficult iv access.
Juvenile rheumatoid arthritis	Poor cervical mobility; TMJ ankylosis; possibility of difficult intubation. ± Restrictive pulmonary disease. ± Restrictive pericarditis and tamponade
Klippel-Feil syndrome	Limited C-spine mobility → difficult intubation. Impaired renal drug excretion.

Marfan syndrome	Atlantoaxial instability: evaluate C-spine before laryngoscopy. Care in positioning is needed. May require larger than normal doses of spinal epidural anesthesia 2° height. Aortic dilation → aortic insufficiency ± aortic dissection/aneurysm. Avoid ↑ BP. Anticipate difficult intubation 2° narrow palate. Lung cysts → pneumothorax.
Muscular dystrophy	Possible cardiomyopathy: Avoid cardiac depressant drugs. ↑ sensitivity to muscle relaxants. MH susceptibility. ↓ gastric emptying and weak laryngeal reflexes. Avoid succinylcholine. May have MVR and cardiac conduction abnormalities. May require postop ventilation.
Myopathies	Avoid all muscle relaxants and respiratory depressants. Postop ventilation may be necessary.
Osteogenesis imperfecta	Bones fracture easily (e.g., with BP cuff): Use extreme care in positioning and intubation. Hypermetabolic fever may occur during anesthesia. Plt dysfunction: difficult airway. Use atropine with caution as it may exacerbate pyrexia. CHD may require antibiotic prophylaxis. ± Difficult airway. ± Restrictive lung disease. Deafness may make communication difficult.
Septic arthritis	Infection/systemic toxicity slows gastric emptying; requires rapid-sequence intubation (Appendix B, p. B-5). Dehydration 2° ↑ T and ↓ fluid intake → hypovolemia/hemodynamic instability. Rx: adequate fluid resuscitation with balanced salt solution.

Patients with neuromuscular disorders (e.g., cerebral palsy, spina bifida, muscular dystrophy) presenting for orthopedic procedures pose special challenges for the anesthesiologist. Other syndromes and chronic conditions with orthopedic manifestations include osteogenesis imperfecta, juvenile rheumatoid arthritis, and EB. The anesthesiologist should review and understand the anesthetic implications of these various syndromes.

Respiratory	Patient's preop activity level is a good indication for baseline respiratory function. Careful assessment is necessary as associated anomalies may affect the

	airway or lungs. Chronic otitis 2° eustachian tube dysfunction is common. Postpone surgery (~2–3 wk) if Sx of acute URI (e.g., runny nose, fever, sore throat, cough) are present. **Tests:** As indicated from H&P; CXR
Cardiovascular	Some pediatric patients with congenital musculoskeletal anomalies presenting for orthopedic procedures have coexisting cardiovascular anomalies. Preop review of patient's H&P is essential. Patients should not be accepted for orthopedic surgery and anesthesia until they are in the best possible physical and emotional condition. For children with CHD or who require cardiac medication, it is advisable to consult with a pediatric cardiologist before surgery. If taking ACE inhibitors, hold AM of surgery, as it may lead to intractable intraop hypotension. ***NB:** The consequences of VAE may be disastrous (e.g., cerebral or myocardial embolization) in patients with R → L shunt lesions. All iv lines, injection ports, and syringes must be air free. **Tests:** Hct; baseline SaO_2; CXR, echo, and EKG as needed
Neurologic	For patients with cerebral palsy presenting for orthopedic surgery, preop understanding of their intellectual functional capacity is necessary. Information about patient's behavioral or intellectual abilities is usually best obtained from parents or guardian. If patient is on seizure-control medication, it is recommended that the medication be continued until surgery. All patients who require Ober fasciotomy or Yount release will have profound weakness of lower extremities, if not of the entire body. Must be careful in the choice of muscle relaxant (generally avoid depolarizing agents). Many patients with muscular dystrophy present for repeated orthopedic procedures. Patients with congenital muscular dystrophy (especially

	Duchenne's or Becker's) can have significant associated cardiac dysfunction. A pediatric cardiologist should be involved in the preanesthetic evaluation of their LV function, size, LV ejection fraction, shortening fraction, and echo exam. It is important to note that asymptomatic carriers of these X-linked muscular dystrophies can have associated echo and EKG abnormalities.
Hematologic	Complications of blood loss remain a major anesthetic consideration in pelvic osteotomies, especially in small children or those who have ↑ bleeding 2° osteogenic bone or bleeding disorders. There is no hard-and-fast rule for an acceptable amount of blood loss before transfusion therapy begins; each case must be individualized. Patients who need ↑ O_2-carrying capacity (e.g., congenital heart disease, sickle cell anemia [SSA], have evidence of V/Q mismatch from preexisting pulmonary disease) will require transfusion at lower levels of blood loss than otherwise healthy children. Blood transfusion therapy must be considered after the loss of 15–20% of the patient's total blood volume. Predonation is limited by age, size, and level of cooperation with blood-collecting techniques. Careful hemodilution can be helpful. Albumin may help to avoid tissue swelling and facilitate early extubation. Cell salvaging can introduce both intracellular and surgical debris back into circulation but may avoid heterologous transfusion.
Laboratory	Tests as indicated from H&P
Premedication	Premedication for separation anxiety (e.g., midazolam) and facilitating induction. Care must be taken if premedication is used in patients with respiratory or cardiac dysfunction. Dosage must be individualized. Children with valvular disease, prosthetic valves, and/or most forms of CHD, as well

	as post–cardiac-correction patients, should receive antibiotics for bacterial endocarditis prophylaxis preop. Avoid long-lasting sedative medications.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Multimodal analgesia is recommended for surgeries with potential for significant postop pain. Preop pregabalin 2 mg/kg and celecoxib 2–4 mg/kg po may be administered as part of multimodal analgesia regimen. Consider use of regional anesthesia and discuss options with family. Consider preop acetaminophen 10–15 mg/kg iv or po as an elixir.

INTRAOPERATIVE

Anesthetic technique

As indicated in the preop considerations, these patient populations cover a wide spectrum, from fit and healthy children to those suffering from a variety of clinical syndromes with airway and cardiorespiratory problems. Thus, anesthesia needs to be tailored to the individual patient. Some older children may benefit from regional anesthesia with sedation. Some may do well with a combined regional/GA technique, whereas still others with difficult airways may require awake FOB. The following sections address some of these concerns.

Induction	**Otherwise healthy:** Standard pediatric (<12 yr) or adult induction. **Difficult airway:** A mask induction and FOL during spontaneous respiration should be considered. Alternatives include the use of LMA/intubating LMA, video laryngoscope, FOL or light wand stylet, retrograde wire intubation, and tracheostomy. **Muscle abnormalities:** These patients may be very sensitive to muscle relaxants, have gastric hypomotility, and be predisposed to MH. Induction should be accomplished by nontriggering agents (e.g., propofol 1–2 mg/kg and rocuronium 0.5–1

	mg/kg) if necessary for intubation. Succinylcholine usually is contraindicated in these patients. Dantrolene must be available, but it need not be administered prophylactically. A study of MH patients showed that 32 out of 89 had preexisting musculoskeletal abnormalities. **Cardiorespiratory compromise**: Inhalational induction, when administered cautiously, may be used safely in this group of patients. Intramuscular (e.g., ketamine 4–8 mg/kg im) inductions are usually safe and effective in neonates and infants with severe cardiac disease.
ERAS	Verify preincision antibiotics. Assess volume status (see p. K-6). Maintain normovolemia and normothermia.
Maintenance	**Otherwise healthy:** Standard pediatric maintenance **Muscle abnormalities:** Maintenance of anesthesia with a nontriggering agent (e.g., N_2O, opiates) and short-acting NMRs is prudent. A peripheral nerve stimulator should be used to monitor muscle relaxation, as the effects of muscle relaxants may be unexpectedly prolonged. **Cardiorespiratory compromise:** The maintenance of anesthesia in this group most commonly is accomplished by use of inhalational agents, additional narcotics, or other iv agents, depending on patient tolerance and postop plans for ventilatory management.
Emergence	**Otherwise healthy:** If a muscle relaxant is used, reverse with neostigmine (0.07 mg/kg) and glycopyrrolate (0.01 mg/kg iv) or edrophonium (0.5 mg/kg) and atropine (0.015 mg/kg iv). Make sure patient is awake and able to protect airway. A vital capacity of >15 mL/kg is considered an adequate sign of recovery of respiratory reserve. **Muscle abnormalities:** Anticipate postop

	respiratory impairment. Suction airway carefully. The response to neostigmine is unpredictable and may precipitate myotonia. Continued postop mechanical ventilation may be required. **Cardiorespiratory compromise:** Tourniquet release may cause significant. ↓ CO and ↓ BP, requiring temporary inotropic support. Otherwise, emergence as in other patients. Discuss with surgeon local wound infiltration. PONV prophylaxis may include dexamethasone (e.g., 30 mcg/kg) and ondansetron (0.1 mg/kg up to 4 mg iv).

Regional anesthesia

Used in patients undergoing lower extremity surgery

Caudal epidural	In young children, the epidural space can be reached easily by the caudal epidural approach, with less risk of dural puncture than with thoracic or lumbar epidural approaches. There is minimal risk of cord injury at the level of the sacrococcygeal ligament. The dural sac, however, can extend to the level of the third or fourth sacral vertebra in the newborn; therefore, care must be taken to avoid an inadvertent intrathecal injection. Bupivacaine provides reliable, long-lasting anesthesia and postop analgesia when given via the caudal epidural route. Bupivacaine 0.25% (or ropivacaine 0.2%) with epinephrine 1:200,000 (1 mL/kg) provides 3–6 h of analgesia for all procedures below the umbilicus. In infants (<2.5 kg), a more dilute solution is used (0.125% or 0.175%), and the volume can be increased to remain below the toxic dose range (2.5 mg/kg). Intraop anesthesia with bupivacaine 0.25% with epinephrine 1:200,000 is given as a bolus with volumes determined by level desired (0.05 mL/kg/segment, not to exceed 1 mL/kg). Preservative-free clonidine (1–2 mcg/kg) as an additive to bupivacaine caudal anesthesia has been shown to increase the efficacy and duration of the analgesia but may also cause some postop sedation.

	Lower doses (1 mcg/kg) are preferred.	
Continuous epidural infusion	Use ropivacaine 0.1–0.125% at a rate of 0.1 mL/kg/h in patients <5 yr; thereafter, patients may require 0.05–0.15 mL/kg/h. Maximum hourly dose not to exceed 0.5 mg/kg/h of ropivacaine. Usually requires postop Foley catheter.	
Peripheral nerve blocks	Use of ultrasonography helps to improve the efficacy and safety of these blocks. Femoral, obturator, and lateral cutaneous nerve of the thigh can be blocked by doing a lumbar plexus block at the level of the L4 vertebra or by doing a 3-in-1 block at the groin. Sciatic nerve can be blocked in the posterior thigh at the apex of the popliteal fossa. Saphenous/sciatic or femoral/sciatic combinations can provide excellent analgesia for distal extremity surgeries. If used in combination, these blocks can provide excellent postop analgesia for most of the lower limb procedures with minimal side effects. Catheters can be left in place for providing continuous postop analgesia. With the availability of safer and less-expensive programmable pumps, most of the blocks can be done even for outpatient procedures, and the children can be sent home with elastomeric pump (e.g., On-Q®) pump infusions.	
Blood and fluid requirements	IV: 22 ga or greater × 1–2 BSS (at maintenance) 4 mL/kg/h: 0–10 kg + 2 mL/kg/h: 11–20 kg + 1 mL/kg/h: >20 kg (e.g., 25 kg = 65 mL/h) Warm fluids for long cases.	There may be rapid fluid shifts in pediatric patients undergoing orthopedic procedures. Close monitoring and adequate fluid replacement will ensure hemodynamic stability. In hip or pelvis surgery, blood loss may be substantial, and adequate iv access is important, as blood transfusion may be required.
Control of blood loss	Tourniquet: 120-min limit	Use of pneumatic tourniquets has become common practice

		in peripheral orthopedic procedures. They reduce intraop blood loss; however, they cause pain and, upon removal, release products of anaerobic metabolism.
Monitoring	Standard monitors. ± Arterial line ± CVP line Temperature	Most pediatric patients presenting for extremity surgery do not require invasive monitoring. An arterial or CVP line may be helpful, depending on patient's medical condition, length of surgery, and anticipated blood loss.
Positioning	✓ and pad pressure points ✓ eyes	Patients with osteogenesis imperfecta or osteoporosis are at risk for fractures and joint dislocations and require special care in positioning.
Complications	MH	Early Sx of MH include hypercapnia, tachycardia, tachypnea, unstable BP, dysrhythmias, cyanotic mottling of the skin, rapid rise in T (1°/15 min), discolored urine, metabolic acidosis, respiratory acidosis, hyperkalemia, and myoglobinuria. Rx: stop surgery and anesthesia immediately; hyperventilate with 100% O_2; activated charcoal filters can be used to remove residual anesthetic gases from the breathing circuit; administer dantrolene sodium iv (starting dose = 1–

		2 mg/kg q5–10min; maximum cumulative dose = 10 mg/kg) by rapid infusion. Procainamide (15 mg/kg) over 15 min may be required for dysrhythmias. Initiate cooling; correct acidosis and hyperkalemia. Maintain UO of at least 2 mL/kg/h. Monitor patient in ICU until danger of subsequent episodes is over (24 h).

POSTOPERATIVE

Complications	MH Respiratory insufficiency	For MH considerations, see above.
Multimodal pain management	PCA Parenteral opioids Spinal opioids Regional/epidural catheter, local anesthetic and opioid infusions	Backup with bolus opioid analgesics.
ERAS	PONV protocol (see p. D-1)	Encourage early enteral nutrition and mobilization.

SURGERY FOR EPIDERMOLYSIS BULLOSA

SURGICAL CONSIDERATIONS

Description

EB is a disabling inherited condition affecting the skin and submucosa leading to recurrent skin blistering due to impaired epidermal and dermoepidermal adhesion. Recessive dystrophic EB is the most common type requiring surgical treatment. Children develop lesions associated with minimal trauma, which most commonly result in contractures of the hands and feet, mouth, and esophagus. Special care is required in handling patients with EB because minor trauma from iv or EKG lead placement ca cause severe blistering. Hand surgery typically required opening up the contracted fingers by removing the cocoon of epidermis. The defects are grafted with full-thickness skin grafts, typically taken from the abdomen. Following sedation or anesthesia, the affected extremity is gently sponged with dilute chlorhexidine solution. A tourniquet is not applied because it is typically not required. A wrist block is administered by the surgeon. The cocoon of scar tissue is removed, the fingers are manipulated to expose the defects, and a full-thickness skin graft is harvested. Generous Bactroban ointment and nonadhesive dressings are placed on the hand, and a well-padded cast is applied at the end of the procedure. Adhesive tape is avoided throughout the procedure.

Usual preop diagnosis

EB

ERAS: Family preop counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop care, and pai

management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE	
Position	Supine
Incision	As necessary to relieve skin contractures on the hands
Antibiotics	Cefazolin 20–40 mg/kg iv up to 2 g
Surgical time	1–2 h. Positioning, iv placement, and sedation/anesthesia are time consuming, often longer than the procedure itself.
EBL	<100 mL
Postop care	PACU → home. Return in 2 wk for intraop removal of cast, dressing change, and first splint application. Splinting and special gloves are the mainstay of postop treatment.
Mortality	None associated with the procedure
Morbidity	Trauma from positioning and monitoring → new blisters
Pain score	7–9 (similar to second-degree burns)

PATIENT POPULATION CHARACTERISTICS	
Age range	1–20 yr; older patients with precancerous or cancerous hand lesions
Male:Female	2–3:1
Incidence	Extremely rare
Etiology	Inherited
Associated conditions	Malnutrition; esophageal strictures; generalized skin contractures; malignant transformation of skin lesions

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

EB is a heterogenous group of rare hereditary disorders characterized by blister formation in the skin in response to minor trauma, friction, or pressure. The most minor form of EB is EB simplex, in which the blisters heal without scarring. The junctiona form often is diagnosed at birth, with blisters caused by the physical trauma of delivery.

These patients develop severe scarring and have a short life expectancy. Patients with the recessive dystrophic form may have strictures of the oropharynx, larynx, and esophagus. Patients may be on long-term corticosteroid treatment. Periop hydrocortisone treatment may be required to compensate for adrenal suppression.

Airway	A careful airway evaluation is essential because these patients may have a difficult airway 2° mucous membrane and skin involvement in the area of the oropharynx, face, and neck. Patients with EB also may have limited mouth opening and neck movement as the result of scarring and contractures. Poor dentition: ✓ for loose teeth.
Skin	Because of the fragility of the skin and mucous membranes in patients with EB, the anesthetic plan should be designed to minimize trauma to the skin and mucous membranes. Friction and shearing forces, not direct pressure, are responsible for new bullae and wound formation.
Gastrointestinal	The most common sites of involvement are the oropharynx, esophagus, and anus. Dysphagia, esophageal stricture, and constipation are common and are the major causes of morbidity, nutritional deficiencies, and growth retardation. Esophageal dilation, insertion of NG feeding tubes, gastrostomy, and colonic interposition have been performed in patients with EB. Esophageal stricture increases the risk of regurgitation and aspiration, and precautions to avoid aspiration should be taken.
Musculoskeletal	Skin lesions can be painful, and some patients will be on chronic opiate medication for pain management.
Hematologic	Chronic blood loss from denuded skin can → anemia and hypoalbuminemia. **Test:** CBC
Laboratory	Other tests as indicated from H&P
Premedication	Adequate premedication is essential to minimize movement during induction. An orally administered

	combination of midazolam (0.6 mg/kg) and ketamine (3.5 mg/kg) facilitates the atraumatic placement of iv lines in the OR. Glycopyrrolate 0.01 mg/kg can be given as antisialagogue. EMLA cream can be applied without adhesive dressing. Avoid long-lasting sedative medications.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Evaluate for concurrent disease, nutritional status, and hydration. Consider preop acetaminophen 10–15 mg/kg iv or po as an elixir.

INTRAOPERATIVE

Patients are placed on sheepskin to cushion pressure points. The following should be available: Albolene liquefying cleanser, Surg-O-Flex® (flexible tubular bandage), Vaseline gauze, Zeroform®, Kerlix®, Webril®, cotton umbilical tape, Mepitel® dressing, and Coban® wrap. No adhesive tape is used. Adhesive portions of EKG leads and electrocautery dispersion plates are removed; the leads and plates are secured to the patient, using Webril® or Surg-O-Flex®. Water-based gels pads (3M Defib pads 2346N) are applied directly to the patient's skin and then the EKG or grounding pads applied over the water-based gel pad.

BP cuff must be applied over multiple layers of cotton padding. Carefully trim the adhesive off the pulse oximetry probe, wrap around the palm or finger, and wrap Coban® around the probe. Alternatively, use adult clip-on probe. Anesthesia masks, ETTs, temperature probes, and all attached monitoring equipment are lubricated with Albolene. Venipuncture can be difficult, and the iv lines will need to be secured with Vaseline gauze and Coban®.

Anesthetic technique

GETA is the preferred method of anesthesia when upper airway manipulation is required or airway protection is compromised. Anticipate difficult airway. Planned FOL is safer than DL. Use smaller ETT to avoid formation of laryngeal bullae. ETT and laryngoscope blade, if used, should be well lubricated. Smaller-than-normal LMA has been used, with the shaft and cuff lubricated. Secure tube with umbilical tape. The safety of GETA, however, is not well documented in junctional EB patients, where columnar epithelium can be involved. Succinylcholine should be used with caution due to potential ↑ K^+ 2° muscle atrophy, although it has been used safely in many instances.

NMRs prolong duration of action 2° ↓ muscle mass and changes in volume of distribution 2° hypoalbuminemia, which results from ill health and poor nutritional status due to high metabolic demands.

IV anesthesia

Ketamine has been utilized for patients with EB undergoing surgical procedures. For anesthesia, use a loading dose of midazolam 0.1–0.2 mg/kg with ketamine 0.25–0.5 mg/kg, followed by a continuous infusion of ketamine (1 mg/kg/h) and midazolam (0.1 mg/kg/h). Glycopyrrolate can be used as an antisialagogue in these patients. Alternatively, propofol (50–100 mg/kg/h) with remifentanil (0.05–0.1 mcg/kg/h) or dexmedetomidine (0.4–0.7 mcg/kg/h) infusions may be used. Titrate medications according to patient's response to surgical stimulation.

Inhalation anesthesia

Inhalation anesthesia may also be performed in cases of difficult iv access and low risk of aspiration.

Local anesthesia

Deep local anesthetic infiltration may be used.

Regional anesthesia

In some patients with EB, regional anesthesia techniques allow maintenance of airway patency, involve minimal epidermal/dermal damage, and can offer prolonged postop pain relief. Brachial plexus anesthesia, epidural anesthesia, and spinal anesthesia have been used successfully in patients with EB.

Emergence	Adequate postop analgesia and parental presence in the PACU may help prevent excessive struggling and skin trauma during emergence and recovery. Plastic O_2 delivery masks should be avoided as they have sharp edges. Avoid rectal route for pain management, as it may cause perianal trauma and blistering. Acetaminophen, ketorolac, and opioids can be used for postop analgesia. PONV should be avoided by using combination antiemetic therapy. Pruritus, a common side effect of opiates, should be treated promptly. Discuss with surgeon local wound infiltration. PONV prophylaxis should include dexamethasone (e.g., 30 mcg/kg) and ondansetron

(0.1 mg/kg up to 4 mg iv).

SURGICAL CORRECTION OF CRANIOSYNOSTOSIS

SURGICAL CONSIDERATIONS

Description

Premature fusion of cranial sutures, or **craniosynostosis**, causes various well-recognized patterns of cranial vault and facial deformities. Abnormal skull growth occurs perpendicular to the fused sutures. Craniosynostosis can occur as an isolated abnormality or as part of a syndrome. Crouzon, Apert, Saethre-Chotzen, Carpenter, Muenke, and Pfeiffer syndromes are the six most common syndromes associated with craniosynostosis. Single or multiple sutures can be involved, the most common being the sagittal suture. This condition is called **scaphocephaly**, in which the cranial vault is bitemporally narrow, with anteroposterior (AP) elongation. **Anterior or posterior plagiocephaly** involves a single coronal suture or lambdoid suture and is characterized by flattening of the forehead on the affected side. **Oxycephaly** ("tower-head deformity") involves bilateral coronal sutures, with a flat, high forehead, whereas **brachycephaly** also involves the cranial base sutures and results in bitemporal bulging, midfacial hypoplasia, an anterior open bite, and hypertelorism. These patients may have severe

sleep apnea and can pose a challenge for airway management. **Trigonocephaly** (triangular head shape; Fig. 12.8-1), with a keel-shaped forehead and hypoteloric tendency, involves the metopic suture.

Surgical correction of these craniofacial anomalies requires a combined plastic surgery and neurosurgery team approach involving the release or resection of the affected suture and simultaneous correction of the asymmetric skull by **bone-flap repositioning or advancement.** Fronto-orbital abnormalities are addressed with **bifrontal craniotomy** and **forehead advancement**, along with advancement of the supraorbital bar (**fronto-orbital advancement**; Fig. 12.8-2). For example, in plagiocephaly, because of the unilateral coronal synostosis, the frontal bone is retruded, and the superior orbital rim is elevated and retruded on this side. Craniectomy is performed, the forehead is removed, the involved coronal suture is resected, and the supraorbital bar is cut above the orbit and down to the lateral orbital wall across the midline. The bar is bent, advanced on the involved side—sometimes up to 1.5 cm—and fixed in this position. Additional bone strips are taken from the posterior cranium and split for use as graft material; the other bone pieces are replaced and fixed with wires, suture, or resorbable plates. Another approach that is being utilized more commonly in infants <12 mo of age is endoscopic repair, followed by postop helmet therapy for up to 6 mo, to allow the skull to mold and grow properly. This approach has been shown to reduce blood loss and decrease surgical time and length of stay and is more successful in younger infants (aged 2–3 mo), single-suture repairs, and in nonsyndromic patients. Clinical outcomes are similar but dependent on compliance with helmet wearing.

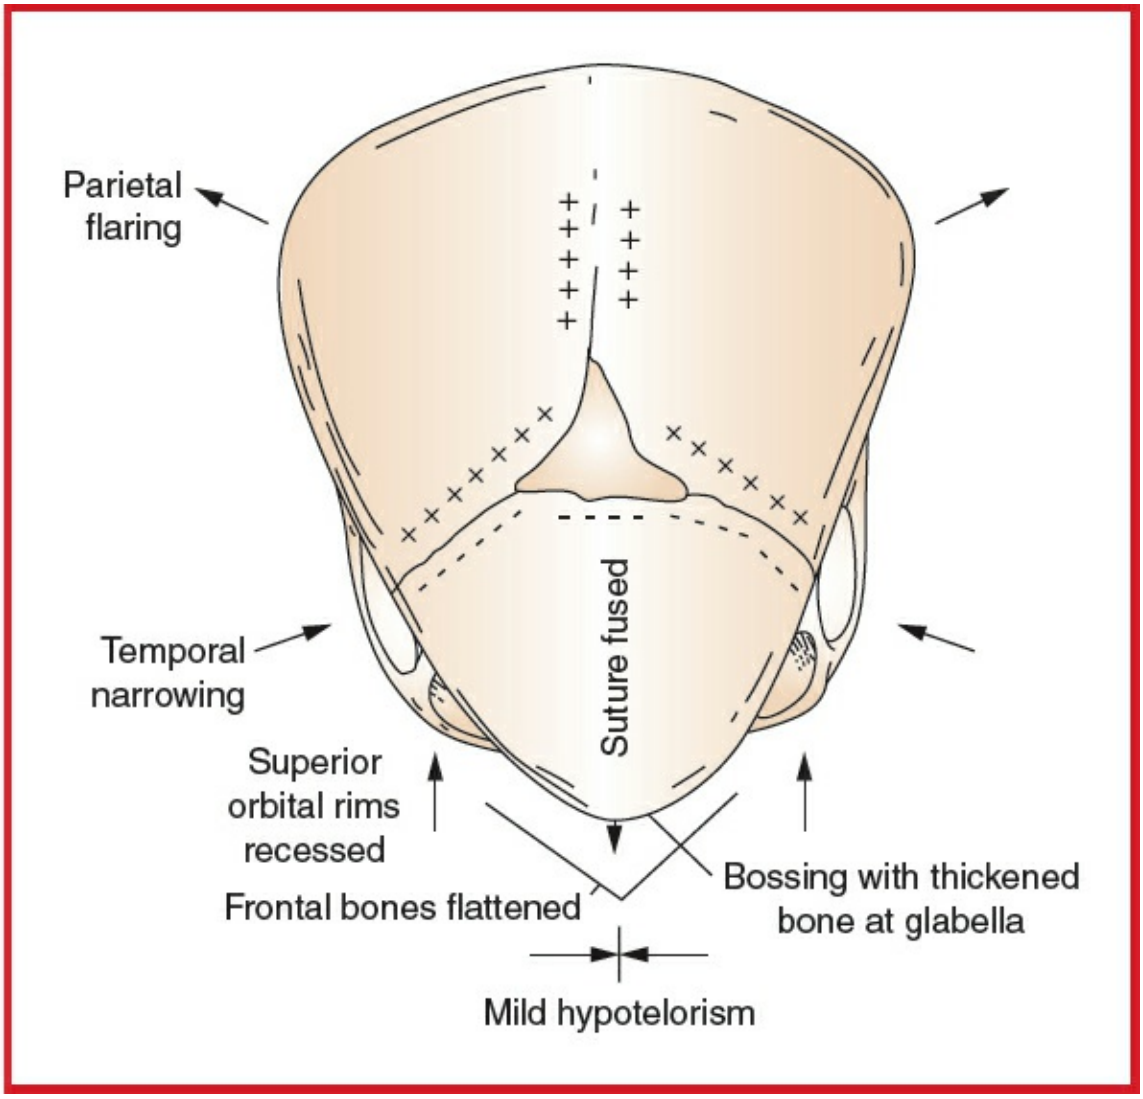

Figure 12.8-1 Skull shape abnormalities in metopic synostosis: Regions of reduced bone deposition (---). Regions of compensatory increased bone deposition (+++). (From Shaffrey ME, Persing JA, Delashaw JD, et al: Surgical treatment of metopic synostosis.Neurosurg Clin N Am1991; 2(3):621–27. Reprinted with permission from John A Persing, MD.)

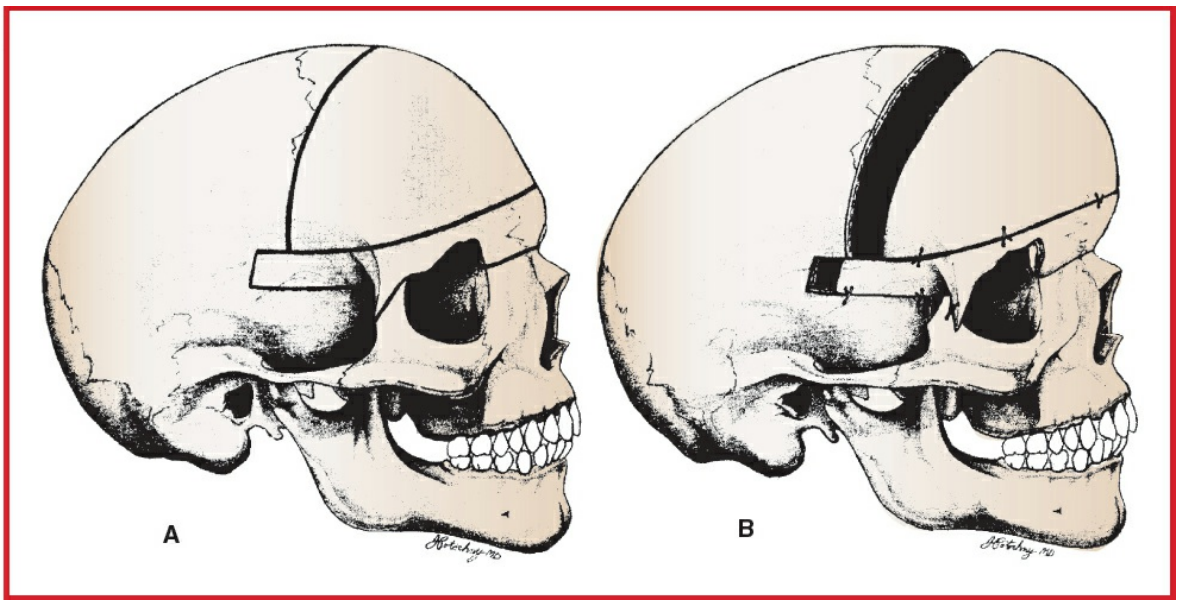

Figure 12.8-2 Fronto-orbital advancement. **A:** Lines of osteotomy for forehead and supraorbital bar advancement. **B:** Fronto-orbital advancement in a tongue-in-groove manner and fixation with wires. (Reproduced with permission from Aston SJ, Beasley RW, Thorne CH, eds.Grabb and Smith's Plastic Surgery, 5th edition. Lippincott-Raven, Philadelphia: 1997.)

Patient positioning, type of headrest, and incision all vary, depending on location of the suture abnormality. If the deformity is mostly posterior (e.g., a sagittal or plagiocephaly case), a prone approach with biparietal or midsagittal incision can be used and may be done endoscopically in the younger infant. Resection of the involved suture and **barrel staving** of the cranium, with grafting for reshaping, works well. Reconstruction as above usually is accomplished at ~3–6 mo of age. Brain mass doubles in size the first 6 mo and triples by 3 yr of age, when ~80% of the brain growth is completed. Brain growth is the driving force for cranial vault growth. All procedures are extradural. Dural tears, if they occur, are repaired to prevent CSF leak and CNS infection.

In syndromic patients, their cranial synostosis deformity is repaired in a manner similar to the procedures described above. Repairs are usually carried out before the age of 12 mo, with a view to midfacial advancement of the primary dentition at maturity either by **LeFort III or by monobloc advancement with or without distraction.** (See Major Secondary Craniofacial Surgical Procedures.)

Postsurgical orthopedic distraction devices can be used to encourage midfacial growth and are commonly used in posterior vault expansion. The syndromic cases may require repeat craniotomy and reshaping at a young age if signs of ↑ ICP appear. Other synostotic cases also should be monitored for ↑ ICP and the need for urgent secondary craniotomy. Marchac and Renier detected ↑ ICP in 13% of single-suture synostosis and 42% of multisuture synostosis. ↑ ICP may increase the risk of dural breach during

craniotomy 2° cranial bone resorption and thinning.

Blood loss can be significant at first incision through the vessel-rich scalp. Raney clips are applied immediately to minimize blood loss. In anticipation of major blood loss, transfusion is often started with the first incision. Severe life-threatening blood loss can occur if the sagittal sinus is breached, and neurosurgical repair must be accomplished quickly. The use of tranexamic acid or aminocaproic acid has been shown to reduce blood loss. Elevation of the bone flaps usually causes diffuse bleeding, which is stopped easily with irrigated bipolar cautery and thrombin-soaked sponges. It is useful to have the patient in the reverse Trendelenburg position from the start. Diffuse bleeding at the cut bone edges and over the bone surfaces can be further controlled with bone wax. Focal bleeding from around the orbit and in the temporal fossa region subperiosteally also can be controlled with bone wax, and positioning in reverse Trendelenburg position. Open vessels, sinuses, and bony edges increase the risk of venous air embolism (VAE). A LeFort/monobloc component to the surgery increases blood loss, especially during the initial mobilization of the facial segment. Injection of local anesthetic with epinephrine, and/or on sponge packs for concurrent application of pressure, will help to control the diffuse mucosal bleeding. Moderate deliberate controlled hypotension is also paramount. Electrocautery and Ligaclips may be necessary for larger vessels (e.g., descending palatine pedicles).

Variant procedure or approaches

In older children (>2 yr), split cranial bone grafts may be required to correct defects caused by bone-flap advancement. Excision of skull segments is commonly accompanied by rigid fixation.

Usual preop diagnosis

Craniosynostosis (sagittal, coronal, metopic, lambdoid); syndromes such as Apert and Crouzon syndromes; ↑ ICP

ERAS: Preop family counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, postop pain management options, possibility of lines, and urinary catheter postop. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE

Position	Usually supine; prone for correction of lambdoidal suture synostosis or posterior sagittal synostosis. If entire cranial vault reshaping (multiple sutures), special padded

	occipital-cheek headrest, because pin fixation is not safe until >2 yr
Incision	Usually bicoronal, biparietal, Meisterschnitt, midsagittal
Special instrumentation	Horseshoe headrest, usually pediatric; occasionally Gardner tongs; Midas Rex craniotomy; resorbable plates and screws
Unique considerations	Control of ICP; spinal drain may be placed; have blood in room; VAE risk.
Antibiotics	Cefazolin 30 mg/kg q3h, or vancomycin 10–15 mg/kg q6h, and cefotaxime 25–50 mg/kg q6h for oropharyngeal contamination or following dural tears
Surgical time	2–6 h
Closing considerations	Blood loss with Raney clip removal. Full head-wrap dressing causes head/neck movement → bucking.
EBL	200–800 mL; may be formidable
Postop care	ICU: 1–2 d in some institutions (further transfusion often necessary in the first 24 h to replace drain losses)
Mortality	0.6–1.6%
Morbidity	Major complications: 14.3% Bone infection: 3–7% Meningitis CSF leak: 4.5% ↑ ICP Air embolus: <1% Blindness: <1% Massive bleeding: <1% Venous thrombosis Neurologic injury: rare
Pain score	4

PATIENT POPULATION CHARACTERISTICS

Age range	2–24 mo (primary correction)
	1:1

Male:Female	
Incidence	Nonsyndromic: 1/10,000 births (most sporadic; few familial patterns) Crouzon syndrome (OSA common): 1/25,000 Apert syndrome (OSA common): 1/100,000
Etiology	Idiopathic; however, some are associated with specific genetic conditions (e.g., Crouzon and Apert syndromes). Other cases may be 2° ↓ brain growth.
Associated conditions	Hydrocephalus; ↑ ICP; mental retardation; airway problems; ocular abnormalities; exotropia (29% Crouzon or Apert syndrome); lagophthalmos; exorbitism

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Patients may have craniofacial anomalies—particularly Apert and Crouzon syndromes—which are associated with midface hypoplasia, obstructive sleep apnea, and in some cases difficult intubation. Apert syndrome may also be associated with congenital cardiac anomalies. Hence, detailed preop evaluation is necessary. Children with single-suture craniosynostosis are usually healthy. Surgery is often performed between 3 and 6 mo of age, preferably when the infant weighs >5 kg.

Respiratory	Patients with long-standing upper airway obstruction due to choanal atresia, mandibular and maxillary hypoplasia, or other causes may have chronic hypoventilation and hypoxia and may experience episodes of apnea. If the patient has Sx of acute URI, delay elective surgery at least 2 wk. The presence of fever, cough, and abnormal chest auscultation necessitates surgical cancellation and pediatric consultation. **Tests:** As indicated from H&P
Airway	Be aware of other congenital anomalies affecting the patient's airway, such as Apert, Klippel-Feil, Goldenhar, Pierre Robin, Treacher Collins, and

	Crouzon syndromes. Review any previous anesthetic records to gain insights into appropriate airway management (e.g., video laryngoscope or FOI may be necessary). Consider elective tracheostomy under local anesthesia in patients with severe airway abnormalities.
Cardiovascular	Consider the coexistence of congenital cardiopulmonary anomalies, particularly in patients with Apert syndrome (autosomal dominant trait, craniosynostosis, midface hypoplasia, syndactyly of hands and feet, ASD, and VSD). Preop evaluation of a patient with a known or suspected heart defect should include thorough H&P, ECG, Hct, baseline O_2 sat, and echocardiogram. For children with Sx of cardiac dysfunction or those requiring cardiac medication, it is advisable to consult with a pediatric cardiologist to optimize the patient's condition before surgery. **Tests:** Preop EKG indicated for patients with CHD, CXR, and echo; others as indicated from H&P
Neurologic	If only the sagittal suture is involved, ICP is usually normal. If more than one suture is involved, brain growth may be impaired, the patient may be developmentally delayed, and intracranial HTN may be present. Older patients presenting for repair are more likely to show signs and symptoms of elevated ICP. Syndromic craniosynostosis often has associated hydrocephalus.
Hematologic	Surgery in early infancy (<9 mo) is common; thus, allowable blood loss is small; blood transfusion usually is required. **Tests:** Hct; PT; PTT; T&C blood
Laboratory	Other tests as indicated from H&P
Premedication	Patients >9–10 mo old may benefit from premedication with midazolam (0.5 mg/kg po). Antibiotic prophylaxis for CHD may be warranted.

	Consult latest AHA guidelines.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Consider preop acetaminophen 15 mg/kg po (2–12 yo).

INTRAOPERATIVE

Anesthetic technique

GETA: Anticipate possible difficult airway. Heat OR to 78°–80°. Forced-air warmer. Heat all fluids to body temperature.

Induction	Surgery for craniectomies is extradural. Either mask induction with N_2O and inhalational agent or iv induction is suitable for the infant with a normal airway. If ICP is suspected to be elevated, consider mild hyperventilation after loss of consciousness. For a difficult airway, intubation may be facilitated by using video laryngoscope or FOI while patient is anesthetized and spontaneously ventilating. In rare situations, tracheostomy, under sedation and local anesthesia, may be necessary. Consider suturing ETT to prevent accidental extubation in prone cases, as unsutured endotracheal tubes can slip through tape due to pooling of oral or nasal secretions.
ERAS	Verify preincision antibiotics. Assess volume status (see p. D-1). Maintain normovolemia. Avoid hypothermia.
Maintenance	Maintenance anesthesia with inhalational agent or balanced (iv) anesthesia and long-acting muscle relaxant should be adequate. Surgery may be prolonged. Control of ICP may be necessary (see below). A remifentanil infusion 0.1–0.2 mcg/kg/min provides profound intraop analgesia and BP control and allows for rapid awakening.
Emergence	Prompt awakening to allow neurologic evaluation is an important goal. Excessive facial edema due to prolonged surgery or high blood loss requiring large-volume fluid replacement, particularly in patients with preoperative

	sleep apnea, may require the patient to remain intubated postoperatively. Check for presence of air leak around ETT in patients with significant facial edema to determine readiness for extubation.	
Blood and fluid requirements	Anticipate large blood loss. IV× 2 (as large as possible) LR @: 4 mL/kg/h—0–10 kg +2 mL/kg/h—11–20 kg +1 mL/kg/h— >20 kg (e.g., 25 kg = 65 mL/h) Warm all fluids. Humidify gases.	Have 1–2 U PRBC or whole blood available in the room. Consider splitting PRBC into aliquots preop to minimize donor exposure. Use freshest compatible PRBC available for infants to minimize risk of hyperkalemia. Consider antifibrinolytics such as tranexamic acid (loading dose 50 mg/kg, followed by infusion of 5 mg/kg/h) or aminocaproic acid to decrease intraop blood loss and blood transfusion needs. Use LR for replacing deficit, maintenance, and third-space fluid loss. Replace blood loss with colloid and PRBC mL for mL. Warm all fluids administered. Significant blood loss begins with scalp incision; allowable blood loss is small so that it is important to begin transfusion early before hypovolemia occurs. Estimation of intraop blood loss may be difficult because of significant loss of blood onto surgical drapes and gowns. EBV for an infant in this age group is 80 mL/kg. Monitor for signs of coagulopathy and transfuse

		FFP and cryoprecipitate platelets as needed. Avoid NS (acidosis, ↑ bleeding) in children <5 yr. Beware of ↑ K^+ and ↓ Ca^{++} associated with massive transfusion.
Control of ICP	Hyperventilation Osmotic diuretic Loop diuretic	In some cases, it may be desirable to ↓ ICP. This can be accomplished by ↑ ventilation ($PaCO_2$ = 25–30 mm Hg), diuretics (furosemide 0.5–1 mg/kg iv), and/or mannitol (0.25–1 g/kg iv).
Monitoring	Standard monitors (Appendix D, p. D-1) + Arterial line ± CVP line ± Precordial Doppler ± Urinary catheter	Arterial cannulation for BP, monitoring of ABG, Hct, electrolytes, etc., ↑ K^+ and ↓ Ca^{++} are most common following transfusion with whole blood or FFP. VAE has been reported during craniectomies in infants; hence, a precordial Doppler and CVP line will be helpful. CVP may be particularly helpful in the infant with marginal cardiovascular status for volume assessment and drug administration. Close attention to $ETCO_2$ and, if available, ETN_2 monitoring is useful. If VAE is suspected, the surgical field should be flooded and the head lowered immediately. CVP may be particularly helpful in the infant with

		marginal cardiovascular status for volume assessment and drug administration and if peripheral iv access is limited. Precordial or esophageal stethoscope is useful in cases where the patient is turned 180° or in cases of marginal pulmonary function.
Positioning	✓ and pad pressure points ✓ eyes	Positioning depends on surgical approach; most are performed with patient supine. The head-up position is commonly used to help decrease venous pressure and blood loss.
Complications	Oculocardiac reflex (OCR) → ↓↓ HR and ↓↓ BP VAE	Notify surgeons. If it does not resolve, give atropine 0.02 mg/kg iv (minimum 0.1 mg). Be prepared to make prompt Dx of VAE (↓ $ETCO_2$, change in Doppler sounds, ↑ ETN_2, ↓ O_2 sat, ↓ BP, ↑ HR) and Rx: notify surgeons, flood wound, ± head down, aspirate CVP, ± vasopressors. Minimizing head-up position, avoiding hypovolemia, and introducing PEEP can help to prevent VAE.

POSTOPERATIVE

Complications	Hypovolemia with ↓ BP Hypothermia	Inadequate volume replacement may result in ↓ BP and acidosis. ✓ Hct to

		establish need for further fluid or blood therapy. Coagulopathy may develop postop; check coags to establish need for blood component therapy.
	Airway complications	Excessive facial edema, history of a marginal airway preoperatively, or severe obstructive sleep apnea with sensitivity to opioids may necessitate maintenance of a secure airway postop.
Multimodal pain management	If intubated, fentanyl and midazolam infusions per ICU protocol Postextubation, consider: Acetaminophen 10 mg/kg iv q6h ATC Lorazepam 0.01 mg/kg iv q6h ATC Hydromorphone RN controlled analgesia 1 mcg/kg continuous and 2 mcg/kg q10min lockout for breakthrough pain. Alternatively: Fentanyl 1 mcg/kg iv Morphine 0.05–0.1 mg/kg iv q2–3h prn Hydromorphone 0.005–0.01 mg/kg iv q2–4h Hydrocodone/acetaminophen elixir (Hycet) 0.15 mg/kg po q6h	
Tests	Follow up Hct postop	Transfuse to keep Hct ≥ 30%.

MAJOR SECONDARY CRANIOFACIAL SURGICAL PROCEDURES

SURGICAL CONSIDERATIONS

Description

These procedures usually are performed on children ≥5 yr. There are two basic approaches. The first involves advancement of the upper face and frontal bone, frequently described as a **monobloc** (Fig. 12.8-3) or **frontofacial advancement**. Occasionally, a LeFort III osteotomy and advancement may be performed depending on the anatomy. The second variation, called **facial bipartition** or **periorbital osteotomy**, is for correction of telorbitism (widely spaced eyes), usually accomplished by a combined extra- and intracranial approach, using both plastic and neurosurgery teams.

Variant procedure or approaches

Many different variations of the above-named procedures can be performed; however, from an anesthetic standpoint, they are not significantly different. The use of **cranial bone grafts** and **rigid fixation** have shortened these somewhat lengthy procedures. Other bone grafts, however, from ribs and iliac crest, are occasionally required. These procedures frequently last ≥6 h, and blood loss can be very heavy. Reconstruction of the forehead and orbital area following a tumor excision, for example, uses a similar

approach but requires additional bone grafts. The use of external or internal distraction devices has eliminated the need for bone grafts and decreased associated complications including infection.

Usual preop diagnosis

Craniofacial malformations; craniofacial deformities; telorbitism or hypertelorism; craniofacial dysostosis

ERAS: Preop family counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, carb loading, postop pain management options, and possibility of lines and urinary catheter postop. **See Appendix K: Pediatric ERAS, p. K-6 to K-8.**

PATIENT POPULATION CHARACTERISTICS

Age range	3–20 yr
Male:Female	1:1
Incidence	Crouzon syndrome: 1/25,000 Apert syndrome: 1/100,000
Etiology	Congenital (80%); occasionally trauma or tumor (20%)
Associated conditions	Depends greatly on the syndrome or disease entity. See Craniosynostosis.

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Craniofacial syndromes often are associated with maxillofacial deformities, mandibular abnormalities, and challenging airway management.

Respiratory	Patients with long-standing upper airway obstruction due to choanal atresia, mandibular and maxillary hypoplasia, etc. may have chronic hypoventilation and hypoxia and may have apnea episodes. If Sx of acute URI, delay elective surgery at least 2 wk. The presence of fever, cough, and abnormal chest auscultation necessitates surgical cancellation and pediatric consultation.

	Tests: As indicated from H&P
Airway	Be aware of other congenital anomalies affecting the airway, such as Apert, Goldenhar, Klippel-Feil, Pierre Robin, Treacher Collins, and Crouzon syndromes. Review any previous anesthetic records for insights into airway management (e.g., need for video laryngoscope or FOI). Consider elective tracheostomy under local anesthesia in patients with severe airway abnormalities.
Cardiovascular	Incidence of CHD is increased in patients with craniofacial abnormalities. Preop evaluation of patient with known or suspected heart defect should include H&P, ECG, Hct, and baseline O_2 sat. For children with Sx of cardiac dysfunction or those requiring cardiac medication, it is advisable to consult with a pediatric cardiologist to optimize patient's condition before surgery. **Tests:** Preop ECG, echocardiogram, CXR indicated for patients with CHD; others as indicated from H&P
Neurologic	Neurologic deficits, if any, should be documented preop.
Laboratory	Hb/Hct; therapeutic drug levels for patients taking anticonvulsants
Premedication	Premedication is helpful for patients > 1 yr—oral midazolam 0.5–0.75 mg/kg or oral ketamine 6 mg/kg about 30–60 min before induction.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Discuss postop pain management. Consider preop acetaminophen 15 mg/kg po (2–12 yo).

INTRAOPERATIVE

Anesthetic technique

GETA, with special consideration given to associated CHD, pulmonary, and airway problems.

Induction	In an otherwise healthy patient, inhalational induction with subsequent placement of iv lines is appropriate. Muscle relaxants facilitate intubation but should be used only when adequate mask ventilation can be ensured. An oral RAE ETT is useful for this procedure and should be secured carefully in place. Suturing in place is often warranted. Intubation in a patient with airway abnormalities may be facilitated by using an FOI or GlideScope™ with patient spontaneously ventilating. In rare situations, tracheostomy, under sedation and local anesthesia, may be necessary.	
Maintenance	Standard pediatric maintenance. Consider use of remifentanil infusion (0.1–0.2 mcg/kg/min) for supplemental analgesia and to facilitate rapid awakening.	
Emergence	Extubate the trachea when patient is awake and protective airway reflexes have returned if appropriate. These patients often require postop intubation and ventilation.	
Blood and fluid requirements	Anticipate large blood loss. IV: 18 ga × 1–2 BSS @: 4 mL/kg/h—0–10 kg +2 mL/kg/h—11–20 kg +1 mL/kg/h—>20 kg (e.g., 25 kg = 65 mL/h) Warm fluids.	The goal of intraop fluid therapy is to replace preop deficits, intraop fluid, electrolyte, and blood losses while providing maintenance fluids. Half of the calculated deficit (hours fasting × hourly maintenance fluid requirement) generally is replaced during the first hour of anesthesia and the balance over the next 1–2 h. Surgical manipulation of tissue will cause 'third-space' fluid loss proportional to the degree of surgical trauma and tissue exposure. It may range from 0 to 10 mL/kg/h.

Control of blood loss	Deliberate ↓ BP is rarely necessary.	Deliberate ↓ BP can be accomplished by use of SNP, esmolol, clevidipine, or potent inhalational agents titrated to effect (MAP 50–60 mm Hg).
Monitoring	Standard monitors Arterial line ± CVP line	Arterial line is essential for monitoring BP during deliberate ↓ BP and for ABGs and blood chemistries.
Control of ICP	Hyperventilation Mannitol Loop diuretics CSF drainage (>1 yr)	For some procedures, it is essential to reduce intracranial volume to facilitate surgical access. If prolonged brain retraction is required, postop cerebral edema may ensue. ↓ ICP by ↑ ventilation ($PaCO_2$ = 25–30 mm Hg), and diuretics (e.g. furosemide 0.5–1 mg/kg iv).
Positioning	✓ and pad pressure points ✓ eyes	Positioning the head above the heart facilitates venous drainage but also increases the incidence of VAE. Do not hyperextend or hyperflex the head and neck. Flexion of the neck will move the ETT downward (mainstem intubation); extension will move the ETT upward (cuff leak).
Complications	Displacement of ETT Oculocardiac reflex (OCR)→ ↓ ↓ HR, ↓ BP	Discuss with surgeon prevention of displacement by prior suturing of ETT to alveolar ridge. Notify surgeon. If necessary,

		Rx: atropine 0.02 mg/kg.
	VAE Major blood loss	VAE should be suspected if sudden ↑ ETN_2, ↓ $ETCO_2$, ↓ O_2 sat, ↓ BP, and ↑ HR occur. Notify surgeon, flood surgical field, d/c N_2O, and support patient hemodynamically.

POSTOPERATIVE

Complications	↑ ADH secretion Diabetes insipidus (see Appendix D, p. D-1)	SIADH or DI may follow brain manipulation and may require pharmacologic intervention for Rx.
	Cerebral edema	Cerebral edema may → ↑ ICP (headache, N/V, ↓ mental status, etc.).
	Pneumothorax Bleeding	Pneumothorax (Sx = ↑ respiratory rate, wheezing, ↑ BP, ↓ CO, ↓ O_2 sat) may occur 2° rib resection for bone graft. ✓ CXR.
Multimodal pain management	Regional anesthesia	Regional anesthesia may be considered (infraorbital block for cleft lip, scalp blocks for frontofacial advancement).
	Nonopiate	Acetaminophen 10 mg/kg iv q6h
	Opiate	Lorazepam 0.01 mg/kg iv q6h Consider RN controlled analgesia with hydromorphone 1 mcg/kg continuous and 2 mcg/kg q8 lockout for breakthrough pain. Alternatively: Fentanyl 1 mcg/kg iv

		Morphine 0.05–0.1 mg/kg iv q2–3h prn Hydromorphone 0.005–0.01 mg/kg iv q2–4h Hydrocodone/acetaminophen elixir (Hycet) 0.15 mg/kg po q6h
Tests	Hct

CLEFT LIP REPAIR—UNILATERAL/BILATERAL

SURGICAL CONSIDERATIONS

Description

Cleft lip may be either unilateral or bilateral and associated frequently with clefts of the alveolus and palate. Surgical repair involves the design and execution of geometric flaps on the medial and lateral sides of the cleft and primary repair of the cleft nasal deformity. The most common unilateral technique is the **rotation advancement flap of Millard** (Fig. 12.8-4). Multiple bilateral lip repairs have been described, some repairing both sides simultaneously and some one side at a time (Fig. 12.8-5). Technique depends on the amount of prolabial and lateral element tissue available. Recently, **primary nasal repair** has been coupled with these bilateral procedures.

These nasal repairs involve extensive mobilization of the alar cartilages and transfer of tissue up into the cleft nasal vestibule and floor, with nasal stents often placed. All of these factors can decrease or occlude nasal airway breathing. Although only a minority of neonates has been found to be true obligatory nasal breathers, this should be kept in mind for those postop patients with respiratory distress.

C
D
E

Figure 12.8-5 Banked fork-flap procedure. In the first stage **(A–C)**, bilateral straight line repairs are done after the prolabium is divided vertically into three forks. The central limb is used to construct the center of the lip. The lateral forks are "banked" at the alar bases for later use in constructing a columella. At the second stage **(D–E)**, bipedicle flaps from the nasal floor, which include the banked forks, are used in combination with a membranous septum incision to elongate the columella and increase tip projection. (Reproduced with permission from Aston SJ, Beasley RW, Thorne CH, eds:Grabb and Smith's Plastic Surgery, 5th edition. Lippincott-Raven, Philadelphia: 1997. After Millard DR Jr: Closure of bilateral cleft lip and elongation of columella by two operations at infancy. Plast Reconstr Surg 1971; 47:324–31.)

Variant procedure or approaches

Other approaches commonly performed are those of the **Davies-** or **Tennison**-type (Z-plasty) lip repairs (Fig. 12.8-6). In large clefts, a lip adhesion may be performed as an initial stage several months before the actual definitive correction of the cleft lip. This procedure basically involves creating a wound on either side and suturing the muscles, mucosa, and skin together. The procedure itself is very short (~45 min). **Presurgical orthopedic devices** may be placed and manipulated, instead of a lip adhesion, to bring a wide, bony cleft into better opposition for a tension-free complete repair. These are custom-fitted and may be fixed with pins to the palate. They are removed in the OR at time of repair.

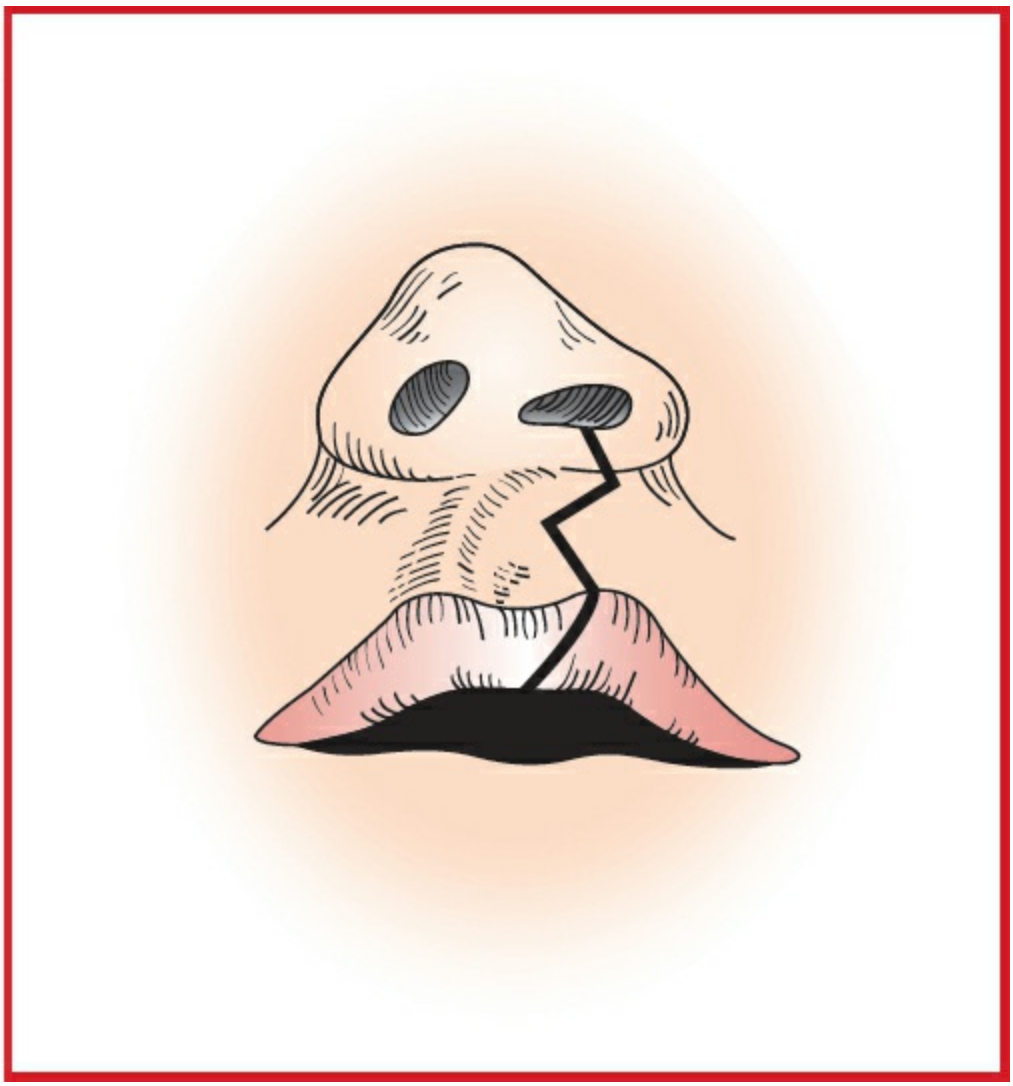

Figure 12.8-6 Z-plasty closure of the lip. (Reprinted from McCarthy JG, edPlastic surgery: cleft lip and palate, and craniofacial, Volume 4, 1st edition. Copyright © 1990 Elsevier. With permission.)

Usual preop diagnosis

Cleft lip/palate

ERAS: Preop family counseling by the surgeon/anesthesiologist should include continuing limiting NPO duration, review of nutritional status, carb loading, and postop pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE

Position	Supine; table rotated either 90° or 180°, with oral RAE or reinforced tube toward chin; patient's head at the edge of head of bed; shoulder roll; neck extended; entire face exposed; scleral shields

Incision	Medial and lateral cleft margins into the nose and in the maxillary vestibule on the cleft side
Special instrumentation	Throat pack (**NB:** ✓ removal before extubation); oral RAE or anode tube
Unique considerations	Local anesthesia with epinephrine is injected **after** lip and nose markings are complete. Pediatric patients should wake up in a calm state because undue crying may place excessive tension on the repair. Immediate elbow restraints for children × 2 wk.
Antibiotics	Cefazolin 30 mg/kg iv
Surgical time	1.5 h (bilateral usually ½ h longer) Lip adhesion: 45 min
Closing considerations	Nasal stent; swelling and ointment may occlude nasal airway; smooth emergence is important.
EBL	5–10 mL (higher with palatoplasty)
Postop care	Elbow restraints × 2 wk; PACU → room overnight → home POD 1
Mortality	Minimal
Morbidity	Infection Wound breakdown Hypertrophic scars
Pain score	4

PATIENT POPULATION CHARACTERISTICS

Age range	1 wk–6 mo
Male:Female	2:1—cleft lip and palate. Isolated cleft palate is more common in females.
Incidence	1/750 for Caucasians; more common in Asians; less in African Americans. Left cleft is more common than right; both are more common than bilateral, in the ratio of 6:3:1.
Etiology	Multifactorial, including both genetic and environmental

	aspects
Associated conditions	Associated anomalies are seen in ~29% of cleft lip cases and may include major chromosomal deletions and/or duplications, along with possible severe mental retardation and CHD.

ANESTHETIC CONSIDERATIONS

PALATOPLASTY

SURGICAL CONSIDERATIONS

Description

Cleft palate can be seen as either an isolated condition or in conjunction with clefting of the lip. The mildest form of cleft palate is the submucous or occult cleft, in which there is no visible cleft but, rather, a nonunion of the soft-palate muscles. This is followed by the incomplete soft-palate cleft and, finally, the complete cleft, which includes soft and hard palates and may extend through the alveolar portion of the maxilla. Special attention needs to be taken in cleft palate repair in children with Pierre Robin syndrome. In spite of delayed closure, 30% of these children develop respiratory distress following one-stage palatal repair. This usually resolves in a few days. Some of these children, however, have an extremely reduced airway secondary to the small mandible and will need other procedures to increase the airway including jaw distraction. In fact, all children with cleft lip and palate demonstrate reduced volume of the oropharyngeal airway. Repair involves mobilizing the lateral soft tissue and moving it toward the midline to close the cleft and elongate the palate, if necessary. The most important goal

of cleft palate repair is the attainment of normal speech. Children with unrepaired or inadequately repaired clefts develop nasal-sounding speech patterns termed rhinolalia. Cleft palate repair, therefore, usually is done when the child is 9–18 mo old, before consequential speech development. In addition to closing the cleft itself, an important goal of palate repair is normal anatomic approximation of the levator palati muscles, which are responsible for oronasal valving in speech and swallowing. The cleft palate is closed by elevating the mucoperiosteum from the underlying bones and approximating it in the midline (**von Langenbeck technique**; Fig. 12.8-7) or using a V-Y type of retrodisplacement and closure (**Wardill-Kilner technique**). In either method, the levator muscles are specifically dissected and the levator sling is reconstructed. A layered closure usually is accomplished, including repositioning of the uvular muscles.

There are several different approaches to the muscle reconstruction in the soft palate, generally termed **intravelar veloplasties.** Z-plasty of the soft palate, also called a **Furlow procedure** (Fig. 12.8-8), has been used to lengthen the palate and reorient the palatal muscles across the cleft. The other procedures basically involve direct closure of the muscles and a pushback to lengthen the palate.

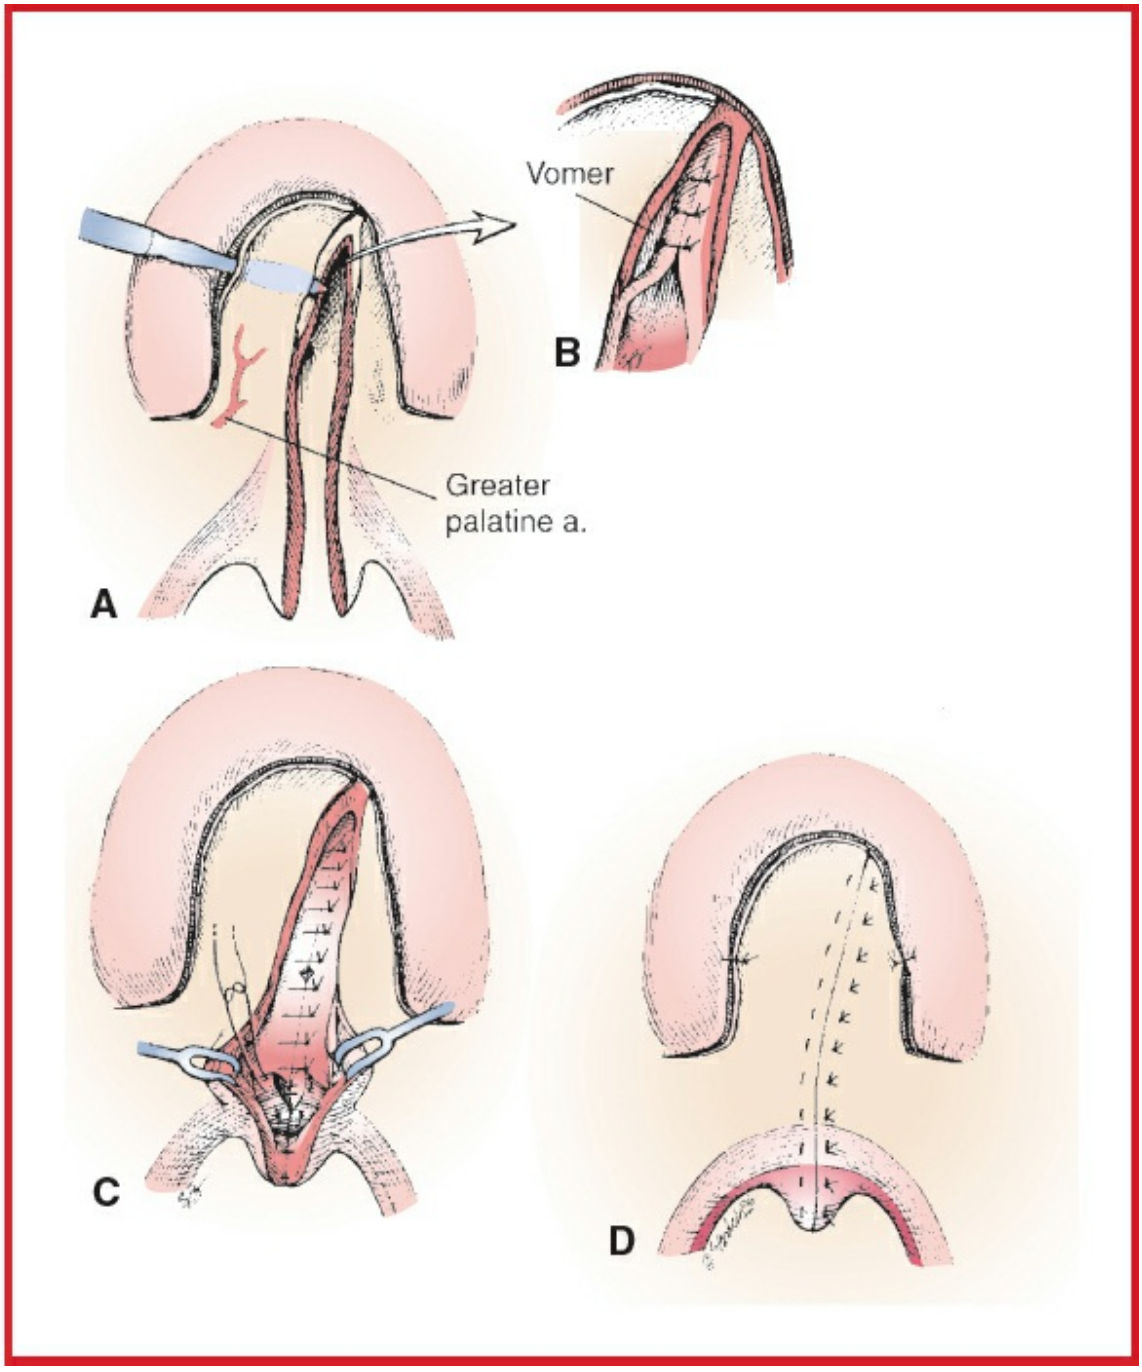

Figure 12.8-7 Palatoplasty technique. **A:** Cleft palate closure after healing of gingivoperiosteoplasty at 11–12 mo of age. Bilateral, unipedicled mucoperiosteal flaps, based on the greater palatine arteries, are elevated. **B:** Anteriorly, the nasal floor is repaired by suturing the vomerine mucosa to the nasal mucosa on the cleft side. **C:** The levator muscles are dissected free from the oral and nasal mucosa and released from the posterior edge of the hard palate. The levator muscles are approximated to each other in the midline. **D:** The oral mucosa is reapproximated in the midline with interrupted horizontal mattress sutures. (Reproduced with permission from Aston SJ, Beasley RW, Thorne CH, eds:Grabb and Smith's Plastic Surgery, 5th edition. Lippincott-Raven, Philadelphia: 1997.)

Usual preop diagnosis

Cleft palate

ERAS: **Preop family counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, carb loading, and postop pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.**

SUMMARY OF PROCEDURE	
Position	Supine; table rotated 90°–180° with oral RAE tube extending down the midline of the lower jaw and taped to the chin
Incision	Edges of the cleft palate and, possibly, the alveolar and pterygomandibular raphe areas
Special instrumentation	Dingman mouth gag (when setting the gag, communication between surgeon and anesthetist allows ETT compression to be noted early); usually, a headlight; oropharyngeal pack
Unique considerations	The gag may be released intermittently to allow reperfusion of the tongue; each manipulation may affect the ETT. Minimal-to-moderate amount of blood in the oropharynx at end of procedure should be carefully suctioned. Also, there may be some respiratory difficulties on emergence. Traction with a tongue suture often proves helpful in restoring patient's airway (maintained 24 h). Usually, oral or nasopharyngeal airways should not be placed in children.
Antibiotics	Cefazolin 30 mg/kg q5–6h (up to 1 g) × 5 d
Surgical time	1–1.5 h
Closing considerations	Child should not wake up crying and hypertensive. Tongue suture may be placed before extubation. **NB:** Dingman gag will stick to the ETT; therefore, holding the tube with a forceps deep in the oropharynx and careful removal of the gag avoid accidental extubation.
EBL	50 mL
Postop care	Elbow restraints; PACU → room; → home next day. OG tube is placed, suctioned, and removed.
Mortality	Rare

Morbidity	Recurrent bleeding (requiring early return to OR): Rare Hematoma under palate Dehiscence of palate
Pain score	4

PATIENT POPULATION CHARACTERISTICS

Age range	6–18 mo
Male:Female	1:3 (isolated cleft palate)
Incidence	1/1000
Etiology	Failure of fusion of the palatal shelves from anterior to posterior. (It can be due to a persistent high-tongue position in utero; increased facial width; reduced facial mesenchyme and/or drugs such as steroids, anticonvulsants, and benzodiazepines; or infection.)
Associated conditions	Multiple associated conditions. Most common is the Pierre Robin syndrome, in which cleft palate is found in association with glossoptosis and a micrognathic retruded mandible. These children frequently have airway obstruction and, even at an older age, may have sleep apnea. Other associations include Klippel-Feil syndrome, Treacher Collins syndrome, CHD, chronic URI, chronic otitis media, and subglottic stenosis.

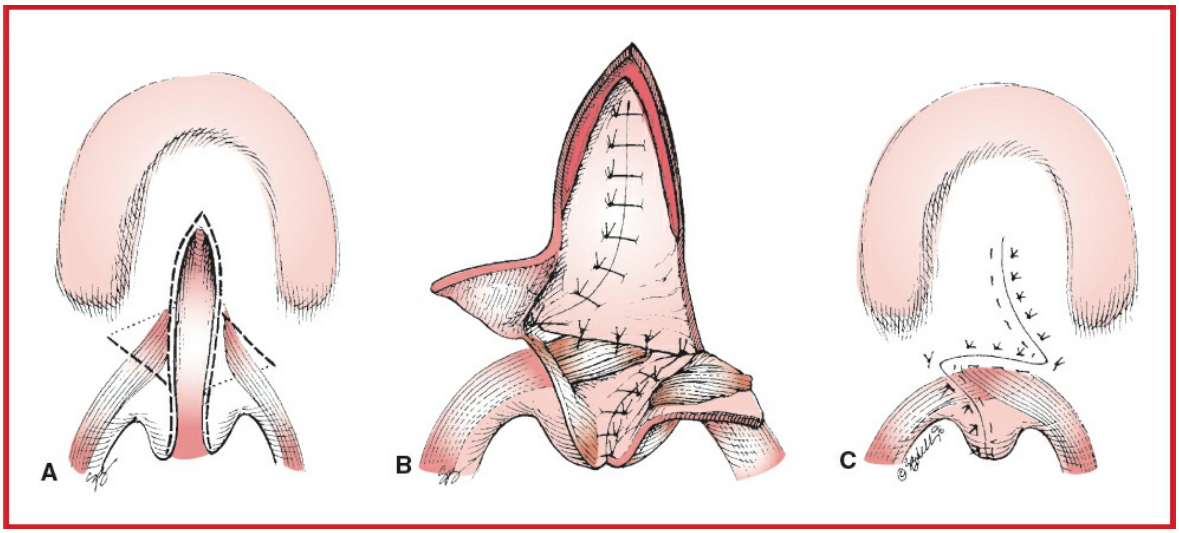

Figure 12.8-8 Double opposing Z-plasty closure of an isolated cleft palate. **A:** Design of the incisions. **B:** Muscle included in the posteriorly based flap. **C:** Final result with recreation of the levator sling. PHARYNGOPLASTY

SURGICAL CONSIDERATIONS

Description

Following the initial repair of palatal clefts, some children or young adults demonstrate continued hypernasal speech patterns, a condition called "velopharyngeal incompetence." This can be 2° a short soft palate, a large nasopharynx, or a soft palate that has inadequate movement either 2° scarring or due to neurogenic problems. The typical repair would be a palatal Z-plasty or superiorly based **pharyngeal flap** (Fig. 12.8-9) to the soft palate. The pharyngeal flap can cause later airway management problems especially with nasoendotracheal intubation.

Variant procedure or approaches

The **Jackson modification of the Orticochea flap** uses the posterior tonsillar pillars, which consist of the palatopharyngeus muscle and overlying mucosa, to create a competent oronasal sphincter (Fig. 12.8-10). The flaps are based superiorly and repositioned horizontally to meet above and behind the soft palate. Although they act to augment the posterior pharyngeal wall, they are also intended to maintain their innervation and, therefore, augment sphincter activity. A posterior pharyngeal wall implant also may be placed. Obstructive sleep apnea may be caused by these procedures and may make airway management difficult.

Usual preop diagnosis

Velopharyngeal incompetence

ERAS: Preop family counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, carb loading, and postop pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE	
Position	Supine, table rotated 90° or 180°; oral RAE tube extending down the midline chin and taped in position
Incision	Involves incisions in soft and hard palates and in the posterior pharyngeal wall
Special instrumentation	Dingman mouth gag (caution with removal and manipulation regarding ETT); headlight
Unique considerations	Avoid oral or nasopharyngeal airways or nasal suctioning.
Antibiotics + other meds	Cefazolin 30 mg/kg q4h (up to 2 g) × 3 d; periop steroids, depending on preop airway
Surgical time	1–1.5 h
Closing considerations	Pediatric patients should not become hypertensive (↑ bleeding). There will be some nasopharyngeal drainage; thorough oral suctioning is important.
EBL	50–100 mL
Postop care	Avoid postop oral or nasopharyngeal airways or nasal suctioning. Be aware of possible occlusion of nasopharynx with flap and bleeding. Tongue suture can be placed for 24 h.
Mortality	Rare
Morbidity	Recurrent bleeding

	Hematoma under palate Dehiscence of palate Nasopharyngeal obstruction Secondary sleep apnea
Pain score	4

PATIENT POPULATION CHARACTERISTICS

Age range	3–11 yr most common
Male:Female	1:1
Incidence	~15% of children undergoing cleft palate repair will need some type of secondary palatal lengthening procedure after 3 yr.
Etiology	Short and scarred palate; neurogenic palate; palate-to-pharyngeal ratio that is too small
Associated conditions	Sleep apnea; Pierre Robin syndrome, with glossoptosis and micrognathia. Treacher Collins syndrome; microtia with craniofacial malformation; subglottic stenosis; CHD. Of special interest: some patients with cleft palate may have **velocardiofacial syndrome**. These children may have **medially displaced internal carotid arteries**, placing these major arteries in harm's way during dissection along the posterior pharyngeal wall.

ALVEOLAR CLEFT REPAIR WITH BONE GRAFT

SURGICAL CONSIDERATIONS

Description

Alveolar cleft occurs as both bony and soft-tissue defects in the alveolar portion of the maxilla in the position of the lateral incisor tooth; thus, an oral/nasal fistula exists with this deformity. The size of the cleft is variable; it may be unilateral or bilateral and is associated with cleft lip and palate. The alveolar segments are often collapsed such that orthodontic expansion is required before bone graft and repair. These devices are maintained to stabilize the graft in situ for a 3-mo healing period. The surgical procedure involves raising mucosal-gingival-periosteal flaps, advancing them, and performing a layered closure, starting with the nasal floor and working toward the oral cavity. A bone graft is placed in between these two layers to consolidate the upper arch. Cancellous bone usually is taken from the iliac crest or corticocancellous bone from the outer table of the skull. Other materials may be used but more controlled studies are needed to ascertain the long-term results.

Most commonly, the bone is harvested from the ilium. This can be accomplished via limited access and a trephine or via an open technique, depending on the amount of bone required. This portion of the procedure, especially by open technique, can add 50–100 mL of blood loss. Most nasal and lip revision surgery should be put off until the alveolus is reconstructed because this is the base on which the lip and nose sit.

Variant procedure or approaches

In young children, the alveolar cleft procedure may be performed without the use of bone grafts at the time of lip or hard palate closure (**gingivoalveoloplasty**, Fig. 12.8-11) with the hope that preop alignment of the clefted alveolus, and periosteal creation of new bone will fill the bony defect and allow subsequent normal tooth eruption. This is not always complete, and some of these children will need later bone grafting at age 7–8 yr, before eruption of the permanent canine teeth.

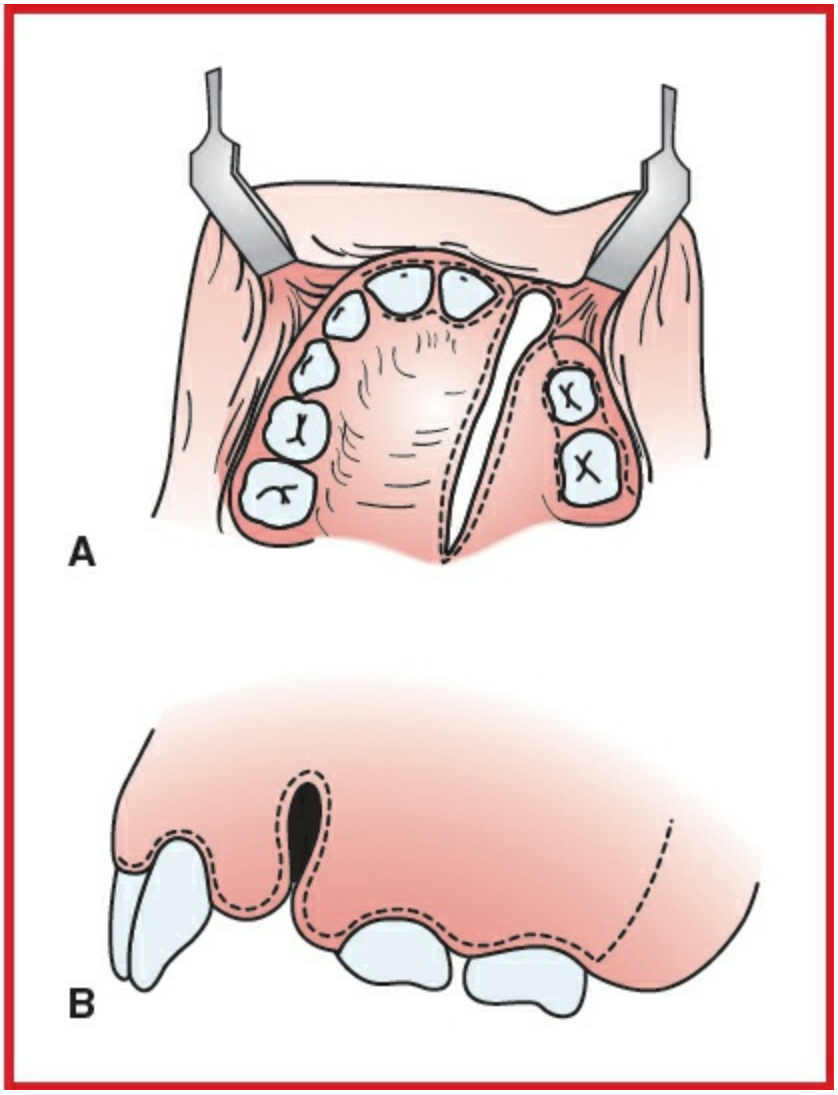

Figure 12.8-11 Gingivoalveoloplasty (GAP). Gingival and mucosal incisions are shown on the palate **(A)** and vestibular **(B)** surfaces, extending along the cleft borders. (Reprinted from Booth PW, Schendel SA, Hausamen J-E, eds:Maxillofacial Surgery, Vol. 1, 1st edition. Churchill Livingstone, Edinburgh: 1999. Copyright © 1999 Elsevier. With permission.)

Usual preop diagnosis

Congenital alveolar cleft

ERAS: Preop family counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, carb loading, and postop pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE

Position	Supine; table rotated 90°–180° ± roll under hip (bone harvest)

Incision	Oral, with the addition of iliac crest incision or scalp incision, either parasagittal or coronal
Special instrumentation	Throat pack; Dingman mouth gag; headlight. Two instrument setups are used, to prevent cross-contamination from oral to iliac surgical sites.
Unique considerations	Important to ensure that the hip iliac crest bone graft site is on the opposite side from the anesthesiologist if the table is rotated only 90°. Midline oral RAE tube to chin. Care when manipulating Dingman, as it sticks to ETT
Antibiotics	Cefazolin 30 mg/kg (up to 1 g) iv preop
Surgical time	1.5–2.5 h
Closing considerations	**NB:** Ensure that throat pack has been removed. Pediatric patients should not wake up agitated. Non–cleft-side oral mouth gag and gentle oral suctioning are permissible; avoid nasal suctioning, especially from the cleft side.
EBL	100–200 mL
Postop care	PACU → ward; walking POD 1 or 2 after iliac grafts
Mortality	Rare
Morbidity	Bone graft loss: 2–10% Infection: 2–10% Refistulization: 2–10% Prolonged hip discomfort (bone graft donor site) Bleeding—oral or at bone donor site
Pain score	6

PATIENT POPULATION CHARACTERISTICS

Age range	8–12 yr
Male:Female	2:1
Incidence	Unknown
Etiology	Multifactorial, including both genetic and environmental aspects
Associated	Associated anomalies are seen in ~29% of cleft lip

conditions	cases and may include major chromosomal deletions and/or duplications, with the possibility of severe developmental delay, CHD.

ANESTHETIC CONSIDERATIONS

See Anesthetic Considerations for Lip and Nose Surgery.

SECONDARY CLEFT LIP/NASAL SURGERY

SURGICAL CONSIDERATIONS

Description

Secondary deformities of the nose and lip develop, following the initial repair of either bilateral or unilateral cleft lip deformities. These subsequent deformities depend on the extent of the initial congenital anomaly, the quality of the surgical repair, and the resulting oral/facial function. Revision can vary from a minimal scar revision (Fig. 12.8-12) to a complete opening and reconstruction of the lip and nose, with or without ancillary procedures such as **septorhinoplasty ± cartilage grafting, forked flaps** (Fig. 12.8-13), **fascial lip augmentation, or Abbe-Estlander flap** (lip-switch flap; Fig. 12.8-14).

Occasionally, the individual born with a cleft lip and palate is severely deficient in tissue of the upper lip. This occurs most frequently in the bilateral condition. Correction involves switching tissue from the midline of the lower lip to the central portion of the upper lip, maintaining a pedicle of soft tissue between the lips, which usually contains the labial artery on one side. This pedicle normally is cut between 7 and 11 d. The redundant tissue in the midportion of the upper lip is transferred to the columellar portion of the nose at the same time, which elongates this section (Fig. 12.8-14). To avoid disruption of the flap, the older child should be cautioned to avoid wide mouth opening in the postop period.

Usual preop diagnosis

Secondary cleft deformity

ERAS: Preop family counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, carb loading, and postop pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

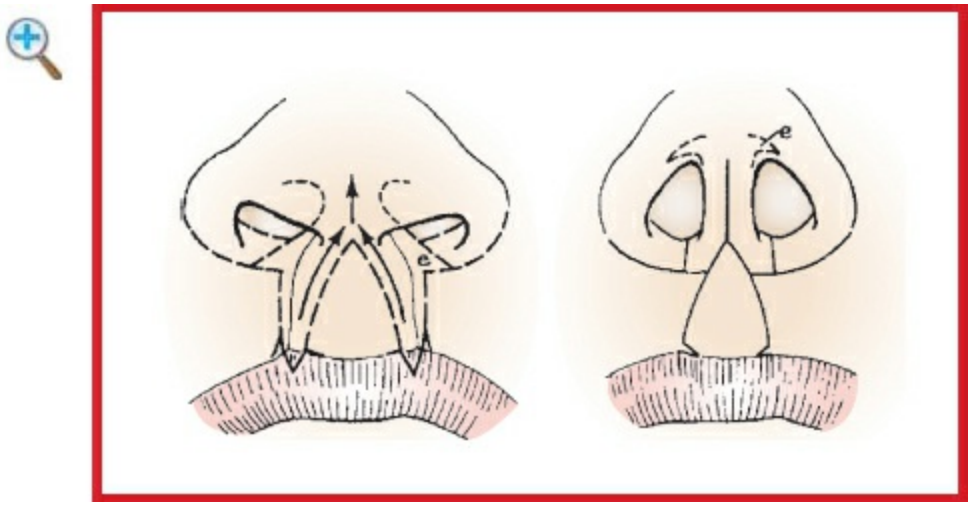

Figure 12.8-13 Short columella associated with the bilateral cleft nose, elongated by forked flaps. (Reproduced with permission from Aston SJ, Beasley RW, Thorne CH, eds:Grabb and Smith's Plastic Surgery, 5th edition. Lippincott-Raven, Philadelphia: 1997.)

SUMMARY OF PROCEDURE

Position	Supine, table rotated 90°–180°; oral RAE; nasal RAE tube when working on lips only (especially if lips are held closed by a flap pedicle, making extubation more difficult)
	Variable, in lip or nasal areas. (See Figs. 12.8-12 to 12.8-

Incision	14.)
Special instrumentation	Throat pack; possibly rhinoplasty instruments; oral RAE tube; headlight; loupe magnification
Unique considerations	Procurement of a cartilage graft is usually from the nasal septum or ear; thus, the head may need to be turned to one side and this area also prepped. Elbow restraints for children. A switch flap leaves the lips connected at their midportion by a thin, easily damaged, soft-tissue pedicle; therefore, the patient should wake up unagitated.
Antibiotics	Cefazolin 30 mg/kg (up to l g) iv preop
Surgical time	Variable, depending on the extent of revision: 0.5–3 h
Closing considerations	**NB:** Remove throat pack.
EBL	Minimal to 75 mL
Postop care	May be obligatory mouth breathing post-rhinoplasty, or lips may be held mostly closed by the pedicle and swelling of a lip-switch flap; consider oropharyngeal airway; avoid wide mouth opening. PACU → room; elbow restraints in young children.
Mortality	Rare
Morbidity	Infection Wound breakdown Flap necrosis: <1% (with lip switch) Bleeding
Pain score	3–5 (depending on extent of procedure)

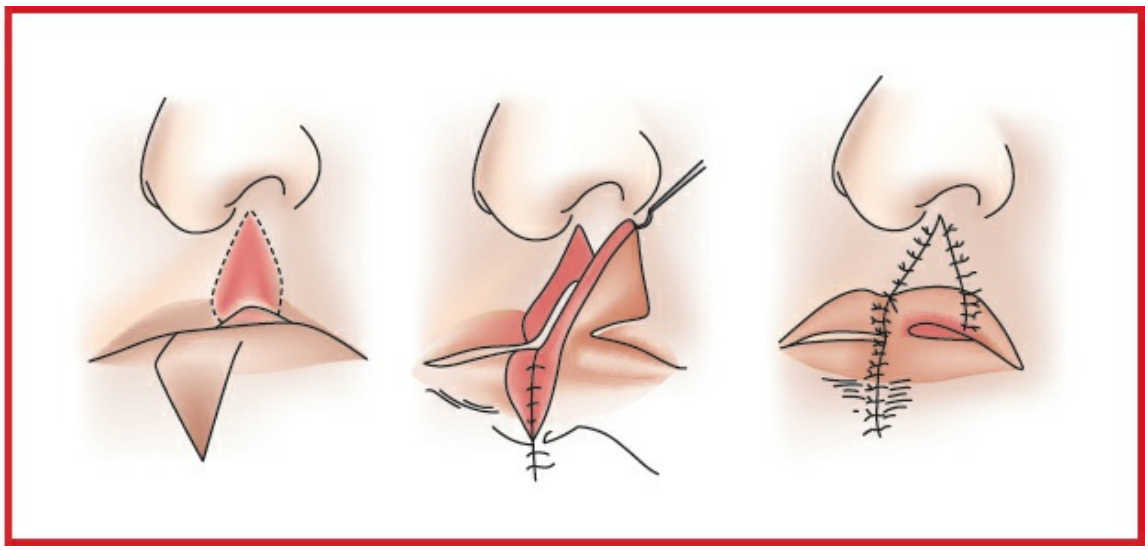

Figure 12.8-14 Abbe-Estlander flap. Note lips sutured together. (Reprinted from Converse JM, ed: Reconstructive Plastic Surgery, Vol. 3, 2nd edition. WB Saunders, Philadelphia: 1977. Copyright © 1977 Elsevier. With permission.)

PATIENT POPULATION CHARACTERISTICS	
Age range	2–50 yr
Male:Female	1:1
Incidence	20–60% of patients with primary clefts
Etiology	Unsatisfactory outcome of previous lip/nose surgery
Associated conditions	Associated anomalies are seen in ~29% of the clefts and may include major chromosomal deletions or duplications, with a possibility of severe mental retardation.

ANESTHETIC CONSIDERATIONS

See Anesthetic Considerations for Lip and Nose Surgery.

ANESTHETIC CONSIDERATIONS FOR LIP AND NOSE SURGERY

(Procedures covered: cleft lip repair; palatoplasty; pharyngoplasty; alveolar cleft repair with bone graft; secondary cleft lip/nasal surgery)

PREOPERATIVE

The anesthesiologist should be aware of the parents' feelings about their child with a congenital malformation. The whole family needs to be treated with sensitivity and compassion. Cleft lip closure may be carried out as early as the first week of life in the healthy neonate; however, many surgeons and anesthesiologists find the Kilner rule of 10 helpful: the child should have an Hb > 10 g, be 10 wk old, and weigh 10 lb. The hard palate usually is closed between the ages of 1 and 5 yr; however, the soft palate should be closed prior to speech development (12–15 mo). **Palatoplasty** and **pharyngoplasty** usually are carried out from 1 to 15 yr. Patients with these midline facial defects are most likely to have other associated anomalies, including CHD, subglottic stenosis, and Pierre Robin or Treacher Collins syndrome. In patients with severe OSA, postop edema may impair ventilation. The possibility of remaining intubated postop should be discussed with the surgical team and the family.

Respiratory	Careful assessment is necessary as associated anomalies may affect airway or lungs. Chronic otitis 2° eustachian tube dysfunction is common. Treat with antibiotics before surgery. Postpone surgery (~2 wk) if Sx of acute URI is present (e.g., runny nose, fever, sore throat, cough). Chronic aspiration may be associated with cleft lip/palate. **Tests:** As indicated from H&P
Airway	Be aware of other congenital anomalies affecting the airway, such as Apert, Goldenhar, Klippel-Feil, Pierre Robin, or Treacher Collins syndrome. Review any previous anesthetic records for insights into airway management. Consider fiberoptic intubation (FOI or video laryngoscope) in patients with suspected difficult airway. Also consider elective tracheostomy under local anesthesia in patients with severe airway abnormalities. Patients with severe subglottic stenosis may require preop tracheostomy. Patients with difficult airways or severe obstructive sleep apnea undergoing palatal surgery should be

	evaluated for ICU monitoring postoperatively.
Cardiovascular	CHD is frequently associated with cleft palate. Preop evaluation of a patient with a known or suspected heart defect should include thorough H&P, EKG, Hct, baseline O_2 sat, and CXR. For children with Sx of cardiac dysfunction or those requiring cardiac medication, it is advisable to consult with a pediatric cardiologist to optimize the patient's condition prior to surgery. **Tests:** Preop ECG, echocardiogram indicated for patients with CHD; others as indicated from H&P
Nutritional	Infants with cleft lip/palate may have problems with oral feeding. Assess nutritional status from physical exam and by comparison to expected growth for age. **NB:** NPO after midnight for solids. Patients should continue to have breast milk until 4 h preop and clear liquids up until 2 h preop.
Neurologic	Delayed development of speech is common in the older child with cleft palate. Some of these children may be hearing impaired. Preop preparation and discussion is important to minimize the impact of these communication problems.
Psychological	Many patients with orofacial congenital malformations require multiple procedures; emotional support and psychological assessment of these patients are essential. Preop visits and consultation with play-therapists can be helpful, particularly if the child with a difficult airway will need a preoperative iv.
Hematologic	High incidence of iron deficiency anemia; T&C for 1 U PRBC (cleft palate) **Tests:** Hct
Laboratory	Other tests as indicated from H&P
Premedication	<9-mo-old rarely needs premedication; >9-mo-old may benefit from midazolam (0.5–0.75 mg/kg po); alternatively dexmedetomidine 1–2 μg/kg can be

	administered intranasal. Consider parent present induction for children with separation anxiety provided no difficult airway is anticipated.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Consider preop acetaminophen 15 mg/kg po (2–12 yo).

INTRAOPERATIVE

Anesthetic technique

GETA; warm room to 75°F–80°F; forced-air warmer.

Induction	Typically, an inhalational induction (sevoflurane ± N_2O/O_2) while patient is breathing spontaneously. Airway obstruction is best treated with positive pressure and jaw thrust +/- oral airway. Anticipate difficult laryngoscopy if large, prepalatal cleft is present. Intubate with oral RAE tube and secure in midline of the lower lip. In patients with difficult airways, FOI or GlideScope/videolaryngoscope may be required. IV glycopyrrolate and nebulized local anesthetics may facilitate FOI. Include amount of nebulized local anesthetic into the calculated max allowable local anesthetic to avoid toxicity. Avoid muscle relaxants for difficult intubations until ETT is placed. For children with difficult airways and a small posterior pharynx, consider preop dexamethasone 0.5 mg/kg iv to decrease palatal edema. After induction, consider morphine 0.1 mg/kg or hydromorphone 0.01 mg/kg and iv acetaminophen 10–15 mg/kg for postop analgesia.
ERAS	Verify preincision antibiotics. Assess volume status (see D-1). Maintain normovolemia. Avoid hypothermia.
Maintenance	Standard pediatric maintenance ± muscle relaxant. Airway is shared with the surgeons. The Dingman mouth gag is used for surgical exposure and may inadvertently

	compress the ETT or cause an endobronchial intubation. Monitor PIP before and after placement of Dingman. Flexion of the neck also may cause endobronchial intubation. Extension of the neck may cause complete or partial extubation. Adequacy of ventilation should be checked after every position change. Bilateral breath sounds should be equal after final positioning. In cases with the table turned 180°, a precordial stethoscope placed over the left chest can help detect endobronchial tube migration. ETT should be sutured to the alveolar ridge in complex maxillofacial procedures. In palatoplasty, the palate is infiltrated with epinephrine (in lidocaine usually) → ↓ blood loss + ↑ dysrhythmias. Confirm maximal allowable local anesthetic dose with surgeons. Moderate risk of airway fire. Reduce FiO_2 and consider throat pack if endotracheal tube leak is substantial. Approximately 18 cm H_2O or greater if patient requires increased ventilator pressure. Throat pack insertion and removal can cause inadvertent extubation. Ensure firm airway connections prior to relinquishing airway. Always have a spare stylet ETT ready in the event of inadvertent extubation.	
Emergence	Pharyngeal (throat) packs are usually placed to prevent aspiration of blood. **NB:** Packs must be removed before extubating the trachea. Consider laryngoscopy to inspect airway and remove blood and clots before extubation. A tongue stitch is useful postop following cleft palate surgery. It may be used to pull the tongue forward to relieve postop respiratory obstruction. Extubation in the lateral (tonsillar) position is useful in promoting drainage of blood and secretions.	
Blood and fluid requirements	IV: 18–22 ga × 1 BSS @: 4 mL/kg/h—0–10 kg +2 mL/kg/h—11–20 kg +1 mL/kg/h—>20 kg	Blood loss is replaced by 3:1 crystalloid or 1:1 colloid (e.g., 5% albumin or 6% hetastarch). Rarely, a blood

	(e.g., 25 kg = 65 mL/h)	transfusion may be indicated for hemorrhage.
Monitoring	Standard monitors	
Positioning	✓ and pad pressure points ✓ eyes	
Complications	Obstructed ETT → ↑ PIP Mucous plugging Hemorrhage Airway fire	✓ ETT to see that it is not partially or completely obstructed by mouth gag. ✓ bilateral breath sounds. Inadvertent extubation/endobronchial intubation.

POSTOPERATIVE

Complications	Retained throat pack	✓ for retained throat pack if there are Sx of airway obstruction in immediate postop period.
	Airway edema → croup Hemorrhage Obstructive sleep apnea	Rx of postintubation croup consists of cool, humidified, 100% O_2 mask or nebulization 2.25% racemic epinephrine (0.5 mL in 3 mL NS). Racemic epinephrine is given for its vasoconstrictor, rather than its bronchodilator, effect. If posterior pharyngeal edema is present, consider dexamethasone 0.5 mg/kg iv.
Multimodal pain	Acetaminophen (10–15	Avoid oversedation in

management	mg/kg po/iv or 20–30 mg/kg pr) q6h Acetaminophen 10 mg/kg iv q6h ATC Lorazepam 0.01 mg/kg iv q6h ATC Consider hydromorphone RN controlled analgesia 1 mcg/kg continuous and 2 mcg/kg q10min lockout for breakthrough pain. Alternatively: Fentanyl 1 mcg/kg iv Morphine 0.05–0.1 mg/kg iv q2–3h prn Hydromorphone 0.005–0.01 mg/kg iv q2–4h Hydrocodone/acetaminophen elixir (Hycet) 0.15 mg/kg po q6h	patients with Abbe-Estlander repair 2° airway obstruction. Aim for child to be mildly sedated (decreases bleeding) but not obstructing; intraop morphine, ketamine helpful to ensure smooth awakening. Caution for airway obstruction in PACU
Tests	Hct, if indicated	Others as indicated

OTOPLASTY

SURGICAL CONSIDERATIONS

Description

There are a number of congenital ear malformations. The two most frequently encountered in the OR are **prominent ear** and **microtia.** Both conditions can be unilateral or bilateral.

Prominent ears are usually an isolated finding. The ear is examined in thirds to determine where the prominence lies, and the surgery is tailored to correct the specific excesses. The antihelical fold is usually flattened and requires reshaping. The prominence of the ear, as measured by its projection from the mastoid process, is decreased accordingly. This usually involves an elliptical skin incision in the posterior ear area, dissection over the mastoid, and one or a combination of three techniques—mattress sutures, cartilage scoring, and/or resection.

Variant procedure or approaches

All procedures are similar, with minor differences in suturing and amount of resected tissue. In addition to the posterior incisions, an anterior incision can be used in some approaches.

Microtia is within the congenital anomaly spectrum of hemifacial microsomia, and the associated facial malformation may include a small asymmetric jaw, creating a difficult intubation. Microtia reconstruction is done by two philosophically different techniques. The first is by autogenous tissue, usually rib, and is done in multiple stages. The second technique uses an alloplastic framework and is done in one longer stage. Reconstruction with autologous rib graft is a multistaged procedure. This donor site comes with the attendant risks of pneumothorax and hemothorax (Fig. 12.8-15). Stage one is the creation of a cartilaginous framework, with placement into a cutaneous pocket symmetric with the normal ear, if present (Fig. 12.8-16). Stage one is accomplished once the rib cartilage has grown to sufficient size—usually, ~6–7 yr of age. Stage two requires transposition of the lobule 3 mo after stage one. Stage three is the elevation with skin graft of the framework from the head posteriorly. Stage four is the creation of a tragus and conchal excavation.

Variant procedure or approaches

Recently, **porous polyethylene implants** have been used to avoid donor-site morbidity, and **temporoparietal fascial flaps** provide coverage to avoid alloplastic extrusion.

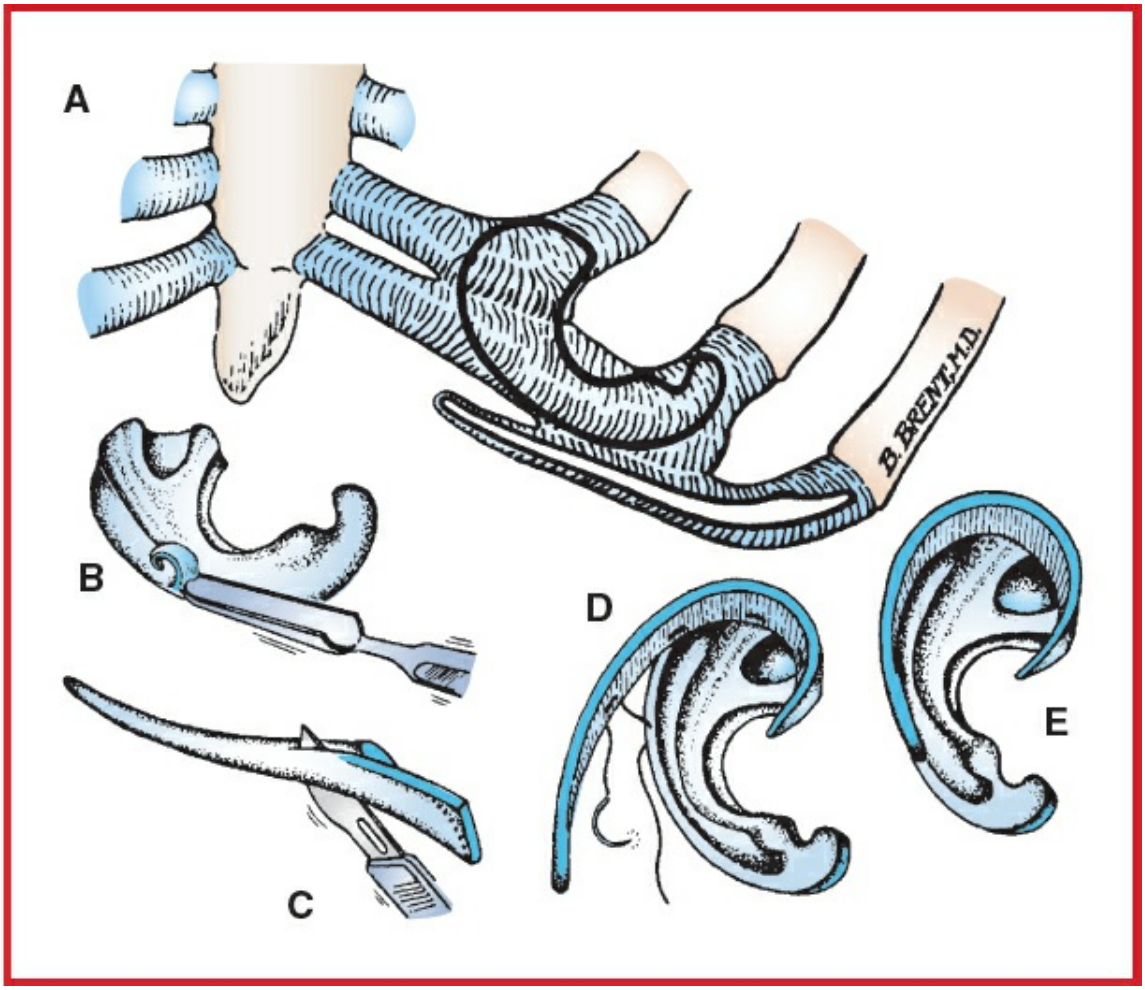

Figure 12.8-15 Fabricating an ear framework from costal cartilage. **A:** Donor site—the contralateral thorax. The helical rim is obtained from a "floating" rib cartilage, the main pattern from the synchondrosis of two cartilages. **B:** Sculpting the main block. **C:** Thinning the "floating" rib cartilage to produce a delicate helical rim. **D:** Affixing the rim to the main framework block. **E:** Completed framework. (Reproduced with permission from Aston SJ, Beasley RW, Thorne CH, eds:Grabb and Smith's Plastic Surgery, 5th edition. Lippincott-Raven, Philadelphia: 1997.)

Usual preop diagnosis

Ear malformation; prominent ears; microtia; anotia

ERAS: Preop family counseling by the surgeon/anesthesiologist should include limiting NPO duration, review of nutritional status, carb loading, and postop pain management options. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

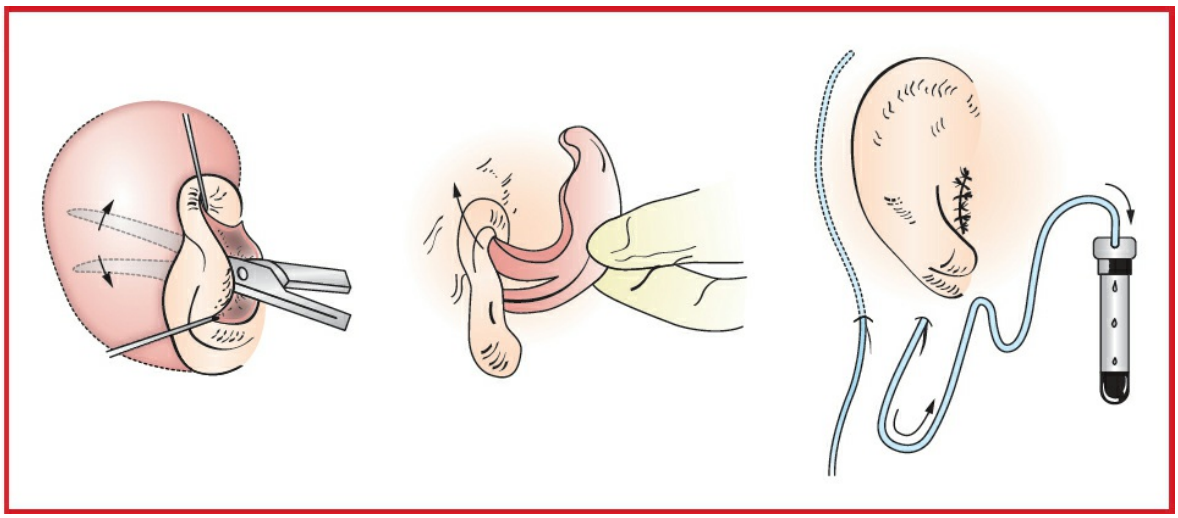

Figure 12.8-16 The cutaneous "pocket." The vestigial native cartilage is excised; then, a skin pocket is created. To provide tension-free accommodation of the framework, the dissection is carried out well beyond the proposed auricular position. Using two silicone catheters, the skin is coapted to the framework by means of vacuum tube suction. SUMMARY OF PROCEDURE

Position	Supine; table rotated either 90° or 180°; oral intubation
Incision	Posterior ear; occasionally anterior ear; microtia, stage-dependent; and chest wall
Unique considerations	Head turned from side to side during operation.
Antibiotics	Cefazolin 30 mg/kg (up to 2 g) iv preop
Surgical time	2–4 h (depends on unilateral vs. bilateral); 1st stage microtia much longer
Closing considerations	Ear dressing requires 5–10 min at the end of the procedure. Delicate vacuum test-tube drainage system in the 1st stage microtia repair fixed to head dressing.
EBL	10–100 mL
Postop care	PACU → room
Mortality	Rare
Morbidity	**Protruding ears:** Hematoma formation: <1%

	Infection: <1 % Asymmetrical ear reduction: <1% Suture extrusion <1% **Microtia:** Pneumothorax or hemothorax Hematoma, infection, and skin loss: 1.6% (total) Overgrowth: 41%
Pain score	4

PATIENT POPULATION CHARACTERISTICS

Age range	6+ yr
Male:Female	2:1
Incidence	Unknown
Etiology	**Microtia:** 9.2% bilateral; 32% left vs. 58% right; 4.9% recurrence within immediate family **Protrusion:** Also seen among family members. Most are bilateral.
Associated conditions	**Protruding ears:** none known **Microtia:** Brachial arch deformities—bone/soft-tissue deficit, 36.5%; facial nerve weakness, 15.2%; cleft lip ± palate, 4.3%; macrostomia, 2.5%; urogenital defects, 4%; cardiovascular malformations, 2.5%; others, 1.6%

PEDIATRIC RENAL TRANSPLANTATION

SURGICAL CONSIDERATIONS

Description

Renal transplantation is the therapy of choice for children with end-stage renal disease providing freedom from dialysis and improvement in growth. Preemptive transplantation is recommended when possible to minimize loss of growth potential and currently accounts for 25% of transplants. The source of the renal allograft may be a cadaveric (40%), living related, or living unrelated donor. More than 90% of donors are adults.

A right curvilinear incision, starting at the pubic symphysis and extending to just below the ribs, is the approach most commonly used even for children as small as 10 kg. The donor renal artery and vein are anastomosed directly to the recipient aorta and vena cava, respectively. An adult-sized kidney may occupy the majority of the right upper quadrant in a small recipient. Meticulous attention to the positioning of the kidney will prevent kinking or twisting of the donor vasculature. This may require mobilization of the right lobe of the liver or even hepatectomy in some cases and almost always a right nephrectomy in small children. The donor kidney can be temporarily taken out of ice

and placed into the recipient to determine the best site for the anastomoses. In this manner, the vessel length necessary to fashion straight yet tension-free anastomoses can be determined. It is important to avoid redundancy in the vessels and ensure a straight line from the renal hilum to the aorta and vena cava without the hooking of one vessel over another. The venous anastomosis is fashioned first. The vena cava is clamped, and an appropriate size cavotomy is made. The renal vein is sutured to the vena cava in an end-to-side fashion. A small vascular bulldog clamp is then applied to the renal vein above the anastomosis to allow for removal of the vena caval clamp and reconstitution of lower extremity venous return to the heart. Heparin is administered, and the aorta is then cross-clamped proximal and distal to the aortotomy. An end-to-side anastomosis is fashioned between the renal artery and aorta, taking care to interrupt the front wall sutures and prevent the purse-string effect of a running suture. Warm ischemia can be minimized during this time by intermittently placing iced slush around the kidney. It is critically important to achieve substantial hypervolemia prior to reperfusion of the adult-sized kidney (ASK) because reperfusion will cause an immediate drain of a large portion of a child's relatively small blood volume into the ASK. This necessitates bringing the central venous pressure to ~10–15 cm H_2O before reperfusion with a combination of crystalloid and colloid to minimize tissue edema. As prophylaxis against ischemia-reperfusion injury, a single dose of iv mannitol is administered at the time of graft revascularization, and low-dose dopamine is also initiated. Adequate renal blood flow to an ASK cannot be obtained in children without maintenance of a hypervolemic state, and infants and small children are frequently kept intubated for 24–48 h postop to maintain control of their respiratory function, while large volumes of fluid are administered.

The type of ureteral reimplantation depends on the quality of the recipient bladder. An extravesicular ureteral reimplantation can be considered in a healthy bladder of adequate size. This requires distending the bladder with GU irrigant via a three-way Foley catheter. The bladder is reflected medially to accomplish the implantation near the posterolateral portion of the bladder with the ureteral orifice located close to the trigone. The detrusor muscle is divided, and a mucosal-to-mucosal anastomosis is fashioned between the bladder and the donor ureter over a ureteral stent. The detrusor muscle is reapproximated over the ureter for an adequate length to create an antireflux valve. If the bladder is of small capacity or defunctionalized, a transvesicular approach to ureteral reimplantation is required. A bladder cystotomy is made at the dome, and the transplant ureter is brought into a shallow, mucosa-denuded, rectangular trough extending from a superiorly placed ureteral hiatus distally to the trigone. The ureter is then spatulated and directly sutured to the urinary mucosa over a ureteral stent. The ureteral stent is sutured to a cystotomy tube brought out through a separate incision in the

bladder for easy removal of the urethral catheter with its associated discomfort while ensuring adequate drainage and prevention of clot obstruction. The cystotomy is then closed and the kidney inspected for perfusion and hemostasis.

ERAS: Family preop counseling/education by the surgeon and anesthesiologist should include limiting NPO duration, review of nutritional status, carb loading, postop pain management options, DVT prophylaxis, physiotherapy plan, possibility of lines, NG tube, and urinary drain postop. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE	
Position	Supine
Incision	Lower quadrant curvilinear
Special instrumentation	Self-retaining retractor Vascular instruments Foley catheter (three-way)
Unique considerations	Recipient hypervolemia (CVP 10–15 mm H_2O) Mannitol, furosemide Dopamine Immunosuppression Potassium-free iv fluids
Antibiotics	Cefazolin 30 mg/kg (1 yr or older; max = 2 g)
Surgical time	3–5 h
EBL	Minimal
Postop care	Maintain hypervolemia (CVP > 10 mm Hg). Maintain adequate SBP > 120 mm Hg with dopamine. Maintain high UO with a combination of iv fluids + Lasix. Goal 150–200 cc/h ICU postop Transplant ultrasound postop
Mortality	<2%
Morbidity	Primary nonfunction: 2.6% Vascular thrombosis: 10.3% Renal artery stenosis: 0.7%

	Other technical: 1.3% Bleeding: 2% Wound infection: 5%
Pain score	7

ANESTHETIC CONSIDERATIONS FOR KIDNEY TRANSPLANTATION IN INFANTS AND CHILDREN

PREOPERATIVE

Patients presenting for renal transplantation tend to fall into two groups: (a) children in the infant/toddler age group who suffer from congenital syndromes (congenital nephrotic syndrome, severe polycystic kidney disease, obstructive uropathies, FSGS) or (b) the older child who may have a variety of conditions including severe autoimmune nephropathies. These children are often the recipients of a living-related transplant, and as such, the surgery proceeds as a somewhat elective procedure. Most patients have been on a well-established regimen of peritoneal or hemodialysis. Preemptive transplantation patients may have more severe electrolyte derangements preop than patients on dialysis.

Airway	Some renal conditions may have associated syndromes and dysmorphia. A thorough airway examination as well as perusal of old anesthetic records should reveal any potential airway problems.
Respiratory	Patients with autoimmune diseases (e.g., lupus) may have pulmonary involvement. Any patient presenting with signs and symptoms of URI should be allowed adequate time for resolution of heightened airway reactivity. Children born with large polycystic kidneys may have pulmonary hypoplasia. **Tests:** Pulmonary function tests, if indicated from H&P
Cardiovascular	Relatively long-standing hypertension and LVH can be seen in this patient population and may require bilateral nephrectomies prior to or during the transplantation. Adequate control of

	hypertension should be achieved during the preoperative admission period. **Tests:** EKG, echocardiogram
Gastrointestinal/hepatic	Patients with polycystic kidney disease may also have hepatic dysfunction and require future liver transplantation. Patients with congenital nephrotic syndrome tend to be hypoalbuminemic and may be on continuous albumin infusions. **Tests:** Albumin, LFTs, PT, PTT if applicable
Renal	Most patients are well maintained on hemodialysis or peritoneal dialysis. Other common electrolyte abnormalities are metabolic acidosis, hypocalcemia, and hypermagnesemia. Be aware of current weight relative to dry weight as some patients may present with dehydration in the postdialysis period. **Tests:** Serum electrolytes, BUN, and creatinine
Hematologic	Anemia and platelet dysfunction are commonly seen. **Tests:** CBC, platelet count
Premedication	Most children will require a premedication to allay separation anxiety. Oral midazolam 0.5–0.75 mg/kg or iv midazolam 0.1 mg/kg (maximum 2 mg) is usually sufficient.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Discuss with surgeon the possibility of regional analgesia for postop pain management. Consider preop acetaminophen 10–15 mg/kg iv or po as an elixir.

INTRAOPERATIVE

Anesthetic technique

GETA

Induction	An inhalational induction with standard monitors will work well in patients without prior iv access. Patients in the infant/toddler age group may have significant venous access problems, and the hemodialysis catheter (if present) may be used provided that sufficient heparinized blood has been aspirated from the dead space of the catheter lumen. Use of muscle relaxation once iv access has been established is necessary for adequate surgical visualization and mobilization. If recently dialyzed, pt may be hypovolemic. Induction of immunosuppression begins in the preop period and continues intraop. Care should be taken to discuss with the surgeon and nephrologist which immunosuppressive agents should be given intraop. If thymoglobulin is used, a dedicated central line port is needed, and premedication with iv Solu-Medrol (1 mg/kg), diphenhydramine (1 mg/kg), and acetaminophen (15 mg/kg) is initiated prior to infusion. Methylprednisolone (10 mg/kg) is given just prior to unclamping of the renal artery upon reperfusion.
ERAS	Verify preincision antibiotics. Assess volume status (see p. D-1). Maintain normovolemia and normothermia. Consider preincision placement of nerve blocks.
Maintenance	Standard balanced anesthetic maintenance. Titration of a long-acting narcotic is recommended, although high doses of meperidine should be avoided due to accumulation of normeperidine. Adequate muscle relaxation is especially important in the patient under 20 kg to facilitate surgical exposure. Any coughing or straining can result in vascular injury to the renal allograft. Significant hypothermia can be seen when the iced organ is placed in the peritoneum. Tachycardia is frequently seen following reperfusion of the ASK due to the relatively large vascular volume it can accommodate and the low vascular resistance. Urine output should be closely monitored postreperfusion.

Emergence	Most children weighing <20 kg remain intubated in anticipation of large fluid shifts due to volume loading. Extubation in the OR is usually feasible for patients larger than 20 kg. All patients recover in the ICU for monitoring of hemodynamics and urine output. Discuss with surgeon local wound infiltration or nerve block (e.g., TAP or rectus sheath blocks) placement.
Management of reperfusion	**Blood and fluids:** Maintenance IV fluids without K^+ Volume loading Albumin loading Blood may be required. Warm all fluids. **Pressor support** **Promoting diuresis**	Preop fluid status is variable. Maintenance fluids should be devoid of K^+. Volume loading to a CVP of 10–15 or titrated to renal allograft turgor postreperfusion is usually requested by the surgeon for infants and small children receiving ASKs to avoid stasis and thrombosis within the allograft. Albumin boluses (10 mL/kg) or PRBC transfusion may be needed to achieve goal CVP. Dopamine (3–5 mcg/kg/min) is started to increase perfusion pressure to the allograft. In addition, vasopressin or epinephrine infusions may be needed to achieve systolic blood pressure of >120 mm Hg necessary for the ASK. For patients >20 kg, the magnitude of volume loading is decreased to a goal CVP of 8–10, which can usually be achieved with crystalloid and albumin alone. Constant communication with the surgical team regarding allograft turgor after

		reperfusion will assist in guiding fluid management. Consider use of TEE in patients with hypertensive cardiomyopathy to guide volume loading to avoid pulmonary edema. Diuresis is promoted just prior to reperfusion of the renal artery with mannitol (0.5 mg/kg) and furosemide (1 mg/kg). Goal urine output after reperfusion is 5–10 mL/kg/h.
Monitoring	Standard monitors Arterial line CVP (2–3 lumens) Hct/electrolytes Urine output (Foley catheter) PIP Temperature control	Adequate blood pressure to perfuse the ASK is crucial as is sufficient preload (CVP 10–15) prior to reperfusion. Invasive arterial blood pressure monitoring is necessary to monitor beat-to-beat variation in perfusion pressure and guide in titrating volume and vasoactive infusions. CVP monitoring is critical to management of volume status. Electrolyte derangements may occur during the case 2° large-volume replacement with albumin or blood products. ↓ Ca^{++} and ↑ K^{+} should be corrected. Hematocrit goal after reperfusion is above 25% though caution should be taken with regard to

		transfusion to avoid renal artery thrombosis. Urine output is closely monitored after ureteral reimplantation. Peak inspiratory pressures should be closely followed as risk of pulmonary edema is increased from volume loading and may be a consequence of thymoglobulin infusion. Care should be taken to avoid hypothermia that may occur following placement of iced allograft into abdominal cavity.
Complications	Ventilatory difficulties Electrolyte abnormalities Hypotension/inadequate renal perfusion Low urine output	

POSTOPERATIVE

Complications	Electrolyte abnormalities Ventilatory difficulties Inadequate pain control in the face of hypotension Hemorrhage Clot retention given small catheter size	
Multimodal pain management	Fentanyl 1 mcg/kg iv Small doses of ketamine (e.g., 1–5 mg iv) can be used for analgesia if patient is intubated.	Care must be taken in the administration of iv opioids to prevent ↓ BP, which may compromise ASK perfusion.

ERAS	PONV protocol (see p. D-1)	Encourage early enteral nutrition, Foley catheter removal, and mobilization. Consider DVT prophylaxis. Chewing gum may promote return of bowel function.

PEDIATRIC LIVER TRANSPLANTATION

SURGICAL CONSIDERATIONS

Description

Liver transplantation was first pioneered in the 1960s as a lifesaving experimental procedure for children with end-stage liver disease (ESLD). Since then, it has developed into the accepted treatment modality for pediatric patients with ESLD or

fulminant hepatic failure. The indications for liver transplantation in children are broad and range from cholestatic cirrhosis secondary to biliary atresia to inborn errors of metabolism that, if untreated, result in devastating neurologic injury.

The current liver allocation system prioritizes pediatric recipients based on a calculated numerical value known as the Pediatric End-Stage Liver Disease (PELD) score. Th PELD score was validated as a model for predicting the 3-mo wait-list mortality. Although exemption points can be petitioned for on a case-by-case basis, a patient's severity of illness generally correlates with the PELD score. Absolute contraindications for liver transplantation include irreversible encephalopathy, uncontrollable infection, and untreatable extrahepatic malignancy. A general contraindication is poor quality of life postop.

The main constraint to pediatric liver transplantation compounding the preexisting organ shortage involves the donor-to-recipient size ratio. The minimum acceptable graft-to-body weight ratio to provide adequate postop liver function is 1%. However, the suitability of a donor is more often determined by the maximum amount of donor liver that a recipient can accommodate in the abdominal cavity. This results in the utilization of several different types of grafts in pediatric liver transplantation.

Type of Graft	Artery	Portal Vein	Venous Outflow	Biliary Reconstruction
Cadaveric full size	Celiac trunk	Main PV	Full VC	Main HD
Cadaveric reduced size	Celiac trunk	Main PV	Full VC	Main HD
Cadaveric left lobe	Common HA	Left PV	Left HV	Left HD
Cadaveric left lateral segment	Common HA	Left PV	Left HV	Left HD
Live donor left lateral segment	Left HA	Left PV	Left HV	Left HD

Although the type of graft used determines certain technical aspects of the hepatectomy and implantation, the general sequence of events consists of:

1. Recipient hepatectomy

2. Anhepatic phase (during which portal venous inflow and hepatic venous outflow are reconstituted)
3. Allograft reperfusion
4. Reconstitution of hepatic arterial inflow
5. Biliary reconstruction

A bilateral subcostal incision is used with a midline subxiphoid extension as needed. The abdomen is explored, and adhesions are lysed taking care to suture-ligate varices in patients with portal hypertension. This portion of the procedure may be tedious and bloody in patients with prior liver surgery. The falciform ligament is divided down to the suprahepatic vena cava. The left coronary ligament is divided, and the left lateral segment is mobilized from the diaphragm. The lesser omentum is divided and the lesser sac entered. The peritoneum of the hepatoduodenal ligament is divided, and a hilar dissection is performed. The connective and vascular tissue of the hepatoduodenal ligament is carefully divided taking care to suture-ligate any varices en masse until the common bile duct is identified. This portion of the procedure may result in significant blood loss in patients with severe portal hypertension and coagulopathy. The common bile duct is then suture-ligated and divided high in the hilum of the liver. The hepatic artery is similarly identified, suture-ligated, and divided. The portal vein is then completely skeletonized. The right lobe of the liver is mobilized from its retroperitoneal attachments to expose the lateral border of the vena cava. In the standard technique, the infra- and suprahepatic venae cavae are encircled taking care not to injure the right adrenal vein, right renal vein, or inferior phrenic veins. The portal inflow is occluded with a vascular clamp followed by occlusion of the infrahepatic and suprahepatic vena cava. At this point, the patient must have adequate circulatory volume to support the interruption of subdiaphragmatic venous return to the heart without developing vasopressor refractory hypotension. Although this degree of circulatory compromise is typically well tolerated by very young children and those with chronic portal hypertension, venous congestion can result in troublesome intestinal edema and hemodynamic compromise in metabolic patients or those with fulminant hepatic failure who lack alternative variceal pathways of venous return. Consideration should be given to a temporary portacaval shunt in such cases. The recipient liver and retrohepatic vena cava are excised, and donor liver implantation begins. In the piggyback technique, which is used in the living donor operation, the liver is completely mobilized from the retrohepatic vena cava by individually ligating the short hepatic veins draining directly from the liver to the cava. The liver is excised with preservation of the retrohepatic vena cava, and venous return can be restored prior to implantation by moving the vascular clamp to the junction of the vena cava with the hepatic veins.

The goal of the surgical team during the anhepatic phase is to minimize the duration of caval disruption with its ↑ associated intestinal edema and variceal congestion. The hepatic vein outflow is first reconstructed by fashioning the suprahepatic caval anastomosis. In the **piggyback technique**, there is no infrahepatic caval anastomosis, and an end-to-end portal vein anastomosis is fashioned next. The liver is flushed with Custodiol® solution (low K^+, buffered donor organ transplant solution) or albumin prior to reperfusion to minimize the risk of cardiac arrest 2° ↑ K^+ and ↓ pH. Venous outflow is then reestablished by removing the suprahepatic caval or hepatic venous clamp prior to opening the portal venous anastomosis. In a standard procedure, the infrahepatic caval clamp is also removed. Reperfusion is the portion of the procedure associated with significant hemodynamic lability, as large volume shifts may occur → pulmonary HTN and RV failure. Alternatively, the release of systemic inflammatory mediators may result in vasodilation and significant ↓ BP. The anesthesia team needs to be ready to pharmacologically intervene. Indiscriminate postreperfusion hypervolemia should be discouraged because CVP > 10 mm Hg can result in significant liver congestion and dysfunction. Hemostasis is achieved prior to arterial reconstruction. Patients who receive cut down or split livers performed ex vivo may have significant bleeding from the cut surface of the liver.

The donor hepatic artery is typically anastomosed in an end-to-end fashion to the recipient common hepatic artery. In situations of large size discrepancy or poor recipient hepatic artery quality, an anastomosis may be fashioned directly to supraceliac or infrarenal aorta. This requires aortic cross-clamping with its associated risk of ischemia-reperfusion injury and renal failure. The surgical team should notice the immediate production of bile and resolution of coagulopathy with clot formation in patients with a well-functioning graft. The biliary reconstruction can then be performed in an end-to-end fashion if possible but frequently requires a Roux-en-Y reconstruction. If a Roux-en-Y is performed, the bowel is divided distal to the ligament of Treitz, and the distal limb is brought up to the bile duct. Intestinal continuity is restored with an end-to-side enteroenterostomy, and a hepaticojejunostomy is fashioned to the Roux limb. Abdominal drains are typically left along the cut surface in split or cut down livers due to the increased incidence of bile leaks.

Compared to adult liver transplant, metabolic disorders account for a larger number of pediatric transplants and have some pre- and intraop considerations that are imperative to successful outcomes. Metabolic geneticists should be consulted in the preop period to assess the patient's immediate preop status and provide recommendations regarding fasting and intraop infusions to avoid precipitating a metabolic crisis during the procedure. Dual-organ transplantation, liver and kidney, is often necessary to prevent

disease recurrence.

Common metabolic disorders include:

1. **Methylmalonic acidemia (MMA):** severe uncontrollable lactic acidosis and metabolic decompensation during surgery. Both glucose and lactic acid levels should be monitored during surgery, and consideration should be given to preop dialysis if patient is to receive a combined liver-kidney transplant as MMA can cause direct damage to the renal allograft. Patients in acute MMA crisis should be medically stabilized prior to organ transplantation as it has been shown such patients are at increased risk for ventricular tachycardia during acute crises.
2. **Oxylosis:** patients should receive pretransplant dialysis to remove oxalate from body tissues so that, following liver transplant to correct the enzymatic defect, the kidney transplant will have an improved outcome.
3. **Atypical hemolytic uremic syndrome:** a combination of preop plasmapheresis and eculizumab (Soliris®) is used to minimize postop recurrence.

Posttransplant, the pediatric patient is taken to the intensive care unit. To ensure adequate hepatic perfusion and minimize risk of hepatic artery thrombosis in the immediate postop period, keep hematocrit <30% to decrease viscosity, and maintain perfusion pressure with goal MAP > 55 mm Hg. To further minimize hepatic artery thrombosis, consider antiplatelet therapy with aspirin and dipyridamole and antithrombotic therapy with dextran in the postop period once the coagulopathy has normalized as evidenced by normalization of INR.

ERAS: Family preop counseling/education by the surgeon and anesthesiologist should include limiting NPO duration, review of nutritional status, carb loading, postop pain management options, DVT prophylaxis, physiotherapy plan, possibility of lines, NG tube, and urinary drain postop. See Appendix K: Pediatric ERAS, p. K-6 to K-8.

SUMMARY OF PROCEDURE	
Position	Supine with arms tucked
Incision	Bilateral subcostal with midline subxiphoid extension as needed
Special instrumentation	Thompson liver retractor; vascular instruments; argon beam coagulator; arterial and central venous access (above and below the diaphragm); Foley catheter

Unique considerations	Hypothermia requiring covering extremities with gauze and plastic to minimize convective heat loss, active rewarming Hypoxemia secondary to hepatopulmonary syndrome Hyperkalemic cardiac arrest on reperfusion Air embolism during dissection and on reperfusion RV failure on reperfusion Pressor refractory hypotension with vena caval disruption DIC/fibrinolysis on reperfusion Severe acidosis Renal failure requiring intraoperative CRRT Coagulopathy and hemorrhage requiring massive transfusion Hypoglycemia
Antibiotics	Zosyn® (piperacillin + tazobactam) 80 mg of piperacillin component/kg every 6–8 h
Surgical time	4–6 h
EBL	300–1500 mL (1–5 U)
Postop care	Optimize hepatic artery flow with goal hematocrit <30 and mean arterial pressure >55 mm Hg. Dextran infusion and dipyridamole and aspirin for end-to-end arterial reconstructions ICU postop Monitor closely for signs of bleeding. Monitor closely for acidosis or worsening coagulopathy suggestive of graft dysfunction. Transplant ultrasound postop.
Mortality	2–5%
Morbidity	Primary nonfunction: <5% Portal vein thrombosis: 2–5% early, 10% late Hepatic artery thrombosis: 5–10% Bile leak: 10–20% Bleeding: 10% Wound infection: 5% Reoperation: 18%

Pain score	10

PATIENT POPULATION CHARACTERISTICS

Age range	0–18 yr
Male: Female	1:1
Incidence	500–600 transplants annually
Etiology	Biliary atresia, 35–40%; TPN related, 15%; metabolic diseases, 10%; acute hepatic necrosis, 10–15%; hepatoblastoma, 3%; autoimmune, 3%; congenital hepatic fibrosis, 2–3%

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Indications for liver transplant (LT) in children include (a) progressive subacute or chronic primary liver disease, such as biliary atresia, (b) metabolic disease of the liver, (c) acute hepatic failure, (d) hepatic tumors, and (e) retransplantation for hepatic graft failure. The most common disorder for which LT is performed in children is **biliary atresia**, accounting for more than 50% of patients. It is the most common cause of chronic cholestasis in infants and children. For the majority of these patients, a Kasai portoenterostomy is performed in early infancy. Even in those infants in whom bile flow is achieved, however, progressive liver failure commonly ensues, resulting in cirrhosis, portal HTN, and malnutrition. Complications include coagulopathy, esophageal varices, hypersplenism with splenomegaly and thrombocytopenia, ascites, and growth failure. Recurrent cholangitis following the Kasai procedure may lead to progressive hepatic injury and repeated hospitalizations for iv antibiotic therapy.

Children with metabolic liver disease represent the second largest group of patients presenting for LT. Some metabolic liver diseases including proximal urea cycle defects and organic acidemias result in hyperammonemia that causes neurologic injury despite having intact hepatic synthetic function and no portal hypertension. In these patients, LT has been shown to prevent further neurologic deterioration, resulting in a trend to transplant patients in infancy. Care should be taken with these patients to avoid catabolic states or acidosis that may exacerbate neurologic injuries. Coordination of care with the metabolic geneticists is critical to ensure that these patients receive the appropriate intravenous glucose and lipid infusions in the perioperative period. Other metabolic liver diseases that result in hepatic injury include Wilson disease, glycogen

storage diseases, and cystic fibrosis. In these patients, impaired hepatic synthetic function and portal hypertension may be present.

Patients with atypical hemolytic uremic syndrome (aHUS), primarily a disorder of complement regulation that is characterized by a triad of mechanical non–immune-mediated hemolytic anemia, renal dysfunction, and thrombocytopenia, may present for combined liver-kidney transplantation. Combined liver-kidney transplantation may be performed in patients with documented mutations of proteins that are synthesized in the liver where hepatic transplantation provides a possibility of cure. These patients are at high risk of graft thrombosis due to low complement factor H levels. Consult nephrologists and surgeons regarding specific perioperative protocol that includes preop plasma exchange transfusion via hemodialysis catheter to restore normal complement and regulatory factor levels, intraop FFP infusion (20–40 mL/kg) prior to liver reperfusion, and postop anticoagulation.

Respiratory	Previous prolonged intubation may have caused subglottic stenosis. Ascites, pleural effusions, and hepatosplenomegaly cause a reduction in lung volumes in children with liver failure. Intrapulmonary R → L shunting through abnormally dilated pulmonary arterioles and impaired hypoxic pulmonary vasoconstriction may cause severe hypoxemia. Pulmonary edema may result from hypoalbuminemia and iv fluid administration, impairing oxygenation as well as ventilation. Supplemental oxygen and, in advanced cases, mechanical ventilation may be required preop. **Tests:** CXR, ABG in hepatopulmonary syndrome
Circulatory	Chronic liver failure may be accompanied by a hyperdynamic circulatory state with ↓ SVR + ↑ CO. On the other hand, cardiomyopathy and/or pulmonary HTN may be present, and CO may actually be diminished. These changes appear to be less common in children than adults. **Test:** Echo
Neurologic	Hepatic encephalopathy is a life-threatening

	complication of ESLD. Causes include accumulation of toxins such as ammonia, GABA agonists, and other neuroactive substances. Cerebral metabolism and the blood-brain barrier may also be abnormal in advanced liver disease. The clinical manifestations of hepatic encephalopathy range from mild somnolence to coma. **Tests:** Head CT to assess for bleed and cerebral edema. Acute liver failure may be associated with severe cerebral edema and ↑ ICP, both of which are risk factors for severe posttransplant brain injury. The pathophysiology of cerebral edema in acute liver failure is not well understood though transplantation of a functioning hepatic graft has been shown to reverse the edema. Monitoring of ICP, hypertonic saline, and CVVH to treat hyperammonemia do not appear to improve outcomes in these patients.
Hematologic	In addition to the coagulation problems secondary to poor hepatic synthetic function, patients with ESLD may have anemia and thrombocytopenia. Anemia may arise from malnutrition and bleeding. Thrombocytopenia may be a result of splenic sequestration. Both conditions are worsened by dilutional effects from increased plasma volume. **Tests:** CBC, PT/INR/PTT, fibrinogen, thromboelastogram
Hepatic	Decreased concentrations of the vitamin K–dependent clotting factors II, VII, IX, and X may lead to severe bleeding. Deficiency of clotting factors may be caused by hepatic synthetic dysfunction as well as malabsorption of vitamin K 2° ↓ bile salts in the gastrointestinal tract or antibiotic therapy. Hypoalbuminemia contributes to low serum oncotic pressure, which predisposes to intravascular hypovolemia, interstitial edema, ascites, and pleural effusions. ESLD results in diminished hepatic drug clearance and reduced hepatic blood flow and hepatic extraction ratio.

	Tests: LFTs, albumin, bilirubin, PT/INR/PTT, fibrinogen, NH_3
GI	Gastrointestinal variceal hemorrhage in patients with portal hypertension is common. Aspiration of blood during an acute bleed can lead to pulmonary decompensation. Previous need for a Blakemore tube should be noted, and one should be available for intraop use. Large protuberant abdomen usually warrants rapid-sequence or modified rapid-sequence induction with rocuronium. Most patients are already on proton pump inhibitors, and some will be on an octreotide drip. Octreotide (a somatostatin mimic) is incompatible with most TPN solutions and usually requires a separate iv for infusion.
Renal	Most children with relative long-term hepatic insufficiency coming to transplant have chronically been on diuretic therapy for management of their ascites. This can result in severe alteration of electrolytes. Hepatorenal syndrome requiring hemodialysis or CVVH is not uncommon in acute hepatic failure. Preop discussion MUST occur with the nephrology team as to the feasibility of intraop CRRT. For small children with limited vascular access, the dialysis catheter may be needed for fluid resuscitation purposes. Communicate with the blood bank to request specific anticipated blood products that will be needed including considerations to minimize potassium load from transfusions of PRBCs (e.g., request freshest or washed units or nonirradiated units). Correction of metabolic acidosis while on dialysis is also preferred. **Tests:** Serum electrolytes, BUN, Cr
Metabolic	Many children with liver failure have severely impaired glycogen metabolism. Preop dextrose infusion (TPN) must be continued intraop. Either the TPN solution or a D25 mixture run at equivalent grams of dextrose per hour can be used. Preop

	consultation with the geneticist is invaluable in the management of complex metabolic disorders. **Tests:** Serum glucose
Premedication	IV midazolam is usually required to facilitate separation from parents. Ketamine 0.5–1 mg/kg iv is also effective in those children with paradoxical reactions to benzodiazepines. Avoid long-lasting sedative medications.
ERAS	Check compliance with presurgical ERAS recommendations (see above) including NPO status. Discuss with surgeon the possibility of regional analgesia for postop pain management.
Preop prep	Preparation of the room, including medications and iv fluids, may take 1 h. Underbody forced-air warmer and water-circulating blanket should be used because the patient is prepped from sternum to pubis. The following infusions are routinely prepared: dextrose-containing carrier, epinephrine, dopamine, vasopressin, and calcium chloride. Rocuronium and fentanyl infusions may be used. The following resuscitation medications must be readily available at a variety of concentrations: epinephrine, phenylephrine, ephedrine, and atropine. Drugs to treat hyperkalemia should be drawn up as unit doses, including sodium bicarbonate (1 mEq/kg), calcium chloride (10 mg/kg), dextrose (0.5 g/kg), and insulin (0.1–0.2 U/kg). A variety of cuffed ETTs should be ready. TEE, ultrasound to aid in vascular access, and rapid infusion systems should be available.

INTRAOPERATIVE

Anesthetic technique

GETA with postop ventilation.

Induction	Following the placement of standard monitors, a rapid-

	sequence induction with rocuronium (1.2 mg/kg) should be considered in patients with large abdominal girth from ascites causing decreased lung volumes.
ERAS	Verify preincision antibiotics. Assess volume status (see p. D-1). Maintain normovolemia and normothermia.
Maintenance	Standard maintenance with volatile agent, muscle relaxation, and fentanyl 10–50 mcg/kg. During periods of instability when vapor concentrations may be low, iv ketamine 1 mg/kg can be used. Nitrous oxide is avoided to prevent bowel distension. PEEP is useful to prevent atelectasis exacerbated by surgical retraction of the diaphragm. Antibiotics are dosed per surgical protocol. ABGs and thromboelastograms are drawn frequently to monitor electrolytes and acid-base status and aid in resuscitation. Establishment of vascular access can be very difficult and may take 1–2 h. Use of ultrasonic guidance can be helpful especially in the profoundly coagulopathic patient. Care should be taken to keep the patient warm during this period of vascular access. Major vascular access should be restricted to the SVC distribution because the IVC will be clamped. In cases of "piggyback" transplantation, the caval clamp time is usually reduced, and if vascular access is severely limited, IVC distribution veins may be used. This should be discussed with the surgical team.
Preanhepatic phase	This phase of surgery begins with surgical incision and concludes when the hepatic/portal vessels are clamped. Opening of the abdomen and drainage of ascites will often improve ventilation though placement of retractors may compromise ventilation. Blood loss during mobilization of the liver may be copious in the presence of portal HTN or adhesions from previous surgeries. Resuscitation with blood products should be guided by hemodynamics and clinical status as well as frequent lab values including ABG and TEG. Hypercoagulability should be avoided if venovenous bypass is planned (not

	commonly used in children <30–40 kg). Large variations in BP and cardiac filling pressures are common during this phase of surgery due to manipulation and rotation of the liver, which may cause intermittent kinking of the vena cava. The anesthesiologist must be constantly aware of the progress of surgery and communicate any protracted periods of hypotension due to surgical manipulation. Transfusion of blood/products may result in hyperkalemia, hypocalcemia, and hypothermia. All products need to be warmed. In patients weighing <10 kg, the freshest available packed red blood cells should be used to minimize potassium load from transfused blood products. A calcium chloride infusion (10 mg/kg/h) can be used to maintain the serum ionized calcium >1.0 and helps avoid BP changes associated with bolus administration of calcium. Hyperkalemia is treated with furosemide (1 mg/kg), correcting acidosis and infusing dextrose and insulin as required. Goals of this stage in preparation for the anhepatic phase include (a) serum potassium <3.5, (b) correction of metabolic acidosis, (c) ionized calcium >1.0–1.2, (d) adequate urine output (0.5–1 mL/kg/h), (e) adequate blood pressure at the lowest CVP possible, (f) hematocrit in the 30 range, and (g) euthermia. Mild hyperthermia may help mitigate the hypothermia created by the iced donor liver during the anhepatic phase. Frequent arterial blood-gas sampling is necessary. Hourly sampling is a minimum, and extreme blood loss may necessitate sampling every 15 min. Blood loss and third-space losses are considerable in this phase of surgery. Edema of internal organs and eventually the transplanted liver is undesirable. Closure of the small abdominal cavity with an edematous liver can cause pressure necrosis as well as abdominal compartment syndrome.
Anhepatic phase	The anhepatic phase begins with clamping of the hepatic vessels and ends with reperfusion of the donor liver.

	Problems during this phase include fibrinolysis, acidosis, and hypothermia. During the anhepatic phase, hydrocortisone (20 mg/kg) is given. Care should be taken at this point to avoid hypoglycemia as it can lead to osmotic diuresis and hemoconcentration. Communication must exist between surgical and anesthetic teams regarding the amount of bleeding present and which products should be used to treat it. Respiratory alkalosis may be desirable to compensate for existing or projected metabolic acidosis. Correct any metabolic acidosis with bicarbonate. Placement of the iced donor liver usually decreases the core temperature by 1.5°C. This coupled with preexisting hypothermia can increase coagulopathic bleeding. The anhepatic phase can be as short as 15 min or longer than 1 h depending on surgical difficulty. In the case of short anhepatic times, the metabolic goals should have been achieved in the preanhepatic phase. Anticipation and preparation for reperfusion should be ongoing. A split liver transplant usually entails more bleeding upon reperfusion, so the appropriate blood products must be present in the room. Anticipation and preparation for reperfusion should be ongoing. Reperfusion takes place after the portal vein and bicaval anastomoses are complete. In the piggyback liver transplant, anhepatic time is reduced because only the hepatic vein(s) and portal vein require anastomosis. Prior to tying the anastomotic suture, the liver is flushed to remove any air from the vessels. A 10-min warning to unclamp is usually given to the anesthesia team. Last-minute electrolyte corrections can be made. The patient is then placed on 100% O_2, low-dose epinephrine infusion (0.03–0.05 mcg/kg/min) and dopamine (3–5 mcg/kg/min) may be started, and inhalational agent should be decreased or turned off. IV midazolam or ketamine may be given to ensure amnesia.
Postperfusion phase	This phase begins with slow unclamping of the portal vein and vena cava with reperfusion of the donor liver.

Unclamping may be associated with hemodynamic instability and even cardiac arrest. Hypotension, tachycardia, dysrhythmias, hypothermia, severe acidosis, coagulopathy, and air embolism or thromboembolism can occur. During the unclamping, the anesthesiologist must simultaneously watch the uniform reperfusion of the liver as well as the blood pressure and ECG waveform. Increased T waves or widening of the QRS complex should be assumed to represent hyperkalemia. IV fluids in the form of RBCs or albumin should be ready in the event of anastomotic bleeding or bleeding from the cut edge of a split liver graft. A small dose of epinephrine (1–2 mcg), bolus of calcium chloride (10 mg/kg) and a bolus of sodium bicarbonate (1 mcg/kg) may help maintain hemodynamic stability during unclamping of the portal vein and vena cava. When giving iv fluids, watch the liver for swelling. The hepatic artery anastomosis is then completed, prior to which the surgeon may request that a dose of heparin (10 U/kg) be given.

Volatile agent can be restarted and the FiO_2 can be reduced. Blood-gas tensions and coagulation parameters should be checked 30–60 min after reperfusion to assess synthetic function of liver allograft. Care should be taken to maintain the hematocrit between 25 and 30, because relative polycythemia may lead to hepatic artery thrombosis.

The biliary system will be constructed either with a duct-to-duct reconstruction or, in cases of the small child or the patient with biliary atresia, with a Roux-en-Y choledochojejunostomy. Patients with previous Kasai procedures will have an existing Roux limb, and biliary reconstruction takes places quickly. Construction of a new Roux limb may take 1–2 h. During this time, it is important to keep up with third-space losses and avoid hemoconcentration while avoiding congestion of the liver. Vasopressors may be required to maintain MAP goals, which should be set after discussion with the

	surgeons.	
Emergence	The patient is taken to the ICU intubated and usually paralyzed to facilitate ventilation. Extubation is deferred to the ICU team. Discuss with surgeon local wound infiltration or nerve block (e.g., TAP or rectus sheath blocks) placement or reinforcement if initially placed >4 h previously. PONV prophylaxis may include dexamethasone (e.g., 30 mcg/kg) and ondansetron (0.1 mg/kg up to 4 mg iv).	
Blood and fluid requirements	Massive blood loss expected IV × 2 as large as tolerated based on age Arterial line in radial and femoral 2–3-lumen CVP line	IV access restricted to SVC distribution. Avoid hand veins for large-volume fluid administration because infiltration is difficult to detect. Two arterial lines are necessary because extreme vasoconstriction may dampen peripheral arterial line; femoral line is interrupted if aortic clamping occurs. Avoid iv solutions containing lactate. Normosol is preferred over NS due to lower sodium content. Administer blood based on hemodynamics and ABG and TEG because EBL is difficult to measure.
	Warm all fluids.	**Fluids to have available:** Normosol®, or NS, PRBC, FFP, cryo, and platelets; 5% albumin
	UO 0.5–1 mL/kg/h	Rapid infusion system if child is large
Monitoring	Standard monitors ETN_2 Arterial line × 2	Five-lead EKG. Bladder temp if child is large enough. Carefully insert nasopharyngeal temp probe.

	I-STAT CVP TEE	I-STAT® (bedside arterial blood-gas sampling) system is useful. Take care during insertion of TEE due to varices. May be difficult to use because continuous orogastric decompression is needed.
Coagulation management	PT PTT Plt count Fibrinogen FSP	Preexisting coagulopathy is very common. Coagulopathy may necessitate administration of products during line placement. Discuss use of cryo and platelets with surgical team prior to administration. Postreperfusion, treat clinical bleeding not lab values.
Positioning	Pad and protect lines. Pad pressure points. ✓ retraction devices	Wrap all stopcocks near patient. Use gel headrest to protect occiput. Check for pressure points due to surgical retraction devices.
Temperature	Warming blanket Control fluid warmers. Wrap patient.	Underbody forced-air warming. Hotline, Ranger, or rapid infusion system. The patient is wrapped with Webril® and Saran® wrap for warmth and to keep patient dry.
Complications	Coagulopathy Hemorrhage Air embolism Cardiac arrest Metabolic acidosis IV infiltration	

POSTOPERATIVE

Monitoring	Serial LFTs PT, PTT Lactate Glucose Bilirubin	Initial LFTs are quite high depending on level of preservation injury. Bile production and normal glucose level are good signs.
Complications	Bleeding Hepatic artery thrombosis Portal vein thrombosis Biliary leak Primary graft nonfunction Rejection Infection Intracranial bleed Electrolyte abnormalities Alkalosis Renal failure	Most care is deferred to the ICU team. Postop vascular ultrasounds are followed. Hepatic artery thrombosis is ominous, and patients are often relisted for transplant if this complication occurs. Hypertensive events in the coagulopathic patient can lead to intracranial hemorrhage.

ANESTHESIA FOR NON–OPERATING ROOM PROCEDURES

GENERAL COMMENTS

- Advances in the fields including radiology, cardiology, and neurology have led to a significant increase in the number of anesthesia procedures performed away from the OR. In line with these changes, the ASA has provided guidelines for the safe delivery of anesthesia at remote locations. Non–operating room anesthesia (NORA) presents significant and often unique challenges for the anesthesiologist. Compared to the general OR population, NORA patients may be less well optimized or even

medically unstable ("too sick for the OR"). The delivery of care may be urgent, while the environment in which that care must be delivered often lacks the amenities and supporting personnel available in an OR. The most common complications of NORA involve airway/respiratory events → brain damage or death, occurring approximately twice as often as in the OR. In most cases, these events were determined to be the result of substandard care and therefore preventable. NORA requires attention to detail, teamwork, and good communication to compensate for the typically resource-poor environment.

- Radiation safety is often of concern in NORA. Fluoroscopy is a significant source of radiation exposure for the anesthesiologist, and distance away from the beam source is the best protection. Six feet of air provides >99% beam attenuation, which is roughly equivalent to 0.5 mm lead (equivalent to the shielding found in heavy "lead" aprons and most shield panels). Although that degree of attenuation is impressive, given the presumed stochastic nature of radiation-induced carcinogenesis, it should not be too comforting.

Anesthetic considerations for non-OR locations (modified from ASA Guidelines) include the following:

- Complete H&P identifying any comorbidity that may require special monitoring or other precautions.
- Primary and backup O_2 sources (e.g., piped O_2 + 1 full E cylinder).
- Adequate and reliable suction.
- Adequate and reliable scavenging system (only for inhalational anesthesia).
- Self-inflating hand resuscitator bag with ability to deliver at least 90% O_2.
- Anesthetic drug supplies and administration equipment.
- Monitoring equipment to allow adherence to the "Standards of Basic Anesthetic Monitoring".
- Sufficient electrical outlets connected to an emergency power supply.
- Wet locations (e.g., cystoscopy, arthroscopy, labor, and delivery) should be equipped with either an isolated electrical source or circuits with ground-fault interrupters.
- Adequate illumination for patient observation and monitoring equipment (flashlight backup).
- Sufficient space for expeditious access to patient, machine, and support equipment.
- Emergency cart with defibrillator immediately available.
- Immediate access to skilled anesthesia support personnel.
- Provision for appropriate postanesthesia care.

ELECTROCONVULSIVE THERAPY

PROCEDURAL CONSIDERATIONS

Description

Electroconvulsive therapy (ECT) is the transcutaneous application of electrical stimuli to the brain to produce generalized seizures for the treatment of selected psychiatric disorders, such as severe depression. There are several important aspects of ECT that are of relevance to the anesthesiologist. The first is the uncontrolled motor activity associated with generalized seizures. Prior to introduction of GA, the most common injuries associated with ECT were compression fractures of the vertebral bodies and broken limbs from violent tonic-clonic motor activity. Even with complete paralysis, the masseter muscles are directly stimulated to contract during seizure induction. As a result, the most common injury currently associated with ECT is broken teeth.

A second consequence of ECT induction is that the electrical stimulus can cause contraction of scalp musculature and a brief dilation of meningeal blood vessels, resulting in postictal headaches in up to 40% of patients. Patients <50 yr and those with a Hx of migraine headaches appear most at risk for post-ECT headaches that may occasionally require aggressive pain management. Other consequences of ECT include ↓ SpO_2 especially in obese patients. The use of THRIVE has been shown to prevent desaturation in apneic obese patients undergoing ECT. Many post-ECT patients wake up agitated and require post-ECT sedation (e.g., midazolam 2 mg iv). On occasion, ECT may result in a prolonged (>2 min) seizure requiring propofol (25–100 mg) or midazolam (1–2 mg) to terminate. ECT may also be a significant hemodynamic stressor, even to the extent of causing MI with acute pulmonary edema. Initially, central parasympathetic centers are activated, resulting in ↓↓ HR in ~30% of patients. Brief sinus pauses are not uncommon. The initial parasympathetic effects are followed by sympathetically mediated increases in HR and BP up to 20–30% above baseline. Mean arterial blood pressure has been known to double in some instances. These

cardiovascular responses can persist for minutes to an hour or more after the procedure is completed.

The optimal position for ECT is supine. Occasionally, the head is kept slightly raised to help maintain an adequate airway and decrease anxiety. Patients typically come to ECT quite anxious about the procedure. ECT is generally performed in a PACU or specialized ECT suite. In many centers, outpatients make up the majority of patients seen for ECT. The electrical stimulus is applied through adhesive leads prepared with a contact gel. These leads are usually applied to the forehead in a bitemporal or right unilateral placement. Monitoring typically includes a two-lead electroencephalogram (EEG) and frequently an electromyogram (EMG) to measure motor activity. Before induction, a BP cuff is inflated to act as a tourniquet and prevent neuromuscular blockade in the distal limb. Thus, an arm or leg can be used to measure motor duration of the seizure. A special ECT device is used to generate the appropriate electrical stimulus. Seizures are typically 30–90 sec in duration, and the entire procedure—from the induction of anesthesia to patient awakening—is generally <15 min. The recovery period averages 45–90 min and allows for monitoring of vital signs, as well as the opportunity for the postictal confusion to clear. Patients can wake up mildly confused to frankly delirious and require close nursing supervision. Treatments are typically performed every other day, and the average number of treatments is 6–12 in the acute management of major depression. However, ECT treatments may be tapered rather than stopped abruptly. Thus, the frequency of treatments may go from 3/wk for acute treatment to 1/wk, 2/mo, and finally 1/mo. Maintenance ECT with a frequency ranging from every few weeks to every few months is commonly prescribed for those patients who respond to ECT but fail to benefit from pharmacotherapy.

The most common morbidities associated with ECT include headaches and myalgias. Postictal confusion is the rule, and some anterograde and retrograde memory loss occurs in most patients who have completed an acute course of ECT. Memory loss is typically confined to the period immediately before, during, and immediately after a series of ECT treatments. There tends to be a cumulative memory loss with subsequent ECT treatments within a given series. In most patients, memory deficits largely subside in the first 1–3 mo following treatments. In rare instances, autobiographical memory loss has been reported for months or years after an ECT series has been completed. Long-term memory loss appears to be more common with bilateral lead placement. ECT-related mortality is estimated at ~4/10,000. Cardiac events account for 67% of all ECT-related deaths, with malignant arrhythmias and MIs accounting for most fatalities. Pulmonary events (obstruction, pulmonary edema, or emboli) account for most additional mortality. Cerebrovascular infarctions or hemorrhages have rarely been

reported with ECT.

Variant procedure or approach: Transcranial magnetic stimulation (TMS) uses intense extracranial magnetic fields to induce intracranial electrical current flow. Although the induced currents can be sufficient to evoke motor responses, seizures are rare. Compared to ECT, TMS is painless and hemodynamically benign. Anesthesia is no required.

Usual preop diagnosis

Depression; mania; catatonia; refractory psychosis

SUMMARY OF PROCEDURE	
Position	Supine
Incision	None
Special instrumentation	Seizure generator and electrodes; EEG/EMG monitors
Unique considerations	Requires muscle relaxation to prevent injury. 50–80 mg of succinylcholine is usually sufficient. Using larger dose of succinylcholine can lead to patient waking up while paralyzed. Bite blocks are required to prevent dental injury. Apply tourniquet (e.g., BP cuff) to one arm before administration of muscle relaxant. A slow heart rate preop may require atropine. A high BP preop may require aggressive hypotensive Rx with beta-blockers, phentolamine, hydralazine, etc. If the seizure duration is not >25 sec, then another seizure may be required. Give more induction agent as needed. Because one arm is not paralyzed, asking the patient to squeeze your fingers will tell you if she/he is awake.
Antibiotics	None
Procedure time	Setup: 5–10 min Treatment: <10 min (seizure duration 25–280 sec)
Postop care	PACU → room or home
Mortality	4/10,000

Morbidity	HA/myalgias/nausea: Common Confusion/memory loss: Common. Be aware that postop hypoxia can present with confusion. Cardiac dysrhythmias: 10–40% (brief asystole common). Keep a close eye on the EKG. MI: Rare Pulmonary edema from excessive iv fluids: not uncommon. Pulmonary aspiration and/or negative pressure pulmonary edema: Rare CVA: Rare
Pain score	2–3 (HA)

PATIENT POPULATION CHARACTERISTICS

Age range	≥18 yr. ECT is rarely performed in adolescents and preadolescents; however, patients in their 90s are sometimes candidates for ECT. There is a preponderance of geriatric patients on many ECT services.
Male:Female	1:2
Incidence	The lifetime prevalence of major depression (the primary indication for ECT) is ~17%; 26% of women and 12% of men are affected. <1% of patients with major depression undergo ECT, and ~400,000 ECT procedures are performed in North America annually.
Associated conditions	Substance abuse (30% of all depressed patients meet criteria for alcohol or drug abuse); panic attacks (30% of depressed patients); psychotic symptoms (14% of patients); HTN and sinus tachycardia; dehydration; self-inflicted trauma; pregnancy

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Patients presenting for ECT usually have failed to respond to antidepressants; however, most will continue to take psychotherapeutic medications. Many older patients will be taking other medications for coexisting medical conditions. Drug interactions are an important consideration for the anesthesiologist (see Appendix F: Tables of Drug

Interactions and Recommendations for Preop Management). The most commonly used medications are listed in Table 13.1-1.

Anesthesia for ECT may seem to be a simple procedure; however, these cases—which seldom take >20 min—can prove very challenging, especially in the geriatric population. ECT can place significant stress on the cardiovascular system; therefore, particular care should be taken to evaluate and optimize the patient's pretreatment cardiovascular status. ECT usually takes place in remote locations, so the anesthesiologist must ensure that the location is properly equipped and complies with ASA Guidelines for Out-of-OR Procedures and Standards for Basic Anesthetic Monitoring.

Table 13.1-1 Commonly Used Medications in the Treatment of Depression

Tricyclic	MAOI	SSRI	SNRI and Other Antidepressants
Amitriptyline (Elavil, others)	Isocarboxazid (Marplan)	Fluoxetine (Prozac)	Venlafaxine (Effexor)
	Phenelzine (Nardil)	Paroxetine (Paxil)	Duloxetine (Cymbalta)
Amoxapine (Asendin)	Tranylcypromine (Parnate)	Sertraline (Zoloft)	Nefazodone (Serzone)
Desipramine (Norpramin)	Transdermal selegiline (Emsam)	Fluvoxamine (Luvox) Citalopram (Celexa)	Mirtazapine (Remeron) Bupropion (Wellbutrin)
Doxepin (Sinequan)	**Lithium** (often used as an adjunctive agent/mood stabilizer in depression)	Escitalopram (Lexapro)	Trazodone (Desyrel)
Imipramine (Tofranil)			**Atypical antipsychotics** (used adjunctively)
Maprotiline			Olanzapine

(Ludiomil)			(Zyprexa)
Nortriptyline (Pamelor)			Quetiapine (Seroquel)
Protriptyline (Vivactil)			Aripiprazole (Abilify)
Trimipramine (Surmontil)			Risperidone (Risperdal)
			Ziprasidone (Geodon)
			s-Ketamine (Spravato)

MAOI, monoamine oxidase inhibitor; SSRI, selective serotonin reuptake inhibitor; SNRI, selective norepinephrine/serotonin reuptake inhibitor.

Respiratory	These patients will require airway management and PPV. Hence, preop assessment of the airway must focus on the ease of mask ventilation and the potential need for ET intubation (e.g., airway compromise or severe GERD).
Cardiovascular	A recent MI (<3 mo) is a contraindication to ECT. Relative contraindications include aortic aneurysm, angina, CHF, and thrombophlebitis. The presence of dysrhythmias, a pacemaker, or ICD is not a contraindication for ECT. For the patient with a pacemaker, a means (e.g. a magnet) should be available to convert the pacemaker to an asynchronous mode. Patients on long-term anticoagulation therapy may require pre-ECT dose adjustment (target INR 1.5–2.5), or they should switch to heparin before each ECT session and return to their standard therapy post-ECT. **Tests:** As indicated from H&P
Gastrointestinal	Patient should be NPO. Patients with Sx of GERD should be pretreated with Na citrate (30 mL po), ± ranitidine (50 mg iv) and metoclopramide (10 mg iv). ET intubation should be considered for all patients at

	risk for aspiration.
Neurologic	ECT is relatively contraindicated in the presence of ↑ ICP, and recent CVA (<3 mo), intracranial mass lesions, or recent intracranial surgery (<3 mo).
Endocrine	Presence of a pheochromocytoma (Sx of which may be confused with a psychiatric disorder) is a contraindication to ECT. <1% of hypertensive patients will have a pheochromocytoma.
Genetic	✓ for family Hx of pseudocholinesterase deficiency. Rocuronium (0.6–1.2 mg/kg) reversed with sugammadex (8–16 mg/kg) is a suitable alternative to succinylcholine. **Tests:** Dibucaine number (normal ≥ 80) and serum cholinesterase level, if indicated from H&P
Hepatic	Hepatotoxicity has been associated with use of MAOI. **Tests:** Consider LFTs for patients on chronic MAOI therapy.
Orthopedic	In patients susceptible to bone fracture (e.g., severe osteoporosis, osteoporosis imperfecta), an increased succinylcholine dosage (1.5 mg/kg) is given to ensure profound muscle relaxation. Patients with severe rheumatoid arthritis may have unstable C-spine, and extreme care should be taken during positioning of head and neck.
Ophthalmologic	Retinal detachment is a relative contraindication to ECT. Succinylcholine should be avoided in patients with glaucoma treated with cholinesterase inhibitors (e.g., echothiophate). Mivacurium (0.15 mg/kg) is a suitable alternative.
Pregnancy	Pregnancy is not a contraindication for ECT (even in the third trimester). After the 4th mo, the need for full-stomach precautions requires rapid-sequence induction and ET intubation. Left uterine displacement should be maintained during treatment. Monitor fetal heartbeat.

Psychiatric drugs	Patients receiving tricyclic antidepressants (TCAs) may have an exaggerated pressor response to direct-acting sympathomimetic drugs, with the potential for tachycardia, dysrhythmias, and hyperthermia. The response to indirect-acting sympathomimetic drugs (e.g., ephedrine) may be attenuated in these patients. TCAs also will increase the effects of anticholinergic drugs (e.g., glycopyrrolate, atropine). Patients receiving MAOIs will exhibit exaggerated responses to indirect-acting sympathomimetic drugs (e.g., ephedrine). In addition, in these patients, succinylcholine metabolism is inhibited (↑ NMB), and meperidine is contraindicated (↑↑ BP, ↑ Sz, ↑↑ T). It is probably unnecessary to discontinue TCAs or MAOIs prior to ECT, as long as these interactions can be avoided. Lithium should be discontinued for at least 3 d prior to ECT to avoid delayed recovery and subsequent posttreatment agitation and confusion. Lithium also is associated with ↑ NMB (succinylcholine and nondepolarizing agents). SSRIs have been associated with prolonged ECT-induced seizure duration and adverse behavioral/neurologic effects following haloperidol administration (use droperidol and metoclopramide with caution). No adverse interactions have been reported between anesthetic agents and SSRIs or SNRIs.
Laboratory	Tests as indicated from H&P
Premedication	Although usually not required, some patients may benefit from an antisialagogue (glycopyrrolate 0.2 mg iv). Patients with Hx of postop N/V will benefit from a prophylactic antiemetic (e.g., ondansetron 4 mg iv). Patients with postseizure muscle pain and headache may benefit from ketorolac (30 mg iv). Some patients will require 500–1000 mg caffeine iv or po to decrease seizure threshold. The iv caffeine effect should be manifest in 5 min. However, po caffeine must be given 30–40 min in advance. Verapamil (not adenosine, which is blocked by

	caffeine) should be available to control supraventricular tachycardia (0.07–0.25 mg/kg over 2 min). Labetalol, hydralazine, esmolol, and diltiazem are alternative drugs for control of HR and BP.

INTRAOPERATIVE

Anesthetic technique

A review of previous anesthetic records is very helpful in formulating the anesthetic plan and in anticipating physiologic changes unique to each patient. Usually brief iv anesthesia (mask oxygenation and ventilation) with muscle relaxation (1–2 twitches) is required to prevent patient injury during seizures. Prior to induction, a tourniquet (BP cuff) is applied to the non-iv limb and inflated to a pressure above systolic. This prevents neuromuscular blockade distal to the cuff and permits direct monitoring of seizure activity. Preop BP control (e.g., labetalol 5–20 mg, diltiazem 10–20 mg iv, or esmolol 0.5–1 mg/kg iv in increments) is often necessary.

Induction	Preoxygenation should be attempted in all patients. In some patients who are intolerant of a mask, a less intrusive blow-by technique may be tried. Anesthesia is induced with propofol (1–2 mg/kg), sodium methohexital (0.5–1 mg/kg), or etomidate (0.1–0.2 mg/kg). An induction dose of etomidate will block stress-induced cortisol production for up to 24 h. Propofol (1–1.5 mg/kg) may be used, but may shorten seizure duration. TCAs and MAOIs can increase sleep time. After tourniquet inflation, succinylcholine (0.8–1 mg/kg) is injected to induce paralysis. Hyperventilation is carried out to enhance seizure activity. A bite block is placed, and then the patient is ready for ECT. In barbiturate-tolerant patients, remifentanil (1–3 mcg/kg) has been used as a means of reducing the barbiturate dose, thereby permitting adequate seizure duration. Patients receiving remifentanil need minimal postseizure BP control.
Maintenance	Given the brevity of this procedure, maintenance of anesthesia is rarely a concern; however, occasionally, a second or third treatment may be necessary if the

	seizures are of inadequate duration (<25 sec) and quality. In this case, a subsequent dose (10–30 mg) of succinylcholine may be needed. Assisted ventilation is necessary until spontaneous ventilation resumes. Of major concern during the seizure period is the hypertensive response. Some patients may need to be treated prior to induction of anesthesia with either labetalol (5–20 mg iv) or esmolol (10 mg q1min) to control HR/BP. SNP (5–50 mcg/bolus iv) is useful to control BP in refractory cases. Profound ↓ HR may occur in the immediate post-ECT period requiring atropine or a chest thump.	
Emergence	Patients should be awake within 5–10 min postseizure and often are disoriented. Small doses of midazolam (e.g., 0.25–0.5 mg iv) may help to control agitation, and blow-by O_2 may be less stimulating. ASA guidelines for postanesthesia care should be followed.	
Blood and fluid requirements	No blood loss IV: 20 ga × 1 BSS @ TKO	
Monitoring	Standard monitors Tourniquet EEG EMG Transcutaneous CO_2	Seizure activity is usually monitored by a psychiatrist observing the tourniqueted limb and by measuring EMG and EEG activity. (These monitors are usually an integral part of the ECT seizure generator.) Transcutaneous CO_2 monitoring may be useful in patients who are apneic for several minutes.
Positioning	Supine	
Complications	Dysrhythmias	Brief periods of asystole and profound bradycardia are not uncommon (usually related to

		parasympathetic overactivity). Treatment is rarely necessary.
	Tachydysrhythmias	Responds well to esmolol (10–15 mg iv) or lidocaine (1 mg/kg iv), although treatment is usually unnecessary.
	↑ BP	↑ BP readily responds to esmolol (10–30 mg) or labetalol (5–20 mg). In refractory cases, 10–50 mcg of SNP may be necessary.
	Dental damage Pulmonary edema Aspiration	Use of bite block is essential. Dental damage is not prevented by muscle relaxation (direct electrical stimulation of facial and jaw muscles).

POSTOPERATIVE

Complications	HA, myalgias	Rx: ketorolac 30 mg iv
	N/V	Rx: ondansetron 4 mg iv
	Disorientation	Rx: midazolam 0.25–0.5 mg iv
	Memory impairment	
	MI/ischemia	
	Dysrhythmias	
	Pulmonary edema/aspiration	
	↑ BP	Prolonged ↑ BP is unusual and may suggest the need for further workup.

INTERVENTIONAL NEURORADIOLOGY

PROCEDURAL CONSIDERATIONS

The indications for endovascular therapy for the brain and spine have continued to grow with the technical strides made in both devices and imaging. Endovascular therapy is now considered first-line therapy in the treatment of many intracranial aneurysms. At most centers, it is the treatment of choice for arteriovenous fistulas (AVFs) and is widely used as an adjunctive therapy for arteriovenous malformations (AVMs) and vascular tumors. Recent data have made endovascular therapy the standard of care for treatment of large vessel occlusions in the setting of acute stroke, and it is also used for the treatment of cerebrovascular stenosis. Many of these procedures can be performed with the patient awake; however, GA or deep sedation often is used to minimize patient movement during procedures that require careful catheter and device control for safe operation. The endovascular procedures used in interventional neuroradiology can be divided into three broad categories: (a) embolization, (b) aneurysm therapy, and (c) cerebral revascularization.

Embolization

This therapy may be used for a variety of lesions, including AVMs, dural AVFs, vein of Galen malformations, vascular neoplasms (e.g., meningioma), hemangiomas, glomus tumors, and juvenile nasal angiofibromas, and for treatment of epistaxis.

AVM embolization is often performed as an adjunct to radiosurgery or microsurgery, although in some settings, embolization may be the definitive treatment. Brain AVMs are generally parenchymal lesions with multiple feeding pial arteries and draining veins. A common goal of embolization is to reduce the size and shunt burden presented by the AVM before either radiosurgery or microsurgical resection. Liquid embolic agents are preferred, with n-butyl cyanoacrylate (NBCA) and ethylene vinyl alcohol copolymer (EVOH) being the most widely used materials for the procedure. Embolization often is preceded by neurophysiologic testing, which may include the superselective injection of a barbiturate into the portion of the intracranial circulation being considered for embolization. This may be accompanied by the use of somatosensory and motor-evoked potential testing. Some pre-embolization testing may be performed with the patient awake to allow for more thorough clinical testing, such as language function. However, some endovascular therapists prefer to use GETA to minimize patient motion, and it is needed when motor-evoked testing is performed.

Dural arteriovenous fistulas drain directly into dural veins or sinuses and are most commonly located in the regions of the cavernous, transverse, and sigmoid sinuses. Because of their location, these malformations are supplied by dural or meningeal arteries. They are acquired lesions but often have no clear etiology or antecedent history. Patients may have a variety of symptoms depending on the location, size, and drainage pattern of the dural fistula. Those arising in the transverse or sigmoid sinus region often present with tinnitus. Cavernous sinus fistulae often present with proptosis and ophthalmoplegia. These cavernous sinus fistulae also may be posttraumatic, developing as a direct large-hole fistula between the internal carotid artery and the cavernous sinus. The embolization process for these dural-based lesions differs somewhat from the technique used for pial-based brain AVMs. Arterial embolization may be used, but venous embolization is often used to definitively occlude the fistula. Embolization of meningeal arteries may be preceded by clinical testing for cranial nerve deficits. This usually is accomplished with the superselective injection of lidocaine before embolization, and it is often preferred to have the patient awake for this procedure. If arterial embolization is utilized, a liquid embolic (NBCA or EVOH is often utilized. Venous embolization is usually done with platinum coil occlusion.

Vein of Galen malformations are congenital lesions that may present in infancy or early childhood. Presenting symptoms include congestive heart failure (CHF)

hydrocephalus, and neurodevelopmental delay. These lesions often require a staged approach to treatment and present a special challenge in the neonate or infant. In general, arterial embolization is performed as the initial endovascular approach, and a liquid embolic agent is used. In some cases, this may be augmented by a venous approach, with embolization using platinum coils.

Tumor embolization usually is performed as an adjunct to the surgical resection of highly vascular tumors (e.g., meningiomas, hemangiomas, hemangioblastomas, glomus tumors, and juvenile nasal angiofibromas). Generally, arterial embolization of meningeal supply vessels is done before surgery, using PVA or trisacryl gelatin microspheres. Physiologic testing with superselective injection of lidocaine often precedes embolization. When there is tumor encasement of a major artery, the patient may also undergo balloon test occlusion followed by permanent occlusion to reduce the risk of intraop bleeding.

Aneurysm Therapy

Endovascular therapy is the treatment of choice for many intracranial aneurysms. The earliest method for endovascular treatment consisted of direct intra-aneurysmal obliteration, filling the aneurysm pouch with detachable platinum coils. A randomized, controlled trial using this technique showed better clinical outcome for patients treated with aneurysm coiling than surgical clipping in the setting of acute subarachnoid hemorrhage.

A spate of new devices and adjunctive techniques have extended the endovascular therapist's ability to treat aneurysms of various sizes and locations that could not be treated with coils alone. Smaller, narrow-necked aneurysms may be treated with a microcatheter through which coils are introduced directly into the aneurysm. Wider-necked aneurysms are more difficult to treat using this technique because coils may prolapse into the parent artery. In this situation, coiling may be done either with balloon remodeling or with the combined use of a stent. Balloon remodeling involves placing a balloon catheter in the parent artery over the ostium of the aneurysm. The balloon is intermittently inflated as coils are inserted to prevent coil prolapse into the parent vessel. Fenestrated stents can also be introduced into the parent artery over the ostium of the aneurysm. The aneurysm is coiled by placing a microcatheter through the stent fenestrations into the aneurysm.

The use of a flow-diverting stent in the parent artery to produce thrombosis of the aneurysm has also become widely used, particularly to treat larger wide-necked aneurysms (see Fig. 13.1-1). These stents are constructed using fine mesh self-expanding metal. They are placed in the parent artery to reduce blood flow into the

aneurysm sac resulting in gradual thrombosis of the aneurysm while maintaining flow in the parent artery. This treatment is generally reserved for unruptured aneurysms as the patients require treatment with antiplatelet agents. Recently another intra-aneurysmal device (LUNA®, Medtronic) consisting of a self-expanding and self-retaining spherical braided mesh of nitinol wires has begun to be used, particularly in aneurysms arising at arterial bifurcations.

Parent artery occlusion is still used for some giant or fusiform aneurysms but has more recently been largely replaced by the use of flow-diverting stents. Parent artery occlusion is generally done in a two-step process. Test occlusion is initially performed with a balloon-tipped catheter, and the patient is evaluated using clinical testing and neurophysiologic monitoring. The testing may be done with controlled hypotension to improve the test sensitivity. If the patient tolerates test occlusion, a permanent occlusion is usually done using coils placed into the parent artery.

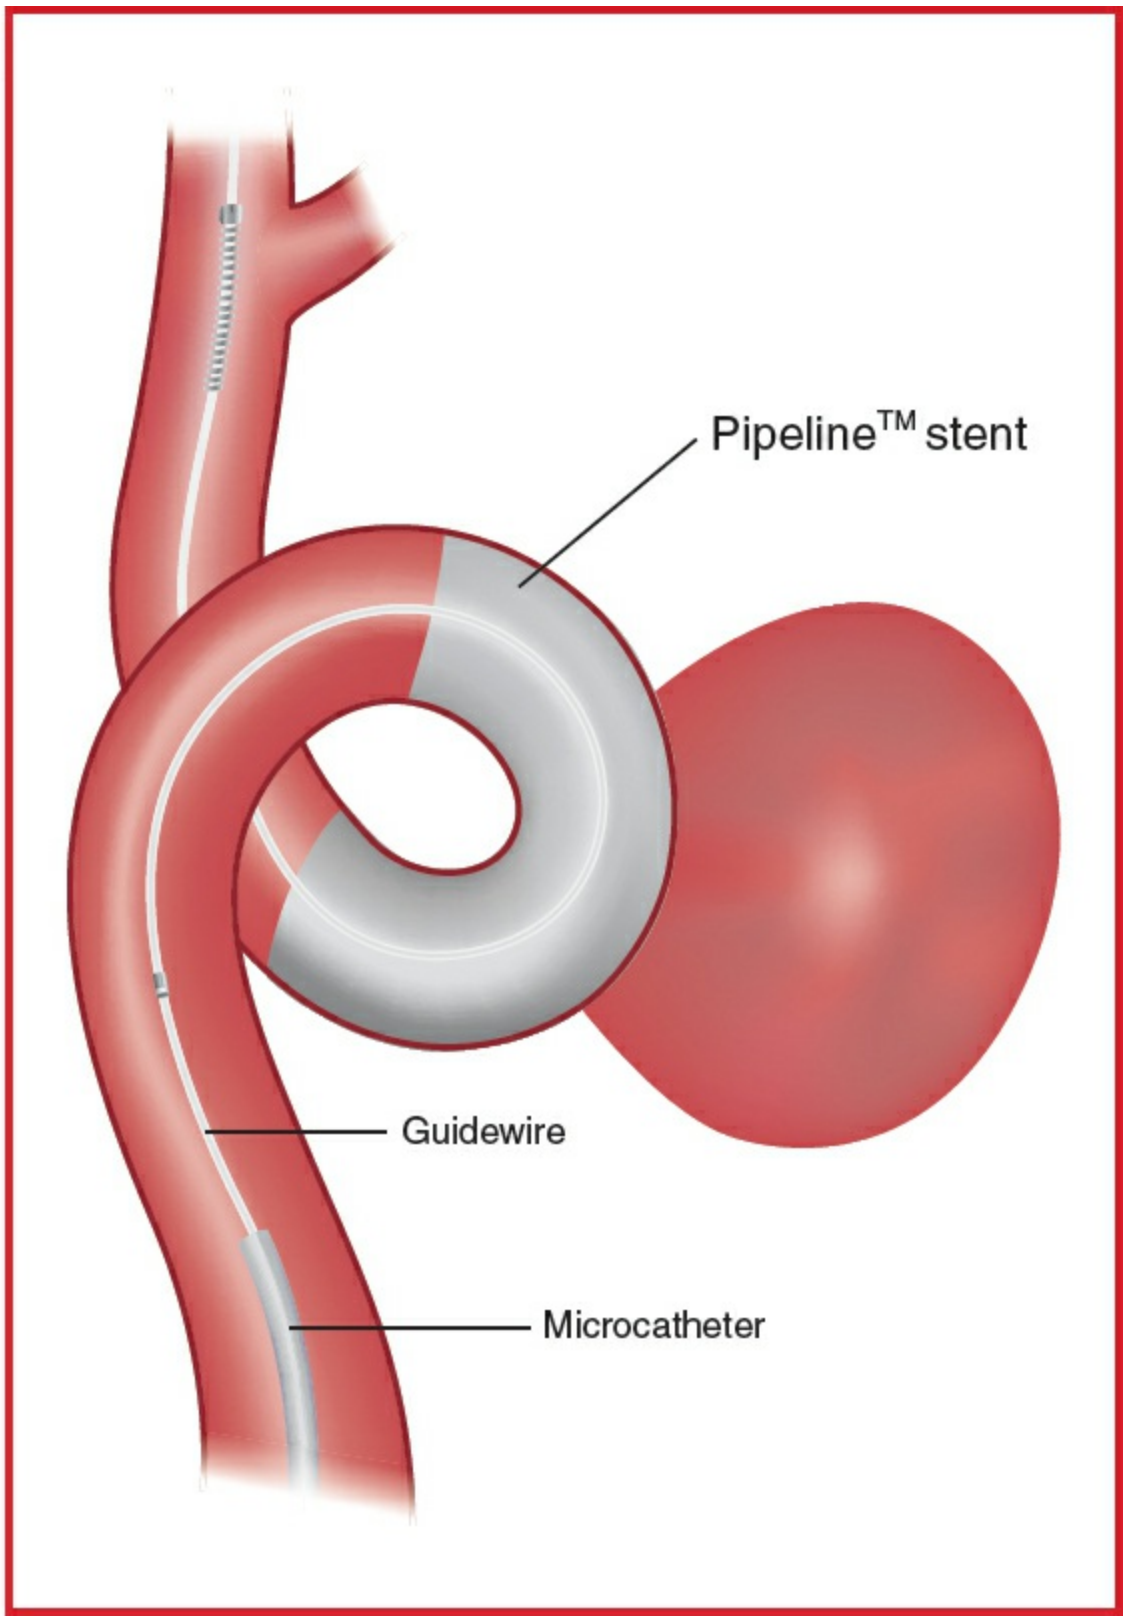

Figure 13.1-1 Example of a fine mesh, flow-diverting stent (Pipeline™) used to treat a wide-neck aneurysm.

Cerebral Revascularization

Acute stroke thrombolysis or thrombectomy is performed to recanalize larger occluded

arteries in the cerebrovascular circulation, including the internal carotid, middle cerebral, vertebral, and basilar arteries. Intravenous tissue plasminogen activator (IV-tPA) had been standard of care when the drug was administered up to 4.5 h following acute stroke onset. Randomized trials using IV-tPA beyond 4.5 h were unable to establish a benefit. In the last decade, endovascular therapeutic devices were introduced and resulted in better recanalization rates and clinical outcomes. These devices include a suction thrombectomy catheter, which can be introduced into the intracranial circulation, and retrievable stents, which are introduced into the thrombus and after entrapping the thrombus are pulled from the circulation. The devices may be used alone or in combination. Recently, five separate randomized trials have shown that endovascular therapy improves outcomes over IV-tPA alone or standard medical therapy in a 6 h (up to 24 h in selected patients) time window with endovascular therapy now being the standard of care for large artery occlusions. Physiologic imaging with either computed tomography (CT) or MR is used at many centers to select patients who will benefit from treatment in these more extended time windows. General anesthesia has become less widely used in these cases as several retrospective studies have suggested better outcomes for patients who are awake during stroke thrombectomy. Unfortunately, these studies are confounded by selection bias, and randomized control trials have not been performed.

Angioplasty and stent placement for symptomatic atherosclerotic stenosis in the cerebrovascular circulation are becoming more widely performed in lieu of medical or direct surgical therapy. Stents with distal protection devices have now been approved for the treatment of cervical carotid artery stenosis. Distal protection devices (e.g., balloon or basket devices) have been shown to reduce the thromboembolic complication rate and are now required for treatment in most cases. A recent large multicenter trial of both symptomatic and asymptomatic carotid stenosis patients found that the composite risk of stroke, myocardial infarction, or death did not differ significantly between stented patients and those undergoing endarterectomy. However, a 2017 systematic review suggests that endarterectomy is the best option for management of asymptomatic carotid stenosis. Arterial stenosis located more distally and intracranial stenotic lesions are treated with angioplasty alone or are stented following angioplasty. There are no efficacy data available for these more distal lesions, and a recent trial of stenting versus medical therapy for intracranial stenosis found that medical therapy had lower rates of stroke and death.

Transcarotid artery revascularization (TCAR): This procedure uses retrograde flow for embolic protection during carotid stent placement. Device placement requires direct access to the affected common carotid artery (CCA) through a small supraclavicular

incision. Dissection is carried down to the CCA, a loose ligature is placed around the CCA and adventitial purse string stitches are placed around the perimeter of the anticipated puncture site. The CCA is punctured and a guide wire is inserted, followed by a dilator and catheter. The CCA is clamped under direct vision, and reverse flow is initiated from the internal carotid artery through a 200 μm filter to a previously placed femoral vein cannula. Transcarotid stent placement then proceeds in the usual fashion with the reversed carotid flow flushing any procedure related embolic debris to the filter for capture.

This procedure can be accomplished with GA or local anesthesia (field block) placed by the surgeon. As usual, with the procedure MAC the anesthesiologist should be prepared to control hemodynamics (art line useful), airway and patient cooperation. ACT goal is 250–300 sec. Some patients will not tolerate the loss of antegrade flow requiring rapid conversion to GA and prompt completion of the procedure.

Vasospasm often accompanies subarachnoid hemorrhage and results in ischemic complications, which are a common cause of morbidity and mortality following aneurysmal rupture. The endovascular therapist is often asked to treat this problem with either drugs or balloon angioplasty. Direct administration of intra-arterial vasodilators, such as verapamil, nimodipine, or nicardipine, has been used particularly for treatment of more distal spasm. More proximal spasm involving the arteries of the circle of Willis is often treated using high-compliance angioplasty balloons.

SUMMARY OF PROCEDURES

	Embolization	Aneurysm Therapy	Cerebral Revascularization
Position	Supine	⇐	⇐
Incision	Femoral artery, catheterization (may utilize brachial or radial artery)	⇐	⇐
Unique considerations	BP control; AVM; anticoagulation; EP monitoring	BP control; ± EP monitoring; anticoagulation	⇐

EBL	Minimal	⇐	⇐
Postop care	Ward or ICU × 24–48 h	ICU	Ward or ICU
Mortality	1–2% (vascular lesions)	⇐	⇐
Morbidity	Overall: ~5% Thromboembolic stroke Hemorrhage (AVM, AVF)	⇐ ⇐ SAH	⇐ ⇐ Vessel rupture/dissection
Pain score	1–2	1–2	1–2

PATIENT POPULATION CHARACTERISTICS	
Age range	Neonatal–elderly
Male:Female	1:1
Etiology	Congenital; acquired (traumatic, infectious, degenerative, etc.)
Associated conditions	SAH ± vasospasm; ↑ ICP; HTN/CAD/PVD; blood dyscrasia

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Patients presenting for diagnostic neuroradiologic procedures may require only local anesthesia and sedation. The newer nontoxic and low osmolality contrast agents have improved patient comfort and tolerance for these procedures while minimizing adverse reactions. Patients presenting for therapeutic neuroradiologic procedures may be restless or uncooperative and, therefore, may require GA to tolerate these often lengthy procedures. The advantages of GA, however, must be balanced against the potential

need for interactive neurologic monitoring (e.g., speech, vision, and mental status assessment) that requires the patient to be awake and cooperative. In this case, close consultation among the neuroradiologist, monitoring neurologist, and anesthesiologist is required in formulating the anesthesia plan. In many cases, time is of the essence, and any delay may reduce favorable outcome.

Respiratory	Access to the airway may be limited; therefore, examination should focus on the need for elective ET intubation. Patients with chronic cough may require GA to ensure immobility. **Tests:** As indicated from H&P
Cardiovascular	Patients with recent intracranial hemorrhage may demonstrate ECG abnormalities (PVCs in 30–80%; ST-T wave changes in >50%), which need to be differentiated from new ischemic heart disease (echo, cardiac enzymes). **Tests:** ECG; other tests as indicated from H&P
Neurologic	Symptoms vary with the location, size, and type of lesion. Aneurysms seldom produce neurologic symptoms unless they leak or rupture, whereas tumors are commonly associated with symptoms of ↑ ICP (HA, N/V, altered mental status, papilledema). Patients with recent cerebral hemorrhages are likely to be medicated with calcium channel blockers (e.g., nimodipine, nicardipine) to ↓ arterial vasospasm. Patients with ↑ ICP or cranial trauma usually will need GETA and mechanical ventilation.
Premedication	Preop sedation may mask the Sx of ↑ ICP or intracranial hemorrhage. Patients at high risk for contrast-media reactions (e.g., patients with previous contrast reaction, allergy to iodine) should receive prophylactic treatment usually consisting of prednisone, 50 mg po q6h × 3, starting 18 h before the study, and diphenhydramine, 50 mg po, 1 h before the procedure.

INTRAOPERATIVE

Anesthetic technique

MAC may be adequate for patients undergoing diagnostic procedures and necessary for patients requiring neurologic assessment during more invasive procedures; otherwise, use GETA or be prepared to rapidly convert to GETA during the procedure. Although several reports suggest that patients receiving GETA for neurointerventional procedures have worse outcomes compared to those receiving sedation, these observations are not based on randomized controlled studies and are inherently biased since the patients most likely to require only sedation are also the most likely to be stable and uncomplicated at the time of the procedure.

Induction	Standard induction. Patients with ↑ ICP should be hyperventilated to an $ETCO_2$ of ~30 mm Hg. In patients with vascular lesions that may leak or rupture, BP responses to laryngoscopy and intubation should be blunted (e.g., remifentanil: 3–5 mcg/kg iv 1–2 min in advance).	
Maintenance	Standard maintenance. Muscle relaxation is usually mandatory to control ventilation and minimize the chance of movement. Maintain normocapnia, although hyperventilation may be necessary to ↓ ICP and may also enhance the quality of the angiogram. Heparin (ACT goal: 250–350 sec; $t_{1/2}$ = ~30 min) may be requested. Protamine should be immediately available.	
Emergence	Prompt awakening is important to permit neurologic evaluation. Ondansetron (4 mg iv) is useful to ↓ PONV. Extubate when airway reflexes have returned after reversal of muscle relaxant. Continuous control of BP may be necessary during emergence phase. Patients typically are transported to ICU immediately following the procedure.	
Blood and fluid requirements	IV: 18 ga × 1–2 BSS @ 3–5 mL/kg/h	Avoid glucose-containing solutions unless the patient is hypoglycemic (<70 mg/dL).
Monitoring	Standard monitors	BP can be monitored from

	Arterial line Urinary catheter	femoral line placed by radiologist. However, another arterial line often will be necessary for postop monitoring in the ICU. Place urinary catheter if procedure is lengthy (>3 h).
	± neuromonitoring	Keep isoflurane or sevoflurane <0.5 MAC and N_2O <50% to minimize interference with EP monitoring. Supplement with remifentanil infusion as necessary. TIVA may be requested in the erroneous belief that motor or sensory EPs cannot be obtained while using inhalational agents.
	Glucose	Keep serum glucose 70–140 mg/dL. Use insulin infusion to control hyperglycemia.
Control of BP	SNP (0.2–2 mcg/kg/min) Maintain normovolemia. Esmolol (50–200 mcg/kg/min)	BP control may be necessary during intracranial catheter manipulation, embolization, and postembolization. Optimal BP management remains unclear. Close communication with the radiologist is important. In general, in patients with acute ischemic stroke, keep SBP 140–180 mm Hg. In acute hemorrhagic stroke, lowering SBP to 140 mm Hg is recommended. SNP/esmolol may be necessary and can be infused through a second peripheral

		iv. Clevidipine (1–21 mg/h; $T_{1/2}$ = 5–15 min) can be used in place of SNP ($t_{1/2}$ = <2 min), although it is significantly more costly (2019).
Positioning	✓ and pad pressure points ✓ eyes	X-ray table may not be well padded → nerve damage.
Complications, contrast related	Common reactions: N/V Itching Urticaria Sensation of warmth Pain Anxiety Rash	These reactions occur in >5% of patients and may require no treatment apart from reassurance or a mild anxiolytic. Mild allergic reactions may be treated with diphenhydramine 25–50 mg iv. Monitor patients for progression of Sx → need for more aggressive therapy.
	Neurotoxic Sx: Hemiplegia Blindness Aphasia ↓ consciousness	These reactions may be related to the hyperosmolarity of the agent. If persistent, procedure should be terminated. Rx may require steroids, and vasopressors to improve perfusion. In the anesthetized patient, these Sx will be masked.
	Major allergic reactions: Bronchospasm ↓ BP Cardiac arrest Pulmonary edema Laryngeal edema Dysrhythmias	Epinephrine (0.25–0.5 mg iv) should be given immediately for severe reactions. **Rx of anaphylaxis** includes the following: eliminate antigens (e.g., contrast agent, latex); secure airway; administer 100% O_2, iv fluids,

		epinephrine, and diphenhydramine + ranitidine. Supplemental Rx may include steroids (e.g., hydrocortisone 5 mg/kg), atropine, $NaHCO_3$, vasopressin, and epinephrine infusion.
Complications, other	Hemorrhage	Reverse heparin (e.g., 1 mg protamine/100 mg heparin after 30–60 min). Intracranial bleeding may require immediate transport to OR for surgical repair.
	Vasospasm	Rx: vasodilators (e.g., NTG or papaverine) delivered by catheter, or balloon angioplasty.
	Occlusion of vessel	Deliberate hypertension may be beneficial. Rx: angioplasty. (Recanalization and stenting may be used for thrombotic occlusions.)

POSTOPERATIVE

Complications	Neurologic deficits	CT scan for evaluation, as prompt neurosurgical intervention may be required.
	Vasospasm	May require Ca^{++} channel blocker (e.g., nimodipine). Consult with neurosurgeon.

DIRECT CURRENT CARDIOVERSION

Bing Liem

PROCEDURAL CONSIDERATIONS

Description

Direct-current (DC) cardioversion is a treatment for various cardiac arrhythmias (e.g., atrial fibrillation [AF], atrial flutter [AFL], other supraventricular tachyarrhythmias [SVT], or, rarely, slow ventricular tachycardia [VT]) that uses a brief, dosed discharge

of electricity across the heart. Depending on the seriousness of the arrhythmia (with respect to its effect on hemodynamic stability), cardioversion to restore normal rhythm may be performed emergently or electively (Fig. 13.1-2).

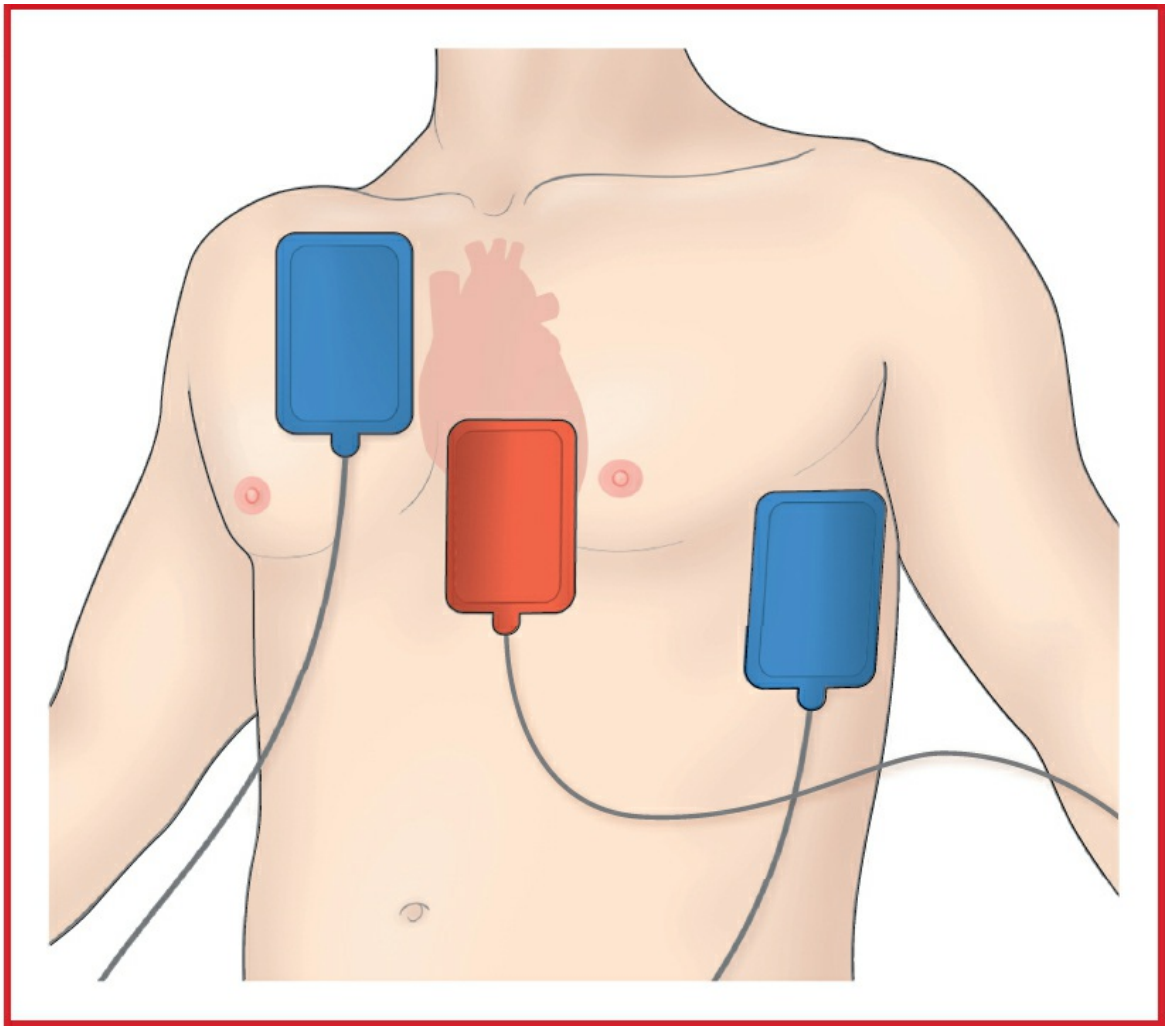

Figure 13.1-2 Positions of defibrillation pads are shown; the AP positions in red and anterolateral in blue. (Modified from Lynn P. Taylor's Clinical Nursing Skills, 5th edition. Wolters Kluwer, Philadelphia: 2019, 970.)

Unlike emergent shock, which is typically performed for ventricular fibrillation (VF), elective cardioversion should always be performed with the patient under deep sedation or brief GA to avoid discomfort. The shock energy is delivered across the heart either from an external source (a defibrillator unit) or internally (from a previously implanted ICD/CRT-D). External cardioversion requires placement of a pair of pads that should be positioned to ensure current flow through the heart. The most common positions are anteroposterior (AP) and basilar-apical/anterolateral (right shoulder and left lateral chest). In one randomized study, the AP position was shown to be more effective than the anterolateral position. Biphasic waveform shock energy is typically 25–200 J (25–

100 J for AFL and SVT and 150–200 J for AF). Most external defibrillators deliver a maximum of 200 J. Special units can deliver up to 360 J, for circumstances requiring higher energy (e.g., very large patients or patients with severe hypertrophic cardiomyopathy). Monophasic waveform is no longer used. When internal cardioversion is performed, the implanted unit is typically set to deliver its full energy (30–40 J biphasic waveform). In either case, the shock is delivered synchronous with the QRS complex as to avoid the vulnerable electrical period (during the T-wave, which may risk induction of VF). In patients with implanted devices (pacemaker [PM] or ICD/CRT-D), the pads should be placed at least 6 inches away from the implanted generator to avoid potential damage to the implanted system. The implanted device should be interrogated before and after the procedure. If unsuccessful, cardioversion may need to be repeated using higher energy, using an alternate pad positions or after infusion of ibutilide (class III agent) to lower defibrillation threshold. If the arrhythmia immediately recurs, cardioversion is repeated after infusion of an antiarrhythmic drug to promote maintenance of normal rhythm.

Usual preop diagnoses: AF, AFL, SVT, and slow VT along with underlying cardiovascular diseases such as hypertension, cardiomyopathy (ischemic or nonischemic), valvular disease(s) (most commonly mitral valve regurgitation), and congenital heart disease(s).

SUMMARY OF PROCEDURE	
Position	Supine with defibrillator pads positioned AP or anterolateral
Unique considerations	In patients with AF, adequate anticoagulation: INR = 2–3 for those on warfarin and uninterrupted use for those on target-specific oral anticoagulants (NOAC) for at least 3 wk prior; otherwise, TEE should be considered to rule out left atrial thrombus.
Antibiotics	None
Procedure time	≤30 min
Postop care	Monitoring of cardiac rhythm in treatment room
Mortality	0.1%
Morbidity	Skin burns: <15% (1st degree); <2% (2nd degree); lesser incidence with biphasic waveform Embolic event: 2% (↑ risk with mitral valve disease)

	Acute pulmonary edema: 1% More serious arrhythmia: 1% Myocardial damage: Incidence unknown, but estimated to be very low—proportional to delivered energy
Pain score	2–3

PATIENT POPULATION CHARACTERISTICS

Age range	All ages
Male:Female	3:1 male predominant but no recent statistics available
Incidence	100,000/yr in the United States
Etiology	Reentry arrhythmia substrates (e.g., AF, AFL, SVT, VT) from hypertensive heart disease, cardiomyopathy (ischemic or nonischemic); idiopathic.
Associated conditions	Systolic or diastolic heart failure, CAD, cardiomyopathy, HTN, valvular heart disease, COPD, obesity, CVA, diabetes, obstructive sleep apnea, obesity

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Patients presenting for cardioversion fall into one of two categories: elective or emergent. The presence or absence of hemodynamic instability will define the category. In the emergency patient, full-stomach precautions may be necessary. Elective cardioversions usually are carried out on patients who have failed drug therapy. In patients with recent onset AF, optimal timing for cardioversion is reported to be 24–48 h after onset.

Respiratory	Preop evaluation of the airway should focus on the need for elective ET intubation (patients with GERD, difficult mask fit, or airway compromise).
Cardiovascular	Relative contraindications to elective cardioversion include ↓ K^+, inadequate anticoagulation, presence of β-blockade, AV block, and rare digitalis toxicity (toxic = >3 ng/mL). The presence of significant CHF, CAD,

	or valvular disease may predispose this patient population to ↓↓ BP in response to anesthetic agents. Consider use of etomidate (0.1–0.2 mg/kg). Patients at ↑ risk for an embolic event include those with Hx of embolization within 2 yr, mitral stenosis, intra-arterial thrombus, CHF, or hyperthyroidism. In these patients, ensure adequate anticoagulation (PT 1.5–2 × baseline, INR 2.0–3.0). It has been suggested that NTG patches near the electrodes be removed prior to cardioversion to avoid risk of explosion. **Tests:** ECG; TEE (✓ for thrombus and size of atrium); digitalis level (toxic = >3 ng/mL → refractory VF following cardioversion); electrolytes; INR
Endocrine	Hyperthyroidism → AF
Gastrointestinal	Full-stomach precautions may be necessary in the emergency patient.
Neurologic	✓ Hx for TIAs or CVAs → ↑ risk of embolic event. Pre- and postprocedure neurologic exams should be done.
Hematologic	✓ need for anticoagulation (see above).
Laboratory	Other tests as indicated from H&P
Premedication	Usually not needed. For the emergency patient, take full-stomach precautions.

INTRAOPERATIVE

Anesthetic technique

Brief GA with mask oxygenation and ventilation

Induction	Preoxygenate patient. For many patients, etomidate (0.1–0.2 mg/kg iv) is the agent of choice (**NB**: etomidate-induced clonus → ECG artifact). Propofol (1.0–1.5 mg/kg iv slowly) until loss of lid reflex can be used in hemodynamically stable patients but may be associated with slower recovery. Supplemental analgesia

	may be provided by fentanyl (e.g., 0.5–1 mcg/kg preinduction) or remifentanil (1–2 mcg/kg), thereby reducing anesthetic requirements.	
Maintenance	Occasionally necessary to repeat cardioversion. Additional small doses of propofol, etomidate, or remifentanil may be required.	
Emergence	Patients should awaken rapidly with full recovery of airway reflexes. Outpatients are usually discharged to home within 1–2 h.	
Blood and fluid requirements	No blood loss IV: 20 ga × 1 NS/BSS @ TKO	
Monitoring	Standard monitors	Avoid placement of ECG electrodes in precordial area.
Positioning	Hospital bed, supine	Procedure takes place at patient's bedside.
Complications	Loss of airway	Use airway manipulation ± artificial airways; always be prepared to intubate.
	VF	Use ACLS protocols.
	↑↑ BP/myocardial ischemia	Cardioversion → catecholamine surge → acute MI in susceptible patient population.
	Severe bradycardia	Rx: atropine (e.g., 0.4 mg iv)
	Thermal injury	Ensure good electrode/skin contact.
	↓ CO	2° anesthetic drugs or myocardial stunning from cardioversion. Rx: inotropic support (e.g., ephedrine)

POSTOPERATIVE

Complications	Recall	Especially in hemodynamically fragile patients. Discuss possibility with patient in advance.
	Systemic embolization	Neurologic exam should be repeated postcardioversion.
	↓ BP/↓ CO/CHF new dysrhythmia	Atrial contraction may not be effective following cardioversion → ↓ CO/↓ BP.
	Renal dysfunction	Incidence: 17%. ✓ renal function labs.
Pain management	Minimal	Myalgias not uncommon; consider iv ketorolac.
Tests	ECG	Verify NSR.

IMPLANTATION OF CARDIOVERTER-DEFIBRILLATOR (ICD) OR CARDIAC RESYNCHRONIZATION THERAPY DEFIBRILLATOR

(CRT-D)

PROCEDURAL CONSIDERATIONS

Description

The implantable cardioverter-defibrillator (ICD) is an effective device for the prevention of premature death from VT or VF. The results of randomized clinical trials involving survivors of cardiac arrest and those considered at risk for sudden death showed the superiority of ICD therapy over conventional medical therapy in lowering the incidence of sudden death and overall mortality. Hence, ICD therapy has become the gold standard for patients considered at risk for sudden death (primary prevention) or those with a history of spontaneous or inducible sustained VT/VF (secondary prevention). Since its inception in 1983, there have been significant advances in ICD technology. The more efficient biphasic shock waveform allows for a much lower defibrillation threshold and, hence, a lower required energy delivery, which, in turn, allowed for dramatic reduction in the generator's size and the need for epicardial electrodes. Furthermore, the firmware now provides significantly broader spectrum in functionality. Newer devices can incorporate the full capabilities of a permanent pacemaker along with resynchronization therapy (see below), the ability to differentiate VT from SVT, and deliver antitachycardia pacing for VT or shock for VF. Therapy for atrial tachyarrhythmias (atrial tachycardia and flutter) with atrial overdrive pacing is also available in select devices. The need for GA in ICD implantation has been diminishing and deep sedation is required mainly during defibrillation threshold testing (DFT). DFT (Fig. 13.1-3) may be unnecessary since clinical trials have shown that ICDs rarely fail in defibrillating VF and, furthermore, that unnecessary ICD shocks are associated with negative cardiovascular outcomes, including increased overall mortality. Thus, deep sedation or GA is necessary only for patients with other cardiovascular and pulmonary comorbidities.

A new ICD system using entirely subcutaneous approach for the lead and generator placement is now available (Fig. 13.1-4). The lead is implanted subcutaneously along the sternum and the generator placed in the lateral chest. The need for DFT with this system is higher than for the standard ICD; hence, deep sedation or GA is required.

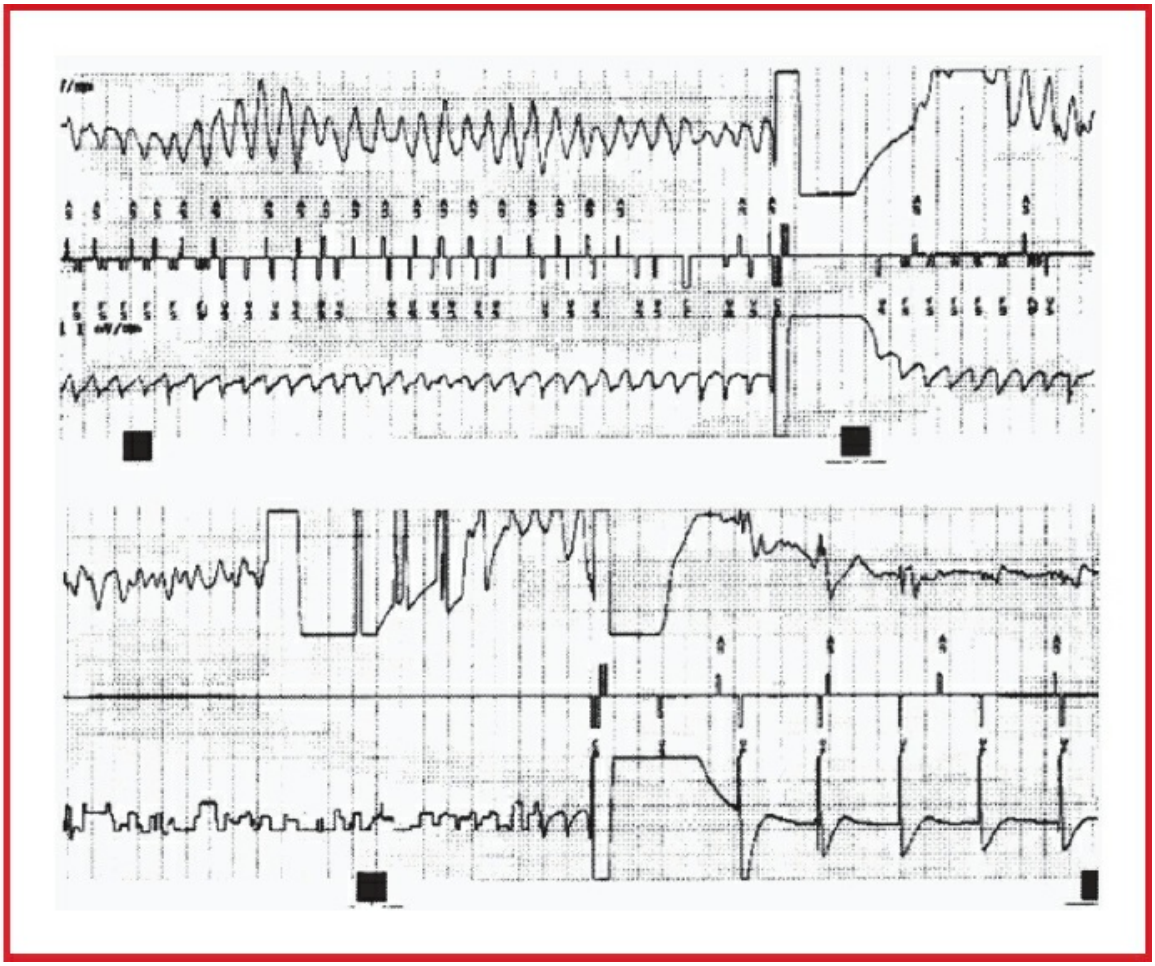

Figure 13.1-3 Induced VF (with underlying AF) is shown on top panel, whereby the first (24-J) shock failed to terminate VF but terminated AF (as indicated by the ICD annotation). The second shock (34-J) terminated VF, resulting in V-paced rhythm with underlying sinus and AV block. Total downtime during VF was 16 sec. Downtime is dependent on the detection time and charge time, which, in turn, depend on the energy programmed.

Cardiac resynchronization therapy (CRT) was developed for symptomatic systolic heart failure (HF) patients with electrical and/or mechanical dyssynchrony, typically an intraventricular conduction delay (e.g., LBBB) causing a mechanical dyssynchrony → systolic inefficiency. Resynchronization of right and left ventricular (LV) depolarization requires implantation of a LV lead into one of the tributaries of the coronary sinus in addition to the other standard pacing leads. The LV lead placement can increase the procedure time significantly, and combined with the more compromised underlying systolic function, monitored deep sedation or GA may be the more appropriate approach for this procedure.

Usual preop diagnosis

Documented, induced, or high-risk VF; moderate-severe heart failure

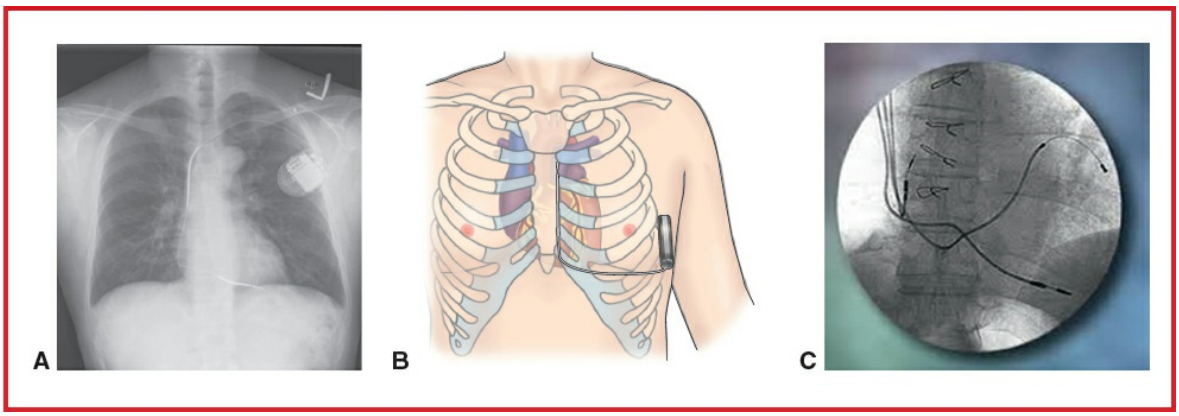

Figure 13.1-4 Shown here is **(A)** the radiograph of a single-lead ICD with dual-coil system, **(B)** subcutaneous ICD system (Modified from Hinkle JL, Cheever KHBrunner & Suddarth's Textbook of Surgical Nursing 14th edition. Wolters Kluwer, Philadelphia: 2018, 697.), and **(C)** the leads in a CRT system.

SUMMARY OF PROCEDURE

Position	Supine with defibrillator pads positioned AP or basilar-apical
Incision	Left pectoral
Special instrumentation	ICD pulse generator, lead(s), and testing system (manufacturer specific)
Unique considerations	VT/VF induction with associated ↓ CO, ↓ BP
Antibiotics	Cefazolin 2 g iv
Surgical time	1–2 h (more for ICD with cardiac resynchronization [CRT-D])
Closing considerations	Routine subcutaneous/submuscular pocket closure
EBL	5–20 mL
Postop care	Monitoring of arrhythmia, pocket bleeding/hematoma, pneumothorax
Mortality	0.1% (transvenous); ≤5% (thoracotomy)
Morbidity	New-onset arrhythmias: ≤5% Pneumothorax: ≤5% (transvenous) Pericardial effusion/tamponade: ≤1% (transvenous)

Pain score	3 (6–9, thoracotomy)

PATIENT POPULATION CHARACTERISTICS	
Age range	Any
Male:Female	Male preponderance
Incidence	>50,000/yr in the United States
Etiology	Reentry substrates from remote myocardial fibrosis, channelopathies (e.g., Long QT and Brugada syndromes)
Associated conditions	LV dysfunction; CAD; cardiomyopathy; HTN; valvular disease

EXTRACTION OF PACEMAKER AND IMPLANTABLE CARDIOVERTER-DEFIBRILLATOR (ICD) LEADS

PROCEDURAL CONSIDERATIONS

Almost all PM and ICD systems are implanted utilizing endovascular lead(s). Thes leads have excellent longevity, typically beyond 25 yr, and hence in the case of a PM implantation for sick sinus syndrome (SSS), most patients will not need a lead "replacement" procedure. However, in younger patients (e.g., PM implantation in the pediatric population and ICD implantation in the young athlete), "replacement" may become necessary. Unfortunately, some leads may undergo premature degradation due to a manufacturing deficiency. In the majority of lead "replacement" (now more

commonly called "revision") procedures, the simple addition of a new lead will suffice, but in some cases where multiple leads are already present, a "debulking" procedure is necessary to avoid vascular congestion or unwanted lead-to-lead interaction. Hence, removal of some, or all, of those leads would be necessary. In some cases (e.g., refractory sepsis or bacteremia), lead removal is considered mandatory. There are other rare scenarios where lead removal is at least strongly recommended. Examples include progressive tricuspid valve regurgitation that is suspected to be caused by the presence of multiple RV leads and where the presence of multiple leads has caused SVC syndrome.

Leads that have been implanted for longer than 1 yr are likely to have adhered to the adjacent vascular wall or endocardial surface. Adhesion sites are typically located in the subclavian vein, the junction of the innominate vein and SVC, along the SVC, the tricuspid valve, and the RV tissue (Fig. 13.1-5). Therefore, removal of chronic leads typically requires fibrotic tissue cutting tools in the form of telescoping sheaths. The forward advancement of the sheaths is done either by manual force or with the aid of thermal tissue ablation (using LASER or radiofrequency [RF] heating). The areas at the junction of the innominate vein and the superior vena cava and along the superior vena cava are of concern in terms of risks for vascular tear because the sheath may not conform to the lead angulation. In utilizing any of these methods, vascular injury is inevitable and may result in transmural tear with rapid exsanguination. Thus, lead extraction procedures should be performed with complete preparation for immediate **emergency sternotomy** with a surgical team on active standby. For these reasons, GETA is a necessity. In addition, the patient should be prepped and draped for possible sternotomy and surgical instruments, and a CPB machine should be in the room with the perfusionist team nearby. Blood products should also be immediately available. Vascular access should be large bore and a central line is advisable. Continuous blood pressure monitoring via an arterial line is mandatory and continuous TEE or standby TTE should be used. The surgical approach of the procedure is similar to a standard implantation or pulse generator change. The patient will have continuous ECG monitoring and external defibrillator/PM pads applied. The pulse generator is removed from the pocket as usual and the leads are released from encapsulation. For the patient who is PM dependent, a temporary PM is mandatory. The temporary PM lead should be placed through a venous entry other than the one being used for the extraction. If temporary pacing support is expected to be necessary for several days or weeks (e.g., in the case of an infected system when reimplantation is delayed), it has become customary to utilize a permanent PM lead with an active fixation, as this will provide more reliable backup pacing. The lead is connected to a permanent PM generator securely taped against the skin, thus improving patient ambulation. The right IJ venous entry is the

best route for placement of this "temporary-permanent" pacing system. In the event of incomplete lead removal, retrieval of the remnant is best done using a femoral approach. Several retrieving tools, such as snares and baskets (Fig. 13.1-6), are available in the market.

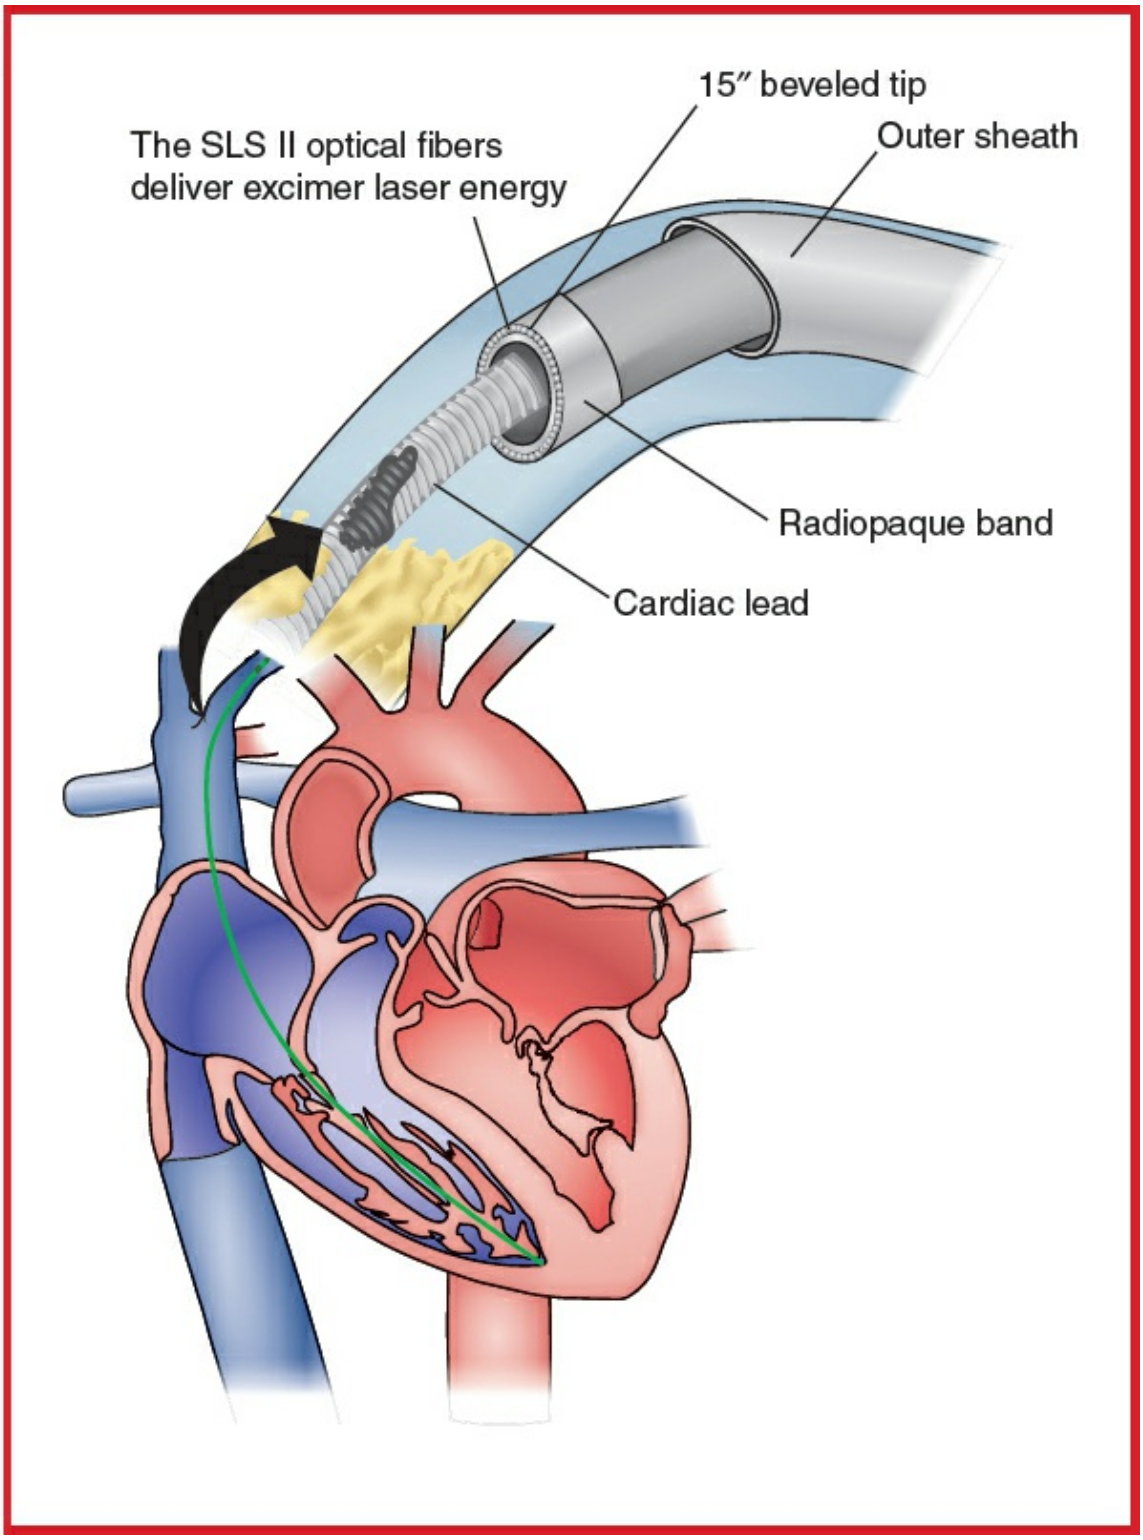

Figure 13.1-5 The laser sheath is placed over the lead to be extracted and advanced into the heart. The laser is then used to ablate scar tissue surrounding the lead to facilitate extraction.

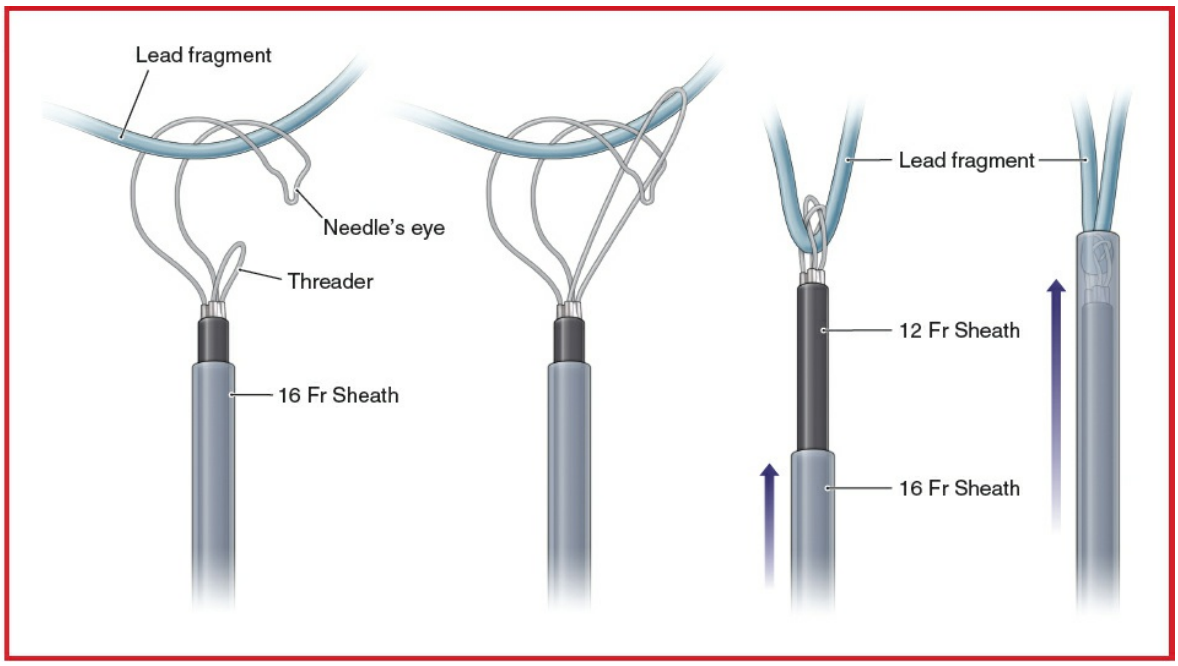

Figure 13.1-6 An example of a lead retrieval tool in use to capture and remove a lead fragment.

CATHETER ABLATION OF ATRIAL FIBRILLATION

PROCEDURAL CONSIDERATIONS

Description

Catheter ablation involves placement of catheters onto the desired cardiac chambers via venous and/or arterial access (most commonly the femoral blood vessels) and more recently via pericardial space. Through the electrodes at the tip of the catheters, intracardiac (or epicardial in the case of pericardial approach) signals can be recorded, arrhythmias can be monitored and/or induced using specific pacing protocols, and small areas of cardiac tissue can be ablated using various modalities. The most common modality is radiofrequency (RF) energy. Other emerging ablation techniques include cooling with cryoenergy and heating using ultrasonic, LASER, and microwave modalities. For atrial fibrillation (AF), the ablation is aimed at the triggers and substrates. The triggers can be found at various sites, most commonly at the entries of the pulmonary veins, superior vena cava, and coronary sinus into the left and right atria. The substrates for AF are believed to be in various areas on the left atrial wall, usually the posterior wall (Fig. 13.1-7).

Unlike catheter ablation procedures for other arrhythmias with a more focused area of interest, AF ablation requires energy delivery at a significantly greater number of sites. In most cases, the mapping and ablation are guided by a three-dimensional tracking system. The procedure also requires access to the left atrium, typically via a transseptal catheterization, which is usually guided by intracardiac echocardiogram. In the typical scenarios, two transseptal sheaths are placed in the left atrium to facilitate recording, pacing, and application of ablation. Typically, pulmonary vein isolation (PVI) is the basic approach. Left appendage isolation is also being performed in some centers. If elimination of left AFL substrate is a target, a significant amount of additional ablations are necessary. Typically, a "roof" line is created as well as a line connecting the left lower pulmonary vein to the mitral valve annulus. More recently, single-shot ablation devices to isolate pulmonary veins (e.g., cryoballoon) have become available (Fig. 13.1-8). These devices allow a single application of energy to produce a circumferential isolating lesion.

The standard procedure typically requires several (2–4) hours to complete. Cryoballoon procedures can be significantly shorter. The patient is continuously anticoagulated with iv heparin. Many centers are now performing the procedure with the patient already fully anticoagulated prior to the start of the procedure. One or more cardioversions may also be necessary, especially in patients with persistent AF. Furthermore, many centers are now using high-dose isoproterenol and adenosine after the ablation to assess likelihood of recurrence.

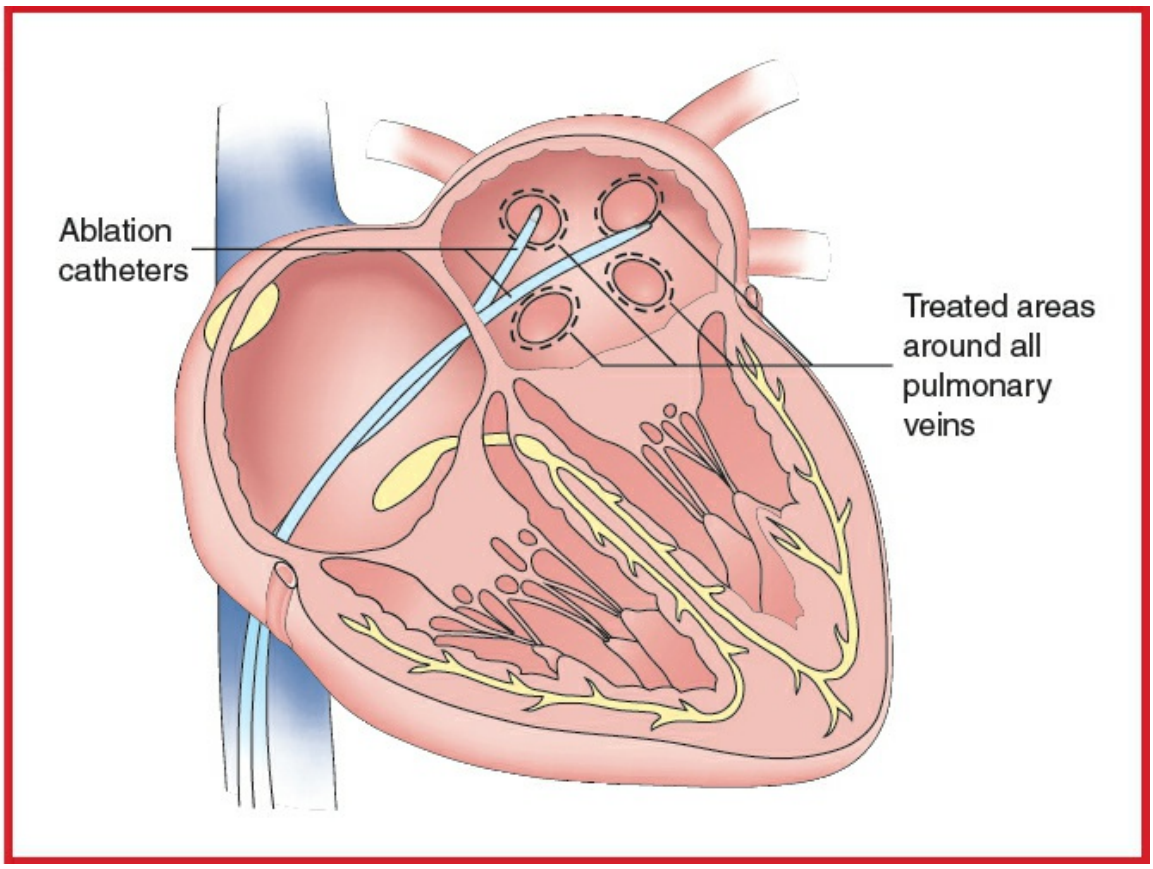

Figure 13.1-7 A transvenous transceptor catheter electrode is used to ablate target areas around the pulmonary vein entry sites to treat atrial fibrillation. Other common target sites include atrial walls as well as SVC and coronary sinus inlets.

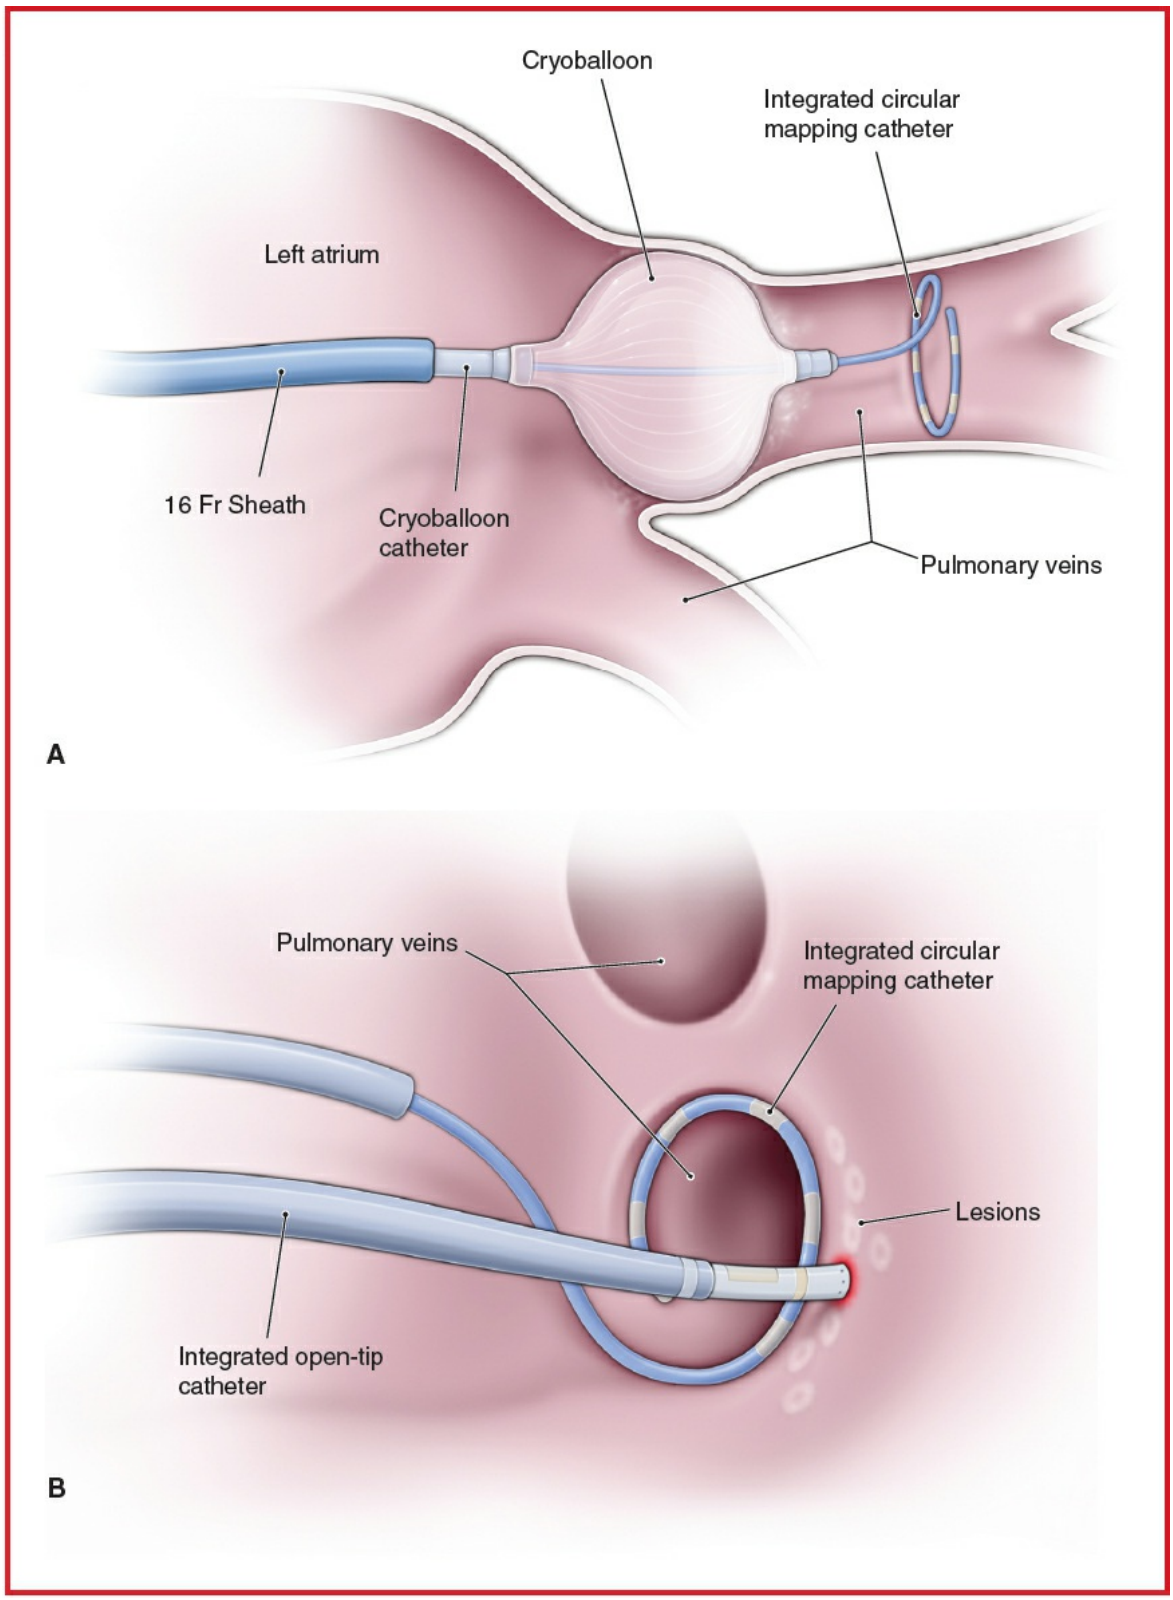

Figure 13.1-8 **A:** Cryoballoon ablation. **B:** Catheter tip RF ablation. Shown on panel **(A)** is localization mapping of an RVOT VT by mapping a single PVC with the same morphology of the VT and on panel **(B)** the cluster of ablation points.

GETA has been the standard modality for providing comfort and safety for patients. In

addition to the length of the procedure, there is a higher risk for cardiac and vascular perforation compared to a simple ablation procedure. The significant ablation volume is associated with an increased chance of left atrial perforation. A misdirected transseptal catheterization in itself can cause perforation of the aorta, posterior wall of the left atrium, and other structures. An emergency thoracotomy may be necessary. In addition to safety, GETA provides a stationary patient, which is critical in the acquisition and maintenance of three-dimensional map accuracy. Transesophageal temperature monitoring has become a standard of care and would be poorly tolerated in unanesthetized patients.

When feasible, AF ablation procedures should be performed in a hybrid procedure room such that, if needed, emergency thoracotomy can be performed with minimal delay. Under expert operators, the need for emergency thoracotomy is low (under 1–2%), and hence, surgical "standby" is not usually necessary, but this precautionary step is advisable for centers with low patient volumes.

CATHETER ABLATION OF VENTRICULAR TACHYCARDIA

PROCEDURAL CONSIDERATIONS

Description

The pathophysiology of VT is diverse. Catheter ablation of VT encompasses a wide spectrum of procedural complexity, and planning must incorporate the patient's underlying cardiovascular status. The most "benign" forms of VT have a focal origin, most commonly in the right ventricular outflow tract (RVOT). The mechanism is usually automatic or triggered activity and hence tends to be self-terminating. Other sites with a similar mechanism are in the LV (e.g., LVOT) and the left fascicles. These patients

typically have preserved LV systolic function. The most "malignant" forms of VT are associated with underlying structural myocardial damage (e.g., prior MI) and nonischemic ("idiopathic") cardiomyopathy. A less common form of cardiomyopathy is arrhythmogenic right ventricular dysplasia/cardiomyopathy (ARVD/C). VT mechanism is reentry, and therefore, it tends to be sustained and results in hemodynamic instability. Other (less common) VTs are those from sarcoidosis and Chagas disease. In patients with congenital disorders, VT can be found in many scenarios, such as noncompaction cardiomyopathy and postop tetralogy of Fallot (ToF).

Unlike the approach to ablation for AF (which is largely anatomical), ablation for VT is similar to that of catheter ablation for SVT. Induction of "clinical" VT is necessary to confirm the site that is critical to the initiation and/or maintenance of the tachycardia. The incorporation of 3D mapping has been a very useful advancement in this quest, but nonetheless, VT typically needs to be induced multiple times during the procedure. This is usually of minimal hemodynamic consequence in the case of the more benign VTs, but in patients with compromised systolic function, induction of sustained VT causes significant hemodynamic sequelae; hence, inotropic support is frequently necessary, such as iv phenylephrine or occasionally a transvenous LVAD device. Repeated cardioversions are frequently involved when overdrive pacing fails, which may cause more systolic dysfunction. While these patients typically already have an implanted ICD, external cardioversion is preferred for better timing. VT induction is again repeated after the ablation has been completed.

Once mapping of the critical focus has been completed, ablation is carried out. The majority of ablation is done via an endocardial approach with/without transseptal access. Some VTs (Chagas and 40% of nonischemic cardiomyopathy) have a critical site on the epicardial surface and therefore require pericardial entry (typically using a subxiphoid approach). For VTs with localized origin (RVOT, LVOT, FT), a small clusters of ablations will usually suffice (Fig. 13.1-9), keeping in mind that some outflow tract origins are located at one of the aortic valve cusps. For these procedures, MAC anesthesia would suffice and also is frequently preferred to allow for "lightening up the sedation," which is frequently necessary to promote induction of these types of VT. For re-entry VT caused by ischemic and nonischemic cardiomyopathy, the critical area is usually an "isthmus" of surviving myocardium in between scars (Fig. 13.1-10). In many cases, a very broad area of "diseased" myocardium (marked by a large area of low voltage) is the cause of VT, especially polymorphic VT; thus, a broad area of ventricular myocardium will be ablated (known as homogenization technique, Fig. 13.1-11). Procedural duration varies significantly, and it is not unusual to encounter long procedure times. Clearly, GETA would be required. Postop care for these patients can

also be challenging as prolonged hemodynamic compromise as well as residual VT episodes can require delayed extubation.

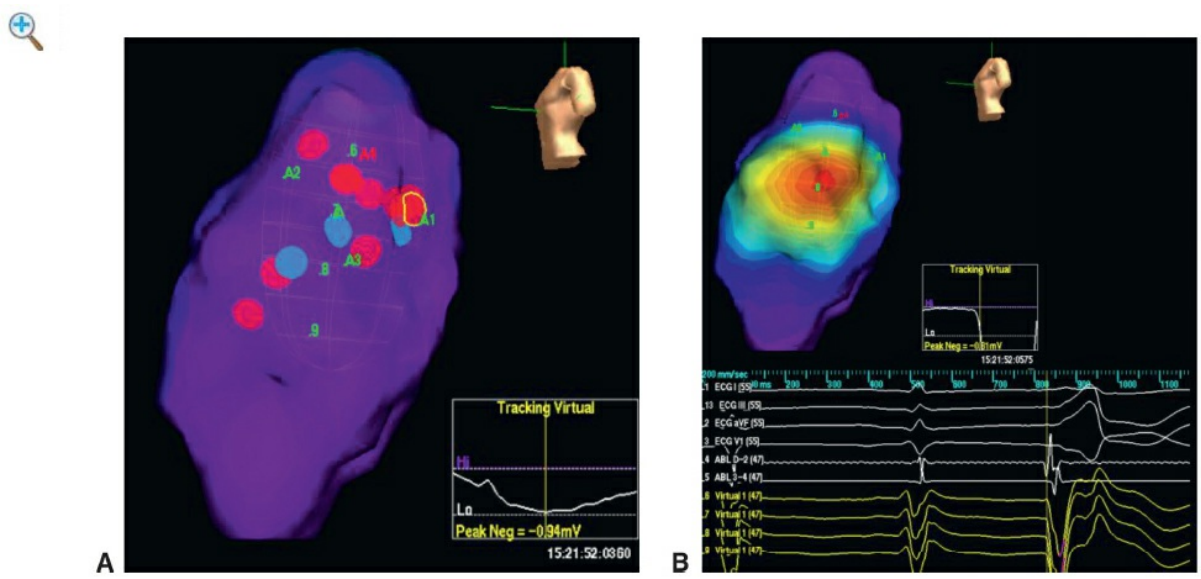

Figure 13.1-9 Shown on panel **(A)** is localization mapping of an RVOT VT by mapping a single PVC with the same morphology of the VT and on panel **(B)** the cluster of ablation points.

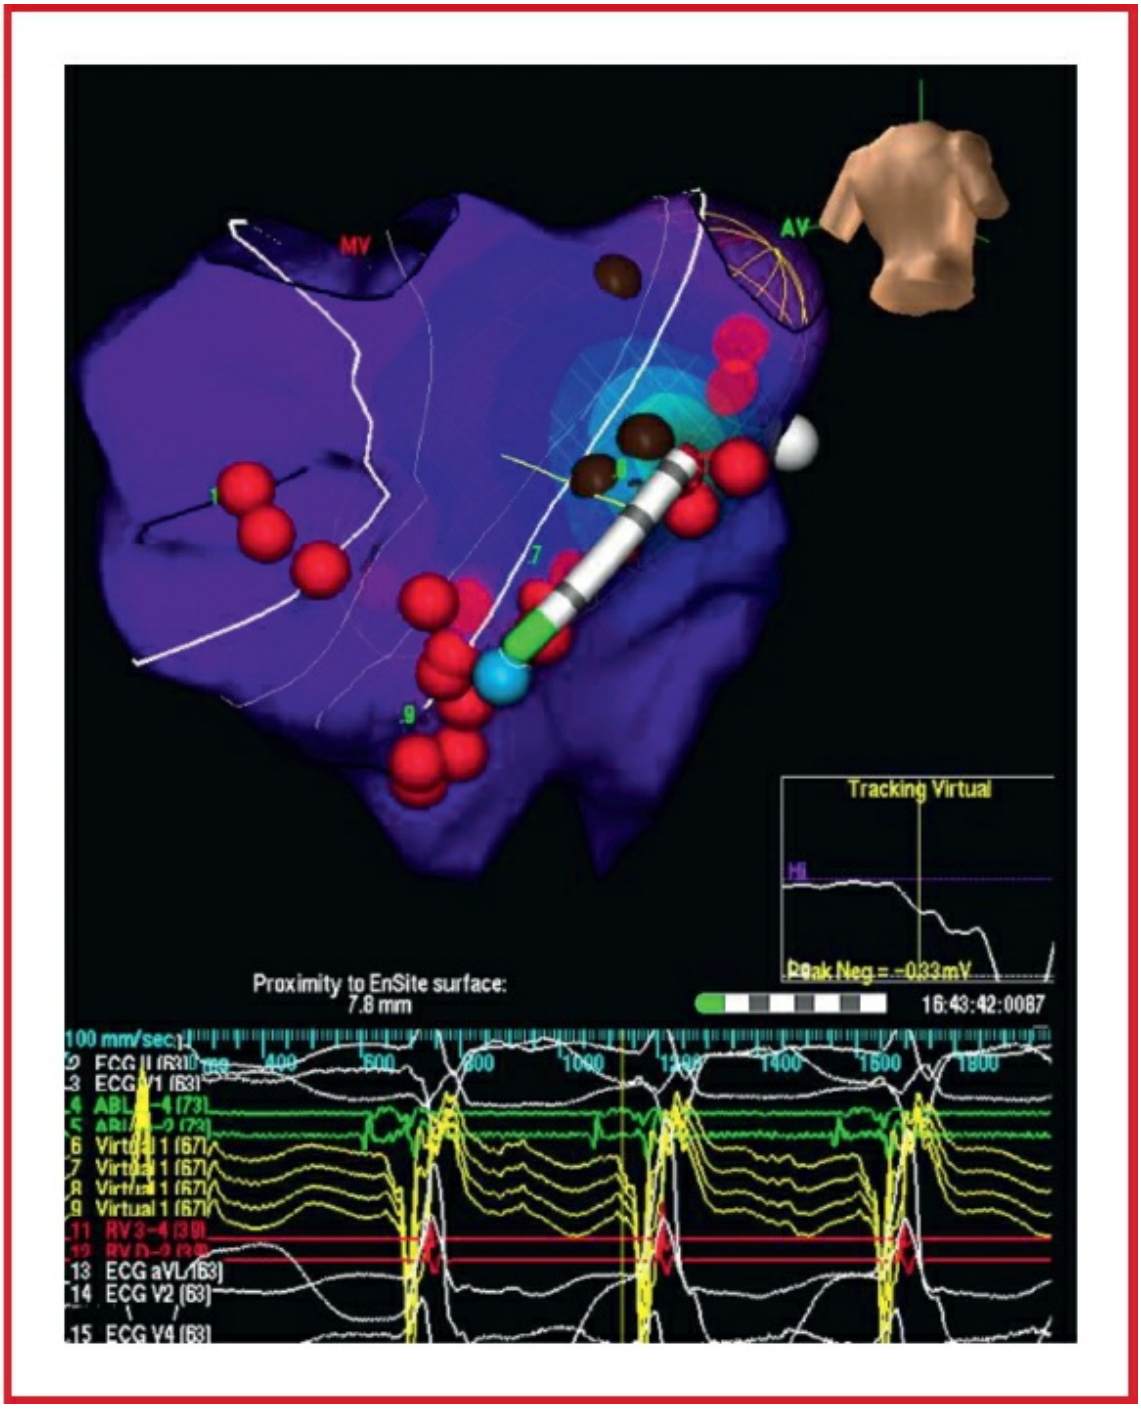

Figure 13.1-10 In the top panel, an "isthmus" ablation was performed based on sites of early activation. In the electrogram (EGM) series (lower panel), the ablation catheter recorded (ingreen) an early sharp depolarization preceding the onset of virtual unipolar signals collected by the multipolar noncontact recording catheter (in yellow).

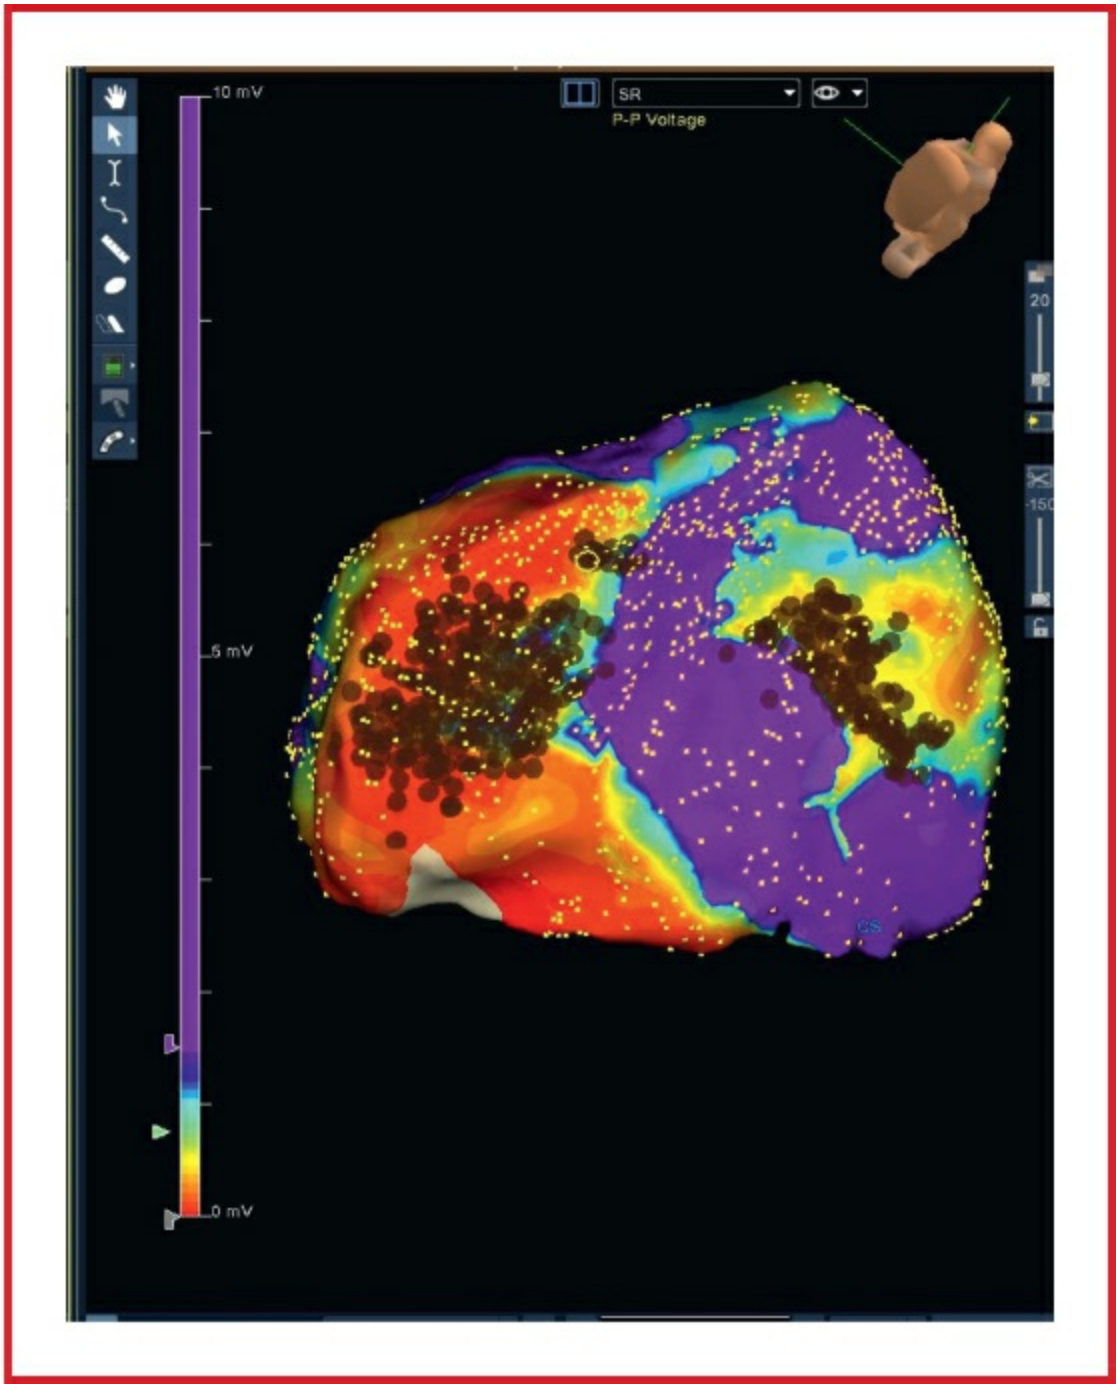

Figure 13.1-11 Shown here is a broad epicardial ablation (brown dots) of areas with low voltage (denoted by colors that are below the set threshold as marked by the arrow on the voltage scale); an example of "homogenization" ablation. The yellow points marked voltage recording points.

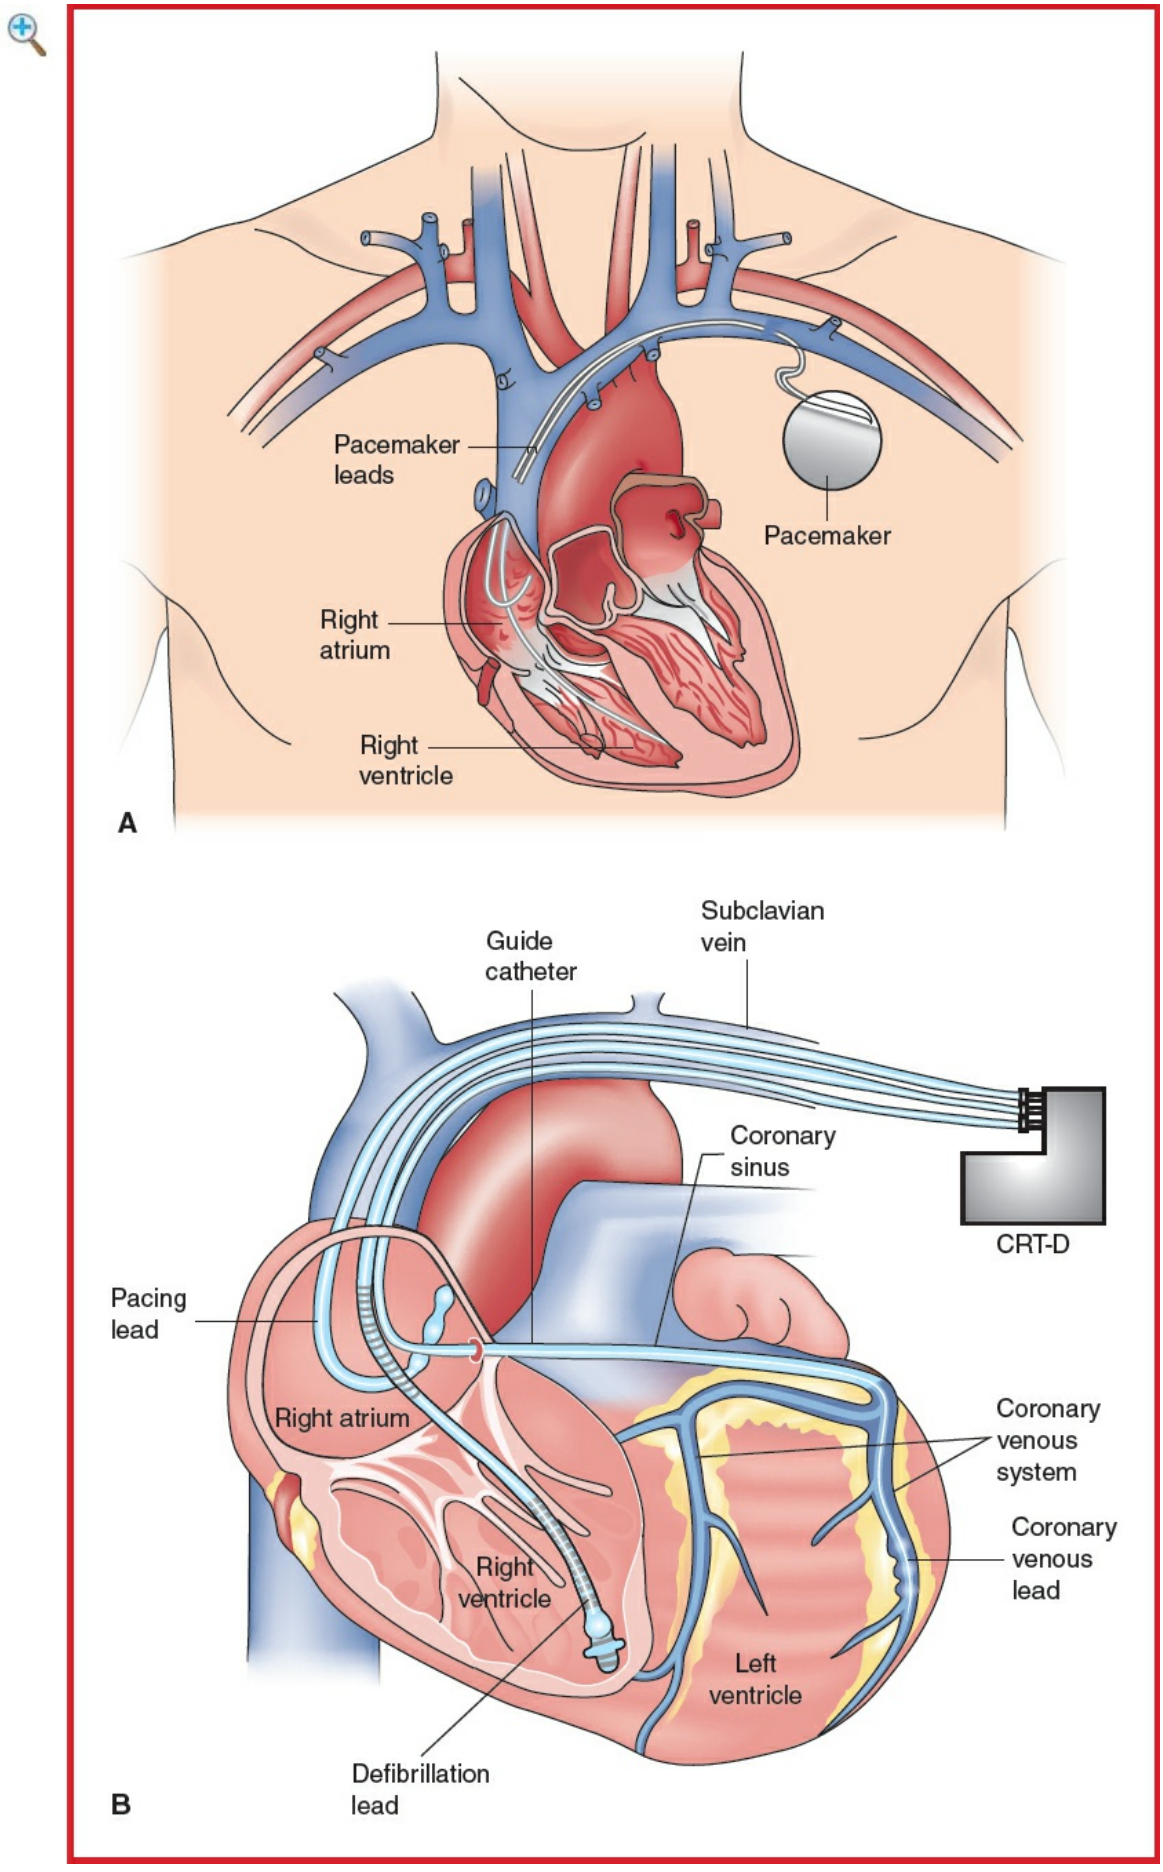
ANESTHETIC CONSIDERATIONS FOR ICD, CRT-D, AND PACEMAKER PLACEMENT; LEAD EXTRACTION; CATHETER ABLATION

PREOPERATIVE

Patients presenting for **ICD/CRT-D placement** may be divided into three populations, based on symptomatology, associated pathology, and probable outcome: (a) **Supraventricular dysrhythmias** (e.g., Wolff-Parkinson-White [WPW] syndrome) usually young and otherwise healthy patients. May be associated with Ebstein anomaly (tricuspid valve defect → RV failure), mitral valve disease, or CAD. Low perioperative mortality (1%). (b) **Ventricular dysrhythmias:** usually older patients with significant ventricular dysfunction (EF = 10–35%) and other pathologies, such as CAD or cardiac failure. These patients have either survived an episode of VT/VF or are otherwise at risk for sudden death. (c) **Congestive heart failure (CHF)** without significant dysrhythmias, usually 2° dilated cardiomyopathy. These patients have very low EFs (10–25%), LBBB, and Hx of failed conventional CHF treatment. The CRT-D device is implanted in these patients to provide paced "resynchronization" of the contractions of the LV and RV. This requires a third pacer lead placed into the coronary sinus to pace the LV independent of the RV (see Fig. 13.1-12B). In this case, the device is not placed primarily for its defibrillator function, but for its ability to pace both ventricles synchronously (biventricular pacing). Patients presenting for **permanent pacemaker insertion** may have a variety of dysrhythmias, including SSS, heart blocks (2nd and 3rd degree), and tachycardias refractory to medication. CRT patients may be quite frail with significant comorbidities.



Pacemaker leads
Pacemaker
Right atrium
Right ventricle
A
Subclavian vein
Guide catheter
Coronary sinus
CRT-D
Pacing lead
Right atrium
Coronary venous system
Coronary venous lead
Right ventricle
Left ventricle
Defibrillation lead
B

Figure 13.1-12 Placement of cardiac leads.

Patients presenting for **lead extraction** typically have infected leads (often methicillin-resistant Staphylococcus) or, less commonly, malfunctioning leads.

Patients presenting for **catheter ablation** usually have paroxysmal or chronic refractory AF or episodic polymorphic VT or VF related to structural heart disease. They may be at significant risk for death (VT/VF) or thromboembolic events including stroke (AF) AF patients may be receiving a variety of medications, including beta-blockers (e.g., carvedilol), calcium channel blockers (e.g., diltiazem) (less often digitalis or amiodarone), aspirin, clopidogrel, warfarin, direct thrombin inhibitors (e.g., dabigatran), or direct Factor Xa inhibitors (e.g., rivaroxaban, apixaban). VT/VF patients will often have a repeatedly activated ICD in place and be receiving amiodarone or sotalol.

Respiratory	May have associated pulmonary disease 2° smoking **Tests:** CXR; consider PFT, as indicated from H&P
Cardiovascular	**ICD:** ICD patients are left on full medication because it usually is impossible to wean them from antidysrhythmic medications before surgery. In most studies, patients have a mean LV EF of 35% and a New York Heart Association functional class of II or III. **Supraventricular dysrhythmias:** Look for precipitating factors in the dysrhythmia and any methods that have been used to terminate the dysrhythmia. Usually, drug therapy is terminated before surgery to make a dysrhythmia inducible. Note type of drugs used to terminate a dysrhythmia. **Ventricular dysrhythmias:** Ask about any methods that have been used to terminate dysrhythmia. Look for associated conditions, including CAD, CHF, cardiomyopathy, LV aneurysm, HTN, mitral insufficiency, and diabetes. Generally, these patients have poor LV function with ↑ sensitivity to myocardial depressants. It is important to note that they may be on combinations of antidysrhythmics. Many of these drugs have

significant negative inotropic effects. Of special note is amiodarone, which has been associated with intractable bradydysrhythmias, refractory vasodilation, and difficulty in weaning from CPB.

Pacemaker: The anesthesiologist should be aware that there is an NASPE code (North American Society of Pacing and Electrophysiology) that describes pacemaker function with a three- to five-letter code (see table below).

Position I Pacing Chamber(s)	Position II Sensing Chamber(s)	Position III Response(s) to Sensing	Position IV Programmability	Position V Multisite Pacing
O = None	O = None	O = None	O = None	O = None
A = Atrium	A = Atrium	I = Inhibited	R = Rate Modulation	A = Atrium
V = Ventricle	V = Ventricle	T = Triggered		V = Ventricle
D = Dual (A + V)	D = Dual (A + V)	D = Dual (T + I)		D = Dual (A + V)

For example, a VVI notation indicates that the ventricle is paced and sensed and there is inhibition by native beats.

Catheter ablation: Most commonly, presenting patients have medically refractory or paroxysmal atrial fibrillation or VT/VF and are at increased risk for thromboembolic events or sudden death. Preop antidysrhythmic and anticoagulant medications should be managed in consultation with the prescribing physician and the interventional cardiologist.

Infected leads: Patients with infected leads may have endocarditis, tricuspid valve dysfunction, and sepsis.

Tests: ECG: ✓ dysrhythmia, ischemia, electrophysiologic report. Echo: ✓ ventricular function, wall motion abnormalities, valvular problems. Cardiac angiography: ✓ ventricular function, CAD, valvular disease, LV aneurysm. ICD: identify and interrogate device.

Renal	Patients with poor ventricular function may have associated renal compromise. Electrolyte abnormalities (K^+, Mg^{++}) may be associated with ↑ cardiac irritability and should be corrected preop. **Tests:** BUN; Cr; electrolytes
Hematologic	Hb/Hct; coag tests (PT, PTT, Plt)
Laboratory	Other tests as indicated from H&P
Premedication	For adults: midazolam 0.5–2.0 mg iv, with careful observation and supplemental O_2.

INTRAOPERATIVE

Anesthetic technique

Local anesthesia with sedation, GA with LMA, or GETA, as indicated. Cathete ablation and placement of most ICDs, CRT-Ds, and PMs are done in the cardiac catheterization suite. ICDs are very small and are implanted in the same position as a PM. If patients are orthopneic due to their CHF, or if the procedure is projected to be long, GA is often preferable. Also, elderly patients may become disoriented with sedation and, thus, may require urgent GA. Lead extraction is often done under GETA.

Induction	Exact type of induction depends on the patient's medical condition. Sedation can be provided with small doses of midazolam (1–2 mg) ± fentanyl (25–50 mcg) titrated to effect. An alternative technique is to use a propofol infusion (e.g., 25–75 mcg/kg/min). Because local anesthesia is provided by the surgeon, the procedure usually is not painful and does not require postop pain control. It is important to avoid oversedating these patients because they will tend to become disoriented and uncooperative. Even if local anesthesia with sedation is provided for the placement of leads and the device, a brief period of GA is usually required for device testing. This can be provided easily with mask ventilation and induction with propofol (e.g., 1 mg/kg iv) or etomidate (e.g., 0.1 mg/kg iv), similar to anesthesia for cardioversion procedures. For those patients requiring GA for the entire procedure, induction with propofol (1–2 mg/kg) or etomidate (0.1–0.3 mg/kg) is often used.

	Muscle relaxants are not required unless intubation is planned. Narcotics usually are not required because local anesthesia is used.	
Maintenance	As previously discussed, verification of correct lead placement usually involves the induction of VF or VT and the testing of the device's capability to restore NSR. External defibrillation should be available at all times, as should antidysrhythmics (e.g., lidocaine and amiodarone). While the device is tested, the patient should be breathing 100% O_2. Multiple testing cycles can result in depressed LV function, and inotropes may be needed.	
Emergence	These patients are extubated (if GETA used). Recovery is in a PACU. If, however, multiple test shocks are needed or the heart displays evidence of injury (need for inotropes, ST-segment abnormalities), then extubation may need to be deferred to ICU.	
Blood and fluid requirements	IV: 16–18 ga × 1 BSS @ 2–3 mL/kg/h	Care should be taken to minimize iv fluids in CHF patients.
Monitoring	Standard monitors ± Arterial line ± CVP/TEE	A CVP catheter or TEE may be used depending on LV function. ICD patients generally require only an arterial line.
	External defibrillation	Because antidysrhythmics may affect the testing procedure, they should be avoided when possible. Defibrillation or cardioversion is treatment of choice.
	Temperature	Normothermia should be maintained.
Positioning	Supine	

	✓ and pad pressure points ✓ eyes	
Complications	Pneumohemothorax Pericardial effusion/tamponade HTN/CHF Coronary sinus rupture/central vein laceration	Rarely, cardiac rupture or central vein laceration may occur during lead extraction. Significant blood loss may occur. Coronary sinus rupture has been reported during biventricular lead placement and may require open repair.

POSTOPERATIVE

Complications	Recurrent dysrhythmias Hemorrhage Myocardial ischemia	Pacemaker lead thrombosis → PE has been reported.
Pain management	Usually managed with oral analgesics	
Tests	CXR	✓ line/lead placement, r/o pneumohemothorax.
	ECG	✓ for ischemia, dysrhythmias.
	Electrophysiologic testing	
	Electrolytes

TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNT (TIPS)

PROCEDURAL CONSIDERATIONS

Description

Hepatic cirrhosis is a progressive disease that eventually results in portal HTN and the development of varices at a variety of sites. Bleeding from esophageal varices is a serious complication of portal HTN, occurring in 25% of patients within 1 yr of diagnosis (~50% mortality). Prior to 1989, surgically placed shunts were used to direct high-pressure portal blood into the systemic venous circulation in patients with recurrent bleeding after endoscopic sclerotherapy or banding. The **transjugular intrahepatic portosystemic shunt (TIPS)** procedure has almost completely replaced surgical shunts.

TIPS is a percutaneous shunt between the portal and systemic circulations. The shunt is created between the hepatic vein and portal vein within the liver parenchyma, maintained by placement of a stent graft. This creates a low-resistance conduit to decompress the portal circulation, thereby decreasing variceal blood flow and ascites formation. Although it can be performed with conscious sedation, balloon dilation of the tract is extremely painful, typically requiring GA.

TIPS was developed initially by Rosch in dog studies in 1969. Palmaz and Richter performed the first successful TIPS in humans in 1989, using metallic stents to maintain the patency of the tract. Since then, TIPS has become the procedure of choice for patients who fail sclerotherapy and banding. In addition, it addresses another common problem associated with cirrhosis: refractory ascites.

Through the right IJ, a 10-Fr sheath is placed in the upper IVC. A catheter/guide wire combination is used to select the right hepatic vein. A wedged hepatic venogram using CO_2 is performed. Injection of iodinated contrast can result in rupture of the liver

capsule and exsanguination. The wedged venogram refluxes contrast through the sinusoids and into the portal vein, thereby providing a map. The catheter is exchanged over a stiff wire for a metallic introducer/needle. A variety of needle kits are available. All include a long introducer sheath and coaxially inserted curved-tip needle or metal cannula, with directional indicator, to help steer the needle toward the right portal vein.

Portal venous pressures are measured, and the pressure gradient between the portal vein and right atrium is determined. Following a portal venogram, the catheter is exchanged for an angioplasty balloon and the tract dilated (Fig. 13.1-13C). The use of covered stents for TIPS creation led to significantly improved patency rates, and for this reason, the Viatorr® (Gore, Flagstaff, AZ) self-expanding covered stent has largely replaced the bare metal stents. The Viatorr is positioned across the tract, and the uncovered portion is first deployed within the portal venous system (Fig. 13.1-13D). The covered portion is then pulled into the tract and deployed in a separate step. The stent may be dilated to a diameter of 8–10 mm using an angioplasty balloon, depending on the stent diameter and desired portosystemic gradient. If necessary, a second stent is deployed to cover any remaining unstented portions of the hepatic tract. Following TIPS placement, portal venogram and pressure gradients are remeasured. Ideally, the pressure gradient following shunting should be between 6 and 12 mm Hg. If the gradient is too high, there is a risk of rebleeding; if too low, there is overshunting of blood, thus bypassing the entire portal venous system and increasing the risk of encephalopathy and liver failure. After successful creation of the shunt, all devices, including the right jugular sheath, are removed, and hemostasis is achieved. Patients are closely monitored in an ICU or step-down unit for 24–48 h.

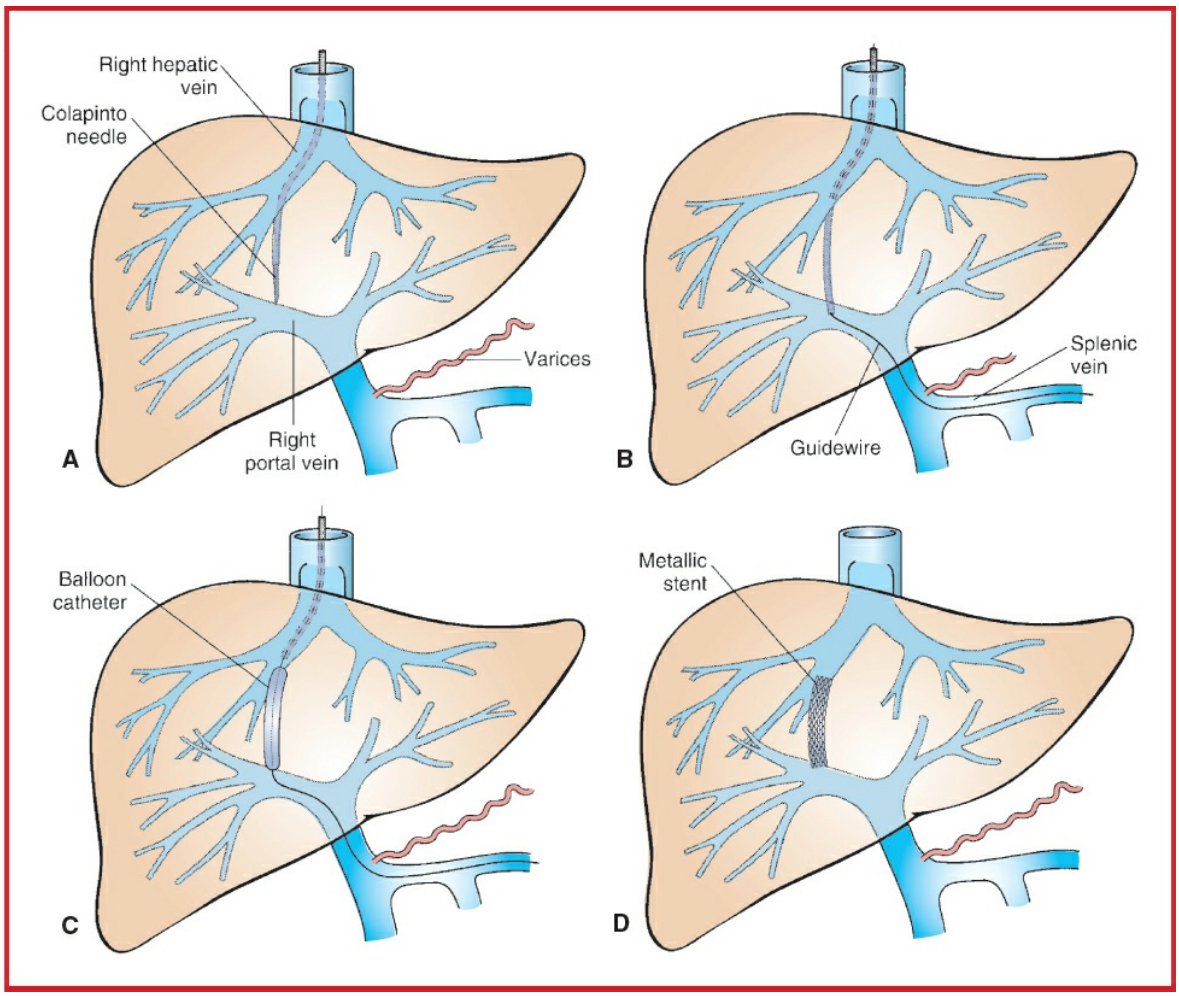

Figure 13.1-13 TIPS placement.**A:** Sheathed Colapinto needle is advanced out of hepatic vein into portal vein branch. Varices are present. **B:** Guide wire is advanced through the needle sheath into splenic vein. **C:** Parenchymal liver tract is dilated using a balloon angioplasty catheter. **D:** The metallic stent is deployed within the shunt tract. (Redrawn from Haskal ZJ, Ring FCurrent Techniques in Interventional Radiology. Current Science, Philadelphia: 1994. Reprinted with permission from Ziv J Haskal, MD.)

Direct IVC-to-portal shunt (DIPS) is a newer alternative to TIPS. Simultaneous venou access is required from both the internal jugular vein and common femoral vein. For DIPS, an intravascular ultrasound (US) probe is used to guide needle puncture from the IVC, through the caudate lobe, and into the main portal vein. Because the tract traverses extrahepatic regions, placement of a covered stent is mandatory. A theoretically fewer number of passes is needed to access the portal vein because the puncture is US guided; however, there is likely a greater risk of intraperitoneal hemorrhage with each puncture attempt.

If TIPS/DIPS is performed for the treatment of bleeding varices, it may be necessary t embolize and sclerose the varices if they persistently fill following shunt creation. This may be accomplished using sclerosing agents (e.g., ethanolamine) with an occlusion

balloon and embolic agents (e.g., metallic coils, Gelfoam™), depending on operator preference.

Usual preop diagnosis

Bleeding esophageal varices (as a result of portal HTN); ascites; Budd-Chiari and hepatorenal syndromes

SUMMARY OF PROCEDURE	
Position	Supine
Incision	Right IJ access
Special instrumentation	Rosch-Uchida, Colapinto, or Hawkins needle set; angioplasty balloons; endovascular stent grafts, marker pigtail, CO_2 injection apparatus, intravascular ultrasound (IVUS) for DIPS, embolic agents (e.g., coils, Gelfoam, ethanolamine) for variceal embolization/sclerosis if necessary
Unique considerations	May need FFP
Antibiotics	Cefazolin 2 g iv
Procedure time	2–6 h
EBL	0–3000 mL
Postop care	ICU or step-down unit; careful fluid management
Mortality	Emergency: 50–100% Postprocedure: See Tables 13.1-2–13.1-5
Morbidity	Encephalopathy: 18–30% Late liver failure: 10–25% Shunt occlusion: 10%/yr Liver capsule puncture → intraperitoneal hemorrhage (continue procedure to decompress portal venous system → ↓ bleeding) Hepatic artery puncture: may require embolization Allergic reactions MI (related to ↑ CVP) Renal failure (usually transient)

Pain score	7–8 (first few hours only)

Table 13.1-2 MELD Score Calculation

The Model for End-Stage Liver Disease (MELD) score is calculated using three objective indicators—serum bilirubin, serum creatinine level (Cr), and international normalized ratio (INR)—according to the United Network for Organ Sharing modification of the original formula:

$$MELD = 9.6 \times \log e\,(cr) + 3.8 \times \log e\,(Bilirubin) + 11.2 \times \log e(INR) + 6.4$$

The MELD score can easily be calculated by accessing the following website: http://www.mayoclinic.org/meld/mayomodel7.html

Table 13.1-3 Overall Mortality Based on MELD Score

MELD Score	No. of Patients	Mortality Rate (%)		
		30 d	3 mo	6 mo
≤10%	28	0 (0, 0)	0 (0, 0)	0 (0, 0)
11–17	83	7.3 (1.7, 12.9)	16.0 (8.0, 24.0)	24.9 (15.1, 34.7)
18–24	40	17.9 (5.9, 29.9)	34.8 (19.4, 50.2)	38.6 (22.4, 54.9)
≥25	15	42.6 (16.7, 68.4)	65.5 (39.9, 91.2)	74.2 (50.0, 98.3)

Patients undergoing elective TIPS creation with a MELD score of 18 or more had a significantly lower 3-mo survival rate than those with a MELD score of 17 or less. Numbers in parentheses are 95% confidence intervals.

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Patients presenting for TIPS procedures have portal HTN usually 2° end-stage live disease (ESLD), which will affect the function of a variety of organ systems, as described below.

Respiratory	Abdominal distension → atelectasis → ↑ pulmonary shunting → hypoxemia (hepatopulmonary syndrome in ESLD) Encephalopathy → hyperventilation → ↓ $PaCO_2$ (respiratory alkalosis with chronic acidosis as compensation). Pulmonary effusion may be present in 5–10% of patients. **Tests:** ✓ CXR (for Sx of atelectasis); ABG and PFT, if indicated
Cardiovascular	Cardiomyopathy (ETOH) and CAD (tobacco) occur at higher incidence in this patient population. Diuretic therapy → hypovolemia + ↓ K^+ (furosemide) or ↑ K^+ (spironolactone). Hyperdynamic circulation 2° to ↓ peripheral resistance and ↓ cardiac reserve are common findings and correlate with poor postop outcome. **Tests:** ECG; electrolytes; cardiac echo, if indicated from H&P

Neurologic	Symptoms of hepatic encephalopathy range from mild confusion to coma. These patients may be very sensitive to narcotics and sedatives. A characteristic finding in liver failure is asterixis (liver flap). Hyponatremia and hypoglycemia may mimic hepatic encephalopathy. **Tests:** As indicated from H&P
Hepatic	Drug metabolism may be markedly reduced; anticipate prolonged effect with sedative and narcotic drugs. Drugs with particularly prolonged action include midazolam, meperidine, ranitidine, and lidocaine. Apparent resistance to all muscle relaxants is most likely due to an increased volume of distribution. Succinylcholine effects may be prolonged in patients with severe ESLD (2° ↓ plasma cholinesterase). **Tests:** Bilirubin; PT; albumin; LFTs
Gastrointestinal	Ascites → ↑ intra-abdominal pressure → ↑ risk of aspiration. Full-stomach precautions and rapid-sequence induction are recommended. Portal HTN → variceal bleeding. If possible, avoid esophageal instrumentation (e.g., TEE, esophageal stethoscope). Gastritis and peptic ulceration may be present.
Renal	Oliguric renal failure may complicate ESLD (hepatorenal syndrome). This may be reversible if liver failure improves. Differential Dx includes prerenal azotemia and acute tubular necrosis. **NB:** Bilirubin metabolites interfere with creatinine measurement and may mask ↑ creatinine levels. **Tests:** BUN; Cr; electrolytes
Endocrine	Hypoglycemia may be present in cases of severe cirrhosis. ESLD patients may have ↓ response to catecholamines. **Tests:** Glucose
Hematologic	Patients may be anemic 2° GI bleeding. The majority of patients will exhibit coagulopathy 2° ↓ hepatic

	synthetic function (all factors except VIII and fibrinogen) and ↓ Plt. Patients may require vitamin K (if coagulopathy is present and time permits), FFP (if PT > 2 sec above baseline), or Plt transfusion (if Plt < 100 K) before procedure; these products should be readily available.
Premedication	**Tests:** CBC; Plt; PT; others as indicated from H&P Patients with significant ascites will require full-stomach precautions. **NB:** Benzodiazepines should be used with caution in liver failure patients.

INTRAOPERATIVE

Anesthetic technique

In some patients (and at some centers), sedation with local anesthesia may be satisfactory; however, balloon dilation of the intrahepatic tract can be exceedingly painful. Remember, these patients may be very sensitive to narcotics → respiratory arrest. GETA is often necessary to provide adequate analgesia and airway protection. The patient will be positioned so that the interventional radiologists can approach both the internal jugular and femoral veins, thus limiting the anesthesiologist's access to the head and airway.

General anesthesia

Induction	Rapid-sequence induction is necessary in patients with encephalopathy, abdominal distention, and recent variceal bleeds (blood in the stomach).	
Maintenance	Standard maintenance. If muscle relaxation is to be maintained, low-dose vecuronium (1–1.5 mcg/kg/min), cisatracurium (3 mcg/kg/min infusion), or rocuronium (5–15 mcg/kg/min) may be used to maintain muscle relaxation.	
Emergence	Extubate when the patient is awake and protective laryngeal reflexes are present. Patient should be transferred to PACU accompanied by anesthesiologist.	
Blood and fluid requirements	Potential for large blood loss	Glucose-containing solutions may be required for patients

	IV: 14–16 ga × 1–2 FFP available Plt available 2–4 U PRBC available NS/BSS (as appropriate)	with hepatic failure ± CHF. ✓ blood glucose levels frequently. Vasopressor response may be impaired.
Monitoring	Standard monitors	Ventricular arrhythmias can be provoked by hepatic vein catheterization.
Positioning	✓ and pad pressure points ✓ eyes	Radiology tables usually are not well padded → nerve damage.
Complications	Portal vein rupture Liver capsule perforation	Intra-abdominal hemorrhage may be massive and require emergency surgery.
	Complete heart block	Patients with preexisting LBBB may require a pacemaker pre-TIPS (2° risk of RBBB during procedure).
	CHF	Shunt → ↑↑ venous return → CHF

POSTOPERATIVE

Complications	Portal vein thrombus	May mimic symptoms of PE or MI
	↑ encephalopathy	2° ↓ hepatic portal blood flow
	Sepsis	
	Bleeding	May require hemodynamic support (e.g., dopamine)
	Fluid/electrolyte disturbance	Stent insertion → ↑ venous return → ↑ diuresis → electrolyte/fluid imbalance
Pain management	IV opiates

ENDOSCOPIC RETROGRADE CHOLANGIOPANCREATOGRAPHY

PROCEDURAL CONSIDERATIONS

Description

Endoscopic retrograde cholangiopancreatography (ERCP) was originally used as a diagnostic procedure; however, it is now almost exclusively used for therapeutic purposes. As with many invasive procedures, success (including the absence of complications) is well correlated with operator experience. Basically, ERCP consists of passing an endoscope through the mouth, esophagus, and stomach into the duodenum, where the papilla of Vater is located. A catheter (sometimes preceded by a wire) is inserted through the sphincter of Oddi into the common bile duct or pancreatic duct (see Fig. 13.1-14). At that point, contrast can be injected, tissue sampled, stones extracted, stents placed, or a sphincterotomy accomplished. The endoscopist may request administration of glucagon (0.25–2 mg iv; side effects, n/v, ↓ BP) to decrease duodenal motility and/or secretin (0.2 mcg/kg iv over 1 min; side effects, flushing, n/v) to help locate the minor papilla.

The overall complication rate is 5–10%, being <5% for simple stone extraction to 20% or more for sphincterotomy. Post-ERCP pancreatitis is the most common complication (up to 40%), being more common in young patients with sphincter of Oddi dysfunction and normal bilirubin levels. Placement of a pancreatic stent may reduce the risk of post-ERCP pancreatitis and is commonly used in high-risk patients. Unfortunately, stent placement itself may cause complications, including ductal and parenchymal injury and

ductal stenosis. Balloon dilation as an alternative sphincterotomy has been associated with a higher risk of pancreatitis.

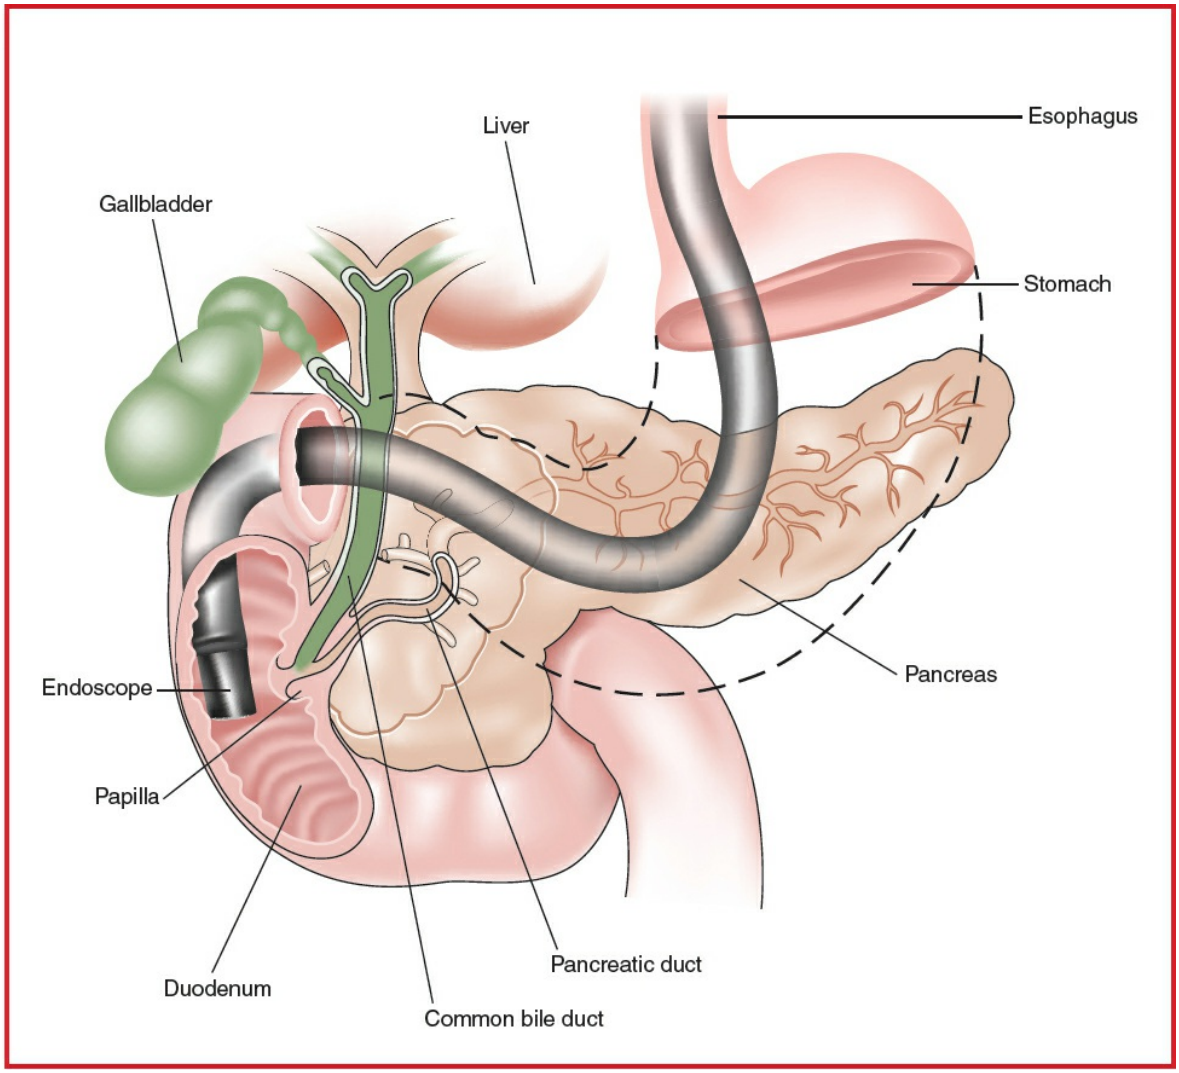

Figure 13.1-14 Anatomy for ERCP.

Usual preop diagnosis

Patients typically present with persistent pain or jaundice as a result of gallstones or other disease processes (e.g., infection, tumor, pancreatitis) that obstruct the bile duct and/or pancreatic duct.

SUMMARY OF PROCEDURE	
Position	Initially left lateral decubitus, rotating to prone
Incision	None
Special	Endoscope (duodenoscope) and supporting equipment;

instrumentation	mouth guard; fluoroscopy
Unique considerations	X-ray protection will be required; glucagon may be requested (0.25–2 mg iv 10 min before procedure; contraindications, pheochromocytoma, insulinoma)
Antibiotics	Ciprofloxacin 500 mg po 30–60 min before procedure is common.
Procedure time	45–90 min
EBL	Usually minimal
Postop care	PACU → home (occasional overnight stay for stone removal or stent placement)
Mortality	Rare
Morbidity	Pancreatitis: typically 5% (1–40% reported) Bowel or duct perforation: <1% Hemorrhage: 0.1–2% Cholangitis/cholecystitis Aspiration Cardiopulmonary (e.g., myocardial ischemia, respiratory arrest)
Pain score	2–4

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Patients presenting for ERCP most commonly have obstruction of hepatic and/or pancreatic ducts. They may be jaundiced with elevation of both conjugated and unconjugated bilirubin or exhibit Sx of pancreatic disease with associated peritoneal and pleural effusions. As a result of underlying disease processes (typically ASA 3–4), they may be quite frail with limited physiologic reserve. Discuss intraprocedure management with the endoscopist.

Respiratory	Airway evaluation should focus on the need for GETA. Access to the airway may be limited during the procedure. Ascites and pleural fluid accumulation → impaired ventilation, ↑ aspiration risk. Gas insufflated during the procedure may further

	compromise ventilation and ↑ aspiration risk. Rales/percussive dullness suggests pulmonary edema/effusion. **Tests:** As indicated from H&P
Cardiovascular	ECG changes are not uncommon during this procedure, and a preop ECG may be helpful. Hypotension is not uncommon. **Tests:** As indicated from H&P
Neurologic	Altered mental status may result from impaired hepatic function.
Hepatic	Hepatic dysfunction → coagulopathy, altered drug metabolism, and other metabolic disturbances. Jaundice is common. **Tests:** As indicated from H&P
Renal	↑ BUN/Cr suggests volume depletion or acute renal failure. In acute pancreatitis, fluid deficit may be severe; volume resuscitate before proceeding. **Tests:** As indicated from H&P
Endocrine	↑ glucose (>180 mg% should be treated preop) **Tests:** As indicated from H&P
Premedication	Morphine may ↑ sphincter of Oddi tone → ↑ductal pressure + ↑ pain. Midazolam 1–2 mg iv may be appropriate in the anxious patient. Consider aspiration prophylaxis (e.g., Bicitra™ 30 cc po; avoid metoclopramide).

INTRAOPERATIVE

Anesthetic technique

Deep sedation using propofol (avoiding respiratory depression or loss of protective airway reflexes) supplemented with topical anesthesia of the oropharynx is sufficient for many ERCP procedures. GETA is associated with a higher procedure success rate and should be considered for complex ERCP procedures, patients at high risk for aspiration, or uncooperative patients.

General anesthesia

Induction	Rapid-sequence induction is necessary in patients with gastroparesis or abdominal distention. Otherwise, standard induction. Consider etomidate (0.1–0.3 mg/kg) for hemodynamically unstable patients.	
Maintenance	Standard maintenance. An immobile patient will be appreciated by the endoscopist. Manipulation of the endoscope may cause ETT movement → mainstem intubation or extubation.	
Emergence	The duodenum and stomach should be decompressed by the endoscopist before extubation. Standard emergence.	
Blood and fluid requirements	IV: 18 ga × 1 BSS @ 3–5 mL/kg/h	Patients with acute pancreatitis may be hypovolemic.
Monitoring	Standard monitors ± Arterial line	✓ glucose in patients receiving glucagon.
Positioning	Left lateral decubitus → prone ✓ and pad pressure points ✓ eyes	
Complications	Pancreatitis Myocardial ischemia Aspiration	Δ ECG may occur in 25% of patients >65 yr.

POSTOPERATIVE

Complications	Myocardial ischemia Hypoxemia Hemorrhage	
Pain Management	Usually managed with oral analgesics	Avoid morphine (↑ sphincter of Oddi tone).

IMAGING AND IMAGE-GUIDED PROCEDURES

PROCEDURAL CONSIDERATIONS

Description

Projectional imaging includes x-ray fluoroscopy, and cross-sectional imaging includes computed tomography (CT), ultrasound (US), and magnetic resonance imaging (MRI) These techniques have become indispensable in modern diagnosis. In addition, a growing number of invasive procedures are being performed using imaging for guidance, not only for diagnostic purposes but also for therapeutic purposes. Indications include Dx of primary or metastatic tumors; tumor staging; Dx of benign processes, including infections; percutaneous drainage of fluid collections; local-regional treatment of tumors and vascular malformations; endovascular treatment of hemorrhage, vascular malformations, aneurysms, and dissections; percutaneous ablation; catheter-directed thrombolysis and thrombectomy; IVC filter implantation or retrieval; placement of portosystemic shunts; recanalization and angioplasty/stenting of chronically occluded veins; endovascular treatment of varicose veins; dialysis-related interventions; percutaneous placement of feeding tubes; percutaneous treatment of urinary and biliary obstructions; and placement of venous access devices.

Selection of imaging modality depends on ease of identification of the target lesion and resolution of surrounding and intervening structures. Patient compliance is crucial to success because image resolution and spatial accuracy require the patient to be immobile during image acquisition and the procedure itself. In compliant adults, most of these procedures may be done using moderate sedation. For procedures in the pediatric population, as well as for more invasive procedures in adults, GA is frequently necessary.

Diagnostic imaging

Pediatric: In general, moderate sedation is sufficient to ensure pediatric patient compliance for diagnostic CT, US, or MRI, but occasionally, GA is necessary (see Section 13.2).

Adults: Almost all CT, US, and MRI studies are performed without anesthesia. Approximately 5% of adult patients are too claustrophobic to complete an MRI study. Some of these patients may benefit from sedation, but use of GA is rare. Most patients with implanted PM and ICDs can safely undergo MRI if appropriate precautions are observed (see Fig. 13.1-15).

Image-guided procedures

Pediatric: Procedures performed on the pediatric patient routinely require GA (see Section 13.2).

Adults: X-ray fluoroscopy and CT- and US-guided procedures, including biopsies, fluid drainage, and tissue ablation, are routinely performed under moderate sedation. More invasive and painful procedures, such as stent graft repair of aneurysms and dissections, and thermal ablation of unresectable tumors, frequently require GA, spinal, or epidural anesthesia. The required site of access and the positioning of the operators should be considered before the procedure. Position of the ETT and central lines can be immediately confirmed using fluoroscopy. Occasionally, iv injection of iodinated contrast medium is necessary, and adverse reactions—such as urticaria, airway edema, hormone release (e.g., from pheochromocytoma), or anaphylaxis—may occur.

Section I - This section is to be filled out by the PATIENT:

The MRI room contains a very strong magnet. Before you go into the room, we must know if you have any metal in your body. Please complete the following:

The field of MRI-guided procedures—sometimes referred to as interventional MR (iMRI) or magnetic resonance-guided therapy (MRT)—reflects the emergence of new magnet geometries, allowing physician access to the patient during imaging. These geometries may be C-arm configurations, parallel discs above and below the patient, or dual rings where the patient is placed either through the apertures of the rings or perpendicularly between the rings. Faster image acquisition pulse sequences are allowing near–real-time feedback. In addition to guiding biopsies and drainage, this technology enables more aggressive procedures, such as craniotomies or percutaneous tumor ablations, to be performed with immediate feedback showing the progress of excision or ablation. Many of these procedures require GA and, accordingly, require MRI-compatible monitoring and anesthetic equipment. For safety, the anesthesiologist and proceduralist also are subject to the same restrictions that apply to patients, so having a pacemaker, ICD, ferromagnetic aneurysm clips, or a metallic foreign body in the orbit precludes that person's suitability to perform these cases. Hybrid systems also are being marketed, combining MRI and x-ray fluoroscopy, CT and x-ray fluoroscopy, or CT and positron emission tomography (PET). These may involve overlapping precautions and risks.

Usual preop diagnosis

Tumor, primary or metastatic; lymphadenopathy; abscess, effusion, empyema, pseudocyst, or other fluid collection; cholecystitis; arterial occlusive disease; aneurysm or pseudoaneurysm; trauma; deep venous thrombosis; chronic venous occlusion; thromboembolic disease; pulmonary embolism; venous insufficiency; implanted IVC filter; biliary obstruction; obstructive uropathy; hydronephrosis; portal hypertension; cirrhosis; renal failure

PATIENT POPULATION CHARACTERISTICS

Age range	All
Male:Female	1:1
Incidence	Common
Associated conditions	**Fluid collections:** Patients may present with fever, sepsis, pain, or ileus. Mass effect, such as with empyema or pericardial effusion, may also affect respiratory or cardiovascular function. Instrumentation or relief of mass effect may induce a vasovagal response or acute bacteremia and sepsis. Some infections (Echinococcus, Entamoeba, methicillin-resistant Staphylococcus aureus [MRSA], vancomycin-resistant Enterococci [VRE]) may require special precautions, such as respiratory isolation, gown/glove standards, and pre- and postprocedure equipment sterilization. **Solid tumors:** Mass effect may result in obstruction of airways, blood vessels, GI/biliary tract, or urinary tract or neural impingement. HTN may be seen with significant renal compression and, occasionally, with neuroendocrine tumors. Hematopoietic, hepatic, or renal compromise may result in coagulopathy or Plt dysfunction. **Vascular pathologies:** Aggressive anticoagulation and/or antiplatelet therapy may be used intraop. Restoration of arterial flow to kidneys may → rapid ↓ of renin production and BP. Interventional procedures for venous thrombosis can → PE. Placement of central vascular access catheters can cause air embolism or cardiac dysrhythmias from right atrial

	irritation. Sclerosis of vascular malformations may result in pulmonary embolism, acute pulmonary vasospasm, and HTN.

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

The adult patient population requiring anesthesia for imaging is medically quite diverse; however, many have in common the inability or unwillingness to lie still during the procedure. Some of these patients are very ill, requiring the services of an anesthesiologist to maintain cardiopulmonary stability. Adult patients should be NPO (solid food and nonclear liquids) for 6 h preprocedure (elective). In general, US and CT scans present fewer problems for the anesthesiologist than MRI. Regardless of the method of anesthesia chosen, these patients must lie perfectly still, the airway must be protected, and IPPV may be required. Thus, children, the cognitively challenged claustrophobic, uncooperative, or critically ill patients usually require GA.

Respiratory	As a result of limited access to the patient's airway, the preop examination should focus on the need for elective ET intubation to protect the airway. ET intubation and mechanical ventilation also may be required in trauma patients, the critically ill, or patients with GERD or sleep apnea. An LMA/iGel may be suitable for patients not at risk of aspiration.
Cardiovascular	Presence of a cardiac pacemaker or ICD is not a contraindication to MRI (see Safety Checklist, Fig. 13.1-15). The presence of PA catheter thermistors or retained pacing wires and lead fragments is a relative contraindication.
Neurologic	Patients with ↑ ICP or cranial trauma usually need GA with mechanical ventilation and intubation. The presence of ferromagnetic aneurysm clips and/or coils may be a contraindication to MRI (✓ with surgeon or radiologist). Some aneurysm clips are nonferromagnetic and are, therefore, MRI compatible.

Musculoskeletal	The presence of spinal instrumentation, metal plates, pins, screws, joint replacements, or other prostheses is usually not a contraindication to MRI.
Premedication	Midazolam 1–5 mg iv (titrated to effect) may be appropriate in the very anxious adult patient; alternatively, lorazepam 1–2 mg po/sl 1 h before procedure.

Considerations for MRI/MRT

The MRI/MRT suite poses many challenges to the anesthesiologist. Because of the intense magnetic fields involved in MRI, any equipment containing ferromagnetic components—such as ECG monitors and anesthesia machines—cannot go near the magnet. Thus, MRI-compatible equipment is mandatory in the area of the MRI scanner. The magnetic field will destroy information on credit card/access card magnetic strips and may damage pagers as well as mechanical devices, including wrist watches and infusion pump motors. A microdrip infusion set can be a suitable replacement for an infusion pump.

Noise	May be very distressing for some patients and may be as high as 110 dB in a 1.5-T scanner and >130 dB in a 3-T scanner. Exposure to noise levels of this magnitude should not exceed 2 h/d. Hearing protection is strongly recommended.
Thermal injury	Thermal injury is caused by induced currents in metal implants or in looped conductors in contact with the skin.
Projectile effect	The magnet has a strong attraction for ferromagnetic objects that can then become lethal missiles; therefore, all objects, including pens, scissors, iv poles, O_2 cylinders, keys, stethoscopes, and eyeglasses or jewelry containing ferrous materials must be removed before entering the scanning room.
Implanted/foreign material	There are several reports describing problems that may occur with cardiac pacemakers (see Safety Checklist; Fig. 13.1-15; failure to pace), aneurysm clips (hemorrhage), and intravascular wires (induced currents). Metal workers may be at special risk for

	ocular damage 2° imbedded particles (see Safety Checklist; Fig. 13.1-15).
Contrast agent	Currently, gadolinium chelates are the primary agents in use and have a higher safety margin than iodinated contrast agents. Adverse reactions, however, occur in ~2% of patients and include HA, nausea, dizziness, hemodynamic instability, dysrhythmias, and nephrogenic systemic fibrosis.

INTRAOPERATIVE

Anesthetic technique

Typically, iv/po sedation, often without the services of an anesthesiologist. Patients unwilling or unable to cooperate will require GA.

IV sedation	In patients with a normal airway and no Hx of GERD, sedation can be carried out most easily using dexmedetomidine (1 mcg/kg loading dose over 10 min + 0.2–0.7 mcg/kg/h infusion) or propofol infusion (25–100 mcg/kg/min), ± midazolam (0.025–0.10 mg/kg) titrated to effect. **NB**: Only MRI-compatible infusion pumps should be used. (A microdrip infusion is a useful alternative.)

General anesthesia

Induction	Standard induction on an MRI gantry (typically in the magnet anteroom). The anesthetized patient is then transported into the magnet.
Maintenance	Standard maintenance. Most commonly, a propofol or dexmedetomidine infusion provides satisfactory sedation for the procedure (see pump considerations, above). Because continuous muscle relaxation is usually not required, spontaneous ventilation may be safest.
Emergence	Emergence (and extubation) is often accomplished after the patient has been moved back to the anteroom, where additional airway and other support equipment

	should be readily available. The patient should be recovered in the PACU, which may be some distance from the MRI suite. Appropriate monitoring and personnel should accompany the patient during transport.	
Blood and fluid requirements	Usually no blood loss IV: 20 ga × 1 BSS @ TKO	
Monitoring	Standard monitors	Monitoring in the MRI/MRT suite presents special problems, discussed below.
Monitoring, MRI	ECG	ECG may be distorted by magnetic fields. Use MRI-compatible electrodes. Twist leads together to avoid creating loops (↓ artifacts, ↓ burns). V5 and V6 are least likely to develop artifacts.
	Pulse oximetry	MRI-compatible oximeters are available. Locate probe outside bore of the magnet (e.g., toe). Avoid burn injury 2° induced current in looped leads.
	BP (NIBP)	Replace all ferrous connections on cuff and tubing with nylon connectors. Use tubing extensions to keep apparatus away from the field.
	± Arterial line	If an arterial line is medically indicated, keep the transducer close to the patient to avoid recording artifacts. Use MRI-compatible transducers and connectors.

		Recording equipment should have radiofrequency filters.
	Precordial/esophageal stethoscope	Often unsatisfactory because of magnet noise. An MRI-compatible, infrared, wireless stethoscope is available.
	Temperature	MRI-compatible T monitors are available, although usually not necessary for short procedures in adults.
	Capnography	MRI-compatible capnographs are available. Long sample lines will distort waveforms, and $ETCO_2$ concentration may not be accurate; however, this is still useful for measuring RR and relative changes in $ETCO_2$.
	PA catheter	PA catheters with thermistors or retained pacing wires are MRI contraindications.
	Urinary catheter	Catheters with T probes may be MRI compatible up to 3 Tesla, but the thermistor must be disconnected to avoid electrical or burn hazards.
	Verbal/visual	The patient and the monitors may be viewed directly (in procedure room) or through a screened window. Contact should be maintained throughout the procedure.
Positioning	✓ and pad pressure points ✓ eyes	CT and MRI gantries may be poorly padded → potential nerve injury.
Complications	Contrast related	Gadolinium → local and

		systemic reactions
	Loss of airway	Patient must be promptly extracted from the magnet bore and moved beyond the range of the magnet to permit use of emergency intubation and resuscitation equipment.
	Psychological	Panic attacks and claustrophobia occur in 5–10% of patients. Use of an eye mask may be helpful in selected patients. Heavy sedation or even GA may be necessary.
	Hearing loss	Temporary hearing loss and tinnitus may be expected in 40% of patients. Prevent by using ear plugs or other forms of hearing protection. GA: ↑ risk of hearing damage 2° stapedius muscle relaxation
	Thermal injury	Results from induced current heating of oximeter probe and looping cables

POSTOPERATIVE

Complications	Hearing loss	See discussion above.
	Thermal injury	See discussion above.

TRACHEOBRONCHIAL STENTING

SURGICAL CONSIDERATIONS

Description

Tracheobronchial stenting may be performed for benign or malignant strictures of upper and lower airways that are unsuitable either for surgical reconstruction or as a temporizing measure. Patients may not be considered surgical candidates due to poor medical condition (e.g., comorbidity, recent thoracic surgery, limited life expectancy) or certain characteristics of the stricture (e.g., active disease, airway inflammation, extensive length, or multifocality). The most common cause of tracheobronchial narrowing is bronchogenic carcinoma, with the leading benign cause being stricture secondary to prolonged intubation. Less common causes include radiation-induced stenosis, polychondritis, tracheomalacia, and, in children, extrinsic strictures 2° vascular malformations.

Since the first lung transplant in 1963, posttransplant bronchial stenosis has joined the list of indications for tracheobronchial stenting. Bronchial stenosis is a relatively common complication of lung transplantation, occurring in single-lung, double-lung, and heart/lung transplant recipients with an overall incidence of 7–40%. It is believed that this complication is 2° the lack of bronchial arterial supply, with resulting airway ischemia. These ischemic stenoses occur at the bronchial suture line and in the more distal airways.

Stent types

There are two primary types of airway stents: silicone based and metallic, with both bare and covered metallic prostheses available. The development of biodegradable airway stents is an active area of research.

Silicone stents

Silicone-based stents (Silastic) are available both as straight, short tubes and as bifurcated Y-shaped devices. Selection of the appropriate size and length is critical. The stent must be long enough to extend across the stricture and of satisfactory diameter to maintain the caliber of the airway. The main **advantage** of silicone stents is that they are easily removed, either when the patient's ventilatory status has recovered sufficiently or when reconstructive surgery is possible. In addition, the stent can be easily repositioned to obtain optimal placement. Bifurcated silicone stents are also available to accommodate the Y-shaped configuration of the carina with extension into the distal trachea and both mainstream bronchi.

Silicone-based stents do have **disadvantages**. Stenotic airways need to be predilated before silicone stent insertion, whereas metallic stents can be placed within a narrow airway lumen and subsequently dilated. Silicone stents frequently become occluded with mucus plugs and granulation tissue or tumor overgrowth; therefore, regular bronchoscopic examination and treatment are necessary to keep the stented airway clear. Silicone stents and covered metallic stents are more likely to migrate than bare stents due to lack of incorporation into the bronchial wall. In general, silicone stents must be placed under GA because of the need for rigid bronchoscopy.

Metallic stents

The main **advantages** of metallic stents are the ease of insertion, a thin wall that rapidly becomes embedded in the airway, and the large gaps in the stent wall that allow normal ciliary function and reduced mucus impaction. The procedure can be performed using flexible bronchoscopy in the interventional room, with sedation. The main **disadvantage** of metallic stents is the difficulty in removing or repositioning these

devices once deployed. Metallic stents become firmly embedded in the wall of the airway and incorporated into the epithelium in <6 wk. Removal can be accomplished by using forceps to grip the wall of the stent and applying a twisting motion to pull the stent away from the wall. Potential complications from this maneuver may be catastrophic, and once these devices are placed, they should be considered permanent. However, if removal becomes necessary, the patient will require TIVA, muscle relaxants, and IPPV. Complications could include tracheal/bronchial disruption, pulmonary artery injury, and pneumothorax and airway obstruction. Another problem associated with metallic stents is the development of granulation tissue either at the ends of the stents or through the interstices. This requires careful follow-up by repeat bronchoscopy and may require subsequent procedures, such as bronchoplasty, restenting, and laser tissue ablation. Because of these potential complications, the FDA issued a warning in 2005 to limit the use of metallic stents in benign airway strictures only after all other treatment options have been explored.

Because of the flexibility and low profile of the deployment systems used for metallic stents, it is feasible to place them under conscious sedation; however, our practice is to utilize GA for tracheal stent placement to reduce patient movement due to the coughing that occurs with tracheal irritation.

Insertion techniques

Silicone stents have low inherent radial force; therefore, strictures need to be dilated before stenting. Rigid bronchoscopy is necessary to allow dilation and subsequent stent placement. Dilation can be performed with the Holinger bronchoscope, which is abutted to the stricture and advanced with a corkscrew motion. Gum-tipped Jackson dilators and various angioplasty balloons also can be used. In patients with tracheal stomas, a T-tube stent can be inserted via either the stoma or the mouth. This extends up to the vocal cords and down as far as the carina. In patients without tracheal stomas, either Y-tubes or straight stents are inserted in a similar fashion. The stent is mounted on the rigid scope, which is advanced across the stricture and then withdrawn, leaving the stent in place. Biopsy forceps are used to advance a limb of the Y-tube into the other bronchus. Placement of stents above the carina in this fashion is relatively straightforward, and the stents can be removed and repositioned until a satisfactory result is achieved. With more distal bronchial stents, the operator's vision is somewhat obscured, and deployment is more difficult.

For insertion of **metallic stents,** cross-sectional and fluoroscopic imaging is used to determine the optimal length and diameter of the stent. During the procedure, selective tracheobronchography may be performed by injecting water-soluble nonionic contrast

through a catheter at the level of stricture. Flexible bronchoscopy helps guide the stent placement with a soft-tipped guide wire being advanced through either the scope or the ETT into the distal airway. In the rare case where the stricture is too narrow and tight to allow passage of a small, flexible bronchoscope, a guide wire is passed, and the stent is positioned before deployment based on fluoroscopy, reconstructed CT images, or bronchography. Using fluoroscopy, the stent is deployed and visually confirmed with bronchoscopy.

Usual preop diagnosis

Bronchial compression 2° carcinoma; posttransplantation anastomotic stricture; radiation-induced stricture; relapsing polychondritis; sarcoidosis

SUMMARY OF PROCEDURE	
Position	Supine
Incision	None
Special instrumentation	Bronchoscope (flexible or rigid); silicone stent; self-expanding metallic stent (covered or uncovered)
Unique considerations	May have to pull the end of the tracheal tube back to the level of the vocal cords to adequately treat the entire trachea. Alternatively, can stent through LMA
Antibiotics	Not usually administered
Procedure time	1–2 h
EBL	0
Postop care	ICU or step-down unit
Mortality	1–5%
Morbidity	Tracheobronchial irritation (usually temporary). Stent malposition → bronchial occlusion or vocal cord paralysis
Pain score	2–4 (first few hours only)

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Respiratory compromise due to airway obstruction may pose a significant management challenge. It is therefore somewhat controversial and institution dependent, whether

these procedures should be performed outside of the OR. A thorough preop workup is necessary before anesthesia. The majority of patients present for palliation of an obstructing pulmonary malignancy or treatment of granulation tissue obstruction of a lung transplant anastomosis. Some may present emergently with impending airway obstruction that precludes a complete preop workup. The choice of anesthesia is primarily a function of the type of stent, surgeon preference, and the comorbid conditions of the patient. In general, silicone stent placement, which requires airway dilation with rigid bronchoscopy, will necessitate GA. Metallic stents can be placed without the need for preceding airway dilation; therefore, either topical anesthesia, with or without conscious sedation, or GA can be used. Immediate improvements in FEV_1, FVC, and PEF can be expected after stenting an obstructed tracheobronchial segment.

Respiratory	Patients with upper or lower airway stricture may present with cough, stridor, dyspnea, and fatigue. Airway obstruction can be classified as dynamic or fixed, depending on whether the obstruction varies with the respiratory cycle. Stridor that worsens during inspiration suggests an extrathoracic dynamic obstruction, whereas expiratory stridor is associated with intrathoracic dynamic obstruction. Other physical findings may include bronchospasm (in COPD patients), clubbing, or cyanosis. Preop fiberoptic bronchoscopic examination and/or high-resolution, thin-section CT scans will help to define the location, size, and extent of the obstruction. In patients suspected of having tracheomalacia, scans are performed at maximal inspiration and maximal expiration to unmask subtle areas of narrowing exacerbated by ↑ intrathoracic pressure on inspiration. Using this information, the appropriate size for an ETT can be estimated and potential problems with tracheal intubation can be anticipated. **Tests:** CXR; PFTs with flow/volume loops (see Fig. 5-14 in Anesthetic Considerations for Mediastinoscopy); CT scans preferably with thin slices and multiplanar reconstructions
Cardiovascular	Directed at any underlying disease process. Restoration of intravascular volume before induction

	of GA is important in patients with hypovolemia 2° chronic malnutrition from malignancy. **Tests:** As indicated from H&P
Musculoskeletal	Patients with lung cancer may have myasthenic syndrome (Eaton-Lambert) with ↑ resistance to depolarizing muscle relaxants and ↑ sensitivity to NDMRs. Post–lung transplant patients on certain immunosuppressive therapies (e.g., cyclosporine) may have prolonged muscle blockade from NDMRs.
Hematologic	Blood cross-match not necessary unless high risk of hemorrhage from injury (e.g., rigid bronchoscopy used in patients with friable tumors). Maintaining adequate O_2-carrying capacity is important in patients with poor pulmonary reserve. **Tests:** CBC; others as indicated from H&P
Laboratory	Other tests as indicated from H&P
Premedication	Patients in respiratory distress are extremely anxious; however, anxiolysis has to be balanced against the risk of impending respiratory arrest in some patients. Careful titration of anxiolytic medications is necessary to avoid oversedation. An antisialagogue (e.g., glycopyrrolate 0.2 mg iv) will help minimize secretions and improve visualization through the bronchoscope. Post–lung transplant patients may be steroid dependent and stress-dose steroid supplement may be required.

INTRAOPERATIVE

Anesthetic technique

Be prepared for an airway emergency. Preparations should be made for emergency rigid bronchoscopy and/or tracheostomy below the lesion. A variety of laryngoscope blades and ETTs of all sizes, including small, uncuffed (5–6 mm) tubes, should be readily available. Endoscopic evaluation of the airway must be performed in a spontaneously breathing patient if the airway lesion has not been defined. Muscle relaxation must be avoided until a detailed examination is completed and the operator is certain an airway can be maintained subsequently. Vocal cord paralysis, which can mimic tracheal

stenosis, can be obscured by muscle relaxation.

Topical anesthesia	Anesthetize palate, pharynx, larynx, vocal cords, and trachea with lidocaine (2–4%), using atomizer (e.g., MADgic™ Atomizer) or having the patient gargle viscous lidocaine (4%). Avoid local anesthetic overdose.
Conscious sedation	Midazolam will increase the seizure threshold in the setting of relative local anesthetic overdose. Other options include dexmedetomidine (0.2–0.7 mcg/kg/h after loading dose) and propofol (10–100 mcg/kg/min), with or without a short-acting opioid (e.g., fentanyl 25–50 mcg; remifentanil 0.05–0.1 mcg/kg/min). Caution should be exercised when mixing opioids and sedatives to avoid respiratory depression.
Induction	Patients should be well preoxygenated. Patients may be unable to lie flat 2° respiratory distress. Low-density helium-oxygen mixtures (Heliox) reduce airflow resistance past the obstruction, which may be beneficial in ventilating the patient. Ideally, spontaneous ventilation should be maintained until the airway is secured. Inhaled sevoflurane, intravenous ketamine, judicious propofol (without opioid), or awake FOB with topical anesthesia is appropriate. Optimally, the ETT is positioned ~1 cm above the lesion. Flexible bronchoscopy of the distal airways is then performed through the stricture, and the distal extent of the stricture relative to the carina is identified. In patients with a stricture near the vocal cords, the use of an LMA is a viable option, as it avoids passing an airway through the lesion and offers the ability to bronchoscopically examine the entire lesion. Avoid muscle relaxation if possible; if necessary, consider small dose of succinylcholine (or rocuronium → sugammadex). Distal or mild airway stenoses may be appropriately managed with an RSI.
Maintenance	Inhalational anesthesia is unreliable in most cases due to the limited ventilation with a bronchoscope in situ (resistance and leak). TIVA is preferable: use propofol

	(50–100 mcg/kg/min) and remifentanil (0.05–0.2 mcg/kg/min) infusions. Once the airway is secured, muscle relaxation can be given to avoid movement or coughing during the procedure. Succinylcholine drip (0.25–1 g/250 mL NS, titrated to twitch suppression; avoid phase II block by keeping dose <5–6 mg/kg) or intermediate-acting (cisatracurium 0.1 mg iv, vecuronium 0.1 mg/kg iv, rocuronium 0.15–0.3 mg/kg iv) muscle relaxant may be used. Manual IPPV through sidearm of rigid bronchoscope or via the swivel connector if fiber-optic bronchoscope is used. High-flow (up to 20 L/min) O_2 or O_2 flush (barotrauma risk) may be required to compensate for leak if rigid bronchoscope is used. Hyperventilate patient in preparation for periods of apnea. Low-frequency jet ventilation (50 psi at 10/min with I:E 1:2–4) via a Sander injector is an alternative. Barotrauma and dynamic lung hyperinflation are potential problems with this approach.	
Emergence	Patient must be fully awake before extubation with no residual neuromuscular blockade. Emergence can be "stormy." Patient may cough violently to clear secretions and blood. Wake-up on low-dose (e.g., 0.5 mcg/kg/min) remifentanil infusion tends to be smoother; consider airway suctioning and lidocaine (1 mg/kg iv) to decrease airway reactivity. Postop O_2 supplementation (preferably humidified).	
Blood and fluid requirements	IV: 18 ga × 1 BSS @ 1–2 mL/kg/h	Transfusion unnecessary except to optimize O_2-carrying capacity or to treat hemorrhage.
Monitoring	Standard monitors ± Arterial line	$ETCO_2$ not accurate during rigid bronchoscopy Art line depending on patient's comorbidities.
Positioning	Supine ✓ and pad pressure points ✓ eyes	

Complications	Hypoxemia	Suction secretions/blood; airway instrumentation may have to be interrupted and bronchoscope removed to improve oxygenation and ventilation.
	Hypercarbia	Commonly 2° inadequate ventilation. May cause increased sympathetic drive with 2° hypertension/tachycardia/dysrhythmias. Simply ↑ TV and RR.
	Hypertension	Ensure adequate ventilation and sedative/anesthesia.
	Bronchospasm	Rx: bronchodilator (e.g., albuterol puff)
	Stent dislodgement	From coughing or movement. Ensure adequate anesthesia and muscle relaxation.
	Bleeding	More likely with rigid bronchoscope
	Tracheobronchial injury Aspiration of debris	Requires frequent suctioning. Major hemorrhage may require thoracotomy using DLT or BB to isolate and/or tamponade bleeding site. Transfusion.
		Patient may need to be kept intubated after the procedure.

POSTOPERATIVE

Complications	Airway edema	Rx with corticosteroids (dexamethasone 10 mg iv) and/or racemic epinephrine nebulizer. Impending airway obstruction will require reintubation.
	Airway obstruction	May be catastrophic. Secretion retention or stent dislodgement. Rigorous suction. Reintubation or restenting

	Stent fracture/migration	May be catastrophic. May require emergent reintubation or restenting
	Pneumothorax	Obtain CXR. May require chest tube placement if >20% or enlarging
	Secretion retention	Humidified O_2
Pain management	None

THERMAL ABLATION OF TUMORS AND OTHER TARGETS

SURGICAL CONSIDERATIONS

Description

Percutaneous thermal ablation is a minimally invasive procedure often used for treatment of liver, kidney, lung, and bone tumors. It is a treatment option for nonsurgical candidates either in conjunction with or as a standalone therapy to radiation and/or chemotherapy.

The most commonly used thermal ablation platforms are radiofrequency ablation (RFA), microwave ablation (MWA), high-intensity–focused ultrasound (HIFU), and

cryoablation. Irreversible electroporation (IRE) is a nonthermal ablation modality which is reviewed separately. With the exception of HIFU, these thermal ablation systems consist of a generator and applicators that are placed into the target tumor percutaneously through small incisions using imaging guidance (US, CT, or MRI) to deliver cytotoxic thermal energy directly into the target lesion. In contrast, HIFU employs MR guidance to deliver focused US energy from an external source to the target lesion without an incision. MWA, RFA, and HIFU utilize tissue heating to >60° C to achieve lethal coagulation, while cryoablation utilizes tissue freezing to less than −40°C to cause cell death.

Mechanism of tissue destruction

In general, temperatures less than −40° C or more than 60° C cause complete necrosis in most tissues, although cell type and local environment can affect these temperature thresholds. RFA is based on the interaction of high-frequency alternating electric currents (460–500 kHz) within living tissue to generate frictional heat. MWA uses dielectric hysteresis with a rapidly oscillating electromagnetic field, typically in the range of 900–2450 MHz, to force polar molecules, primarily water, to continuously realign in order to generate heat, rendering it more useful in tissues with poor electrical conductance. HIFU uses an acoustic lens to concentrate multiple intersecting beams of US onto a focal target, achieving high acoustic intensities to generate heat.

Heat-based ablation aims to cause acute coagulative necrosis within the target tissues. Initial thermal injury involves the expression of heat shock response with increased thermal resistance in tissues that survive the primary insult. As temperatures increase within the target tissue, irreversible damage occurs with microvascular thrombosis, ischemia, and hypoxia. When temperatures reach more than 60°C, proteins denature and plasma membranes melt, leading to nearly instantaneous cell death.

To achieve rapid cooling, cryoablation devices employ the Joule-Thomson effect, whereby gas, typically argon, cools when rapidly expanded at room temperature after being forced through a narrow opening in the distal end of a cryoprobe. Freezing-based ablations destroy cells at temperatures less than −40°C through ice crystal formation and osmotic shock. Initially, as tissues are cooled, cellular metabolism slows down and ice begins to form outside of the cell, leading to a hyperosmotic extracellular space and cell dehydration. Subsequent thawing can cause fluid influx into the cell with swelling and membrane rupture. When there is rapid cooling, ice crystals can form within the cell, expanding the cell to cause irreversible cell membrane damage.

Techniques of percutaneous thermal ablation

For applicator-based systems, probe number and positioning are often determined based

on preprocedural and periprocedural imaging and manufacturer recommendations. Most commonly, US and/or CT are used to guide probe placement into the target lesion. Some centers use MRI for imaging guidance. The generator or device is activated and output is gradually increased to a predetermined maximum. The treatment time is also programmed into the unit and monitored throughout the procedure. The operator can adjust the ablation time and power during the procedure based on the size of the ablation zone. For cryoablation, two alternating freeze-thaw cycles are typically used to achieve successful tumor necrosis. RFA and MWA ablation zones can be monitored using CT and/or US with varying degrees of success. In contrast, cryoablation allows for direct visualization of a low-density ablation "ice ball" by noncontrast CT.

RFA requires the use of grounding pads typically placed on the patient's thighs. If a single RFA probe is used, at least two and, preferably, four pads (96 cm^2 surface area each) or the equivalent (minimum total surface area ~200 cm^2) must be used. If a three-probe cluster is used, at least four grounding pads or their equivalent (~400 cm^2 surface area) must be used. The grounding pads and the treatment probes are connected to the RF generator. MWA does not require grounding pads. Furthermore, newer-generation MWA devices may be more effective for treatment of larger (>3 cm) tumors compared to RFA.

Treatment volume varies according to the size and number of ablation probes, the modality, duration of treatment, and local blood flow. For heat-based ablations, tumor cells adjacent to large blood vessels may not be treated thoroughly due to the heat-sink effect of flowing blood, which carries away the thermal energy once deposited. It is important to note that MWA is less susceptible to heat-sink effects. Cryoablation is thought to be sparing of sensitive adjacent structures, such as nerves, and would be useful in areas such as the chest or abdominal wall as compared to heat-based therapies. Additionally, temperature-sensitive structures (e.g., bowel) near the planned ablation zone can be displaced using hydrodissection, pneumodissection, and/or percutaneous balloon catheter placement.

Liver ablation

The most well-known and best-studied application of RF is in the treatment of primary and metastatic liver tumors. RF has been used widely to treat hepatocellular carcinomas (HCC) as well as liver metastases. Prospective and retrospective studies have demonstrated that complete necrosis can be achieved in 90% of tumors measuring <3 cm in fewer than two sessions. However, the success rate drops markedly in tumors measuring >3.5 cm, with complete necrosis achieved in <50% at two sessions. MWA is increasingly being favored over RFA in this application given shorter ablation times,

higher efficacy in the treatment of larger lesions (>3 cm), and decreased susceptibility to heat-sink effects. Cryoablation is avoided in the liver given its association with increased bleeding risk and a DIC-like reaction termed “cryoshock.”

Renal ablation

Renal tumors smaller than 3 cm in diameter can be ablated successfully with both RFA and cryoablation. Emerging data on MWA for renal tumors are promising. For central renal tumors, cryoablation is favored because of decreased risk for injury to the collecting system and ureter. Overall, the efficacy for percutaneous ablation for small renal tumors is reported to be >90% with a complication rate of ~7%.

Lung ablation

Percutaneous RFA, MWA, and cryoablation in patients with primary lung cancer or lung metastases demonstrate low rates of serious complications. Pneumothorax is seen in ~30% of cases (similar to rates reported for lung biopsies). Efficacy of RFA of lung tumors has been limited due to the inherent poor conduction of electric current and heat in aerated lung. MWA is not susceptible to these limitations and is thus able to create predictable and larger ablation zones in lung. Cryoablation can effectively ablate tumors in the lung and has the advantage of being relatively resistant to the cold-sink effects of ventilation compared with heat-based ablations. Another advantage of cryoablation is seen with tumors in close proximity to the mediastinum or chest wall as it is less likely to cause thermal damage to these structures.

Bone ablation

Percutaneous thermal ablation has been applied to both benign and malignant painful bone tumors. The first use was for thermocoagulation of small, painful osteoid osteomas. The pain caused by osteoid osteoma is related to prostaglandin production by the cells of the small, central vascularized tumor nidus. Pain relief is obtained only after complete removal of the nidus, surgically or percutaneously. RFA has emerged as the method of choice for treating osteoid osteoma. Patients typically have 1–2 d of postprocedure pain that differs from the pain caused by osteoid osteoma. Relief of the osteoid osteoma pain almost always occurs within the first 24–48 h. Cure with one treatment session can be as high as 90%, and retreatment can be performed if the first treatment is not immediately successful or if the patient’s pain recurs. MWA may have a role in the future as antennae with shorter ablation zones become available.

Metastatic disease to the bone can be associated with intractable pain. Preliminary studies of percutaneous thermal ablation of painful metastatic bone lesions for pain relief show promise. The results of these trials suggest that although both heat-based

ablation and cryoablation can be effective, cryoablation is associated with more rapid and durable pain relief.

Prostate ablation

Transrectal ablation of localized prostate cancer using HIFU has shown promise as a non-invasive treatment modality. Although still a subject of clinical trials, it is FDA and Medicare approved. The procedure uses MR and US image guidance for targeting accuracy. Procedural discomfort often requires GA.

Parkinson disease and essential tremor treatment

Transcranial HIFU has been used to mitigate the signs and symptoms of tremor-dominant Parkinson disease and essential tremor. This is accomplished by ablating specific targets in the thalamus, globus pallidus or adjacent areas. Studies suggest that this technique can be as effective as invasive procedures including deep brain stimulation. Most patients will not require the services of an anesthesiologist.

Usual preop diagnosis

Primary or metastatic hepatic, pulmonary and renal malignancies; osteoid osteoma; prostate cancer; Parkinson disease.

SUMMARY OF PROCEDURE	
Position	Supine, prone, or lateral decubitus
Incision	Over the site to be accessed
Special instrumentation	RFA probes and generator microwave generators and probes; ultrasound probes
Unique considerations	Mild ↑ or ↓ T during procedure; RFA and MWA can be painful, while cryoablation is not.
Antibiotics	Cefazolin 2 g; occasionally ciprofloxacin 500 mg iv
Procedure time	2–4 h
EBL	None
Postop care	Step-down unit
Mortality	<5%
Morbidity	Postprocedure pain at site Hepatic hemorrhage: Rare Pneumothorax (during hepatic dome lesion ablation,

	pulmonary ablation) Hepatic abscess (↑ incidence in patients with previous biliary manipulation)
Pain score	5–8 (first few hours only)

PATIENT POPULATION CHARACTERISTICS

Age range	Adults
Male:Female	M > F
Incidence	Uncommon
Etiology	Pain; metastatic cancer; primary malignancies; neurodegenerative disorder
Associated conditions	metastatic cancer; chronic pain

ANESTHETIC CONSIDERATIONS

Patients presenting for percutaneous thermal ablation range from those with end-stage lung cancer to otherwise healthy chronic pain patients. In addition, analgesic/anesthetic requirements are highly variable, depending on the size and location of the target lesions. Close communication between the various care providers is essential to achieving a positive outcome.

Respiratory	Access to the airway may be limited in the typical interventional radiology suite; thus, a patient with a potentially difficult airway may require elective intubation. Appropriate airway adjuncts (LMA/iGels, light wand, fiberoptic cart, etc.) should be readily available. Intraop risks include the possibility of pneumothorax, so needle decompression supplies also should be available. Lung cancer patients presenting for tumor ablation may have compromised pulmonary function and require objective assessment of pathophysiology with PFTs and/or ABG analysis. **Tests:** PFTs, ABG, as indicated from H&P

Cardiovascular	HTN and CHF are seen frequently in elderly patients presenting for these procedures. These patients may have a severe disease process, which may be complicated by other significant comorbidities. The potential for cardiac ischemia should be evaluated carefully. **Tests:** ECG, echo, noninvasive stress testing as indicated from H&P
Neurologic	A thorough neurologic exam is important to document neurologic deficits that are present before the procedure.
Hepatic	Patients may have coagulation defects and mental status changes 2° systemic liver disease. The potential for severe hemorrhage from vascular injury, the risk of aspiration, and the lack of cooperation (encephalopathy) should all be taken into account when planning the anesthesia. Patients with severe liver disease also may exhibit hepatopulmonary or hepatorenal syndrome manifested as hypoxemia or renal failure. Consider the need for preop correction of coagulation and fluid status. **Tests:** LFTs; ammonia; INR
Endocrine	The possibility of endocrine and metabolic derangements should be assessed. Lung cancer patients may have electrolyte problems 2° SIADH, whereas patients with liver disease are prone to developing hypoglycemia. **Tests:** As indicated from H&P
Hematologic	Consider the possibility of chronic anemia or hypercoagulability 2° neoplastic disease. Chemotherapy or systemic disease may have depressed bone marrow function and altered the activity of WBCs and Plts. **Tests:** Hct, Plt count, or CBC, as indicated by H&P
Premedication	Sedation must be adjusted according to patient requirements. Small doses of midazolam, titrated to minimal sedation, are most reasonable (0.5–1 mg

	increments). Patients with end-stage disease often require very little premedication.

INTRAOPERATIVE

Anesthetic technique

Sedation or GA, depending on the size and location of lesions, patient comorbidities, patient positioning, and ablation modality. Most ablations are well tolerated with MAC; however, large lesions may require GA. MWA procedures also tend to require GA secondary to pain during ablation.

MAC

MAC cases are performed with fentanyl (25–150 mcg) and midazolam (0.5–2 mg) boluses, combined with a propofol infusion (25–100 mcg/kg/min). The substitution of remifentanil (0.02–0.1 mcg/kg/min) for fentanyl allows rapid titration of analgesia for the brief periods of intense stimulation.

Induction	Standard induction, preceding placement of an ETT or LMA	
Maintenance	Standard maintenance. Because procedures are of an unpredictable duration, short-acting muscle relaxants (e.g., rocuronium 0.6 mg/kg) are advised. Propofol (25–100 mcg/kg/min) and remifentanil (0.02–0.1 mcg/kg/min) are an appropriate combination that easily can be titrated to effect. Persistent intraop HTN may be treated with labetalol (5–25 mg) or hydralazine (5–20 mg).	
Emergence	Standard emergence. Short-acting analgesics (e.g., fentanyl 25–150 mcg) should be used in outpatients. Prophylactic treatment with antiemetics (ondansetron 4 mg iv) is beneficial because there is a high incidence of PONV.	
Blood and fluid requirements	IV: 20–14 ga × 1–2 BSS: 2–4 mL/kg/h	Larger access needed for hepatic lesions
Monitoring	Standard monitors ± Arterial line	

	± Urinary catheter	Foley for longer procedures (> 2 h)
Positioning	✓ and pad pressure points ✓ eyes	Radiology tables often poorly padded. Underbody Bair Hugger™ may be useful for avoiding hypothermia.
Complications	Hemorrhage	Blood or colloid should be readily available, if the need is anticipated. Large retroperitoneal hemorrhage can develop, yet not be appreciated until blood loss is extensive.
	Pneumothorax Hemothorax	Needle decompression and/or thoracostomy tube placement may be necessary during thoracic or high hepatic procedures.
	Electrical shock Thermal injury	RFA can produce serious injury if not properly grounded.
	Hyperthermia	Patients may develop rapid T increases 2° direct heating of large lesions.

POSTOPERATIVE

Complications	PONV Hemorrhage	Common Occult blood loss may continue for several h after the procedure is terminated.
Pain management	Multimodal pain management	Postprocedure pain is usually well tolerated.
Tests	Postprocedure HCT, as indicated

IRREVERSIBLE ELECTROPORATION (IRE ABLATION)

SURGICAL CONSIDERATIONS

Description

Electroporation is a method of exposing cells to ultrashort high-voltage electrical pulses to create small pores in the cell membrane. In reversible electroporation, the induced cell membrane porosity is temporary and cells are able to recover. This transient increase in cell permeability has been used in research for delivery of DNA, RNA, and macromolecules, such as antibodies, drugs, and tracers into cells. With the application of higher electrical voltages, permanent pores are created, resulting in disruption of cell homeostasis and apoptotic cell death. This process is known as **irreversible**

electroporation (IRE) and has emerged as a minimally invasive tissue ablation method. IRE presents several advantages compared to the traditional temperature-based ablation methods (i.e., RF or MWA and cryoablation). Because IRE uses nonthermal energy, it avoids undesirable thermal damage to surrounding tissues. IRE is able to induce cell death in a selective, well-defined manner and has been shown to preserve extracellular structures and connective tissue scaffolds, including large blood vessels and bile ducts. It is also not susceptible to perfusion-mediated heat-sink or cold-sink effects that can lead to suboptimal treatments when using temperature-based ablation methods. As such, IRE may be better suited for ablation of tumors located in close proximity to major portal or hepatic veins and arteries, bile ducts, or bowel.

Mechanism of tissue destruction

IRE utilizes high-voltage pulses ranging from 1000 to 3000 V/cm to create an electric field across the tissue between electrodes placed by the operator. Therefore, the shape and size of the IRE ablation field can be manipulated to include the entire area to be ablated. The intensity of the electric field within a given tissue is dictated by the distance between the electrodes and the voltage difference across the electrodes. The creation of permanent nanopores in the cell membrane irreversibly impairs the cell's ability to maintain homeostasis, resulting in cell death via apoptosis. Apoptosis is a natural, tightly regulated process in which cells are phagocytized by immune cells and then replaced by innate cellular regeneration. This process results in minimal damage to surrounding tissues with minimal fibrosis and scarring. Although the major mechanism of tissue ablation in IRE is electroporation, thermal tissue damage is possible if excessive electric fields are applied. Every electrical field produces thermal energy, which is referred to as the Joule effect. If the parameters of IRE are not chosen correctly, the electrical field generated can cause thermal damage, negating the nonthermal advantages of this therapy.

Techniques of irreversible electroporation

Careful planning is necessary before beginning IRE treatment to determine the proper placement and number of electrodes that will achieve the desired outcome. The commercially available NanoKnife™ IRE system (AngioDynamics; Latham, NY) has treatment planning software program that helps determine the number and placement of electrodes needed for the desired ablation zone. The voltage setting is determined by the distance between each pair of electrodes with the purpose of generating at least 1000 V/cm between them. The number of electrodes used depends on the site and volume of the target area and ease of electrode access. Current flow is determined by tissue resistance and degree of IRE achieved.

With the patient under GA, electrodes are placed in a predetermined pattern in the target area using US and/or CT guidance. To minimize the risk of cardiac dysrhythmias, the patient's electrocardiogram is synchronized to the IRE device such that pulses are delivered during the refractory period of the cardiac cycle. Typically, 70 brief pulses of high-voltage (1500–3000 V) direct current between 20 and 50 A are delivered in groups of 10, at intervals of 70 ms (bipolar) or 100 ms (unipolar). At 2-cm probe spacing and 3000 V delivered, the maximum effective treatment area is 2 cm diameter from each probe (maximum of 4 cm total ablation diameter).

Pancreas IRE: IRE has been shown to be successful in managing surgically unresectable pancreatic tumors encasing the celiac and superior mesenteric vessels.

Liver IRE: Clinical IRE was first attempted in patients diagnosed with HCC with promising clinical results. Liver function tests were normal at 24 h and at 1, 3, and 6 mo postop. There was, however, an expected increase in alanine aminotransferase, a marker for acute hepatocyte damage. Most patients with increased levels will return to baseline levels after 1 mo.

Prostate IRE: IRE has been shown to be a safe and technically feasible primary treatment for localized prostate cancer in carefully selected men.

Usual preop diagnosis

Most centers perform IRE on primary or metastatic malignancies in the liver, kidney, lung, prostate, and pancreas.

SUMMARY OF PROCEDURE	
Position	Supine or prone
Incision	Over the site to be accessed determined by preop CT, MRI, or US
Special instrumentation	AngioDynamics IRE electrodes and NanoKnife IRE generator
Unique considerations	Stimulation of skeletal muscles and diaphragm (minimized by the use of muscle relaxants) ↑ cardiac dysrhythmias ↓ T during lengthy procedures in CT room
Antibiotics	Cefazolin 2 g iv; >120 kg = 3 g iv, redose in 4 h
Procedure time	1–2 h

EBL	Usually minimal (although large-volume blood loss may occur during ablation of liver tumors)
Postop care	PACU then step-down posttreatment unit
Mortality	<5%
Morbidity	Post-procedure pain at site Brachial plexus injury (during positioning for liver ablation) Pneumothorax (related to lung ablation, segment VIII, or dome liver ablation) Subcapsular hematoma (related to multiple needle punctures) Intraperitoneal hematoma (related to pancreas ablation)
Pain score	3–8 (first few hours only)

PATIENT POPULATION CHARACTERISTICS

Age range	Adults
Male:Female	50:50
Incidence	Uncommon
Etiology	Primary and metastatic tumors
Associated conditions	Liver, lung, kidney, pancreas, prostate cancer

ANESTHETIC CONSIDERATIONS

GA is mandatory for IRE procedures. Because the high-voltage electrical pulses can cause intense whole body muscle contractions, complete neuromuscular blockade is required. To minimize the risk of inducing cardiac dysrhythmias, treatment is performed with cardiac synchronization. Defibrillator pads are placed prior to initiation of treatment. The electrocardiogram should be closely monitored.

Respiratory	Lung cancer patients presenting for tumor ablation may have compromised pulmonary function and require objective assessment with PFTs and/or ABG analysis before the procedure. Access to the airway may be limited in the CT/MRI scanning suite. Intraop

	risks include the possibility of pneumothorax. Tests: PFTs, ABG, as indicated from H&P
Cardiovascular	Patients with underlying cardiac disease are especially susceptible to IRE-induced cardiac dysrhythmias. History of cardiac arrhythmias is a contraindication for IRE. A defibrillator should be available in the procedure room. The potential for myocardial ischemia should be evaluated carefully. Defibrillator pads are preferably placed on the patient prior to initiation of treatment. A cardiac anesthesiologist is not usually required. **Tests:** ECG, echo, noninvasive stress testing as indicated from H&P
Neurologic	A thorough neurologic exam is important to document preexisting neurologic deficits.
Hepatic	Patients may have coagulation defects and mental status changes related to liver disease. Patients with severe liver disease may exhibit a hepatopulmonary or hepatorenal syndrome manifested as hypoxia or renal failure. Consider the need for preop correction of coagulation and fluid status. **Tests:** LFTs; ammonia; INR
Endocrine	The possibility of endocrine and metabolic derangements should be assessed. Lung cancer patients may have electrolyte problems 2° SIADH, while patients with liver disease are prone to developing hypoglycemia. **Tests:** As indicated by H&P
Hematologic	Consider the possibility of chronic anemia or hypercoagulability 2° neoplastic disease. Chemotherapy or systemic disease may have depressed bone marrow function and altered the activity of WBCs and platelets.
Premedication	Consider midazolam 0.5–2 mg iv. Patients with end-stage disease often require very little premedication.

INTRAOPERATIVE

Anesthetic technique

GETA with muscle relaxation is usually required to minimize any involuntary movement caused by IRE ablation. Some small-volume ablations may be tolerated with MAC, and anesthetic requirements should be discussed with the radiologist.

Induction	Standard induction	
Maintenance	Standard maintenance. Procedure duration may be unpredictable. It is important that adequate neuromuscular blockade is maintained due to intense direct muscle stimulation that may be caused by IRE treatment.	
Emergence	Standard emergence. Short-acting analgesics (e.g., fentanyl 25–150 mcg) should be used in outpatients. Prophylactic treatment with antiemetics may be beneficial because there is a high incidence of PONV.	
Blood and fluid requirements	IV: 20–14 ga × 1–2 BSS: 3–5 mL/kg/h	Larger iv access may be needed for procedures with a high risk for, e.g., hepatic lesions.
Monitoring	Standard monitors ± Arterial line ± Foley catheter	↑ BP (20–30 mm Hg) is common following treatment cycles but may be extreme during treatment of upper pole renal tumors (inadvertent adrenal stimulation). Arterial line may be useful for ablation procedures near the heart, for large-volume ablations, and in patients with renal impairment.
Positioning	✓ and pad pressure points ✓ eyes	Extension of the arms above the head may be required for optimal imaging; if prolonged, this may result in

		a brachial plexus injury, particularly when the patient is in a supine position.
Complications	Hemorrhage	Blood should be readily available for high hemorrhage risk procedures. Large retroperitoneal hemorrhage may develop.
	Pneumothorax	Needle decompression and/or thoracostomy tube placement may be necessary during thoracic or high hepatic procedures.
	Muscle stimulation	Intense stimulation of skeletal muscles and the diaphragm may be produced. Movement should be minimalized by use of muscle relaxants. Neuromuscular monitoring is useful to maintain a constant level of neuromuscular blockade.
	Dysrhythmias	Application of large currents may cause dysrhythmias. Occasionally, the treatment pulses may capture the ventricles resulting in a short run of ventricular tachycardia, which should resolve at the end of each 10 pulse treatment cycle. Although rarely required, a defibrillator/external pacer should be available.
	Acid-base and electrolyte disturbances	Patients may develop ↑ K during ablation of very large tumors or in the presence of

	Hypothermia	preexisting renal impairment. Monitor arterial blood electrolytes during the procedure in those patients. Patients may experience ↓ body temperature during lengthy procedures in the scanning room. Underbody hot-air blankets may be used.

POSTOPERATIVE

Complications	Complications PONV Hemorrhage	Common Occult blood loss may continue for several hours after the procedure has terminated.
Pain management	Standard pain management	Postprocedural pain is usually mild and well tolerated.
Tests	HCT, as indicated

PEDIATRIC RADIATION THERAPY

PROCEDURAL CONSIDERATIONS

Susan Hiniker and Sarah S. Donaldson

Description

Modern pediatric radiation therapy (XRT) requires that the patient be in a stable and reproducible position for daily treatment. Sharply defined beams with secondary collimation are used to irradiate the tumor volume and to spare normal tissue. Patient movement may undermine techniques for sparing normal tissue, and although movement cannot be completely prevented, it must be minimized. In very young children, it is often impossible to prevent movement and achieve adequate cooperation for radiation treatment. In such cases, daily anesthesia is required. Close cooperation of the radiation oncology and anesthesia teams allows for safe and reproducible daily treatment. In general, children older than 3 or 4 yr can be persuaded to lie still for radiation therapy. Children from 2.5 to 4 yr may cooperate during the treatment (which is usually <15 min), but not for the treatment planning and simulation, in which an immobilization-stabilization device is made (often requiring 1–1.5 h). In most infants and young children (<4 yr), anesthesia is essential.

The optimal position for XRT must also be optimal for the anesthesiologist. Ideally, the area to be treated is determined using 3-dimensional conformal techniques to optimize treatment and to minimize normal tissue exposure. This requires a cross-sectional imaging study (e.g., CT scan), with the patient in the identical position as will be used during the radiation treatment. A series of radiographs are taken at the treatment-planning (simulation) appointment, which typically lasts 1–1.5 h and requires GA. It is essential that there be no patient movement between exposures; if the patient moves, the entire procedure must be repeated. Typically, the patient is transported to the CT suite for a 3-dimensional treatment-planning CT scan. Anesthesia preparation may be initiated in the treatment-planning suite or in a nearby preparation room. After scans are obtained, individual beam-shaping devices are made, and a multistep process of contouring begins for treatment planning.

Seven to 10 d following the initial planning session, the patient often has a verification procedure, which is usually of shorter duration—generally requiring only 30 min of anesthesia time. The verification procedure consists of a series of radiographs using the beam-shaping devices, which simulate the treatment to be given. When this procedure is successfully completed, the anesthetized patient is moved to the treatment room. The child is put in the identical position achieved during the planning/verification procedures, and treatment is administered.

The first day or two, and weekly thereafter, a verification x-ray (called a “port film”) is taken to confirm the accuracy of the treatment field. The treatment itself is only a few

minutes in duration for each field; ideally, the entire procedure is completed within 15–30 min. A form of radiotherapy treatment planning and delivery known as intensity-modulated radiation therapy (IMRT) may require slightly longer treatment times due to the larger number and increased complexity of fields treated, while volumetric modulated arc therapy (VMAT) may be of shorter treatment time. A course of treatment may be only a few days or may last for 5–6 wk, generally with treatment given 5 × per week. Occasionally, multiple (2–3) treatments per day are given at 4–8 h (usually 6 h) intervals. At the initial appointment, the patient's optimal position is determined, an immobilization device is constructed, and measurements are taken. The immobilization device is usually a body cradle or cast, and often a head/face mask is made for head and neck or brain treatment. Initially, temporary marks or Band-Aids® are used; however, when the final positioning has been determined, a more permanent mark, such as a tattoo, may be applied. Often, a head holder with a mask is applied to ensure the position for XRT.

In managing certain brain tumors (e.g., medulloblastoma, high-grade intratentorial ependymoma, germ cell tumors, and CNS leukemia), **cranial spinal irradiation** (CSI) may be used. Conventionally, this procedure requires that the patient be placed in the prone position with the head flexed as much as possible to minimize a cervical lordosis. This positioning, however, creates special difficulties for the anesthesiologist. If the child is intubated for the setup, the radiation stabilization device must allow space for the ETT. If the child is not intubated, there must be adequate access to the airway. Current techniques allow patients to be treated with CSI in the supine position facilitating easier airway access for the anesthesiologist, more secure patient immobilization, and faster treatment times.

Fractionation

Pediatric protocols have been testing the efficacy of giving multiple fractions (treatments) of radiation 2–3 × per day, usually at 6-h intervals, to allow higher total radiation doses to be administered with possible less normal tissue morbidity. These schemes have been or are being evaluated for children with central nervous system tumors and total body irradiation (TBI) in preparation for bone marrow transplantation. Until proven to be of increased efficacy, such schemes should remain part of large protocol studies. The timing of radiotherapy may be at 4-, 6-, or 8-h intervals 2–3 × per day, depending on the protocol. These studies provide several challenges for anesthesiologists, radiotherapists, and parents. Radiotherapy under anesthesia, however, has been successfully administered to infants undergoing multiple fractions per day. Attention must be given to potential malnutrition and/or dehydration from prolonged periods of NPO status.

Total body irradiation

Although most TBI techniques are administered with the patient standing, infants and small children must lie prone and supine for the treatment. This positioning requires sedation and/or anesthesia. Gastrointestinal upset, sometimes provoked by the radiation, presents an additional challenge for proper radiotherapy technique, as well as for anesthetic management.

Cranial or body radiation/radiosurgery/IGRT

The technique of using precision, stereotactically localized radiation with a highly collimated radiotherapy photon beam, as generated from a linear accelerator, is currently being employed for select patients with small cranial, base-of-skull, or body tumors. There is increasing enthusiasm for this technique for infants and children with recurrent posterior fossa and cerebral tumors, craniopharyngiomas, optic nerve and chiasmal gliomas, and small AVMs. Radiosurgery has historically required a frame-based technique that requires 6–10 h of continuous anesthesia while a patient undergoes application of a metal frame, CT localization, and multiport radiotherapy treatment. However, newer technology, using image guidance, called image-guided radiation therapy (IGRT) now allows frameless radiation delivery to the cranium or body. This technique requires a 1–1.5-h treatment planning and simulation session followed by a single fraction or limited number of treatment sessions each lasting 1.5–2 h. These approaches require close coordination between the anesthesiologist, neurosurgeon, oncologic surgeon, and radiotherapist.

IMRT/protons/VMAT

Recent developments in external beam radiotherapy techniques have allowed for increasingly conformal treatment using IMRT or proton therapy. However, these complex techniques generally involve image-guided therapy and a greater number of beam directions, thereby resulting in longer overall treatment times. The development of VMAT, in which dose is delivered using a single gantry arc rotation, has allowed for treatment of very conformal volumes with increased speed as well as delivery of fewer monitor units. VMAT is increasingly used in the treatment of pediatric patients, particularly in those who require anesthesia during treatment.

Usual preop diagnosis

Leukemia; brain tumors (benign or malignant); retinoblastoma; solid tumors of childhood

SUMMARY OF PROCEDURES

	Standard XRT/IMRT	TBI	Frameless Radiosurgery
Position	Supine or prone	Supine or prone	Supine or prone
Unique considerations	If prone: head flexed for maximal straightening of the C-spine	May be repeated 2–3 ×/day at 4–6 h intervals	Head extended for stabilization of airway
Anesthesia time	Planning: 30–120 min Treatment: <15 min (IMRT: 15–30 min)	45–60 min <20 min	30–90 min 90–120 min
Postop care	PACU → home	PACU → room	PACU → home

PATIENT POPULATION CHARACTERISTICS

Age range	Usually ≤4 yr
Male:Female	1:1
Incidence	NA
Associated conditions	**Brain tumors:** ↑ ICP is of concern in these patients. Postradiation edema following the first few treatments may further ↑ ICP, with potential for brainstem herniation. Some children with brainstem tumors are particularly difficult to anesthetize, perhaps because of disruption of nerve pathways in those areas of the brainstem that are affected by anesthetics. **Neuroblastoma:** Neuroblastomas are capable of secreting catecholamines and related substances; hence, there is a potential for paroxysmal HTN during anesthesia induction. In these children, the principles of anesthetic management are similar to those for pheochromocytoma. **Retinoblastoma:** It is imperative that the patient be properly immobilized with no movement, as even a mm of change, as occurs with a sigh, may cause unnecessary radiation to the radiosensitive lens and

	anterior chamber. Optimal anesthesia prevents nystagmus and motion of the head. Even minimal lateral or rotary nystagmus may increase the risk of cataract induction.

ANESTHETIC CONSIDERATIONS

Rebecca E. Claure and Brenda Golianu

PREOPERATIVE

Orientation to the XRT suite, positive reinforcement, and play therapy can reduce the number of children requiring anesthesia for XRT; however, the majority of children ≤4 yr will require anesthesia. A detailed preanesthesia visit is essential and is also an opportunity to gain the confidence of both child and parents. The majority of these patients will have received chemotherapy and should be evaluated for side effects. The importance of NPO status needs to be stressed repeatedly, discussing the potential danger of emesis during treatment. Written instructions regarding preop protocols are extremely helpful in this context. For children with cancer, prolonged preop fasting for XRT once or twice daily could severely compromise an already marginal nutritional intake. Infants, children, and adolescents should be encouraged to drink clear liquids until 2 h before treatment. Milk and solid foods should be held for an appropriate time interval (6–8 h depending on age; see Appendix D: Standard Pediatric Anesthetic Management). Reassessment before each anesthetic is recommended because the patient's medical status may change during the course of radiation therapy. Some children will have Sx of ↑ ICP, which must be taken into account when designing an anesthetic plan to avoid ↑ $PaCO_2$ and other factors that may further ↑ ICP.

The most common diagnoses are primary CNS tumor (28–33%), retinoblastoma (9-26%), acute leukemia (9–26%), neuroblastoma (2–18%), lymphoma (8%), rhabdomyosarcoma (5–7%), Wilms tumor (5%), and Ewing sarcoma (5%). The total number of treatments can range from 1 to 65 (median 20–24). Many patients require a mold of the head and neck. Children can range in age from infants to adolescents, with a median age of 2.4–3.8 yr.

Respiratory	Careful evaluation for respiratory compromise due to chemotherapy. Patients with Sx of URI (rhinorrhea, cough, fever) are commonly seen during XRT treatment. If Sxs are significant, XRT should be

	delayed, and the patient should be evaluated by primary service. Fortunately, most children can be managed without the use of an ETT, which itself can increase the risk of oxygen desaturation, laryngospasm, and bronchospasm. The benefit of XRT vs. delaying treatment must be balanced against the risks of anesthesia. **Tests:** As indicated from H&P
Cardiac	Careful evaluation for cardiac compromise due to chemotherapy **Tests:** As indicated from H&P
Neurologic	Patients with intracranial tumors may have ↑ ICP. Postradiation edema following the first few treatments may further ↑ ICP. Sx includes irritability, HA, N/V, and papilledema. Suspicion of ↑ ICP mandates ETT intubation and controlled ventilation to induce hypocarbia.
Laboratory	Tests as indicated from H&P
Premedication	Usually unnecessary in this patient group. Parents usually present for induction, and majority of patients have some form of central venous access or heplock in situ. If inhalational induction is necessary, midazolam 0.5–0.75 mg/kg po may be helpful.

INTRAPROCEDURE

Anesthetic technique

Provision of anesthesia to children at sites remote from the OR is challenging. During XRT, patients must remain immobile so that the tumor can be reliably irradiated while minimizing damage to uninvolved tissue. Anesthetic goals should include patient immobility, rapid onset, brief duration of action, and prompt recovery. The anesthetic should allow maintenance of a patent airway and spontaneous ventilation in a variety of body positions. Propofol bolus and infusion have been shown to be safe and effective for XRT. Higher doses may be needed due to tolerance with repeated treatments. Ketamine is rarely used, but may be effective if there is a history of reaction to propofol. Ketamine is a potent sialagogue and can cause nystagmus, which may interfere with precision radiation of retinoblastomas. It may cause prolonged or unpleasant

emergence and should be avoided in patients with ↑ ICP. Choice of anesthetic technique may be limited by equipment or logistical issues. Anesthesia machines may not be available in all XRT suites.

Induction	**IV:** Propofol (2–4 mg/kg), titrated slowly to effect. Additional propofol boluses may be needed as patients may develop tolerance. Intubation is usually not needed. **Inhalation:** Mask induction with sevoflurane is appropriate in children without iv access and may be preferred by some children. The airway can almost always be maintained by careful positioning and extension of the neck. It is essential that this same degree of extension/flexion be maintained for each treatment. A molded immobilization device may be placed over the patient's head and neck, limiting airway access and potentially causing airway obstruction.	
Maintenance	**IV:** Propofol (100–250 mcg/kg/min) by continuous infusion. Supplemental O_2 should be administered via nasal prongs. **Inhalation:** Sevoflurane in O_2	
Emergence	Patients awaken rapidly following cessation of propofol infusion or sevoflurane. XRT may cause nausea/vomiting, so antiemetics should be given (ondansetron 0.1–0.15 mg/kg). Avoid dexamethasone (may conflict with chemotherapy protocols and in rare cases may cause tumor lysis syndrome).	
Blood and fluid requirements	IV: Central access BSS: Routine maintenance	Majority of children receiving radiotherapy have some form of central venous access.
Monitoring	Standard monitors	A critical problem is the lack of access to the patient and monitors during XRT. A video camera with a zoom lens can focus on the monitors, and a second camera is trained on the patient. In XRT suites with a viewing window, a

		small marker may be placed on the chest so that the rise and fall of chest motion are seen easily.
Positioning	✓and pad pressure points ✓eyes	Careful positioning 2° possible chemotherapy-induced peripheral neuropathy
Complications	Airway obstruction	Respiratory obstruction may occur; it usually responds to nasal or oral airways and careful repositioning.
	Patient movement	Deepen anesthesia

POSTPROCEDURE

Complications	PONV	Many patients have chemotherapy-induced nausea, which may be exacerbated by anesthesia, XRT, and stress.
	Central line sepsis	Patients may be immunocompromised following chemotherapy. Attention to sterility during access of the central venous line is critical because repeated use by multiple health care providers → ↑ risk of catheter contamination. Aseptic preparation of anesthetic iv medications, especially propofol, is important.
	Cerebral edema	In patients with ↑ ICP, XRT can provoke an acute ↑ ICP,

		with consequent ↑ HA, ↑ N/V, ↓ consciousness, and cardiac arrest. These patients should be monitored × 24-h post-XRT.
Pain management	Standard approaches	Radiation treatments are not associated with pain, but narcotics may be useful in relieving pain associated with neoplastic disease.

PEDIATRIC CARDIAC CATHETERIZATION AND ELECTROPHYSIOLOGY

PROCEDURAL CONSIDERATIONS

Lynn F. Peng, Anne M. Dubin, Stanton B. Perry, Jeffrey A. Feinstein, and Katsuhide Maeda

Cardiac catheterization and electrophysiology testing have evolved over the recent decades from purely diagnostic tools to combined diagnostic and therapeutic

procedures. Although the use of GA varies from institution to institution, higher levels of sedation are required at a minimum for critically ill patients, those requiring complex interventional strategies, small children who must remain totally still, and when TEE is used for image-guided therapy. A thorough review of diagnostic and interventional cardiac catheterization and electrophysiology is not possible in this chapter, and the interested reader is referred to the multiple textbooks available on the subject.

The placement of anesthesia equipment for these procedures must allow for (a) proper positioning of the patient, (b) easy access to the head and neck and/or groin for the physician performing the procedure, and (c) rotation and angulation of the imaging equipment. The goal of sedation in all of these procedures is to provide a nontraumatic, safe environment for the patient. Many patients can be cared for adequately and safely using conscious sedation; however, there is a subset of pediatric patients who may require GA. This group may include patients with complex congenital heart disease, ventricular dysfunction, or airway abnormalities.

It is important to understand that certain anesthetic agents may alter cardiac conduction, making arrhythmia inducibility more difficult. Catecholamine-dependent arrhythmias, such as an automatic atrial tachycardia, may be impossible to induce with the patient under GA. Furthermore, the arrhythmia itself may complicate anesthetic care, by causing sudden decreases in BP due to excessively rapid rates. In patients undergoing radiofrequency ablation (RFA) in areas close to other critical structures of the heart, GA may be necessary to keep the patient motionless during application of energy. During anesthesia, the use of muscle relaxants may mask diaphragmatic/phrenic nerve stimulation during mapping and poses the risk of ablation of structures other than the abnormal pathway. In patients returning for a previous failed ablation, controlled ventilation using low tidal volumes to minimize electrophysiologic catheter movement may be helpful.

VASCULAR ACCESS

The modified **Seldinger technique** of cannulating blood vessels percutaneously is used to establish vascular access for cardiac catheterization. (The femoral and IJ veins are most commonly used for venous access.) Transhepatic access to the IVC has been used safely and successfully in patients without femoral venous access. The femoral artery is most commonly used, although the carotid and axillary arteries may be used for specific procedures or when there is bilateral femoral artery occlusion. In newborns, the umbilical artery and vein may be used. Access may be especially difficult in patients who have undergone multiple previous procedures. In the most severe cases,

reconstructive transcatheter techniques, including **balloon angioplasty** and **stent implantation** to rehabilitate the vessels, have been used to allow future catheter-based diagnostic and therapeutic interventions.

Infiltration of the skin and the subcutaneous tissues with a local anesthetic agent to reduce pain is used when the procedure is being performed under conscious sedation. With GA, infiltration of a local anesthetic agent may be helpful as placement of lines can be stimulating. The use of local anesthetic is helpful in minimizing the amount of GA used to produce a similar depth of anesthesia in patients with depressed myocardial function. Local anesthetic may also be deferred to the end of the procedure to alleviate pain and discomfort at vascular access sites during recovery.

HEMODYNAMIC DATA

O_2 sat measurements are made routinely in the various cardiac chambers, venae cavae, and great vessels. These measurements are used to calculate the systemic flow (CO, Q_s), pulmonary flow (Q_p), the ratio of the pulmonary to systemic flow (Q_p:Q_s), and PVR and SVR.

It is ideal to obtain the data with the patient awake and breathing spontaneously in room air. This is rarely possible in pediatric patients. The use of light anesthesia and sedation during the diagnostic part of the study facilitates acquisition of data in as near-normal state as possible. It is important to recognize and limit effects on intracardiac and intrapulmonary pressures and systemic and pulmonary resistances when the procedure is done under GA with IPPV. Though one could argue that the work of breathing and airway apparatus resistance are less with an LMA compared to an ETT, improper seating of the LMA can influence the pressure waveforms. Thus, for patients with obstructive airway disease, a mask supplemented with an oral airway may be more helpful. At a minimum, and when tolerated, baseline hemodynamic measurements should be performed with an FiO_2 as close to 0.21 as possible. In some cases, additional diagnostic information may be collected to study the effects of O_2, NO, vasodilators or inotropes, exercise and balloon occlusion of intracardiac or extracardiac shunts on the CO, pulmonary flow, and PVR and SVR.

From O_2 sat, dissolved O_2 (PO_2), and Hb measurements, the O_2 content (mL/dL) of the mixed venous blood and systemic arterial blood is used to calculate systemic AV O_2 content difference. Pulmonary AV O_2 content difference is similarly estimated by calculating the O_2 content of pulmonary venous and arterial blood. Systemic (Q_s) and

pulmonary flow (Q_p) can then be derived using the **Fick principle:**

$$\text{Flow (Q) (L/min)} = \frac{O_2 \text{ consumption (mL/min)}}{\text{AV } O_2 \text{ difference (mL of } O_2\text{/L of blood)}}$$

$$\text{Pulmonary Flow } (Q_p) = \frac{O_2 \text{ consumption}}{\text{Pulmonary vein } SaO_2 - \text{Pulmonary artery } SaO_2}$$

$$\text{Systemic Flow } (Q_S) = \frac{O_2 \text{ consumption}}{\text{Systemic artery } SaO_2 - \text{Mixed venous } SaO_2}$$

Based on Ohm law, which states V = IR, where V = voltage (or pressure drop) across a circuit, I = the current (or flow) through the circuit, and R = the resistance in the circuit. SVR and PVR can be calculated as follows:

$$PVR = (PA_p - LA_p)/Q_p$$

$$SVR = (Ao_p - RA_p)/Q_S$$

where PA_p = pulmonary artery pressure; LA_p = left atrial pressure; Ao_p = aortic pressure; RA_p = right atrial pressure; PVR = pulmonary vascular resistance; and SVR = systemic vascular resistance.

When the partial pressure of dissolved O_2 is <100, the PO_2 portion of the equation can be ignored, and the flow can be calculated using the O_2 consumption and O_2 sat measurements alone.

$$\text{Systemic Flow } (Q_S) = O_2 \text{ consumption/(systemic arterial } O_2 \text{ content} - \text{systemic venous } O_2 \text{ content)}$$

$$\text{Pulmonary Blood Flow } (Q_p) = O_2 \text{ consumption/(pulmonary venous } O_2 \text{ content} - \text{pulmonary arterial } O_2 \text{ content)}$$

$$\text{Systemic Flow } (Q_S) = O_2 \text{ consumption/13.6} \times \text{Hgb} \times (\text{systemic artery saturation} - \text{mixed venous saturation})$$

$$\text{Pulmonary Blood Flow } (Q_p) = O_2 \text{ consumption/13.6} \times \text{Hgb} \times (\text{pulmonary vein saturation} - \text{pulmonary artery saturation})$$

ANGIOGRAPHY

Biplane cineangiography is performed to delineate intracardiac or vascular anatomy and to evaluate ventricular function. Images are obtained by injection of radiographic contrast agents through angiographic catheters positioned in appropriate locations. The

angiograms may be performed in posteroanterior and lateral projections or by angling the cameras to obtain cranial, caudal, left anterior, or right anterior oblique projections. Based on the site of injection and the information required, the injection may be performed with a power injector, delivering large amounts of contrast quickly, or by hand.

INTERVENTIONAL PROCEDURES

Valvuloplasty

Aortic valvuloplasty

A retrograde approach from the femoral artery generally is used, although an antegrade and transseptal approach from the femoral vein is preferred by some. In either approach, following hemodynamic evaluation and angiographic estimate of the aortic valve annulus, a wire is positioned across the valve, and a balloon catheter is advanced over the wire and positioned across the aortic valve. The balloon is then inflated and deflated quickly. The inflation of the balloon leads to a transient loss of CO, ↓ SBP, and occasionally may be accompanied by ↓ HR. These hemodynamic changes recover quickly on balloon deflation. Although complications of aortic valvuloplasty are rare, the anesthesiologist must be "prepared for the worst," which includes annular rupture and the creation of significant aortic regurgitation. Supplementation with oxygen and airway intervention, including intubation, should be considered for complicated interventional procedures.

Pulmonic valvuloplasty

After femoral venous or IJ access is obtained, the technique for balloon dilation of the pulmonary valve is nearly identical to that outlined above for the aortic valve. Loss of CO and ↓ HR are seen during the time of balloon inflation with this intervention as well. Although annular rupture is also a potential complication of this procedure, the creation of pulmonary insufficiency is of less concern and better tolerated than aortic insufficiency. Consider supplementing with 100% oxygen during interventional procedures, prior to the period of diminished cardiac output. If complications occur, airway intervention, including intubation, should be considered. Age-appropriate airway equipment and suction should be readily available.

Angioplasty

A number of transcatheter treatment options are available for management of **pulmonary artery stenoses**, including **balloon angioplasty** and **endovascular stent implantation.** Angioplasty has been shown to be highly effective in anatomically appropriate cases with a low complication rate. Hemodynamic and angiographic assessment of the lesion

is obtained, followed by selection of an optimal balloon catheter, based on both the size of the stenosis and surrounding "normal" tissue. Using the same "over-the-wire technique," a balloon is advanced and centered over the stenosis. Hemodynamic and angiographic data are assessed following each intervention. A high index of suspicion for complications—including dissection or pulmonary artery tear, obstructive intimal flaps, thrombi, and reperfusion pulmonary edema—is justified, as management may require ventilatory manipulations and/or emergent cardiovascular resuscitation. Consider endotracheal intubation prior to intervention since airway management in the presence of pulmonary edema and/or blood in the airway can be difficult to manage.

Balloon angioplasty of coarctation of the aorta may be performed for treatment of native or recurrent coarctation. Angiography of the aorta is performed to delineate the coarctation and estimate the dimension of the coarctated segment and the adjacent aorta. As with other angioplasty techniques, the balloon size is based on the dimensions of the stenotic area and surrounding vessel. Transient loss of lower body perfusion and ↓ HR are to be expected, as with balloon valvuloplasty, on inflation of the balloon. Pressure and angiographic data are obtained to determine adequacy of results and absence of complications. There is a 4–5% incidence of intimal tear and dissection that, in most cases, are nonprogressive. Rarely, aortic disruption may require emergent surgical repair.

Endovascular stent placement

Stent implantation in the pulmonary arteries or for aortic coarctation is used to maintain vessel diameter and decreased gradients in patients unresponsive to balloon dilation. Stents are mounted on balloon catheters, and the balloon/stent combination is advanced over a previously placed wire. A long sheath (originating in the groin or neck) is placed across the area of narrowing to prevent the stent from slipping off the balloon catheter as it makes its way through the heart or vessels. After the stent has been properly positioned, the long sheath is withdrawn to expose the balloon/stent combination. The balloon is inflated to expand the stent and appose it to the vessel wall. Placement of long sheaths, particularly through the right ventricular outflow tract (RVOT), can be difficult and may result in transient bradyarrhythmias and loss of CO.

Closure of congenital defects

Atrial septal defects (ASDs)

As many as 80–85% of secundum ASDs may be amenable to device closure in the cath lab. Most devices currently used include a left atrial disc with an occlusive membrane, a central spool or connecting pin, and a right atrial disc with an occlusive membrane. The membrane occludes flow through the defect, and within months, the device becomes

incorporated into the septum due to endothelialization. Concomitant use of TEE or TTE is indicated and serves three purposes: (a) to ensure an adequate rim for device placement, (b) to confirm appropriate placement of the device so as to avoid valvar structures, and (c) to confirm that once deployed, the device remains seated in the appropriate position. Thus, the use of GETA is preferred. Upon echocardiographic examination and confirmation of an adequate rim for device placement, a prophylactic antibiotic (usually a cephalosporin) is administered by the anesthesiologist. A sizing balloon inflated across the defect permits estimation of the stretched diameter. A long sheath is then placed across the defect over a wire. The device attached to the delivery cable is loaded in the long sheath and advanced to the left atrium. The left atrial disc is opened; the device is withdrawn until the left atrial disc is in contact with the atrial septum; then, the right atrial disc is opened, effectively "sandwiching" the atrial septum between the two discs.

Ventricular septal defect (VSD)

Closure with a device can be performed in the cath lab for isolated or multiple muscular VSDs, as well as perimembranous defects. The technique requires establishment of a continuous AV guide wire loop across the defect. Most often, the wire course is from the femoral vein, through the right atrium, into the RV, across the VSD, out the aortic valve, around the aorta, and out the femoral artery. The device is then deployed via a long sheath placed across the VSD through the RV aspect. Hemodynamic compromise may be seen with tension on the wire if aortic or tricuspid insufficiency is induced. Transient arrhythmias are routine while crossing the VSD and deploying the device. Great care must be taken to avoid entrapment in the mitral, aortic, and tricuspid valves during device deployment. In addition to fluoroscopy, TEE or TTE is used to guide placement of the device. Recent improvements in the devices have significantly reduced the morbidity of this procedure.

Coil occlusion

Aortopulmonary collaterals, AVMs, Blalock-Taussig (B-T) shunts, venous collaterals, coronary artery fistulae, and patent ductus arteriosus (PDA) have all been successfully occluded using the technique of coil embolization. The embolization coils consist of a metal wire, either stainless steel or platinum, and may additionally have Dacron strands, which are available in multiple sizes, lengths and shapes. As with other device procedures, antibiotic prophylaxis is indicated. Although PDA or coronary artery fistula embolization may obviate the need for surgery, most embolizations serve to either reduce the cardiac workload by decreasing the amount of shunting or simplify a planned surgical procedure.

The technique for coil closure of collaterals or other communications is straightforward. A catheter is placed in the vessel to be occluded, and a selective angiogram is done to delineate the anatomy and diameter of the vessel to be closed. Coils that are slightly larger than the diameter of the vessel are used because the vessel will distend when the coil is deployed. Using a long "pusher" wire, the coil is advanced through the catheter and deployed in the vessel. Repeat angiography is performed to confirm complete closure. If residual flow remains, additional coils are placed. Coil dislodgement and embolization to a distal blood vessel are the most common complications. In general, the errant coil can be retrieved in the cath lab without much difficulty and a new coil of a larger size placed to occlude the vessel.

OTHER PROCEDURES

Endomyocardial biopsy is commonly performed for rejection surveillance in patients following cardiac transplantation. It also may be performed in patients presenting with acute onset of cardiomyopathy for histopathologic Dx of myocarditis. The preferred site for obtaining cardiac biopsy is the RV aspect of the intraventricular septum. The specimen is obtained with a biopsy forceps advanced to the RV through a long sheath. It is usual to obtain four to five specimens to improve the diagnostic gain, as the histopathologic changes can be patchy. Complications of endomyocardial biopsy include cardiac perforation and tricuspid valve damage. GA is required in patients with compromised airway and/or cardiopulmonary status from lymphoproliferative disease or obesity 2° to steroid therapy. With right heart catheterization and biopsies, the arms are usually at the patient's side. However, with annual studies, as with all studies requiring left heart catheterization, the arms are pulled upward toward the head. Though this permits observation of the IV site, utmost attention to detail in padding pressure points is needed, specifically to avoid brachial plexus injury.

A variety of other transcatheter therapeutic procedures may be performed in the cardiac cath suite. **Rashkind balloon atrial septostomy, static balloon septoplasty, Brockenbrough transseptal needle puncture,** and **radiofrequency-assisted perforation** of the pulmonary valve or the atrial septum are all less commonly used than the procedures described above, but routinely are undertaken in high-volume cath labs.

ELECTROPHYSIOLOGY STUDY (EPS)

Patients with atrial or ventricular arrhythmias may require either diagnostic or therapeutic interventions in the cath lab. EP studies are catheterization procedures in which intracardiac electrical signals are recorded via specialized catheters that can

both record electrical activity and stimulate the heart. These studies often are used to make a Dx of the mechanism of arrhythmia, assess the hemodynamic impact of the arrhythmia, assess efficacy of pharmacologic therapy, and map the location of abnormal conduction pathways or automatic foci. Although routine studies usually take 2–3 h, some may be quite lengthy. For all procedures, access is obtained via the RIJ or femoral vein; thus, the head may be turned to the side. Though providing easier access for the cardiologist, it makes airway management more tenuous. Pressure on/near the trachea can promote coughing.

Radiofrequency ablation (RFA) is a procedure in which abnormal electrical conducting pathways or automatic electrical foci (identified by EPS) are destroyed using the application of RF energy delivered through a deflectable electrode catheter. This procedure was first described in pediatric surgery in 1991, but has rapidly become a preferred therapeutic option for supraventricular tachycardia in this population. On some occasions, RF lesions must be placed close to other critical structures in the heart (e.g., AV node).

With advances in technology and an increased understanding of high-risk pediatric patient populations, **transvenous pacemaker** and **implantable cardioverter defibrillator (ICD)** placements are becoming more common in the pediatric population. Pacemaker placement has become more common as data have accumulated regarding the risk of sudden death in patients with congenital complete heart block, as well as increased survival with postop heart block. New indications for ICD placement in patients with long-QT syndrome, congenital heart disease, and hypertrophic cardiomyopathy have increased the number of ICD implantations in the last 5 yr. These procedures are commonly performed in the cath lab under GA. However, for the placement of loop recorders and subcutaneous ICDs, light sedation can be considered.

Transcatheter valve placement

Pulmonary valve

The most common site for interventional valve replacement is the pulmonary valve. These cases are performed via the femoral or jugular veins. A stiff wire is placed in secure position from the access site to a distal PA branch. A long sheath is then placed across the RV outflow tract and is used for angiography and intervention. There are multiple steps in this procedure involving first pulmonary valvuloplasty of the conduit, bioprosthetic valve, or native pulmonary valve (see pulmonary valvuloplasty above). Contained conduit tear occurs in about 5% and does not have any hemodynamic consequence. The next step involves bare metal stent placement across the site of intended valve deployment in order to open up stenotic and calcified conduits or to

provide a landing zone in a native outflow tract. A covered stent can be used to cover more sizeable tears. The same hemodynamic instability can occur during stent placement as during valvuloplasty with the added risk of stent malposition or embolization. After proper stent placement, the transcatheter valve is then prepared and delivered. The manipulation of the delivery system to properly position the valve can cause short-lived dysrhythmias. Repeat hemodynamic measurements and angiography are performed after valve deployment.

Tricuspid valve

The procedure is similar to PV in that a stiff wire is positioned across the tricuspid valve. Balloon valvuloplasty is performed to open up the stenotic leaflets and to size the bioprosthetic tricuspid valve. The transcatheter valve is then deployed within the tricuspid valve. Again, with balloon angioplasty and valve deployment, there can be a temporary ↓ CO and ↓ O_2 saturations that return once the balloon is deflated.

Aortic valve

This is a much more common procedure in adults; however, AV replacements occasionally do occur in pediatric patients. The approach is usually from the femoral artery although a hybrid procedure can be done with surgeons and an LV apical approach. From the femoral artery, the AV is crossed retrograde and a stiff wire is positioned in the LV. Valvuloplasty may first be performed (see Aortic Valvuloplasty). For valve deployment, rapid ventricular pacing (of the RV) is performed, and TEE is used to confirm proper placement. Potential complications include aortic regurgitation or paravalvular leak, aorta injury secondary to the wire or delivery system, and other vascular injury.

ANESTHETIC CONSIDERATIONS

Claudia Benkwitz and Lisa Wise-Faberowski

PREPROCEDURE

Cardiac catheterization and interventional procedures in children, ranging from those requiring simple diagnostic procedures to those requiring complex interventional procedures, such as balloon angioplasty/valvuloplasty, stent placements, or closure of shunts have facilitated care of younger, smaller, and sicker patients. These patients are often challenging for the anesthesiologist due to their abnormal cardiac anatomy and physiology. Many of them have undergone repeated catheterizations and have had multiple anesthetics. All patients require a thorough preanesthetic evaluation with

emphasis on cardiorespiratory function and associated comorbidities (almost 30% of patients show associated anomalies or syndromes with Down syndrome being the most common). Most children will follow the same NPO protocol as they would for surgery. Particular attention should be paid to patients with single-ventricle physiology (Fontan circulation), who are dependent on their venous return for hemodynamic stability and oxygenation as well as being prone to shunt thrombosis, specifically when dehydrated. In such patients, early establishment of IV access to prevent dehydration is advisable. Clear liquids can be given up to 2 h before surgery. Similarly, Williams syndrome patients with pulmonary, aortic outflow tract, and/or coronary obstruction are at risk of sudden death upon anesthetic induction if they have an inadequate preload.

Previous anesthesia	✓Surgical, interventional, and radiologic procedures; h/o difficult access; endotracheal tube size and anesthetic techniques; problems with previous anesthetics
Family history	✓Family history for anesthetic-related problems; h/o malignant hyperthermia
Prematurity	✓Gestational age. Need for postop admission and apnea monitoring if <55 wk postconceptual age; any associated clinical problems
Neurologic	✓Head ultrasound in neonates to rule out ischemia and hemorrhage; note preoperative neurologic status due to risk of embolism during procedure; h/o seizures or developmental delay. Heparinization during cardiac catheterization may increase the risk of bleeding.
Craniofacial and airway	✓H/o difficult airway; any surgery to the airway; h/o tracheal stenosis due to multiple intubations in the past; stridor due to laryngo- or bronchomalacia; h/o loose teeth. DiGeorge (22qll deletion) and William syndrome patients may present with abnormal airway anatomy. Trisomy 21 patients and post–heart transplant patients on steroids may present with obstructive airway disease. **Tests:** Recent bronchoscopy, imaging of the airway
Respiratory	✓Current problem(s): ✓Respiratory reserve (i.e.,

	playing activities, respiratory rate, nasal flaring, intercostal/subcostal retractions, diaphoresis). ✓H/o cyanosis, chronic cough, steroid use for RAD and other chronic respiratory problems → ensure that they are under optimal control. ✓H/o recent URI → risk of adverse perioperative events. Note: frequent "URIs" along with FTT may be signs of pulmonary overcirculation in the setting of large L → R shunts as opposed to being of infectious etiology ✓Patients with pulmonary hypertension may have obstructive sleep apnea. ✓Cardiac transplant patients can develop lymphoproliferative disease, which results in redundant lymphoid tissue in the pharynx and epiglottis → possible airway obstruction. ✓Requirement for supplemental O_2, CPAP, BiPAP, nitric oxide. Medications for pulmonary HTN should be continued. **Tests:** SpO_2, CXR to r/o infiltrates, CHF and cardiomegaly, PFTs. Compare with baseline. Assess perfusion scan for distribution of PBF if necessary.
Cardiovascular	✓Current problem(s): ✓Past surgical history, pacemaker, ICD, etc. If the patient has a pacemaker → check settings, indication(s), underlying rhythm, pacer dependency, and last interrogation. ✓Existing shunts → may affect anesthetic plan and FiO_2. ✓Assess cardiopulmonary reserve (e.g., exercise tolerance, diaphoresis, SOB, feeding difficulties, poor weight gain). ✓H/o syncope, hypoxic spells, and chest pain. Transplant patients may develop CAD. ✓Arrhythmias, palpitations, murmurs, pulses in all extremities. **Tests:** SpO_2, ECG; BP (upper/lower extremity) ✓Recent echo, cardiac catheterization +/− CT/MRI/MRA reports
Gastrointestinal	✓Feeding difficulties, reflux due to chronic use of steroids. May have G-tube/Nissen. ✓Some single-ventricle patients may have hepatic dysfunction and protein-losing enteropathy (↑ risk

	ascites, pleural/pericardial effusion, infection). Alagille patients may also present with hepatic dysfunction and hyperbilirubinemia. SaO_2 saturation measured using pulse oximetry or NIRS may pose difficulties as high bilirubin levels can affect light absorbance.
Renal	✓Patients with CHF are frequently on diuretics and/or ACE inhibitors/digoxin → expect hypovolemia and potential electrolyte disturbances (i.e., ↑ ↓ K^+). ✓Transplant recipients may develop renal dysfunction due to antirejection medication or HTN. ✓Patients may have had renal insult during previous surgery. **Tests:** ✓BUN and Cr as these patients are also at risk for renal injury due to contrast and also to guide hydration therapy.
Endocrine/steroid	✓Transplant patients are on steroids. ✓for other endocrine concerns.
Hematology/ immunology	✓History of previous transfusions and reactions. Immunologic deficiency that may affect the type of blood transfusion (e.g., neonates require CMV-negative blood and products). **Tests:** Recent hematocrit
Syndromes	✓For coexisting syndromes and associated anomalies
Ob/Gyn	✓Last menstrual period
Vascular	✓H/o thromboembolism. H/o difficult access and vascular occlusion
Current medications	✓Stop warfarin before cardiac catheterization. Anticoagulate with heparin if needed; d/w cardiology. ✓Coagulation studies prior to procedure. ✓Antiarrhythmic drugs are usually stopped prior to EP studies unless the arrhythmia is frequent and poorly tolerated. Hold diuretics and ACE inhibitor starting the night before due to ↑ risk for hypotension

	following induction; continue other cardiac meds.
Laboratory	✓CBC: Use Hgb/HCT baseline to determine need for transfusion; ↑ Hgb/HCT suggests chronic hypoxia; transfusion threshold will vary depending on patient age and comorbidities. Severe anemia should be corrected prior to cath. ✓Have T&C blood available in the catheterization lab for procedures with risk of increased bleeding. ✓WBC: if the child has a h/o fever and recent URI. ✓Electrolytes/Bun and creatinine, especially if the patient is on diuretics and/or digitalis. ✓Coagulation studies. ✓Drug levels (e.g., digitalis, antiseizure medications) to ensure therapeutic range. Pregnancy test must be done the morning of surgery if patient has attained menarche.
Premedication	✓Midazolam 0.5–1.0 mg/kg po or via G-tube. Ketamine 5–8 mg/kg po or via GT may be added in either extremely uncooperative patients or those with significant hemodynamic instability (i.e., severe AS, PAH, ventricular dysfunction), in whom an inhalational induction would not be safe. In patients unwilling to take PO premed, nasal dexmedetomidine 1–3 mcg/kg may be used, however may take 30–45 min to reach full effect. Be cautious in patients with OSA as they are more sensitive to respiratory depression. Cyanotic patients should have SaO_2 saturation monitored before and continuously after premedication. Antibiotics are given to patients as required for SBE prophylaxis per most current (2007) AHA guidelines and for those undergoing interventional procedures. In patients scheduled for EP studies in whom anxiety is a known precipitant of the arrhythmia, preop anxiolysis is a relative contraindication as it may result in a false-negative study.
NPO	ASA fasting guidelines should be followed (see p. D-1, NPO guidelines). Prolonged NPO in single-ventricle physiology and other shunt-dependent lesions should

	be avoided, as shunt flow might decrease with dehydration → ↑ viscosity → ↑ shunt thrombosis. Special consideration for patients with hypertrophic cardiomyopathy (HCM) and Williams syndrome patients.
Equipment	Transport patient to and from the catheterization lab with a pulse oximeter and other monitors as appropriate. Equipment to manage difficult airway and hemodynamically unstable patients should be readily available (e.g., difficult airway cart, I-stat, arterial line, blood pump, pumps to infuse vasopressors, pacemaker, defibrillator, NIRS).

INTRAPROCEDURE

Anesthetic technique

Cardiac catheterization can be done under sedation, monitored anesthesia care, and general anesthesia. Intravenous access is usually in an upper extremity as the lower extremities may be needed for unilateral or bilateral femoral access by the cardiologist. Intravenous contrast administered in an IV in the left upper extremity may be requested to confirm vascular patency for transvenous pacemaker wire placement. A spontaneously breathing patient is preferable so as to mimic normal baseline cardiac and respiratory physiologic state and to perform subsequent hemodynamic calculations. General anesthesia with an ETT may be a safer option to provide a secure airway for neonates and younger children as the surgical field often covers the entire patient. However, there is wide variety of practice among different institutions with regard to airway management. Patients with moderate to severe pulmonary hypertension present extra challenges, and care for these patients differs as well among institutions. Because physiologic changes associated with intubation, and more likely extubation, might result in a pulmonary hypertensive crisis in these patients, sedation is favored by some anesthesiologists. However, others prefer muscle relaxation and ETT placement, as hypoxia-hypercarbia related to an unsecured airway can also lead to life-threatening increases in PAP. Older children or patients undergoing procedures of shorter duration with no other significant comorbidities may tolerate incremental IV sedation with local anesthesia.

A large variety of drug regimens can be used to provide anesthesia/sedation for children undergoing cardiac catheterization procedures. These include propofol, ketamine, remifentanil, dexmedetomidine, midazolam, fentanyl, and morphine infusions either

alone or in combination. While all have been used successfully, bradycardia/sinus arrest, heart block, hypotension, transient increase in systemic and pulmonary pressures (SVR > PVR) after rapid bolus injection, as well as insufficient anesthesia/analgesia and prolonged recovery have been reported.

Several approaches have proven safe and effective. Currently, there is no consensus on what constitutes optimal anesthetic management. Propofol and ketamine, propofol and dexmedetomidine, dexmedetomidine and ketamine, as well as volatile anesthetics, in combination with spontaneous ventilation or GETA, have all been safely employed. Often, there is institutional preference for one or the other, based on previous clinical experience.

A few sample regimes are reviewed here:

- Propofol 10 mg/ketamine 1 mg or "ketofol" at a dose of 50–200 mcg/kg/min
- Propofol (50–200 mcg/kg/min) and dexmedetomidine (0.5 mg to 2 mcg/kg/h). This regimen eliminates concerns about ketamine-related secretions with the attendant need for glycopyrrolate, but may delay discharge from PACU due to prolonged sedation.
- Dexmedetomidine (2 mcg/kg/h) and ketamine (20 mcg/kg/min) supplemented by additional ketamine +/− midazolam as needed

Independent of what technique is ultimately used, normoxia and normocarbia are key for these procedures, since hypoxemia, hyperoxemia, acidosis/alkalosis, and PPV all exert significant disturbances in pulmonary vascular resistance. PPV decreases systemic venous return, particularly in the setting of depleted intravascular volume. This is of particular relevance in those patients with restrictive RV or single-ventricle physiology, where pulmonary blood flow is mostly passive and depends on adequate preload. When possible, patients with Glenn and Fontan physiology should be allowed to breathe spontaneously. This improves systemic venous return, pulmonary blood flow and hence systemic blood flow, and cardiac output. Both circulations are dependent on passive pulmonary blood flow as opposed to a shunt physiology (BT or central), which provides active pulmonary blood flow. Pulmonary blood flow and adequate cardiac output depend on PVR.

ECMO backup should be considered in patients with poor ejection fraction and critically ill neonates, as well as for some patients with severe PAH or Williams Syndrome, who have a significantly higher mortality regardless of the anesthetic technique. Rarely, for certain interventional procedures, surgical backup and OR availability may have to be prioritized. Significant preparation and coordination are necessary to transport a newborn from the delivery room to the catheterization lab for

emergent procedures such as an atrial septostomy.

Induction	Standard inhalation or iv induction (see p. D-1). As in all patients with CV morbidities having anesthesia, the choice of anesthetic drugs must include careful consideration of their effects on myocardial contractility, preload and afterload, pulmonary and systemic vascular resistance, and respiration. FiO_2 should also be carefully controlled in ductal or shunt-dependent lesions where a balance of Q_p:Q_s is desired.
Maintenance	General anesthesia with volatile agents (e.g., sevoflurane) or TIVA techniques as previously described may be used. O_2 supplementation via mask/nasal cannula might be appropriate in many cases; however, an ETT/LMA to protect airway should be strongly considered in high-risk patients and/or interventions. For EP procedures, the Supreme LMA with the orogastric port allows for ease in placement of a transesophageal pacing probe if needed. EP procedures are long; thus, an LMA provides for not only a protected airway during IJ access, but allows for controlled ventilation when minimal catheter movement is desired. Most catheterizations require the patient to be maintained on room air for accurate SaO_2 sat and pressure measurements. With higher FiO_2 (>0.3), firstly, it will be necessary to consider the dissolved oxygen fraction when calculating Q_p with the Fick equation. Secondly, high inspired FiO_2 will likely result in a reduction of PVR, thereby increasing the Q_p/Q_s ratio. More importantly, any FiO_2 changes should be communicated with the interventionist so that Q_p:Q_s calculations can be corrected. Similarly, routine use of antisialagogues should be avoided so that the heart rate remains at baseline. The same holds true for other vasoactive drugs, such as ephedrine and phenylephrine. If deemed necessary, and after other measures have failed, (e.g., adjustment of anesthetic depth, volume resuscitation, etc.), their intended use should be

	communicated prior to administration. EP studies are best managed with iv propofol 75–200 mcg/kg/min, because this agent has the least ability to induce dysrhythmias or to interfere with the induction of tachyarrhythmias for diagnostic purposes. Sevoflurane or isoflurane (<1 MAC) as well as a combination of propofol and ketamine (7.5–20 mcg/kg/min) is also acceptable. In contrast, remifentanil and dexmedetomidine have both been shown to significantly depress sinoatrial and atrioventricular nodal function and are therefore not desirable in patients undergoing EPS for ablation of SVT or in patients with prolonged QTc. In patients with a history of prolonged QT interval, TIVA (propofol/remifentanil) has been recommended since both drugs have been shown to have none to minimal effects on the QTc interval. Caution should be exercised with reversal agents and various antiemetics, including 5-HT_3 receptor antagonists, since they can also prolong the QT interval. Since the electrophysiologist is often aware of the likely underlying mechanism of the arrhythmia, this allows for adaptation of the anesthesia technique that is the least likely to interfere with the patient's electrophysiology. Heparin 50–100 U/kg is given for patients with arterial sheaths. The activated clotting time (ACT) should be in the range of >200–300 sec during the procedure and <175 sec when the catheters are removed. Once the sheath is removed, a considerable amount of time is needed to attain hemostasis. NO +/− inhaled prostacyclins may be required for the Rx of pulmonary HTN. In the latter case, check with RT to ensure the appropriate setup for administration via either ventilator or nasal cannula is available. A special injector is needed when administering NO via nasal cannula.
Emergence	If the patient's clinical status allows for deep extubation, it can be done to prevent coughing. Interventional procedures and EP/ablation likely require hospital admission for observation. For neonates with SV physiology or other patients with complex underlying

	disease, comorbidities or significant hemodynamic instability, a prearranged ICU bed might be advisable.	
Blood and fluid requirements	IV: 20–22 ga × 1 BSS PRBCs Fluid warmer	A second volume iv may be desirable for interventional cases. The cardiologist will also have a venous access line that can be used if necessary. Interventional procedures may cause tearing of vessels and/or myocardium and can cause abrupt hemorrhage; therefore, blood must be available in the room. Neonates can lose significant blood during access and sampling and may also require transfusion. Follow serial Hcts. In patients who are TPN dependent or receiving G-tube feeds, hypoglycemia may occur. Glucose monitoring is helpful and the administration of glucose containing fluids may be indicated.
Monitoring	Standard monitors, including ± arterial line ± Foley catheter ± NIRS	Respiratory monitoring can be performed via oxygen masks or nasal cannulae adapted to measure CO_2 flow in a spontaneously breathing patient. Discuss with the cardiologist if A-line access is required. Frequently, the femoral artery is cannulated for the catheterization and may be available for use. However, access may be limited at critical times (e.g., stenting or coiling) and not available during a critical induction; therefore, a peripheral

		arterial line may be desirable. ST-segment analysis (requiring proper lead placement) is useful in patients with a tenuous hemodynamic state, ductal-dependent lesions, or Williams syndrome. CAD is the leading cause of death in posttransplant patients. For cases of long duration, consider Foley catheter placement. Monitor temperature. In ductal-dependent lesions, monitoring of both pre- and postductal saturations may be helpful. Cerebral oximeter monitoring is recommended in single-ventricle and in other cyanotic lesions as pulse oximetry is a poor predictor of changes in cerebral saturation. Arterial line also plays an important role in patients with poor cardiac function and/or placement of melody valve.
Positioning	✓pad pressure points	Supine, arms may be flexed above the head to allow fluoroscopy of the chest. Adolescent patients are at risk of brachial plexus injury. Keep extension <90°.
	✓cover eyes	All ECG leads and monitoring wires must be cleared from axilla and chest to allow fluoroscopy. Corneal abrasions are not uncommon as often the patient's face is covered by surgical drapes and cardiologists may rest their arms, hands, and instruments on

		the patient's face.
Complications	Airway obstruction	Rx: Airway support, oral/nasal airway, LMA. Intubate if necessary.
	Aspiration	Rx: Suction, and secure airway if needed. Bronchodilators, H_1- and H_2-blockers if needed. CXR. O_2 monitoring. Admit if postop oxygen requirement persists.
	Arrhythmias	Determine etiology, whether hemodynamically stable or not. Cardiovert/defibrillate/emergency drugs as necessary. Check electrolytes and ABG. Consult EP.
	Hemorrhage (access site, rupture of vessels, tamponade)	Rx: Fluid resuscitation with crystalloid, 5% albumin and/or blood; vasopressors as needed. Secure airway, 100% FiO_2. Check Hct.
	Valvular incompetence (severe regurgitation/annular rupture)	Rx: Secure airway, volume resuscitation, vasopressor support, consult surgeon and proceed with emergent surgical repair if needed.
	Hypoxemia	Try to determine the cause. Check Hct in single-ventricle patients. Rx: Airway support; increase FiO_2. Intubate and ventilate as needed.
	Pulmonary hypertensive crisis	Avoid hypoxia, hypercarbia, acidosis, and pain/agitation. Rx: FiO_2 100%, deepen anesthetic if tolerated. Consider NO and systemic vasopressors.
	Contrast reaction/anaphylaxis	Rx: Support airway, 100% FiO_2, intubate if needed: phenylephrine, volume

		resuscitation, steroid, antihistamine, H_2-blocker.
	Hypothermia	Especially neonates. Rx: Forced-air warming device, heat lamp. Increase environmental temperature.
	Air embolism	Rx: 100% FiO_2; identify and occlude source; Trendelenburg; fluid resuscitation; vasopressor support. Aspirate air from central access if possible.
	Positioning injury	Especially brachial plexus injury. Careful documentation, consult neurologist. Prevention = diligent positioning is key.
	Vascular thrombosis/stroke	Support airway, 100% FiO_2, intubate if needed; obtain emergent brain CT; consult neuro/stroke team.

POSTPROCEDURE

Complications	Hematoma at access site Ischemic limb Emergence delirium Pericardial tamponade Corneal abrasion Recurrent arrhythmia
Pain management	Postop analgesia is usually managed with acetaminophen, or fentanyl; rarely are long-acting opioids (morphine, hydromorphone) needed; care should be taken to avoid hypoxia or hypercarbia. The access sites are commonly infiltrated with local anesthetic by cardiologist. Use of ketorolac should be discussed with the cardiologist.
Tests	CXR, if indicated

TTE, if clinical picture is suggestive of tamponade

PEDIATRIC ONCOLOGIC PROCEDURES

Kristin Sun, Neyssa Marina, Rebecca Claure, and Brenda Golianu

Pediatric oncology patients represent a unique population of patients who come for frequent procedures requiring anesthesia over the course of several years. These patients require anesthesia for a variety of procedures: diagnostic imaging, surgical resection, radiation therapy, central line placement, and multiple minor procedures for staging and intrathecal chemotherapy. The pediatric anesthesiologist is in the position of caring for these patients for long periods from initial diagnosis, through years of induction and maintenance therapy, and finishing with end of therapy procedures. More than in other patient populations, the anesthesiologist plays a critical role in a child's experience over several years in the hospital environment.

Pediatric oncology patients now often have a 5-yr survival rate of over 80%. It is important to keep in mind the possible effects of anesthesia and sedation on the developing brain. Current recommendations are primarily based on extrapolating animal studies to humans. The main concerns are in patients under 3 yr of age who are undergoing procedures over 3 hours or are having multiple anesthetics. Oncology patients face a unique combination of stressors from illness, hospitalization, and multiple painful procedures that may affect psychoemotional development. Anesthesiologists and oncologists need to be mindful of these issues and be prepared to discuss the risks versus benefits of anesthesia. Conscious sedation may be an alternative to GA; however, most children under 12 yr of age will be better served by a brief GA for each procedure.

When patients first present for evaluation of possible malignancy, either solid organ tumors or hematologic cancers, they may undergo multiple imaging studies such as computed tomography scans of the chest, abdomen, and pelvis, bone scintigraphy, and magnetic resonance imaging scans. These studies are not painful, but require patients to be immobile for anywhere from a few minutes to over an hour. Sedation or general anesthesia is usually required, especially in patients under 5 yr of age.

For solid organ tumors of the brain, chest, abdomen, pelvis, and bone, pediatric patients may undergo daily doses of radiation therapy over the course of several weeks before or after resection. Although radiation therapy may only be a few minutes long, the specific anatomic dosing requires the patient to be immobile, again requiring multiple brief anesthetics. Solid organ tumors involve major surgical resection, or diagnostic tissue biopsy, either before or after concomitant radiation therapy or chemotherapy.

In the initial evaluation of hematologic diseases, patients must undergo evaluation of bone marrow with bone marrow aspirates and/or biopsies. Involvement of the cerebrospinal fluid is evaluated with a diagnostic lumbar puncture (LP). These patients then go on to require repeat bone marrow procedure and serial LPs for staging and for

intrathecal chemotherapy dosing when indicated. Approximately 50% of leukemia patients will develop CNS disease without intrathecal prophylaxis.

In addition to the above diagnostic and treatment procedures, the majority of pediatric oncology patients undergo placement of indwelling central venous catheters, including percutaneous intravenous central catheters (PICC), Hickman or Broviac catheters, or portacaths. With the exception of PICC placements, most of these catheters are inserted under anesthesia and in a sterile operating room environment. When full therapy is completed, central venous line removal again requires sedation or general anesthesia.

PREPROCEDURE

Pediatric oncology patients are followed very closely during their treatment, undergoing at least monthly physical exams to evaluate for side effects of therapy to determine whether proceeding with the prescribed therapy is indicated. When these patients require invasive procedures, it is essential to work with the primary oncology team to evaluate whether the requested procedure is elective or urgent. All patients undergo routine periodic blood counts to determine the safety of continuing chemotherapy dosing. Occasionally, a procedure, such as LP for intrathecal chemotherapy, may be postponed if blood counts have dropped too low. Checking with the primary team is important to determine if the procedure is to proceed as planned. It is important to remember that the toxicity of chemotherapeutic drugs may affect every organ in the body beyond the target cancer tissue.

A thorough preanesthetic history and physical exam should be performed for all major and minor cases and the standard NPO protocol applied.

Respiratory and airway	Major surgical procedures for patients with symptoms of upper respiratory infection (e.g., cough, fever) are postponed unless there are circumstances (CNS disease, bone marrow relapse) that require the treatment to proceed. In those circumstances, LPs and BMAs can be performed either with sedation or with the use of local anesthesia. A number of chemotherapeutic agents have been associated with pulmonary toxicity: bleomycin (2–5%), BNCU (20–50%), busulfan (2.5–11.5%), cyclophosphamide (rare), and methotrexate (rare). The use of these agents requires follow-up evaluation to make certain

the patient is able to proceed with his/her procedure. Patients who present with an anterior mediastinal mass may present with signs and symptoms of superior vena cava compression or with superior mediastinal syndrome with tracheal compression. It is critical to recognize and evaluate patients with a mediastinal mass prior to inducing general anesthesia. The adolescent patient presenting with a new diagnosis of Hodgkin or non-Hodgkin lymphoma or acute lymphoblastic leukemia should be carefully assessed for the possibility of a mediastinal mass. Younger patients may also present with symptoms of anterior mediastinal compression. Careful preop evaluation should be made for respiratory symptoms or compromise, as well as obtaining a chest x-ray, and possibly even chest CT scan. Careful consideration should be given to performing diagnostic procedures under minimal sedation, since general anesthesia in these patients can result in significant cardiorespiratory complications and fatality. Preop treatment with irradiation or corticosteroids may reduce tumor size; however, this may also change tissue pathology. Key features in GA management, if absolutely required, are the maintenance of spontaneous ventilation, no paralysis, having a rigid and flexible bronchoscope immediately available, and preparing for postop ICU monitoring.

Routine airway assessment is essential. Chemotherapy may result in severe, painful oral mucositis or stomatitis. Patients are also more susceptible to infectious viral oral lesions, such as herpetic lesions, and may require isolation. Frequent URI may occur due to immune compromise. Fever, loose cough, wheezing, or coarse BS requires evaluation and likely postponement of any procedures.

Tests: All pediatric oncology patients undergo

	weekly complete blood counts to evaluate for toxicity from therapy. In addition, patients who have received any of the agents associated with pulmonary toxicity undergo pulmonary function tests at regular intervals. Although some chemotherapy agents are associated with pulmonary toxicity, the cumulative doses of those agents are such that most patients are asymptomatic. CXR may be indicated to evaluate upper respiratory symptoms.
Cardiovascular	Anticancer treatment can produce a wide range of cardiac toxicity. Anthracycline-induced cardiomyopathy, while rare, can lead to significant cardiovascular compromise. This complication is associated with the use of cumulative doses >300 mg/m. Cardiomyopathy is insidious in origin and most commonly presents many years following treatment with doxorubicin, daunorubicin, or amacrine. The use of high doses of radiotherapy is also associated with cardiac complications, including constrictive pericarditis, atherosclerosis, and early myocardial infarction. Signs of CV toxicity may include SOB, ECG changes, rhythm disturbances, pericarditis, or CHF. Preop hemodynamic status needs to be evaluated. Patients on steroid therapy may develop steroid-induced hypertension. It is important to obtain a careful history of any antihypertensive medication, especially a record of medications taken on the day of the procedure or surgery. Conversely, patients who are dehydrated or anemic may become significantly hypotensive after induction of general anesthesia. These patients may require preop hydration, and vasoactive medication should be available for intraop use. Patients actively receiving chemotherapy may also have 3rd spacing and may need aggressive hydration and/or pressor support. **Tests:** Patients receiving any agents associated with cardiac toxicity are monitored at yearly interval with

	echocardiograms and electrocardiograms. These tests do not need to be performed routinely prior to a procedure requiring GA unless history and physical exam suggest a change in the patient's clinical condition.
Hematologic	Bone marrow suppression occurs with all cytotoxic drugs. The anesthesiologist and oncologist need to work together to evaluate anemia and thrombocytopenia. Due to myelosuppression, anemia is common in oncology patients. In assessing the degree of anemia in a given patient, it is important to assess his or her overall clinical appearance and hemodynamic compensation. A very low hemoglobin level <6–7 increases the patient's risk of significant BP instability during GA. For the procedure planned, can the patient tolerate the stress from anesthesia, and is there further blood loss expected during the procedures? Patient assessment with expectations for the surgical/diagnostic procedure will determine whether red blood cell or platelet transfusion is required preop. If no transfusion is planned and the patient is anemic, prepare fluid replacement, colloid (e.g., albumin), and/or vasoactive support. **Tests:** Complete blood counts are performed once to twice a week in all pediatric oncology patients. These tests help determine whether continuing with the prescribed therapy is indicated. Baseline platelet and hemoglobin counts need to be measured before proceeding with lumbar punctures and bone marrow aspirates.
Neurologic	Peripheral neuropathies due to vincristine, vinblastine, cisplatin, and procarbazine may be present. Patient should be carefully positioned and padded. These patients may require additional attention to preop pain management and anxiolysis, with supplemental intraop and postop pain control.
GI/Hepatic	Many chemotherapy agents cause significant nausea

	and vomiting. Patients may present with these symptoms preop or may be dehydrated due to vomiting and poor fluid intake. Hepatotoxicity may also occur from chemotherapy or radiation therapy. Asparaginase can induce severe pancreatitis. ✓LFT, amylase, lipase.
Endocrine	Most cancer patients are treated with corticosteroids at some point in their therapy. Steroids can lead to weight gain, suppression of the stress response, and rarer complications such as psychosis. In addition, steroid-induced hyperglycemia may require pre- and postop glucose monitoring and insulin therapy.
Premedication	For major procedures, individualized premedication is recommended. Since oncology patients often have an indwelling intravenous catheter, or are familiar with having venipunctures and iv placed, iv induction is frequently used. Intravenous midazolam may be easily administered when required for anxiolysis. Some patients may require premedication with oral midazolam or lorazepam, if they do not have iv access. However, many radiology and minor oncology procedures may be performed in a less restrictive environment, such as a procedure room, where the parents may stay with their child through induction. For the very anxious patient, or a child who has undergone significant emotional trauma in the hospital environment, preop counseling with a child life specialist or psychologist can be very important and helpful in alleviating fears and helping the child adjust to the stress of frequent hospital/procedure visits.

INTRAPROCEDURE

Anesthetic technique

For major surgical procedures, GETA management is indicated. Below are recommendations for pediatric oncology patients undergoing minor procedures.

Procedures such as LPs and bone marrow aspirates are usually short, 10–20 min. Adolescent patients may be evaluated by their provider or the anesthesiologist for possible conscious sedation. Younger patients usually require brief general anesthesia —inhalation or intravenous.

Induction	For lumbar punctures in the patient without iv access, a brief inhalation anesthetic may be adequate. However, since most patients will have iv access, intravenous anesthesia with propofol provides adequate anesthesia, causes less nausea, and allows a rapid recovery. Standard protocol should include meticulous sterile technique in using the central venous line and confirmation of blood aspiration and catheter flow, both prior to beginning induction and after repositioning the patient in a lateral decubitus position. On positioning a patient for lumbar puncture in the left lateral position, it is possible to dislodge the portacath needle, with resulting extravasation of fluid or propofol into the subcutaneous tissue.
Maintenance	Intermittent boluses of propofol 0.5–1 mg/kg may be used or an infusion of 200 mcg/kg/min. N_2O or low-dose sevoflurane may be added. For BMA, add fentanyl 1 mcg/kg or hydromorphone 1–2 mcg/kg for postop pain management. The provider performing the procedures infiltrates the area with lidocaine. For Broviac catheter removals, heparin must be removed from the catheter and discarded before use for induction. A sufficient bolus of propofol (e.g., 0.5–1 mg/kg) must be given just prior to pulling the catheter. Additional iv usually is not warranted because the procedure is normally ≤10 min, but may be desirable if postop pain medication is anticipated. Occasionally, the catheter may break during attempted removal, and the surgeon will have to make a skin incision to allow for removal of the internal fragment. In such cases, a peripheral iv may be inserted quickly to facilitate administration of additional propofol, or mask anesthesia may be given. If the SpO_2 decreases,

	blow-by O_2 with gentle head and neck positioning are generally sufficient. For more significant obstruction, deepening of anesthetic with additional propofol and positive pressure ventilation may be needed.	
Emergence	Allow child to awaken in procedure room. Ondansetron 0.15 mg/kg for patients receiving intrathecal chemotherapy during their lumbar puncture. Avoid dexamethasone, as steroids may be part of the patient's chemotherapy protocol or may precipitate tumor lysis syndrome.	
Blood and fluid requirements	Patients may require blood or factor supplementation prior to or during procedure based on preop laboratory values.	It is important to be aware of patients where fluid restriction may be required, such as in a recent bone marrow transplant patient, or patient with graft vs. host disease, who may have complications of fluid overload. Sodium bicarbonate infusion is common during chemotherapy and should be continued during anesthesia when possible.
Monitoring	Standard monitors	
Positioning	Lateral decubitus (lumbar puncture) Supine, seated, or prone (bone marrow aspiration, biopsy) Supine (Broviac)	
Complications	Airway obstruction	Head and neck repositioning, jaw thrust
	Retained central venous catheter	May require open surgical procedure
Postprocedure pain management	Lumbar punctures are not generally painful, whereas bone marrow aspirations and biopsies can be. Preop care includes the application of EMLA cream to the LP or bone marrow site, as well as having the oncologist infiltrate	

with lidocaine after induction. For pain management, low-dose fentanyl 1 mcg/kg or hydromorphone 2 mcg/kg may be used and repeated in the PACU if needed. Check with the oncologist before administering acetaminophen. Acetaminophen is not routinely given for pain prophylaxis due to the possibility of masking a fever. Acetaminophen is not given unless needed and should never be given as a rectal suppository to the immunocompromised patient. Some patients may have chronic or acute pain syndromes due to tumor bone pain or as a side effect from chemotherapy. These patients need to be evaluated on an individual basis for their pain management. After lumbar punctures, the patient should remain in a horizontal position for at least 30 min to prevent post–dural puncture headache.

UPPER/LOWER GI ENDOSCOPY

Ann Ming Yeh, William Berquist, Rebecca E. Claure, and Brenda Golianu

Upper and lower endoscopy allows for accurate diagnosis and treatment of gastrointestinal diseases. Diagnostic indications for upper endoscopy include dysphagia; odynophagia; persistent vomiting; abdominal pain with weight loss/anorexia; acid peptic disease, dyspepsia, and heartburn despite medical therapy; diarrhea, hematemesis, or melena; obtaining samples or biopsies; and diagnosis of infection or disease (graft vs. host disease, inflammatory disorders, malignancy) especially in an immunocompromised patient. Indications for colonoscopy include evaluation of gross or occult bleeding, symptom evaluation of new-onset constipation or unexplained diarrhea or abdominal pain, screening or surveillance for inflammatory bowel disease, and screening for colorectal neoplasia. Therapeutic indications for gastrointestinal endoscopy include esophageal dilation, foreign body removal, sclerotherapy or banding of esophageal varices, hemostasis with directed thermal or injection therapy, percutaneous endoscopic gastrostomy tube placement, decompression of sigmoid volvulus or megacolon, polypectomy, PEG placement, and removal or change of gastrostomy or GJ tubes. Children presenting for endoscopy may have congenital and acquired abnormalities of the GI tract. Examples include repaired tracheoesophageal fistula (TEF) with esophageal dysmotility or strictures, ingestion of a caustic material, and presence of a foreign body.

Many endoscopy procedures are done with sedation only. Requests for anesthesia are dependent on the gastroenterologist's preference, as well as the severity of the patient's underlying illnesses. All patients must receive a complete preanesthesia H&P and follow the same NPO protocol used for surgery (see Appendix D: Standard Pediatric

Anesthetic Management). Patients undergoing colonoscopy require bowel preparation to have the colon free of solid stool for adequate visualization. Common bowel preparation regimens include a combination of magnesium citrate, bisacodyl, and polyethylene glycol.

Absolute contraindications of upper and lower endoscopy include suspected perforation and peritonitis in a toxic patient. Relative contraindications include coagulopathy, neutropenia, fulminant colitis, bowel obstruction and toxic dilation with increased risk of perforation, torrential colonic bleeding, poor bowel preparation, and cardiopulmonary instability.

Overall complication rates of upper GI endoscopy are generally rare, with complications estimated at 0.3% risk of bleeding following an EGD with biopsy and risk of perforation in <0.3% of cases. Hypoxia secondary to sedation, hematoma, missed lesions, and infections are also potential infrequent complications. Complications of colonoscopy occur in <2% of patients, with bleeding and perforation reported in <0.3% and 0.3%, respectively.

ANESTHETIC CONSIDERATIONS

Gastrointestinal	Carefully evaluate for esophageal dysfunction and Sx of GERD. The stomach and bowel will be insufflated with air during the procedure, possibly increasing the likelihood of reflux.
Laboratory	As indicated from H&P. Hct, plt, INR, T+S, if GI bleeding
Premedication	If inhalation induction is planned, administration of midazolam 0.5–0.75 mg/kg po may be helpful for anxiolysis. Consider midazolam for younger children requiring an iv induction (1–2 mg).

INTRAPROCEDURE

Anesthetic technique

Upper GI endoscopy for esophageal dilation, foreign body removal, severe GERD gastrointestinal bleeding, and banding/sclerotherapy of esophageal varices requires GETA. For children ≥2, with no contraindications, supplemental O_2 via nasal cannula, spontaneous respiration, and propofol infusion can be considered. Children ≤2 have a

higher incidence of complications when not intubated due to the relatively large endoscope. Complications include partial airway obstruction, tracheal compression, laryngospasm, bronchospasm, and desaturation. Placement of the endoscope in the mouth precludes the ability to use a mask or LMA. For lower GI endoscopy (e.g. colonoscopy), supplemental O_2 via nasal cannula or mask, spontaneous respiration, and propofol infusion may be preferable.

Induction	If rapid-sequence indication is indicated, iv catheter should be placed prior to induction. Proceed with preoxygenation, cricoid pressure, propofol (2–3 mg/kg), and succinylcholine (1–2 mg/kg) or rocuronium (1 mg/kg). ETT should be well secured to the side of the mouth. If risk of aspiration is relatively low, a standard pediatric iv or mask induction is appropriate (see Appendix D: Standard Pediatric Anesthetic Management).
Maintenance	GETA with inhalational agents or iv infusion of propofol (100–250 mcg/kg/min), ± remifentanil (0.05–0.10 mcg/kg/min). Alternatively, GA/sedation may be continued with supplemental O_2 via nasal cannula, spontaneous respiration, and infusion of propofol (100–250 mcg/kg/min), ± remifentanil (0.05–0.10 mcg/kg/min). If intubated, careful observation and/or holding the ETT prevents inadvertent extubation during removal of the endoscope. If spontaneously breathing, careful attention is needed to observe for breath holding, laryngospasm, and/or desaturation.
Emergence	If intubated, extubate awake. Emergence in procedure room. Patients usually transported to and recovered in PACU.
Blood and fluid requirements	No blood loss. IV: 22 or 24 ga × 1 BSS at maintenance
Monitoring	Standard monitors (see Appendix D: Standard Pediatric Anesthetic Management)
Positioning	✓and pad pressure Lateral decubitus for upper

	points ✓ eyes	and lower endoscopy
Complications	Airway obstruction Hypoxemia 2° gastric insufflation Inadvertent extubation Pulmonary aspiration GI perforation	Due to endoscopist working in the mouth and pharynx

POSTPROCEDURE

Pain management	Acetaminophen (35–40 mg/kg pr or 10–15 mg/kg po 10 mg/kg iv), hydromorphone (0.01–0.015 mg/kg iv), or morphine (0.05–0.1 mg/kg iv)

ANESTHESIA FOR THE PATIENT WITH EPIDERMOLYSIS BULLOSA (EB)

Erin Bushell and Louise Furukawa

Introduction: Care of the patient with epidermolysis bullosa (EB) is always challenging, requiring familiarity with the disease and its sequelae and how it affects the ability to perform the procedure and anesthetic. This section will focus on recessive

dystrophic EB (RDEB), as it is the most common form in patients presenting for esophageal dilation. Esophageal stricture is present in 50% of patients by age 10 with a cumulative risk of stricture of 95% by age 45. Generally speaking, procedures performed out of the OR take the patient and provider away from resources and help, adding additional risk and complexity. Out-of-OR procedures have been identified as higher risk for adverse events, particularly in shared airway cases such as endoscopy. Furthermore, a primary tenet of Crisis Resource Management is "know your environment," which can be difficult if the procedure takes place in an infrequently utilized location. EB patients often require multiple procedures at specialty institutions. The cost of travel and caregiver loss of wages can be prohibitive; therefore, coordinating multiple procedures under the same anesthetic may be desirable. The care of the EB patient in a multidisciplinary clinic is optimal.

PREPROCEDURE CONSIDERATIONS

Education of team members	• EB clearly known beforehand and indicated on schedule • Staff (including anesthesia techs) familiar with care of EB patient • Special equipment or supplies available
Past anesthetic history	• Vascular access history • Past anesthetic records with previous intubation techniques (disease is progressive so old records may not predict current airway status) • History of PONV, postop pain/sore throat
Craniofacial/airway	• Review of past records • In-person visit or video interview important. Document detailed oral exam. Important to include pictures in preop note • H/o stridor concerning for extensive pharyngeal scarring • H/o corneal abrasions/scarring. Note eye care regimen. Careful dental exam—poor dentition common. Esophageal stricture may compromise the ability to swallow oral secretions.

Respiratory	• Severe kyphoscoliosis or extensive cicatricial scarring may impair pulmonary mechanics and cause restrictive disease.
Cardiac	• Cardiomyopathy may be present with mean age of onset 9–12 yr.[5] • Signs and symptoms similar to patients without EB. Active patients will have DOE. Most will display orthopnea and edema.
Gastrointestinal	• Stricture, poor nutrition, hypoalbuminemia, and iron deficiency anemia are common.
Renal	• Some patients have renal failure—increases risk for cardiomyopathy (cause unknown)[5,6]
Hematology	• Multifactorial anemia common • Many receive Fe infusion vs. transfusion[5]
Oncologic	• Squamous cell carcinoma (SCCA) can arise as early as the second decade of life. • Metastatic SCCA is the principal cause of death in patients with RDEB.
Chronic pain	• Chronic pain is experienced by every patient due to extensive wounds and arduous dressing changes. Some use narcotics frequently.
Psychological	• Chronic pain, anxiety, PTSD, and regression are common. • Most patients have a very close attachment to caregivers. • Caregivers may have difficulty relinquishing control and should be allowed to participate in the preoperative process.
Current medications	

	• Patients should continue essential preoperative medications.
Lab tests	• CBC; hematologist may ask for additional tests such as iron studies. • If vascular access is difficult, labs are often drawn after anesthetic induction. • Chemistries if renal failure is present
Premedication	• Some patients allow IV access preop. • Many (even older) patients may have significant psychological trauma and request mask induction. • ELA-max (lidocaine) cream is useful. • Ultrasound-guided access is helpful and US gel is safe. Oral or GT versed OK to use. • IM premedication may also be indicated.
NPO	• Standard NPO guidelines apply. • Many patients have gastrostomy tubes and should be hydrated with clear liquids until NPO cutoff time.
Check-in process	• Staff involved with checking in the patient should be aware of disease and have modified equipment for monitoring vital signs. • Sheepskin should be placed on the gurney and follow patient throughout procedure. • Caregiver should be able to stay with patient and assist preoperative preparation.

INTRAOPERATIVE ANESTHETIC CONSIDERATIONS

Induction: IV **IV induction—TIVA**	**Adults and pediatric patients with IV access**: A standard IV induction followed by a TIVA is appropriate. Preoxygenation can be accomplished by careful application of the face mask (as below) or using a heated, humidified high flow nasal cannula such as the Optiflow™. Most awake patients tolerate flows of 30

No IV—inhalational	lpm, which then can be increased to 70 lpm after induction to maintain oxygenation during intubation. IV access is often difficult. Asking the patient and caregivers about which veins have been successfully used in the past and use of ultrasound is advised. Elastic tourniquets should generally be avoided. However, if a hand tourniquet is not sufficient, an elastic tourniquet may be carefully placed over Webril™. The area may be gently cleaned with baby shampoo on a moist gauze or an alcohol swab, taking care to avoid any shear stress. The IV must be secured with care. Mepilex® transfer foam can be used to pad under the IV hub, Mepitel® may be placed over the catheter, and a self-adherent wrap such as Coban™ is used to secure the IV by wrapping it circumferentially around extremity. It is suggested that an extension such as a T-piece be used so the IV may be disconnected during patient positioning and transfers without risk of displacement. Once patient is induced and an IV has been placed and secured, a TIVA allows for maintenance of anesthesia while securing the airway. **Pediatric patients without IVs**: An inhalational induction with sevoflurane and N_2O (see p. D-1) is appropriate for these patients. Great care must be taken to avoid trauma from the face mask and jaw thrust. Petroleum jelly or other petroleum-based lubricants applied to a well-inflated mask and petroleum jelly gauze beneath the mask can reduce the risk of mask-related facial trauma. Mepilex® transfer foam can be used to pad the area over the angle of the mandible to reduce trauma related to jaw thrust. Again, avoidance of shear stresses is of primary importance. (Note: These patients may have psychosocial issues due to their illness and psychological trauma related to past procedural experiences, and this may necessitate inhalational induction in patients older than one traditionally would consider this approach.) Intubation: Patients with EB often have ankyloglossia,

	limited mouth opening, and intraoral and pharyngeal mucosal scarring and adhesions. They tend to have patent natural airways, so ventilation is not difficult, but intubation can be both difficult and potentially traumatic to friable tissues. Therefore, fiberoptic intubation with a smaller tube than would normally be used is recommended. Microlaryngeal tubes (MLT)—pediatric diameter tubes that are adult size in length, and have a standard adult cuff—can be used for both oral and nasal intubations. Once placed, the ETT is tied with umbilical tape placed over petroleum jelly gauze to avoid trauma to the face and lips. There is no way to truly secure the ETT in these patients, and it is, therefore, recommended that the anesthesiologist manually hold the tube during times when the risk of accidental extubation is high such as when the dilating catheters and endoscopes are being placed or removed. Nasal intubation may decrease the risk of accidental extubation and thus should be considered for complex cases. It is strongly suggested that during the time out, the team review the importance of having the proceduralist notify the anesthesiologist prior to inserting or removing anything from the mouth so the anesthesiologist may take appropriate steps to prevent unintentional extubation.
Maintenance	TIVA with short-acting agents such as propofol (100–250 mcg/kg/min) and remifentanil (0.1–3 mcg/kg/min). Muscle relaxation is not necessary.
Emergence	Patients awaken rapidly after discontinuation of TIVA. A narcotic should be employed to address postop pain and an antiemetic such as ondansetron (0.1–0.15 mg/kg for children, 4 mg for adults) should be given. Dexamethasone (0.1 mg/kg for children, 4 mg for teens, or 4–8 mg for adults) will reduce nausea and the edema that occurs following these procedures. Deep extubation should be considered as it reduces coughing on tube in these patients already prone to sore throat and trauma.
Blood and fluid	No blood loss. Routine maintenance fluids

requirements	IV: 22 or 24 ga × 1 BSS at maintenance	are required unless a major complication such as esophageal perforation occurs.
Monitoring	Standard ASA monitors (see p. D-1). Applied without adhesives to avoid shear injury	Standard monitors must be applied in a nonstandard fashion to avoid injury to the patient.[5] EKG leads may be either applied to gel pads such as Defib-Pads (3M™) covered with moistened 2 × 2 gauze to prevent the gel from drying out and sticking to the patient's skin and secured with Coban™ if on an extremity or merely placed on patient's chest. Adhesive pulse oximetry probes should be rendered nonadhesive by placing transparent film dressing such as a Tegaderm™ adhesive side to adhesive side and trimming away the excess. The probe may then be secured to a digit (or stump if pseudosyndactyly is present) with Coban™. The blood pressure cuff may be placed over the patient's existing dressings or over Webril™ to avoid skin trauma due to cuff inflation.
Positioning	✓and pad pressure points ✓eyes Sheepskin under patient	A sheepskin pad underneath the patient can provide protection as well as a means to move the patient in a way

that avoids shear stress. Instead of utilizing a roller to move the patient between bed and gurney, which can create a significant amount of shear stress, the patient is lifted directly up using the sheepskin, moved through the air, and placed carefully down upon the bed. The majority of EB patients, including adults, are of low weigh and small physical size and can be easily moved in this manner by the operative team.

A moisturizing cream or ointment such as Albolene[R] or Eucerin[R] applied to the cheeks and lips can reduce the risk of a facial trauma due to airway management. Careful attention must be paid to the eyes as the majority of these patients have corneal blistering and other ocular complications associated with EB and are at extremely high risk for perioperative eye injury. An ophthalmic ointment or methylcellulose eye drops should be applied to both eyes, which should then be closed to the extent possible and covered with Mepitel™ and moistened 2 × 2 gauze.[6] Prior to draping the patient, it

	is advisable to carefully examine the patient by head-to-toe checking to ensure that all pressure points are padded and that no iv lines or monitoring cables are against the patient's skin. NB: Drapes should not touch the skin directly, as they may stick to the skin and create new lesions when removed.
Complications	Esophageal perforation and bleeding are the most common procedure-related complications, and the patients should be intubated to provide airway protection should this occur. If perforation does occur, it is considered a surgical emergency and the patient should proceed to the OR. The majority of complications are related to the patient's disease and injury from positioning. Careful attention to protect the patient from these injuries is paramount. • Esophageal perforation/rupture/mediastinitis. • Contrast esophagram may be performed during the procedure to rule out esophageal injury. • Formation of new lip, intraoral, pharyngeal, or esophageal blisters from manipulation during anesthesia or pharyngeal/esophageal trauma during the dilation procedure.
Pain	• Sore throat due to intubation may be caused by traumatic intubation but also by excessive endotracheal tube cuff pressures. It is therefore important to use MLT tubes instead of non-MLT small tubes with excessively inflated cuffs. • Sore throat and odynophagia caused by the dilation procedure are also common in the postoperative period. • May use narcotics as well as nonnarcotic adjuvants. • Oral budesonide mixed with honey or sucralose may help ease postoperative discomfort.

PONV	• Postoperative nausea and vomiting are common. • Dexamethasone, ondansetron, and adequate hydration are helpful.
Restenosis	• A recent study suggests that regular treatment with budesonide slurry may slow the development of restenosis.

POSTPROCEDURE

Pain management	Acetaminophen (35–40 mg/kg pr or 10–15 mg/kg po 10 mg/kg iv), hydromorphone (0.01–0.015 mg/kg iv), or morphine (0.05–0.1 mg/kg iv)

CROSS-SECTIONAL IMAGING (CT, MRI)

Rebecca E. Claure and Brenda Golianu

PREPROCEDURE

A complete preanesthetic H&P should be performed in all cases and the usual NPC protocol followed (see Appendix D: Standard Pediatric Anesthetic Management). Fo MRI, thorough questioning regarding potentially ferromagnetic implants (neurostimulators, cochlear implants, pacemakers, surgical clips, infusion pumps, etc.) is critical. Direct questions regarding suitability of implants for scanning to radiologist.

Respiratory	Procedures for patients with Sx of URI (nasal congestion, cough, fever) are usually postponed for 3–4 wk unless the study is urgent. If Sx are minor, the study may proceed.
Cardiovascular	Pacemakers are usually contraindicated. Prosthetic heart valves may be contraindicated (identify the type of valve present and consult with radiologist). Fresh surgical clips (e.g., recent PDA ligation) may also represent a contraindication for MRI. For cardiovascular patients, hold ACE inhibitors the morning of the procedure.
Neurologic	Head CT or MRI may be performed in patients with seizure disorders or brain tumors. Review seizure meds and ✓serum levels if appropriate. Recent drug levels may not be necessary in children with well-controlled or stable seizure disorders. If ↑ ICP or ↓ intracranial compliance are present (e.g., 2° tumors or hydrocephalus), the anesthesia plan should include tracheal intubation with controlled

	ventilation. Metal surgical clips or coils are usually contraindications for MRI. Children with head trauma may have concurrent C-spine injuries.
Laboratory	As indicated from H&P. Usually none required
Premedication	If inhalation induction is planned, administration of midazolam 0.5–0.75 mg/kg po may be helpful for anxiolysis. If iv induction is planned, apply topical anesthesia (see Appendix D: Standard Pediatric Anesthetic Management).

INTRAPROCEDURE

Unique considerations for MRI

See Adult Out-of-OR Procedures, p. 1686.

Anesthetic technique

CT scans: With current scanners, many studies can be completed in <10 min. Each set of data takes 2–3 min to collect, allowing many children to complete scans without any sedation. In some institutions, children undergo noninvasive CT scans with sedation by radiology personnel. For more complex cases, sedation/GA is provided by an anesthesiologist. Most commonly, noninvasive CT scans are performed with inhalation anesthesia via mask or with a continuous infusion of propofol (100–250 mcg/kg/min). For patients undergoing invasive CT-guided procedures (needle biopsy, placement of drainage tubes, such as thoracostomy tube, etc.), GETA is usually performed. Techniques include inhalational anesthesia and/or continuous infusion of propofol (100–200 mcg/kg/min) and remifentanil (0.05–0.10 mcg/kg/min).

MRI: MRI requires GA more often than noninvasive CT because prolonged immobility is required for up to 1–2 h. Options include inhalational anesthesia with an MRI-compatible anesthesia machine or continuous propofol infusion with an MRI-compatible infusion pump. Hypothermia frequently occurs in small children. The cooling fan for the magnet can sometimes be turned off to decrease heat loss (discuss with MRI technician). One blanket over patient is usually permissible. The iv, airway circuit, and monitors require extensions. Ferromagnetic objects in the MRI environment are a hazard. Objects can be propelled toward the magnet with sufficient speed and force to result in serious or fatal injury to the patient and/or health care provider.

Induction	Standard pediatric mask or iv induction (see Appendix D:

	Standard Pediatric Anesthetic Management) can be accomplished in the CT scanner room or in a special induction area outside the MRI scanner. After induction and stabilization of the airway, the patient and all personnel entering the MRI scanner should undergo a second check for removal of metal objects and equipment. Once check completed, transport patient into scanner and resume monitoring.	
Maintenance	GA continued with supplemental O_2 via nasal cannula, spontaneous respiration, and infusion of propofol (100–250 mcg/kg/min). In children with an LMA or ETT, maintenance with inhalational agent or propofol infusion. Typically, these patients do not require muscle relaxants, and spontaneous breathing is appropriate unless controlled ventilation is required to treat ↑ ICP or for protocols involving breath holding for prolonged periods of time (e.g., several minutes for abdominal scans). Most infusion pumps need to remain a specific distance from the MRI scanner. The appropriate distance is dependent on the degree of shielding of each particular magnet. Adequate ear protection should be routinely used during MRI.	
Emergence	Transport MRI patient back to induction area for emergence so that airway equipment is readily available. Patients are transported to and recovered in PACU.	
Blood and fluid requirements	No blood loss. IV, if required: 22 or 24 ga × 1 BSS @ maintenance	
Monitoring	Standard MRI-compatible monitors	For infants, use a child-size NIBP cuff on the leg.
Positioning	Ear protection necessary ✓and pad pressure points ✓eyes	
Complications	Airway obstruction	Repositioning, nasal or oral airway
	Hypothermia	Minimize duration of scan in

		younger patients. Have available warming devices—blankets, Bair Hugger, warming pads, etc.
	Burn injury	From inappropriate placement of pulse oximeter probe or EKG. Avoid coiling of wires and use only MRI-compatible monitors.
	IV contrast reaction	
	Hearing loss (MRI)	

POSTPROCEDURE

Pain management	Noninvasive procedures are painless. Acetaminophen (35–40 mg/kg pr, 10–15 mg/kg po, or 10 mg/kg iv), hydromorphone (0.01–0.015 mg/kg iv), or morphine (0.05–0.1 mg/kg iv) as appropriate for invasive procedures

SURGICAL CONSIDERATIONS FOR ECMO

PROCEDURAL CONSIDERATIONS

Gary Hartman and Claudia Mueller

Extracorporeal membrane oxygenation (ECMO) for prolonged periods (3–21 d) allows cardiopulmonary support for newborns and children with reversible respiratory failure. The most common indications are meconium aspiration and pulmonary HTN associated with congenital diaphragmatic hernia. The procedure is performed in the NICU with OR techniques. Patients are given anticoagulants prior to cannulation. Subsequently, repair of the diaphragmatic hernia also may be performed in the NICU on ECMO support before decannulation. (Fig. 13.2-1 shows ECMO schematic.)

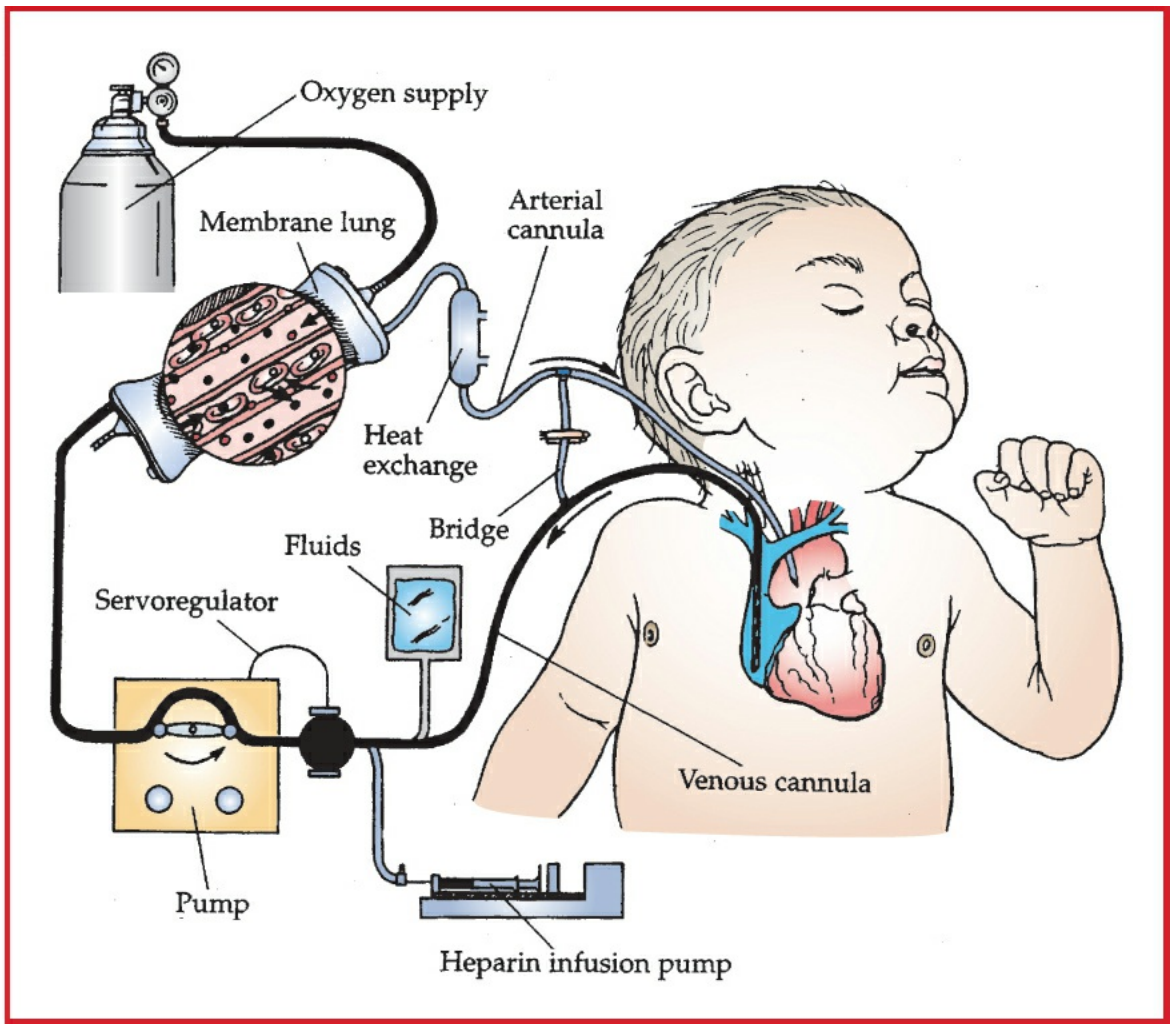

Figure 13.2-1 ECMO circuit illustrating venoarterial (VA) cannulation. Venous blood is withdrawn by gravity through a servoregulator to prevent pump from actively siphoning venous return. A pump delivers blood back to the arterial cannula after it passes through the membrane oxygenator and heat exchanger. Venous return is from the right atrium, whereas arterial infusion is into the aortic arch in double-cannula (VA) or right atrium (venovenous) techniques. (Reproduced with permission from Baker RJ, Fischer JE: Mastery of Surgery, Vol. I, 4th edition. Lippincott Williams & Wilkins, Philadelphia: 2001.)

The potential detrimental effects of the diaphragmatic repair on respiratory function can be managed with increased circuit flow. ECMO also has been helpful in some newborns with cardiopulmonary failure following correction of congenital cardiac defects. Vascular access is accomplished with one (venovenous) or two (venoarterial) cannulae. The IJ vein is cannulated in both methods with the tip of the cannula in the right atrium. In venoarterial ECMO, the common carotid artery is used with the tip o the cannula at the aortic arch. The wound is closed around the cannulae, which are secured to the infant's scalp.

Usual preop diagnosis

Meconium aspiration; diaphragmatic hernia

SUMMARY OF PROCEDURE	
Position	Supine
Incision	Right neck incision; subcostal for hernia repair
Special instrumentation	ECMO circuit (Fig. 13.2-1)
Unique considerations	Anticoagulation
Antibiotics	Broad spectrum based on underlying condition
Surgical time	1–2 h
Closing considerations	Assess for changes in ventilation (e.g., PIP, pre- and postductal ABG); assess hemostasis.
EBL	>5–10 mL/kg
Postop care	Paralysis maintained; fentanyl infusion at 2–4 mcg/kg/h
Mortality	Based on underlying conditions
Morbidity	Respiratory failure Sepsis
Pain score	6–7

PATIENT POPULATION CHARACTERISTICS	
Age range	Primarily neonatal with increasing use in older children

Male:Female	1–2:1
Incidence	1:4000 live births
Etiology	Unknown
Associated conditions	For diaphragmatic hernia: congenital heart disease (15%); renal anomalies; intestinal atresia; CNS abnormalities

ANESTHETIC MANAGEMENT FOR SURGICAL PROCEDURES UNDER ECMO

Claudia Benkwitz and Lisa Wise-Faberowski

ECMO has become a standard therapy for refractory neonatal and pediatric cardiorespiratory failure. Over the past 2 decades, the indications for ECMO have changed. The use of ECMO for neonatal respiratory failure peaked in the early 1990s but its use has now decreased with the development of alternative strategies such as surfactant, high-frequency oscillation, and inhaled nitric oxide. In contrast, cardiac indications for ECMO have continued to increase especially for cardiopulmonary arrest (ECPR) refractory to standard CPR management. Improved patient outcomes with ECMO have been achieved by combining new technologies with refined management strategies and improved training of personnel.

Anesthesiologists may find themselves encountering an increasing number of neonatal and pediatric patients on ECMO support for various surgical procedures and imaging studies. Successful management of these patients includes meticulous planning, comprehensive teamwork, communication, and attention to detail. Intrahospital transport of these patients often requires multiple personnel from various medical specialties, and therefore, it is important to elect a team leader prior to transport and to allocate specific tasks (e.g., protection of ECMO cannulae) in order to avoid any confusion or conflict.

The delivery of anesthetic agents can be via a TIVA technique or a combination of intravenous and inhalation agents. However, the oxygenator membrane of the bypass circuit can sequester varying amounts of lipid-soluble intravenous agents, such as fentanyl, altering the plasma levels and resulting in unpredictable hemodynamic changes. Volatile anesthetics are not routinely available on ECMO circuits due to difficulties with scavenging. Anesthetic agents cause preload and afterload changes, and therefore additional volume (blood products and colloids) and vasoactive agents should

be readily available in order to maintain adequate filling and blood pressure.

It is important to keep in mind that altering the surgical table height and thus the patient's height will have an impact on the venous return to the ECMO circuit (passive gravity-assisted drainage); hence, the perfusionist must be informed before undertaking this maneuver.

Diaphragmatic hernia repair is the most common noncardiac procedure undertaken on ECMO support. ECMO therapy protects the pulmonary alveoli from ventilator associated barotrauma and oxygen toxicity while maintaining tissue oxygenation. Prior to surgery, a trial period off bypass is used to assess the adequacy of conventional ventilation independent of ECMO. If the neonate is unable to be weaned, then the surgery occurs on full ECMO support. ACT is maintained at ~200 sec by the addition of heparin to the ECMO circuit. The potential detrimental effects of diaphragmatic repair on respiratory function can be managed with increased circuit flow.

Monitoring includes heart rate, arterial blood pressure, temperature, and pump flow rate with frequent ABGs and VBGs.

The majority of practitioners employ VA cannulations for ECMO support (see Fig. 13.2-1) although some centers prefer VV ECMO support if hypoxemia is the primary indication.

INTRODUCTION—ANESTHESIOLOGIST'S PERSPECTIVE

Richard A. Jaffe, MD, PhD and Terri D. Homer, MD

DEFINITION OF OFFICE-BASED ANESTHESIA

Office-based anesthesia (OBA) is distinct from outpatient anesthesia in a freestanding surgery facility. OBA is used in many medical specialties, including most dental subspecialties, dermatology, plastic surgery, ophthalmology, otolaryngology, and gynecology. The procedures described in this chapter are representative of the ways in which anesthesia is used in medical/dental offices. Although anesthesia practiced in an office carries the same risks, burdens of responsibility, and skill requirements as in a fully equipped surgical center, in the office setting, the anesthesiologist may be expected to arrange for the oxygen supply, suction, monitoring, and emergency equipment. They may even bring a portable anesthesia machine with them from site to site. This unique challenge for the anesthesia provider includes working with personnel unfamiliar with anesthesia concerns, converting the office into a facility appropriate for anesthesia, selecting appropriate patients, providing safe and effective anesthesia/analgesia, and properly preparing and recovering the patients.

STATE REGULATIONS REGARDING OFFICE-BASED ANESTHESIA

Many states have laws listing strict requirements for medical facilities where anesthesia is provided for surgical procedures. Some states have regulations based on the type of surgical procedure performed. Others regulate and credential the facility based on the type of anesthesia used (i.e., GA, iv, local). Still others base regulations on the type of facility itself. In California, for example, dental offices are regulated differently than medical offices. For many years, the California Dental Board has regulated anesthesia in the dental or oral surgery office by credentialing the anesthesia provider and/or the office facility itself. An oral surgeon, dentist, or physician issued a GA permit by the Dental Board goes through a credentialing process by one or two examiners that includes direct observation of an anesthesia case, demonstration of emergency drills, and examination of required monitoring and resuscitation equipment on site. The permit allows the holder to provide GA in any dental office. The Dental Board also issues "Conscious Sedation" permits to those dental practitioners who qualify and want to use this technique. Physicians in California wishing to have iv sedation or general anesthesia available in their office must first be accredited as a surgery center by one of

several agencies providing this service such as AAAHC.org.

EQUIPMENT NEEDED FOR OFFICE-BASED ANESTHESIA

In the office setting, the anesthesia provider may or may not have the use of an anesthesia machine or other sophisticated equipment that is readily available in a surgical center. In some respects, however, this setting is analogous to other non-OR locations. The ASA Guidelines for Nonoperating Room Anesthetizing Locations covers all types of out-of-OR facilities, and these recommendations should be followed. Appropriate monitoring—including pulse oximetry, ECG, and BP—is required. Many portable monitors have $ETCO_2$ monitoring capability, which may be useful for the spontaneously ventilating, sedated patient. A precordial stethoscope is quite useful for monitoring respirations, especially in the dental patient, in whom airway obstruction is a frequent occurrence during the procedure. Also in accordance with the ASA guidelines, full resuscitation equipment, an adequate source of O_2 (and backup O_2), a functioning suction, adequate lighting and electrical outlets (with backup battery source), and a telephone with immediate access to a hospital ER also must be available. In the credentialed medical (nondental) facility, these items are required to be on site. In the dental facility, they may or may not be present. It is the responsibility of the anesthesia provider to make sure these items are available in the medical or dental facility before administering an anesthetic.

ANESTHETIC TECHNIQUES IN THE OFFICE SETTING

Typically, the anesthetic techniques in the office setting can range from conscious sedation to GETA. The type of procedure, the patient's clinical status, and the surgeon or dentist's preference all contribute to the decision of which technique is best for that particular situation. In the pediatric patient having dental restoration work, "conscious sedation" is not adequate because most often the dental restoration required is very extensive and will likely take several hours to accomplish. In this situation, GETA with nasal intubation (or oral intubation if nasal intubation is not possible) is usually the best choice of anesthetic technique. In the patient having dental implant placement, minimal or moderate sedation may be all that is required. The oral surgeon may require the patient's cooperation at times during the procedure. The patient undergoing full-face laser resurfacing will most likely require deep sedation or GA because this procedure can be quite painful. However, because sedation is a continuum, the anesthesia provider must be prepared to rescue any patient receiving any sedation in the office (see Continuum of Depth of Sedation, ASA Guidelines).

PATIENT SELECTION

As in all medical facilities, the patient's safety is of paramount importance. In the office setting, the ability to achieve a successful outcome is dependent first of all on appropriate patient selection. The patients presenting for OBA will fall into several categories, depending on the procedure and the patient's age and medical condition. An "appropriate patient" can be an ASA 1 or 2 patient. They may even be an ASA 3 if (a) their medical problems are stable and well controlled with medication and (b) the office procedure itself will not pose an undue risk to them.

PREOPERATIVE PREPARATION

An important role of the anesthesiologist is to educate the patient (or patient's parents, as appropriate) about the office anesthesia experience. A preop phone call discussing the patient's medical history, past anesthesia experience (in a hospital, surgery center, or dental office), the NPO requirements, the anesthesia technique(s) to be used, postanesthesia expectations, and the anesthesia fees is essential. A written packet describing some of this information can be given to the patient in advance.

Safe and accepted NPO requirements on the day of the procedure are as follows:

- A light meal at least 6 h before the appointment.
- Clear liquids (including Gatorade, Jell-O, fruit popsicles) up to 2 h before the appointment.
- The patient's usual medications should be continued on the day of the procedure.

RECOVERY AND DISCHARGE

In a medical or dental office, often there is no separate recovery area designated as such. It is common practice for the patient to be recovered by the anesthesiologist in the treatment room until they can open their eyes and maintain an adequate airway without assistance. At that point, any iv or monitors that may have been used can be removed. If it is a pediatric patient, the parents may be brought into the room, although recovery remains under the supervision of the anesthesiologist. Office anesthesia patients can be discharged when they are well oriented, their pain and nausea are controlled, and they have a responsible adult to accompany them. They may still feel drowsy, but this should not prevent them from being able to walk with assistance.

Discharge instructions regarding appropriate postop activities should be given to the responsible adult with the patient. Generally, patients are asked to adhere to the following instructions upon discharge:

- NPO except clear liquids in the first 2 h after arriving at home. (Unless the ride is >1

h, we ask the patient not to drink anything in the car on the way home from the procedure facility.)
- A light meal after the first 2 h, if the patient wishes.
- Adults should take it easy the rest of the day and have a responsible adult companion for at least 4 h after the procedure.
- No driving for 24 h.
- Children should stay home for the rest of the day postprocedure, under the direct supervision of a responsible adult.

The anesthesiologist also should give the responsible party (parent, friend, other relative) his/her pager or cell phone number in the event they need to contact the anesthesiologist after patient discharge.

FACIAL REJUVENATION: LASERS AND RF TISSUE TIGHTENING

SURGICAL CONSIDERATIONS

David A. Berman, MD

Description

A variety of medical devices have been approved for use to improve skin concerns, such as wrinkles, precancerous skin lesions (actinic keratoses), discoloration, acne scars, traumatic scars, and sagging skin. In the mid-1990s, laser resurfacing using the fully ablative CO_2 laser was very popular. This procedure yielded wonderful results, but extensive heat from this procedure caused some undesirable side effects such as

scarring or pigmentation problems, prompting the industry to develop the cooler and more conservative resurfacing tool using the erbium laser. Less than a decade later, a novel fractionated laser resurfacing device was developed that removed only a fraction of the skin in a pattern reminiscent of pixels in newspaper print. Certainly, the risks and side effects were reduced compared to the older technology, though this more conservative approach rendered a more modest improvement of skin concerns. Further research led to the development of nonablative technologies such as radiofrequency/ultrasound/nonlaser light-based devices, most of which resulted in better side effect profiles and positive outcomes. Although the holy grail of devices would render a no downtime, painless procedure void of negative effects, the search for such continues to elude us. Meanwhile, physicians who perform these procedures should encourage patients to opt for office-based anesthesia and thus make the experience a more pleasant one for all involved.

Because some devices deliver a tremendous amount of heat to the skin surface, ablating both the epidermis and a portion of the dermis, nerve blocks and local anesthetic infiltration are often inadequate, thus requiring either iv sedation or GA. Facial nerve blocks may be performed to supplement iv sedation. After a Betadine® prep, anesthetic eye drops are used, followed by the insertion of protective corneal shields. The treatment then begins with one or more passes performed at various energy levels.

Usual preop diagnosis

Wrinkles; precancerous skin lesions (actinic keratoses); acne scars; traumatic scars

SUMMARY OF PROCEDURE	
Position	Supine, with shoulder roll. Surgeon at head of table
Antibiotics	None during procedure. Some patients will require antivirals and/or antibiotics started 1 d before procedure.
Surgical time	30–60 min
Postop care	Supine position, occasional ice packs, antiviral medications/antibiotics. Some require facial dressings.
Mortality	None reported
Morbidity	Bacterial infection Herpes simplex virus reactivation Delayed reepithelialization

	Fat atrophy Hypertrophic or keloid scar formation Corneal abrasion Delayed healing with redness Hyperpigmentation and hypopigmentation
Pain Score	3–6 depending on the type of medical device used

PATIENT POPULATION CHARACTERISTICS	
Age range	18–85 yr
Male:Female	1:4
Incidence	*Facial rejuvenation procedures: ~340,000/yr in US
Etiology	Solar radiation, acne, or trauma resulting in scars

*2018, American Society for Aesthetic Plastic Surgery.

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Some facial rejuvenation procedures are quite painful and can be very stressful to the patient; thus, local anesthesia is often inadequate. For these procedures, it is important to make sure that the patient with chronic HTN and/or other cardiovascular or respiratory disease is being adequately treated for these problems before undergoing either laser resurfacing or RF tissue tightening. A preop ECG (taken within the last year) is recommended for those patients >60 yr old or those being treated for HTN.

Premedication	In the adult patient, an oral premed can be given, if necessary, before the patient arrives in the office for the procedure. Lorazepam 0.5–1.0 mg po 1 h before the appointment will help relax the severely anxious patient.

INTRAOPERATIVE

Anesthetic technique

MAC and/or GA

MAC/GA	During full-face laser resurfacing procedures, the patient will need to be under deep iv sedation, unless the surgeon is willing to use a large amount of local anesthetic (often RF tissue tightening will require less sedation, depending on the device used). Usually, a combination of intermittent doses of midazolam (1–2 mg iv), meperidine (25 mg iv), ketamine (25–30 mg iv q1h prn), and propofol (25–50 mcg/kg/min iv) will provide an adequate anesthetic state. If a nasal airway is inserted, nasal O_2 can be used (limit FiO_2 to ≤0.30). Otherwise, O_2 should be administered between facial passes if a laser is used. Again, the patient is not electively intubated, but an LMA may be needed if it is difficult to maintain a patent airway. Usually, patients having this procedure will require at least 75–150 mg meperidine (or its equivalent) to relieve the painful burning caused by multiple passes of these devices. Patients will shiver and sustain HTN and tachycardia unless an adequate level of analgesia is achieved. Because of the narcotic requirement, they should have prophylactic antiemetics during the procedure. Dexamethasone (8 mg iv) and metoclopramide (15 mg iv) or ondansetron (4 mg) are a good combination.	
Blood and fluid requirements	IV: 20 ga × 1 BSS @ 2–4 mL/kg/h	
Monitoring	Standard monitors	
Positioning	✓ and pad pressure points ✓ eyes (eye shields in place)	
Complications	Laser fire	Use intermittent, low-flow O_2. Consider wrapping foil around cannula. Limit FiO_2 to ≤0.30.

POSTOPERATIVE

Complications	PONV
Pain management	Oral analgesics
Recovery and discharge	The patient recovering from a full-face procedure usually has received a lot of anesthetic medication in a short period of time. They often require at least 45–60 min to recover in the office. Vital signs should be stable (↑ BP and HR must be treated). Pain and nausea also should be under control. These patients must be accompanied by a responsible adult who can stay with them at home for a few hours after the procedure. A follow-up phone call to the patient by the anesthesiologist that evening is very helpful and appreciated.

OFFICE DENTAL REHABILITATION UNDER DEEP IV SEDATION

SURGICAL CONSIDERATIONS

Vernon J. Adams Jr, DMD

Description

Dental rehabilitation includes the restoration of good dental health by removal of caries and decayed teeth, replacement of crowns or bridges, root canals, and periodontal treatment. A throat pack with external tie is placed and a mouth prop inserted. Dental rehabilitation is usually done in phases, one quadrant at a time. A rubber dam is placed to isolate the teeth that will be treated. All dental caries are removed, the restorations are placed, and all debris is irrigated and suctioned away from the rubber dam, which is then removed. This sequence is repeated in other quadrants as needed. After the operative phase of treatment is completed, the next treatment phases proceed (e.g., taking impressions for various appliances or dental prosthetics, dental extractions, or a dental prophylaxis). After the treatment is completed, the dentist examines the mouth and removes any loose gauze, debris, or other material left over from the treatment before the anesthesiologist begins the process of emergence from anesthesia.

Usual preop diagnosis

In-office dental rehabilitation usually focuses on treatment of the patient who is unable

to be treated in a conventional setting for primarily behavioral/emotional reasons. These include dentophobia; pediatric patients who are excessively apprehensive and/or combative or who have a significant amount of dental caries; "special needs" pediatric patients—autistic, mentally retarded, developmentally delayed—and patients with mild-to-moderate forms of cerebral palsy.

SUMMARY OF PROCEDURE	
Position	Supine, on a dental chair or bench. A pillow under the knees will improve comfort and prevent sliding.
Incision	± Gingival or intraoral mucosa
Special instrumentation	Dental setup
Unique considerations	Intubation recommended; throat pack placed; airway protection of paramount importance
Antibiotics	None used routinely
Surgical time	90–180 min
EBL	Minimal
Postop care	Recover in lateral position
Mortality	Rare
Morbidity	Biting of lips or tongue 2° local anesthesia: 1% Bleeding: 1% Infection: <1% Delayed bleeding: rare
Pain Score	1–3; higher for certain procedures (e.g., extraction of impacted tooth or when all quadrants of the mouth are restored)

PATIENT POPULATION CHARACTERISTICS	
Age range	13 mo+
Male:Female	1:1
Incidence	>20,000/yr in the United States
Etiology	Poor oral hygiene and/or dietary habits; lack of

	continuing periodic dental care

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

In the pediatric dental office, the patients presenting for GA are those who cannot cooperate due to age (too young), too anxious, or to a preexisting mental or physical disease. Examples include a 20-mo-old child with early childhood caries, an 8-yr-old autistic child, or a child of any age with cerebral palsy, obesity, Down syndrome, or other congenital syndrome. Obviously, the anesthetic treatment plan must be tailored to the patient's individual needs. These patients must be screened in advance for clinical conditions that would put them at risk for problems intraop or postop. Specifically, a patient with any cardiac, respiratory, endocrine, or neurologic problem must be evaluated. If the clinical condition is mild, stable, and under good control, the patient may be considered for GA in the office. Examples of such conditions include mild non–steroid-dependent asthma, corrected congenital heart disease, or a stable Sz disorder. The child with Down syndrome, obesity, snoring, or OSA may pose a very difficult problem in this setting because airway obstruction can occur easily under deep sedation. Also, these patients frequently have concurrent congenital heart disease. The child with a current or recent URI always poses a dilemma. Although there is controversy on this issue, these children generally should have their procedures postponed because their chances of sustaining periop respiratory problems are higher than normal.

Premedication	There are several options available for preprocedure sedation. In the older child (>8 yr) who is psychologically mature, an iv can be placed without premedication. In a dental office that is equipped with N_2O, the patient can breathe a high-flow N_2O/O_2 mix through a nasal mask for 10 min before iv placement. If the patient accepts the mask, this technique can help lessen the patient's fear of and reaction to the iv. The use of a 30-ga needle for infiltration of buffered 2% lidocaine and, sometimes, the use of EMLA cream (placed 30 min in advance) can be very helpful. Oral premedication is used commonly in children 4–8 yr old. Midazolam (0.5–0.7 mg/kg; maximum = 20

mg) mixed in an appropriate dose of liquid acetaminophen, given in the office 20 min before the procedure, can provide adequate sedation. In some, the addition of oral ketamine 2–3 mg/kg to the midazolam solution may result in a better sedating effect, especially in older pediatric patients.

Although an oral premed is popular and usually effective in the hospital setting, it may not be appropriate in the setting of the dental office for a variety of reasons. First, many of these children are not cooperative with oral hygiene or with taking oral medications at home and will not cooperate with taking them in the office. The special-needs children or adults will often be totally unable to take an oral premed. Second, many of the patients are anxious that the oral premed may not be effective. Third and may be most important, having any volume in the stomach adds to the risk of aspiration management, which is extremely problematic in the dental office.

One safer and certainly more effective and predictable premedication for the young healthy child (6 yr or younger) or for the special-needs child is an intramuscular injection consisting of ketamine 2 mg/kg, midazolam 0.2 mg/kg, and glycopyrrolate 0.1 mg/kg. The anesthesiologist can administer this injection while the patient is in his or her parents' arms in the waiting area. Within 5 min after the injection, the patient will be sedated adequately to allow a smooth separation from the parent and sufficient amnesia for induction. Most parents will accept this premed option when the anesthesiologist explains the rationale for it in advance, usually during the preop phone call.

In the child over age 6, an inhalation induction without premed may work very well, especially when explained properly to the child and the parent.

After the premed, the induction of GA in the adult, pediatric, or special-needs patient in the dental office

	is similar to anesthetic induction in the OR. Monitors are placed, and in the pediatric patient, this is followed by an inhalation induction, and then the placement of the iv. Intubation (preferably a nasal ETT) follows. After confirmation of proper ETT placement, throat packs are placed with dental floss tied to them and left outside the mouth as a reminder of their presence in the throat. If x-rays are needed, the dentist and/or the dental assistants will get these done after the patient is intubated and then, finally, dental treatment can begin. There are no special considerations for maintenance of GA, and an inhalation agent, TIVA or a combination, can be used. Some intraop narcotic should be used in the pediatric patient for postop analgesia as well as to minimize emergence delirium. Local anesthetic is often avoided in the pediatric patient undergoing a dental procedure under GA to avoid the possibility of the child biting a numb lip, cheek, or tongue as they recover. In the healthy adult patient undergoing dental work or oral surgery with GA, local anesthesia is usually administered by the dentist or oral surgeon intraop. The routine use of prophylactic intraop antiemetics is highly recommended and may include a combination of dexamethasone, metoclopramide, and ondansetron.

INTRAOPERATIVE

Anesthetic technique

If necessary, a flexible LMA can be used for airway management. Following sedation, the patient is placed in the dental chair, with the head positioned to maintain an open airway. A shoulder roll may be needed to help with head extension. Monitoring—including pulse oximeter, ECG, BP cuff, and precordial stethoscope—is attached. O_2 is supplied, and $ETCO_2$ can be measured through a nasal cannula. An iv is started if not previously placed. A nasal airway is positioned with care (to avoid epistaxis) after the dental x-rays are taken. The anesthesiologist must be constantly vigilant in maintaining

an open airway in these patients in the face of an oral procedure. Placing a flexible LMA may make airway management easier without interfering with the dental procedure. A propofol infusion can be started at a rate of 100–150 mcg/kg/min. Administration of a small amount of meperidine (e.g., 5–15 mg iv) may be useful in alleviating emergence delirium, especially if there is not adequate local anesthesia.

Emergence	No special considerations, except that throat packs must be removed.
Blood and fluid requirements	IV: 20–22 ga × 1 BSS @ 2–4 mL/kg/h
Monitoring	Standard monitors
Positioning	✓ and pad pressure points ✓ eyes

POSTOPERATIVE

Complications	PONV	These patients may swallow blood, with consequent PONV.
Pain management	Oral analgesics	Acetaminophen can be started ~4 h after discharge.
Recovery and discharge	In the dental office, there may not be a separate, designated recovery area. Usually, the pediatric patient is recovered by the anesthesiologist in the treatment room for at least 30–45 min, or until the patient is opening his/her eyes and maintaining a normal airway without assistance. At this point, the iv and monitors can be removed and the patient can continue recovering with his/her parents or family in the office until the patient can keep his/her eyes open, follow commands, seem calm, and is free of nausea. Postop instructions given to the parents include no outside or unsupervised activities for the rest of the day, no drinking or eating in the car on the way home, clear liquids for the first h, and	

	gradually advancing the diet to soft foods. The anesthesiologist should give the parents his/her pager or cell phone number so they can call with any questions that arise after they are at home. Regardless, a follow-up phone call from the anesthesiologist is always a good policy.

DENTAL IMPLANTS AND BONE GRAFTING

SURGICAL CONSIDERATIONS

Azeem K. Lakha, DMD

Description

A dental implant consists of a tooth root–shaped titanium post that is used to support a crown, bridge, or denture. Dental implants are inserted surgically into the mandibular or maxillary alveolar bone where teeth are missing. Single implants may be done with local anesthesia, but multiple or complex procedures are best accomplished with iv sedation. After the local anesthetic is administered, a mucoperiosteal flap is raised over the edentulous alveolus, and the bone is exposed. Precise drill holes are made in the bone, and the implants are screwed or tapped into place. Bone grafting may be necessary around the implants to fill in defects and is carried out using autologous, allogeneic, xenogeneic, or synthetic materials. In most cases, the gum tissue is closed over or around the implant. The bone is allowed to heal around the implant, and 2–6 mo later, the implant can be used to attach crowns, bridges, or dentures. In cases where there is insufficient bone, a bone graft is necessary **before** implants can be placed. Typically, bone grafts are allowed to heal for 6 mo before implant insertion. Most minor grafting procedures are accomplished in the dental office under iv sedation and local anesthesia. Major grafts requiring extraoral donor sites may have to be done under GA via nasal ETT intubation.

Usual preop diagnosis

Acquired or congenital absence of dentition

SUMMARY OF PROCEDURE

Position	Supine, with head tilted back, using an articulating headrest in the dental chair

Incision	Intraoral mucoperiosteal flaps
Special instrumentation	Precordial stethoscope
Unique considerations	Throat packs are used to prevent aspiration of teeth, crowns, blood, and irrigation fluids. Ensure that they are removed at the end of the case.
Antibiotics	Prophylactic antibiotics, given orally before surgery
Surgical time	1–3 h
EBL	25–100 mL
Mortality	Rare
Morbidity	Infection: 1% Bleeding: Rare Delayed bleeding: Rare Aspiration: Rare
Pain score	1–4, depending on procedure

PATIENT POPULATION CHARACTERISTICS	
Age range	17+ yr
Male:Female	1:1
Incidence	Becoming more common as technology improves
Etiology	Tooth loss

ANESTHETIC CONSIDERATIONS

PREOPERATIVE

Many patients having dental implant procedures are older and/or have multiple medical problems. The anesthesiologist should be consulted in advance about these patients so that questions about their medical conditions can be answered and a current list of medications can be obtained. Sometimes, the patient's primary care physician needs to be contacted to discuss details of medical Hx. If chronic medical conditions are stable, patients often can receive "conscious sedation" and monitoring by the anesthesiologist for this procedure in the office.

Premedication: Usually not necessary

INTRAOPERATIVE

Anesthetic technique

MAC: These patients are not intubated electively. In the adult patient having dental implants, the maintenance of a lightly sedated state can be achieved using a combination of iv midazolam, fentanyl (or meperidine), ± low-dose ketamine (20–30 mg/dose). A pulse oximeter, ECG, BP cuff, precordial stethoscope or $ETCO_2$ monitor, and nasal O_2 should be in place. Glycopyrrolate (0.1–0.2 mg) should be given to decrease secretions. Dexamethasone 4–8 mg and metoclopramide 15 mg are useful as an antiemetic combination. Usually, the oral surgeon needs the patient's cooperation at some point during the procedure; therefore, propofol is not an ideal drug to use. It can be given, however, in small doses to the patient who requires more than the other drugs for sedation. Occasionally, the adult patient in this setting will require a nasal airway.

Emergence	No special considerations, except that throat packs must be removed at end of procedure.
Blood and fluid requirements	IV: 20–22 ga × 1 BSS @ 1–3 mL/kg/h
Monitoring	Standard monitors
Positioning	✓ and pad pressure points ✓ eyes

POSTOPERATIVE

Complications	PONV	These patients may swallow blood, with consequent PONV.
Pain management	Oral analgesics	
Recovery and discharge	In the dental office, there may not be a separate, designated recovery area. Usually, the patient is recovered by the anesthesiologist in the treatment room until the patient is responding appropriately. At this point, the iv and monitors can be removed and the patient can continue recovering with	

	family/accompanying adult as necessary in the office until the patient is comfortable, free of nausea, and able to drink water or fruit juice.

SECTION 15.0

EMERGENCY PROCEDURES FOR THE ANESTHESIOLOGIST

ANESTHESIOLOGIST
Frederick G. Mihm, MD

EMERGENCY CRICOTHYROTOMY

Clinical situation

Typically, this procedure is performed in a hypoxic patient with an obstructed airway who cannot be ventilated with a mask or LMA and cannot be intubated.

Emergency "Stab" Cricothyrotomy

Equipment	• Scalpel, preferably with no. 11 blade • ETT no. 6 • Syringe for inflating cuff • Prep solution such as alcohol, chlorhexidine, or povidone-iodine

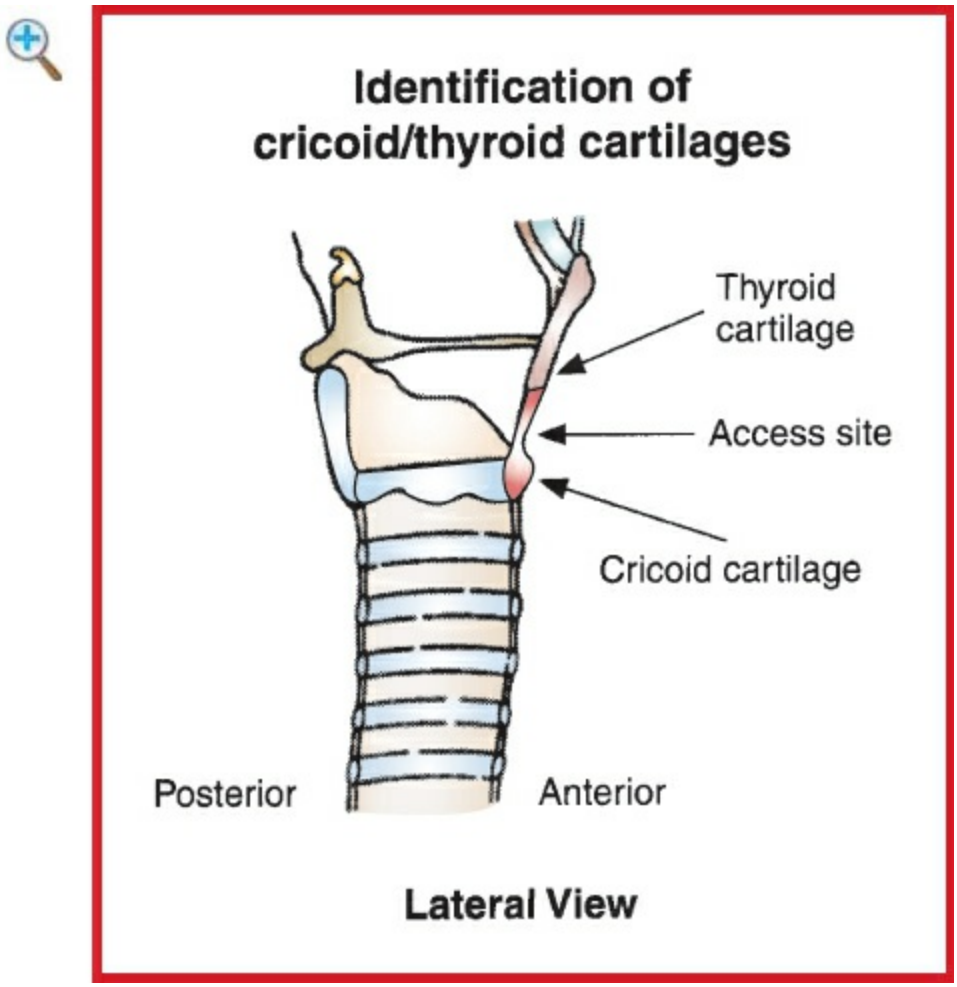

Figure 15.1 Identify cricoid membrane.

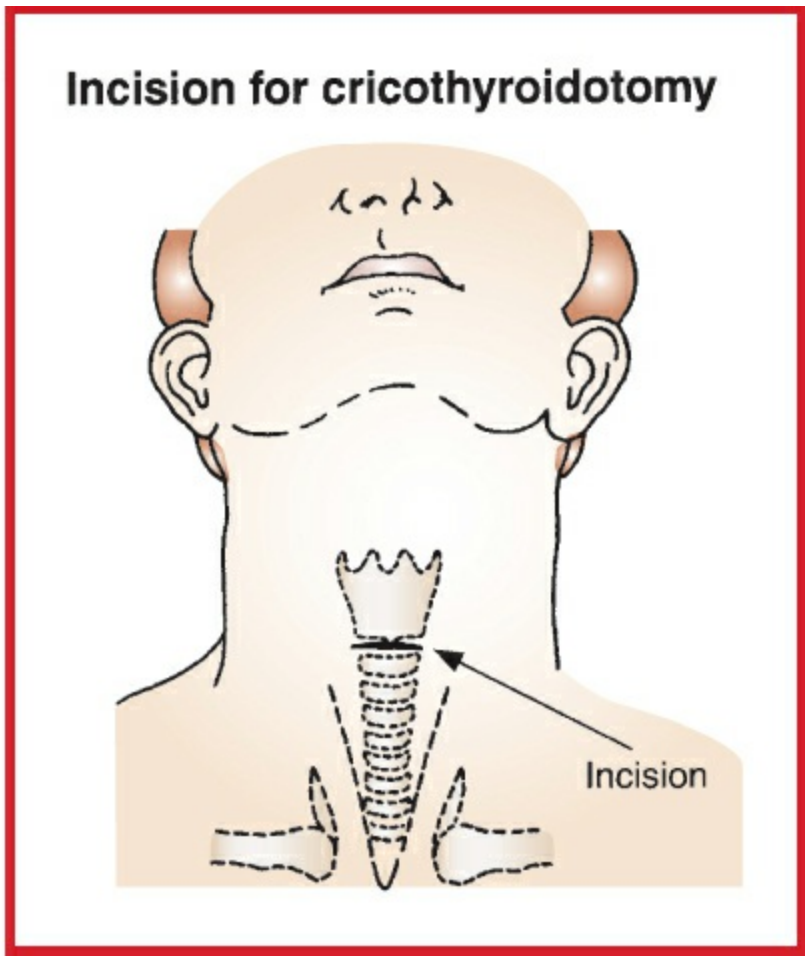

Figure 15.2 If possible, extend head and place bolster between scapula. Palpate thyroid and cricoid cartilages and then identify cricothyroid membrane (CTM). Skin incision may be vertical if unsure of CTM location, as a finger inserted through a vertical incision may have more ability to palpate the CTM by blunt pressure in a vertical or horizontal search.

Procedure	1. Prep skin if time permits. 2. Identify cricothyroid membrane between cricoid and thyroid cartilages (Fig. 15.1). 3. Make 2- to 3-cm transverse or vertical incision through skin. 4. Make 2.5-cm incision through cricothyroid membrane with single stab (Fig. 15.2). 5. Reverse scalpel, place handle into wound, and turn 90° to expand incision. 6. Pass tracheostomy tube (or standard ETT) into trachea. 7. Inflate cuff on tracheostomy/ETT. 8. Ventilate patient with capnography if possible. 9. Secure tube.

Emergency "Four-Step" Cricothyrotomy

Equipment	• Scalpel with no. 11 blade • Tracheal hook (may be improvised by bending a 16-ga needle into a hook with a hemostat) • ETT no. 6 • Syringe for inflating cuff • Prep solution such as alcohol, chlorhexidine, or povidone-iodine
Procedure	1. Right hand dominant operator stands on patient's left side. Position with head and neck extended. 2. Prep skin if time permits. 3. Nondominant hand identifies cricothyroid membrane while stabilizing thyroid cartilage. Dominant hand makes 2.5-cm transverse incision through skin and cricothyroid membrane with single stab, keeping blade in place. 4. Nondominant hand places tracheal hook into incision, lifting cricoid cartilage ventrally, and then scalpel is removed. 5. Dominant hand inserts ETT and then removes tracheal hook. 6. Inflate cuff. 7. Ventilate patient with capnography if possible. 8. Secure tube.

Emergency "Bougie-Guided" Cricothyrotomy

Equipment	• Scalpel and hemostat (central line kit) • ETT no. 6 • Syringe for inflating cuff • Bougie (pediatric 10 Fr for ETT 4.0–5.5 or adult 15 Fr for ETT 6.0) • Prep solution such as alcohol, chlorhexidine, or povidone-iodine
Procedure	1. Operator may stand at head or either side of the patient. Position with head and neck extended. 2. Prep skin if time permits.

3. Nondominant hand identifies cricothyroid membrane while stabilizing thyroid cartilage.
4. Dominant hand makes a 3-cm incision (vertical or transverse) through skin.
5. Nondominant hand index finger placed into incision, palpates cricothyroid membrane with a side-to-side motion, and then finger is removed from incision.
6. Dominant hand makes a 2.5-cm horizontal incision in the cricothyroid membrane.
7. Dominant hand inserts coude tip end of bougie via incision seeking tracheal clicks and hang-up sign.
8. Pass ETT over bougie into trachea. If difficult, use hemostat to dilate cricothyroid membrane with bougie in place and then pass ETT (Fig. 15.3).
9. Remove bougie.
10. Inflate cuff.
11. Ventilate patient and monitor capnogram if possible.
12. Secure tube (Fig. 15.4).

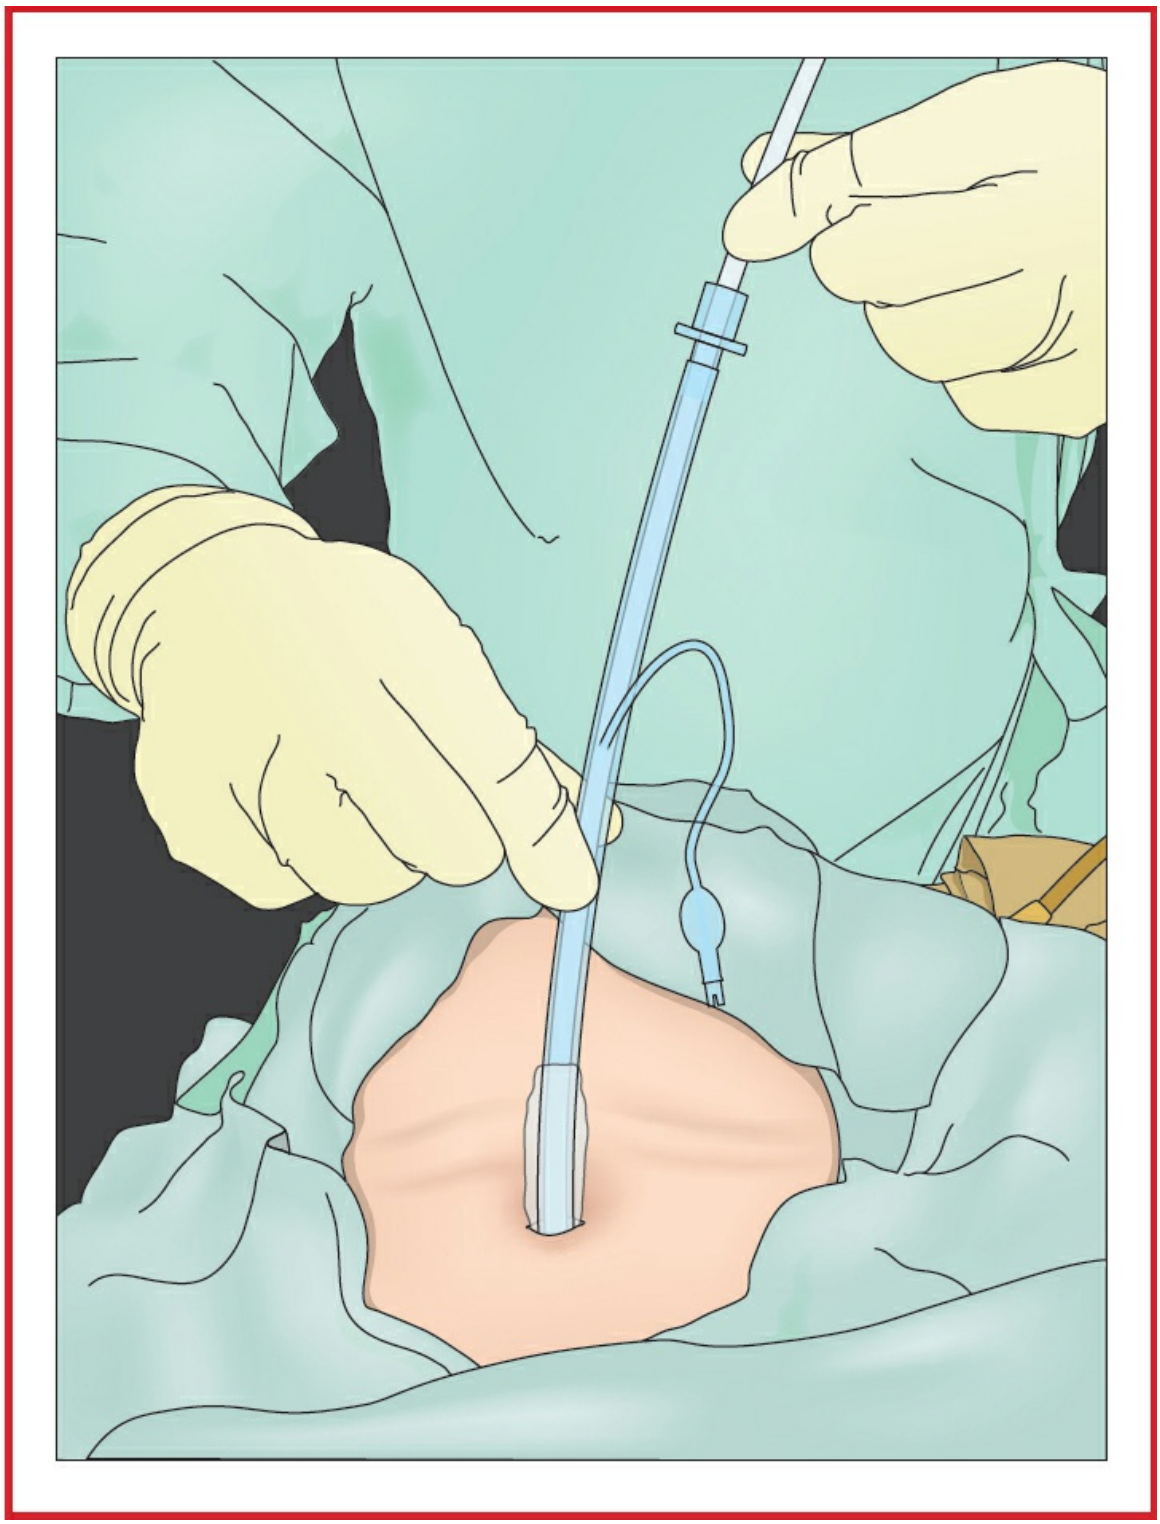

Figure 15.3 Adult bougie 15 Fr passed via incision with coude tip directed caudally attempting to feel for tracheal clicks and/or carinal hang-up sign. Average depth from skin to carina is 12–15 cm. A 6.0 or greater ETT will pass over an Adult 15 Fr bougie.

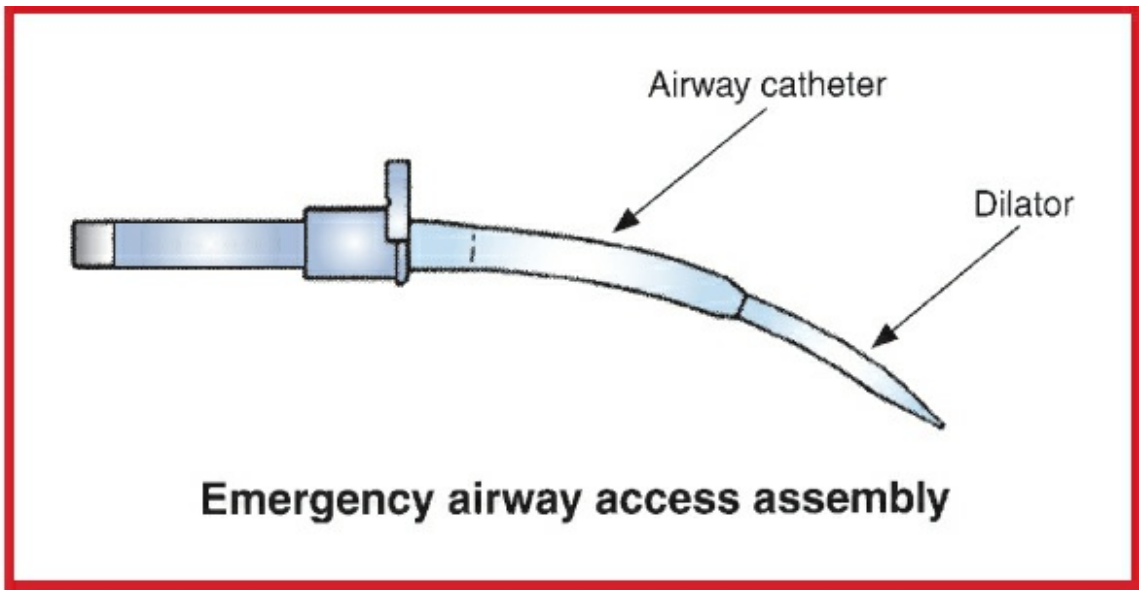

Figure 15.4 Melker cricothyroidotomy kit with dilator passed firmly into airway catheter prior to accessing the CTM.

EMERGENCY PERICARDIOCENTESIS

Clinical situation

The patient typically has severe ↓BP unexplained by any other causes (e.g., anesthetic drugs, autoPEEP, tension pneumothorax) and consistent with acute cardiac tamponade (dyspnea, tachypnea, ↓BP, ↑HR, electrical alternans, ↓voltage EKG, ↓pulse pressure or pulsus paradoxus, ↑CVP/JVD, distant heart sounds) ± equalization of pressures (RAP ~ RVEDP ~ PAD ~ PAOP) ± confirmation by TEE/TTE. Because of the high intrapericardial pressures, all "filling pressures" of both right and left heart appear high when preload is actually very low. In severe cases, patients will experience cardiac arrest with pulseless electrical activity (PEA).

Equipment	• 10-mL syringe • 18-ga spinal needle
Procedure	1. Identify xiphoid process and point 1 inch below and 1 inch left of midline (Fig. 15.5). 2. Prep skin below xiphoid. 3. An 18-ga spinal needle is directed toward the left shoulder and inserted at a ≤45° angle to the skin. 4. Attach needle to syringe, and direct needle at ≤45° to the skin under rib toward left shoulder (Fig. 15.5).

5. If pericardial fluid is withdrawn, BP will ↑ immediately.

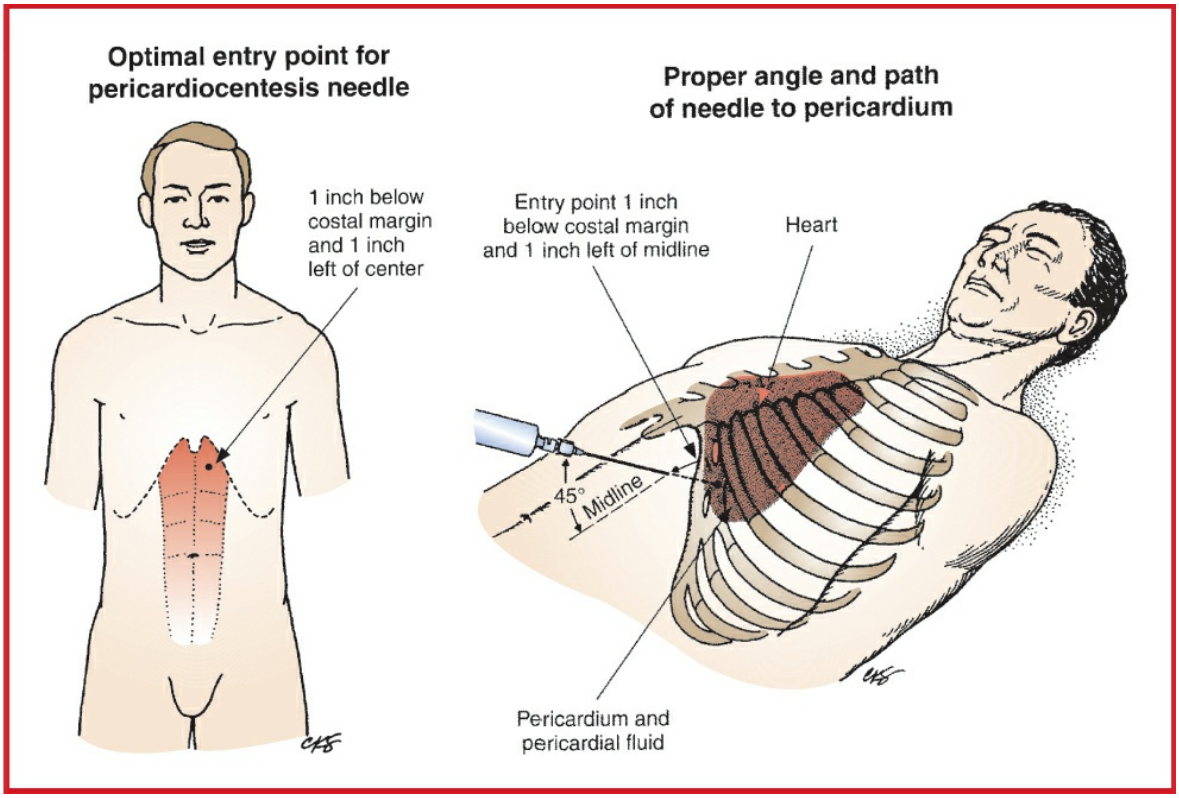

Figure 15.5 Emergency blind pericardiocentesis. Once diagnosis of cardiac tamponade is made, elevate head of bed to 30–45° to allow gravity to assist in fluid access. If hemodynamics do not allow this, place the patient into a supine position. The access site is 2.5 cm below the xiphoid process and 2.5 cm to the patient's left. An 18-ga spinal needle is directed toward the left shoulder and inserted at a ≤45° angle to the skin. The stylet is removed, a syringe with stopcock attached, and the apparatus advanced with aspiration. If time allows, anesthetize the route with lidocaine 1–2% 5–10 mL.

EMERGENCY ULTRASOUND-GUIDED PERICARDIOCENTESIS[1,5]

In the above-described setting of respiratory and hemodynamic stability, ultrasonography may be used to aid in diagnosis and treatment of cardiac tamponade. If you are unfamiliar with basic cardiac ultrasonography, a stat consult with a skilled ultrasonographer is necessary for performance of an ultrasound-guided pericardiocentesis. Precepted hands-on training must be sought prior to using ultrasound for diagnosis or treatment of cardiac tamponade.

Cardiac tamponade is a clinical diagnosis. Ultrasound findings include pericardial fluid with a "swinging heart" (ultrasound visualization of electrical alternans); increasing

pericardial pressure causes right atrial systolic collapse, right ventricle diastolic collapse, septal shift toward left ventricle in systole; respiratory variation across tricuspid and mitral valves; in addition, IVC plethora with no respiratory variation may be seen. Patients with normal, stable hemodynamics and pericardial effusion do not require emergent pericardiocentesis.

Equipment	Minimum • Skilled ultrasonographer • Ultrasound machine with phase array, curvilinear, or vascular access probe • Ultrasound gel or lubricant • Syringe • 18-ga 5-inch spinal needle or 18-ga Tuohy needle or longest 18-ga angiocatheter/needle available
	Preferred • Alcohol, chlorhexidine, or povidone-iodine skin prep • Sterile gloves • Skilled ultrasonographer • Ultrasound machine with phase array, curvilinear, or vascular access probe • Sterile ultrasound probe sheath with gel • 10-, 20-, or 60-mL syringe • 18-ga spinal needle • 3-way stopcock • Lidocaine 1–2% 5–10 mL with 5-mL syringe and 3-inch 25-ga needle
Subxiphoid Approach	1. Identify xiphoid process and point 1 inch below and 1 inch left of midline (Fig. 15.5). 2. Prep skin, then attach needle to 3-way stopcock on a syringe. 3. Use ultrasound probe with sterile sheath to find largest accessible collection of pericardial fluid in the subxiphoid space. A subxiphoid four-chamber view or short-axis midpapillary view should be attempted. Note that you may need to pass the needle through the liver to get to the pericardial space. If no chest compressions are being performed, consider positioning the patient in slight head-up or left lateral decubitus position to

optimize fluid accessibility. If the patient is conscious, consider local anesthetic injection along anticipated needle path under ultrasound visualization.

4. Place needle next to probe in same alignment to the skin and pericardial fluid (Fig. 15.6).
5. Advance needle tip under direct ultrasound visualization (Fig. 15.6).
6. When needle tip enters fluid collection, withdraw fluid. If flowing freely, continue to withdraw fluid until syringe is full, or you may turn the 3-way stopcock open to atmosphere to allow pericardial pressure to decompress. (If unsure of needle tip position, abort attempt or consider injection of 1- to 3-mL agitated saline via needle to identify location of tip relative to pericardial fluid.)
7. Remove needle once hemodynamics have improved with fluid removal.
8. Monitor patient for reaccumulation of pericardial fluid and consult for formal evaluation and possible pericardial drain placement.

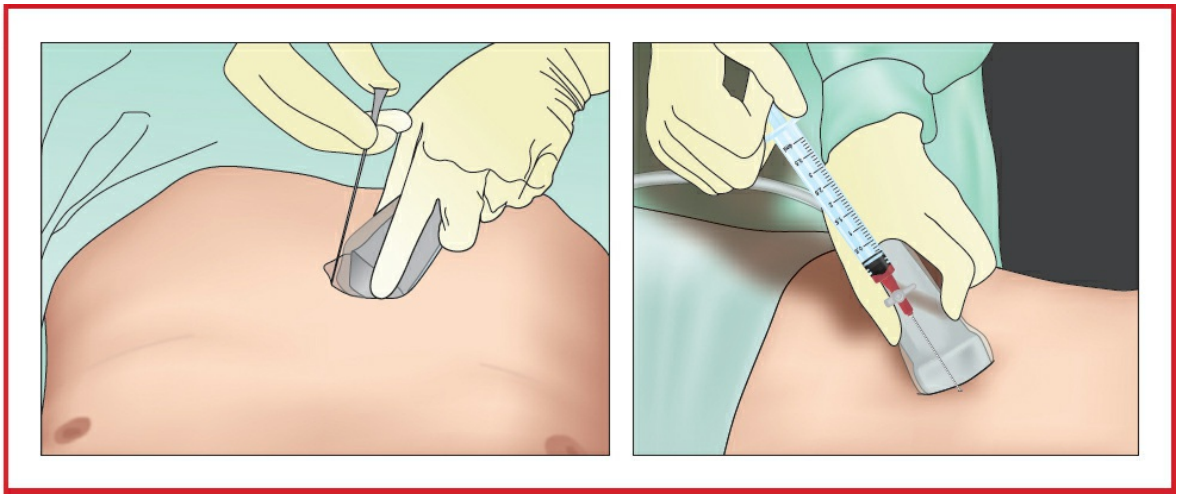

Figure 15.6 Emergency ultrasound-guided pericardiocentesis. Subxiphoid approach. Once ultrasonographic diagnosis of cardiac tamponade is made, elevate head of bed to 30–45° to allow gravity to assist in fluid access. If hemodynamics do not allow this, place the patient into a supine position. The subxiphoid access site is 2.5 cm below the xiphoid process and 2.5 cm to the patient's left. With the ultrasound probe in place, visualizing the effusion and the heart, an 18-ga spinal needle is directed toward the left shoulder and inserted at a ≤45° angle to the skin. The stylet is removed, a syringe with stopcock attached, and the apparatus advanced with aspiration under direct visualization. If unsure of needle tip location, stop advancement and wait for expert help or consider injection of 1–3 mL of agitated saline to visualize tip location. If time allows, anesthetize the route with lidocaine 1–2% 5–10 mL. Both in-plane

and out-of-plane techniques are acceptable.

Parasternal Approach (Fig. 15.7)	Prep skin, then attach needle to 3-way stopcock onto syringe. Use ultrasound probe with sterile sheath to find largest accessible collection of pericardial fluid in the parasternal area; 4th or 5th rib interspace along left sternal border. Note that you should not pass the needle through the pleural space/lung/vessels to enter the pericardial space. If patient is conscious, consider local anesthetic injection along anticipated needle path under ultrasound visualization. Place needle next to probe in same alignment to the skin and pericardial fluid. You may use color flow Doppler to visualize vessels in intended needle path. Advance needle tip under direct ultrasound visualization. When needle tip enters fluid collection, withdraw fluid. If flowing freely, continue to withdraw fluid until syringe is full, or you may turn the 3-way stopcock open to atmosphere to allow pericardial pressure/fluid to decompress. (If unsure of needle tip position, abort attempt or consider injection of 1- to 3-mL agitated saline via needle to identify location of tip relative to pericardial fluid.) Remove needle once hemodynamics have improved with fluid removal. Monitor patient for reaccumulation of pericardial fluid and consult for formal evaluation and possible pericardial drain placement.

Suggested Reading

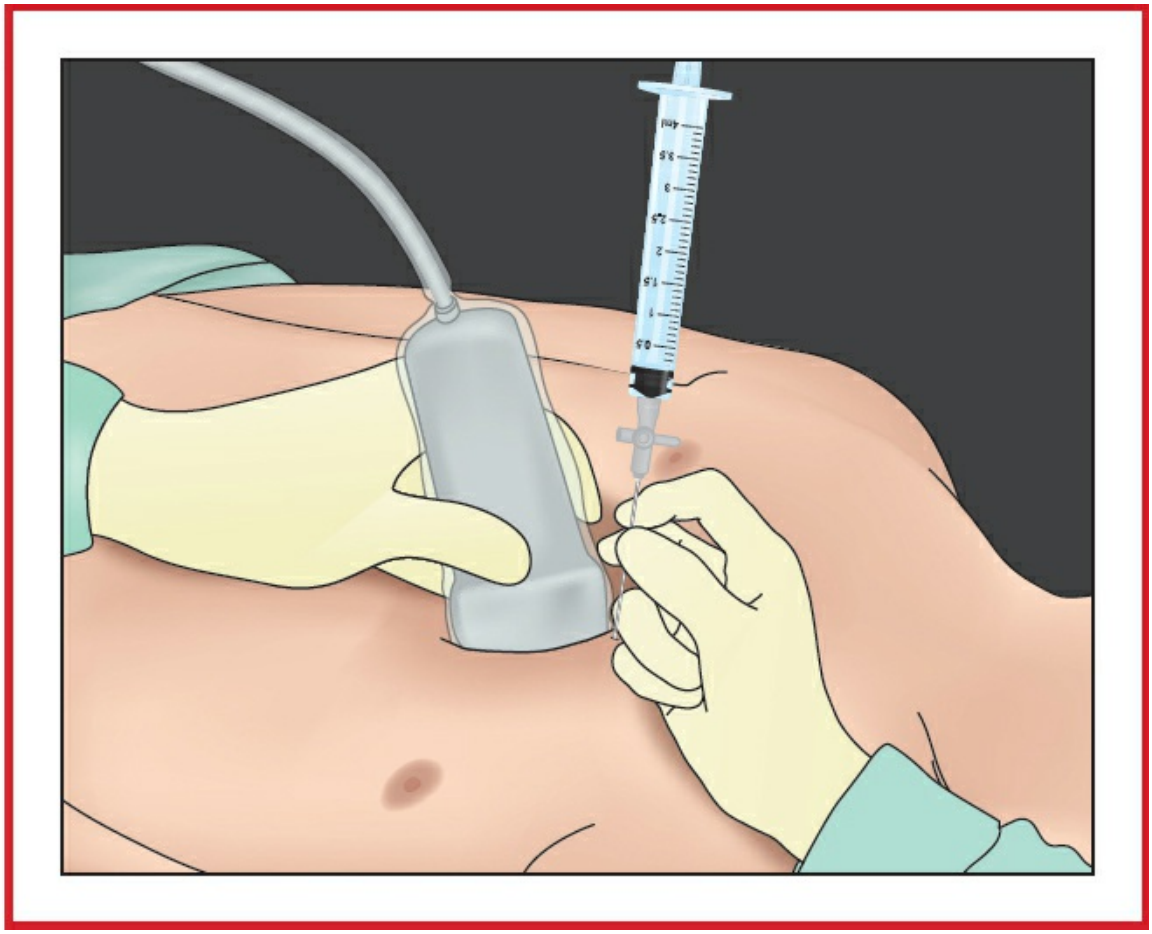

Figure 15.7 Emergency ultrasound-guided pericardiocentesis. Parasternal approach. Place the patient supine or in Trendelenburg to maximize fluid collection size in intended needle path. Identify the heart and fluid collection in the 4th or 5th intercostal space between the sternum and the midclavicular line. Be sure that the lung is not entering into ultrasonographic view. An 18-ga spinal needle is directed toward the patient's back and inserted at a 90° angle to the skin. The stylet is removed, a syringe with stopcock attached, and the apparatus advanced with aspiration under direct visualization. If unsure of needle tip location, stop advancement and wait for expert help or consider injection of 1–3 mL of agitated saline to visualize tip location. If time allows, anesthetize the route with lidocaine 1–2% 5–10 mL.

EMERGENT NEEDLE/CATHETER THORACOSTOMY

Clinical situation

A patient is experiencing severe hypotension and hypoxemia unexplained by any other cause (e.g., autoPEEP, cardiac tamponade) and consistent with acute tension pneumothorax (dyspnea, tachypnea, tachycardia, syncope, ↑P_{aw}, ↓movement of involved chest, ↓breath sounds, ↑resonance to percussion, and ↑rib interspace distance compared to uninvolved side) and cardiovascular Sx related to ↑thoracic pressures and ↓preload (↓BP, ↑HR, ↑pulse pressure, ↑CVP). The CVP is artificially elevated, reflecting the hig intrathoracic pressures. Actual (transmural) CVP is very low. In severe cases, patients may experience cardiac arrest with pulseless electrical activity (PEA) because high intrathoracic pressures effectively stop venous return to the heart.

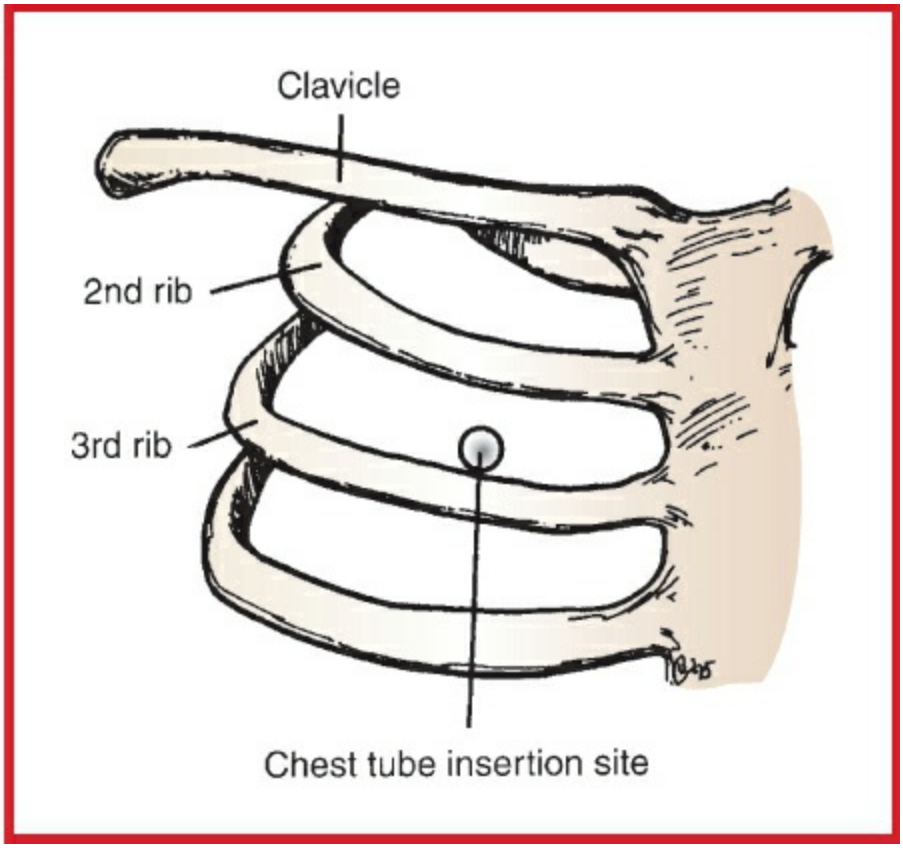

Figure 15.8 Midclavicular 2nd intercostal space. Lateral needle decompression in the 4th or 5th midaxillary line. To avoid injury to neurovascular bundle, insert needle along upper border of the inferior rib at the selected space.

Note: AutoPEEP MUST be ruled out first, particularly when the diagnosis is bilatera

tension PTX. AutoPEEP is effectively ruled out (except with a ball valve airway lesion) by disconnecting the ETT from ventilator/Ambu® bag and allowing patient to exhale. If the patient's condition immediately improves, you have made the diagnosis of autoPEEP.

Note: With a pneumothorax, release of the pressure that has built up in the chest is a lifesaving maneuver. A large-bore chest tube does not need to be placed emergently. The much simpler needle/catheter thoracostomy is effective and less demanding for the nonsurgeon.

Equipment	One of the following: • 16-ga needle or iv catheter/needle (preferred) with a length of 5 cm • 16-ga single-lumen CVP kit • Alcohol, chlorhexidine, or povidone-iodine skin prep
Procedure	1. Identify the space. Identify the 2nd intercostal space by palpating the angle of Louis (union of manubrium and sternum); then move laterally to find the insertion of the 2nd rib. The interspace directly below this rib is the 2nd intercostal space (Fig. 15.8). Access should occur in the midclavicular line in this space. Alternatively, the anterior or midaxillary line in the 4th–5th intercostal space may be used. Identify the anterior axillary line by drawing an imaginary line caudally from the anterior axillary fold to rib space at or above the nipple line. 2. Prep skin. 3. Enter the selected intercostal space anteriorly over the upper border of the inferior rib to avoid neurovascular bundle running along the underside of the superior rib. 4. With entry into the pleural space, there may be an audible rush of air and with immediate hemodynamic improvement. 5. Remove needle. 6. The angiocatheter may be held in place until a chest tube is inserted. 7. Note: A more permanent chest tube will still need to be placed (i.e., the patient no longer has a tension

	pneumothorax, but still has a pneumothorax). This can be done in a more controlled situation by someone skilled in that procedure.

EMERGENT ULTRASOUND-GUIDED NEEDLE/CATHETER THORACOSTOMY

Tension pneumothorax diagnosis and management have been described earlier. If progressive pneumothorax with worsening cardiopulmonary function is suspected, a skilled ultrasonographer is needed to rule out pneumothorax prior to tension pneumothorax development. Lung ultrasound has >90% sensitivity and >90% specificity for pneumothorax.[6] A vascular access, curvilinear, or phase array probe with a depth field of 6 cm using 2D imaging may be utilized to detect pneumothorax. 2D and M mode may be used to identify signs to rule in or out a pneumothorax. Precepted hands-on training must be sought prior to using ultrasound to diagnose or treat pneumothorax.

Equipment	• Skilled ultrasonographer • Ultrasound machine with phase array, curvilinear, or vascular access probe • Ultrasound gel or lubricant • 16-ga needle or angiocatheter/needle
Procedure	1. Identify pneumothorax with ultrasound.[7] 2. Scan least dependent area of chest with ultrasound probe (in supine patients—3rd–5th rib interspace midclavicular line) at 6 cm in 2D with indicator toward the patient's head and held perpendicular to chest wall (Fig. 15.9). 3. Identify the pleural line and seek lung sliding. Lung sliding confirms that the lung is touching the chest wall. Presence of lung sliding rules out large tension pneumothorax. 4. Seek B lines in 2D. Presence of B line rules out large tension pneumothorax in the scanned space. 5. Check for seashore sign in M mode at site of lung sliding (Fig. 15.10). Presence of seashore sign rules out large tension pneumothorax in the scanned space.

6. Alternatively, absence of seashore sign and presence of bar code (Fig. 15.11) sign indicate pneumothorax. The lung point sign is a moving dark point seen at the interface of normal lung sliding to the air of the pneumothorax. If lung point sign is present, this indicates pneumothorax.
7. If all the above signs are absent and A lines are present, this does not rule out or in pneumothorax. Other modalities such as CXR or CT for diagnosis or continuing with diagnostic/therapeutic needle thoracostomy will be required.
8. Prep skin. Place angiocath/needle to side of probe.
9. Enter the selected intercostal space anteriorly over the upper border of the inferior rib to avoid neurovascular bundle; attempt to visualize needle tip.
10. With entry into the pleural space, there may be an audible rush of air, and there should be immediate hemodynamic improvement.
11. Remove needle once hemodynamics or ventilation improves to avoid lung laceration. The angiocatheter may be held in place until a chest tube is inserted.

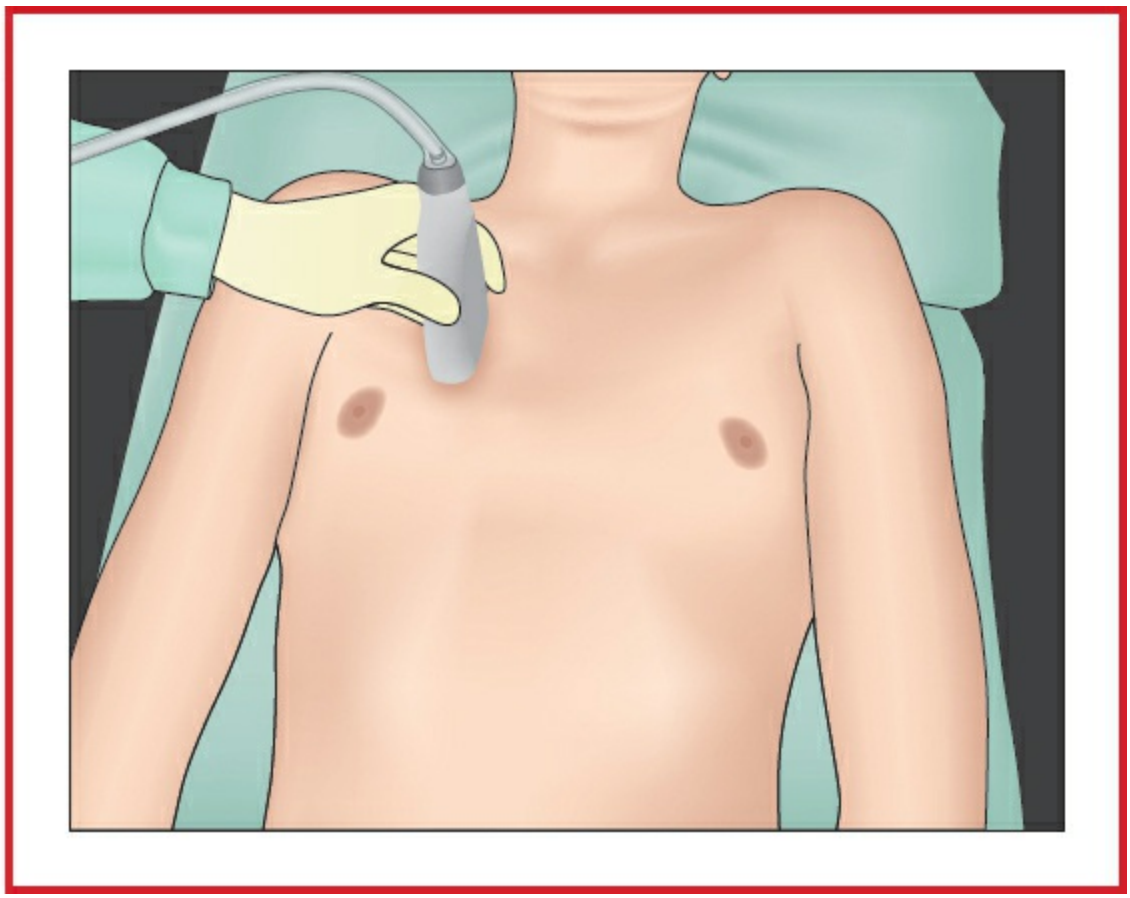

Figure 15.9 Place probe with indicator toward patient's head, perpendicular to chest wall, at the 3rd–5th intercostal space midclavicular line. In a supine patient, gas typically rises to this least dependent area of the chest cavity. You may move the probe caudally to scan multiple rib spaces in the midclavicular and axillary lines. (Ueda K, Ahmen W, Ross AF: Intraoperative pneumothorax identified with transthoracic ultrasound. Anesthesiology 2011; 115(3):653–5.[8])

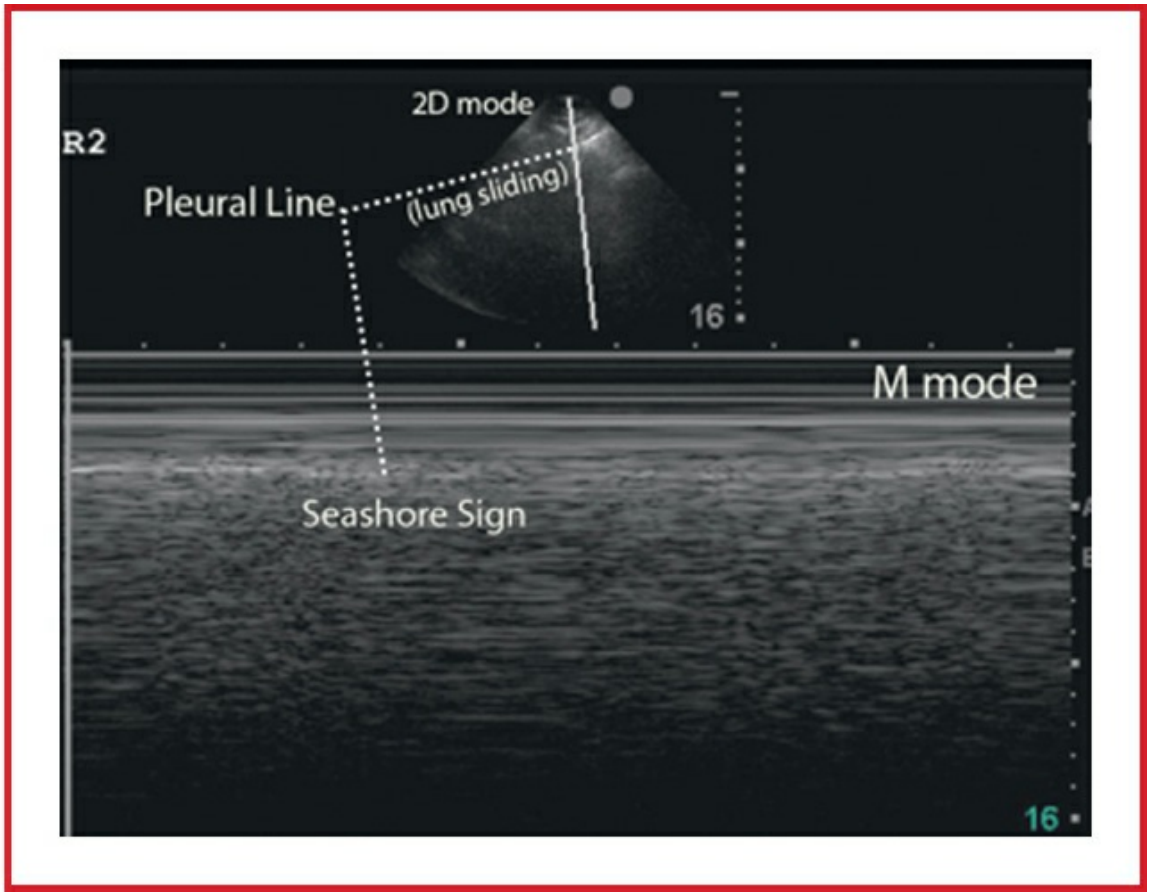

Figure 15.10 Seashore sign. M mode between the rib interspace with normal lung motion. The less mobile subcutaneous tissues and pleural tissues are seen as horizontal lines implying "waves" landing on a "sandy beach," the moving lung tissue represented by granular pattern below the pleural line.

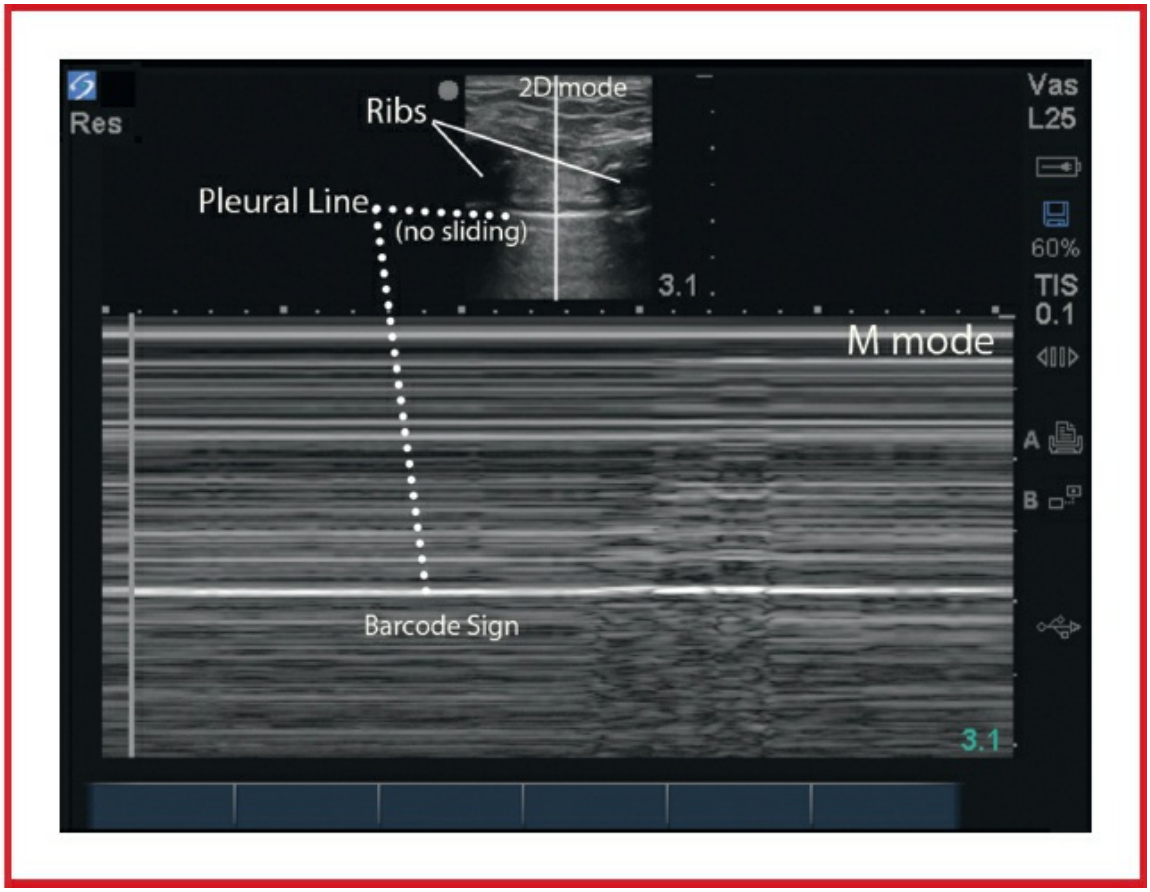

Figure 15.11 Bar code sign. During respiratory cycle, the "sand" (normal granular pattern) under the pleural line is replaced by "bar code" horizontal lines, indicating no lung sliding. (You-Ten KE, Siddiqui N, Teoh WH, et al: Point-of-care ultrasound (POCUS) of the upper airway.Can J Anaesth 2018; 65(4):473–84.[9])

EMERGENCY INTRAOSSEOUS ACCESS

Emergency intraosseous (IO) access is indicated when immediate vascular access is needed, and peripheral/central access is not possible, and endotracheal medication administration will not suffice. We discuss the use of the EZ-IO system of IO access Contraindications include burn, infection, or fracture of bone selected for access, joint replacement at selected site, or inability to identify landmarks.

Procedure	1. Prior to attaching the EZ-Connect®: ensure clamp is open. Prime set and purge air. Identify and clean insertion site (Fig. 15.12). 2. Snap EZ-IO needle set with plastic hub onto EZ-IO power driver (Fig. 15.13); (Red 15 ga, 15 mm for <40 kg. Blue 15 ga, 25 mm for >40 kg. Yellow hub 15 ga,

45 mm, >40 kg and excessive tissue or humerus site).

3. Remove needle safety cap.
4. Gently press needle set through skin until tip touches bone.
5. At least 5 mm of the catheter must be visible (Fig. 15.14).
6. Squeeze driver trigger and apply gentle, steady pressure. Release trigger when sudden "give" or "pop" is felt, indicating entry into medullary space. If driver stalls or will not penetrate the bone, you may be applying too much downward force. Humerus site: to improve stability, needle should be advanced 2 cm after contact with bone. In adults, advance needle until catheter hub is against the skin. Change sites for access rather than have repeated attempts at the same site.
7. Remove power driver and stylet; confirm catheter stability with at least three of the following four methods:
   - Stability of catheter
   - Ability to aspirate
   - Physiologic or pharmacologic changes with medication administration
   - Adequate flow rate
9. Secure with EZ-stabilizer or have an assistant manually stabilize hub until secured, roll 2 sets of 4 × 4s into tight cylinders, apply cylinders in a parallel orientation around catheter, "sandwiching" the hub, then secure with tape or transparent adhesive film with hole cut out for hub access.
9. Attach EZ-Connect® extension set. DO NOT ATTACH A SYRINGE DIRECTLY TO THE EZ-IO CATHETER HUB EXCEPT WHEN DRAWING BLOOD FOR LABORATORY ANALYSIS (STABILIZE NEEDLE SET).
10. Flush the EZ-IO catheter with normal saline (10 mL for adults; use appropriate weight-based dose for smaller patients). For patients responsive to pain, consider lidocaine up to 0.2–1 mg/kg io slowly prior to saline

	flush.
EZ-IO Removal	Attach Luer-lock syringe. Rotate syringe and catheter clockwise while using traction to withdraw catheter—DO NOT ROCK OR BEND THE CATHETER DURING REMOVAL (Fig. 15.15).

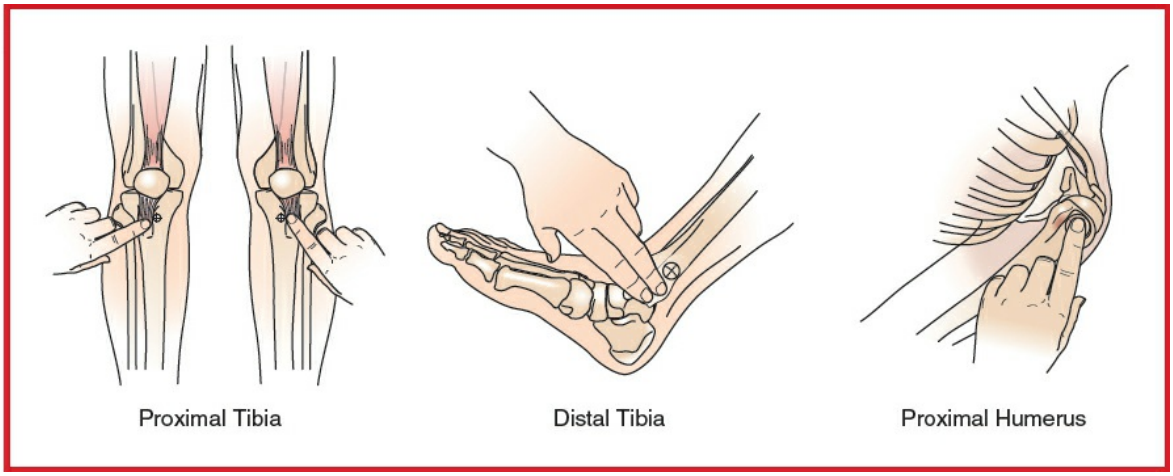

Figure 15.12 Identify and clean insertion site (proximal or distal tibia or humeral head).

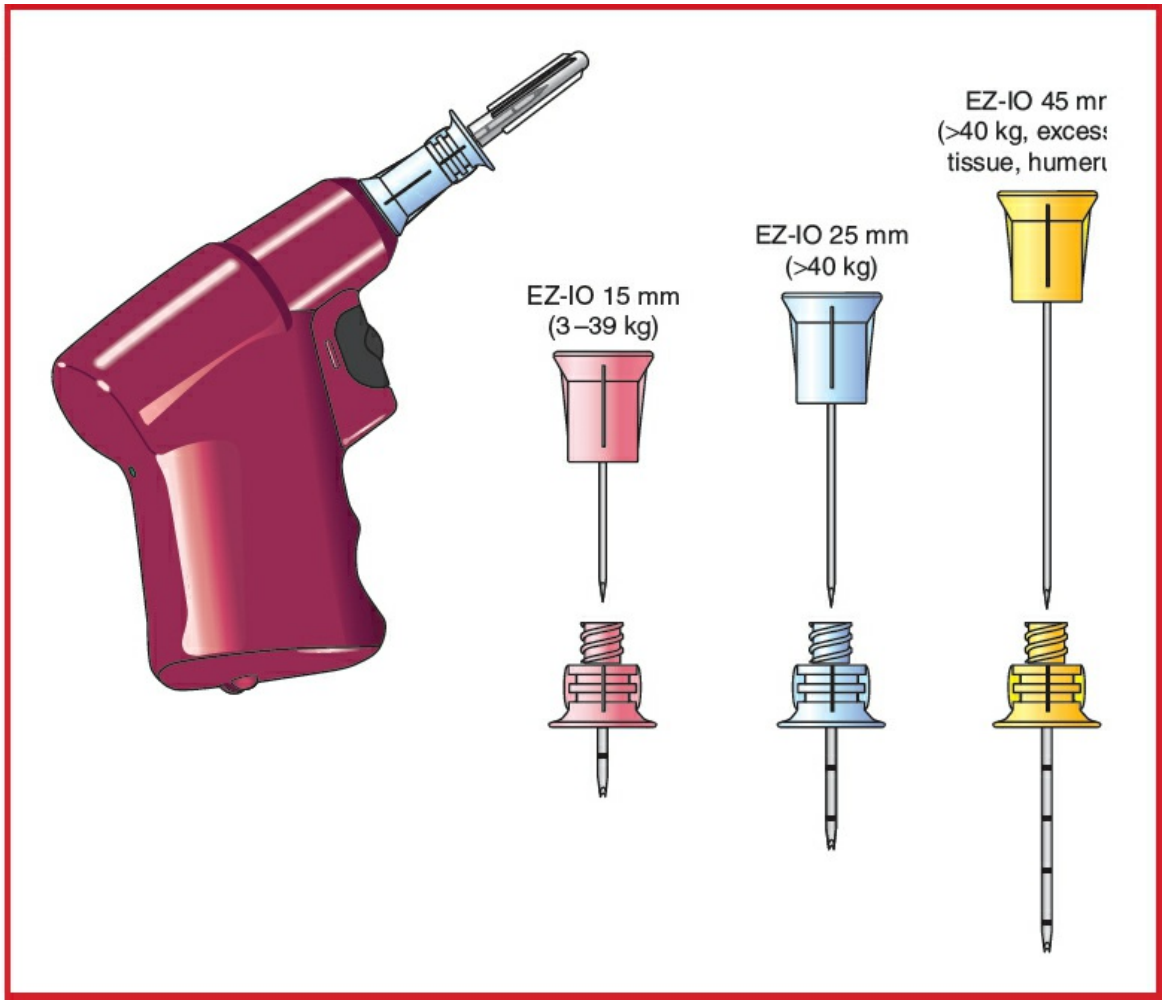

Figure 15.13 EZ-IO power driver and needle set sizes.

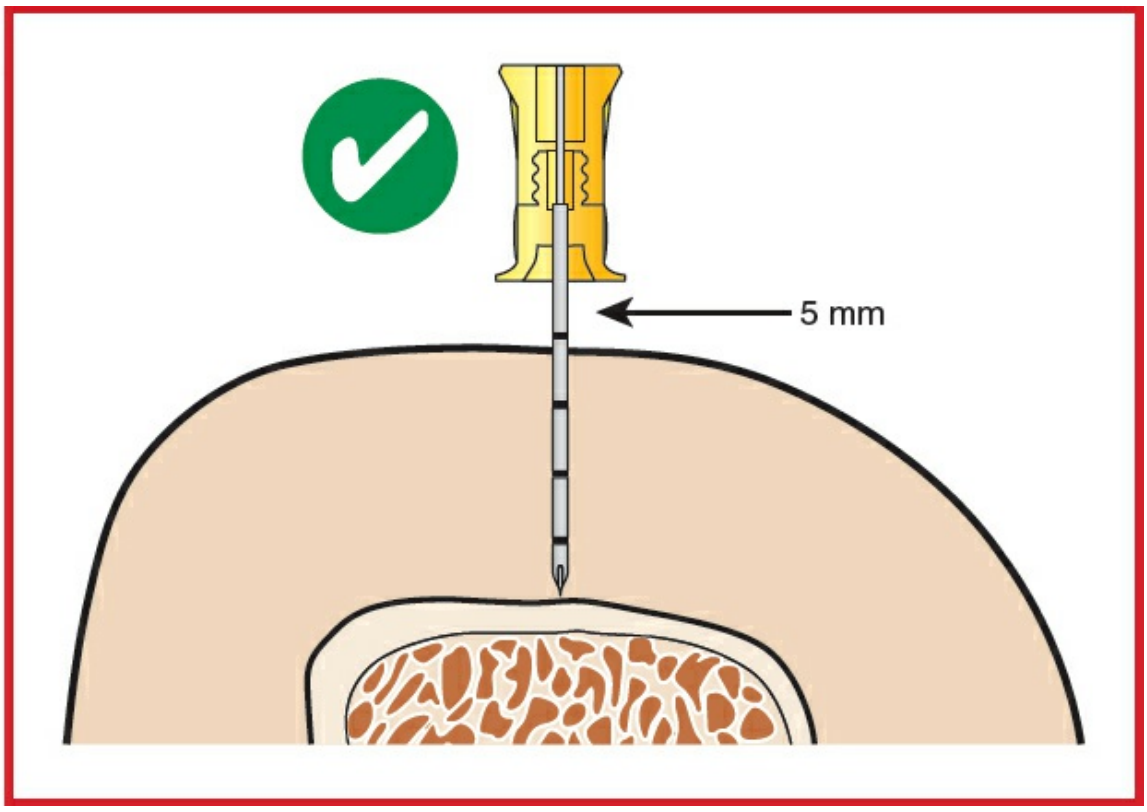

Figure 15.14 At least 5 mm of the catheter must be visible after pressing needle through skin to contact bone and prior to squeezing trigger.

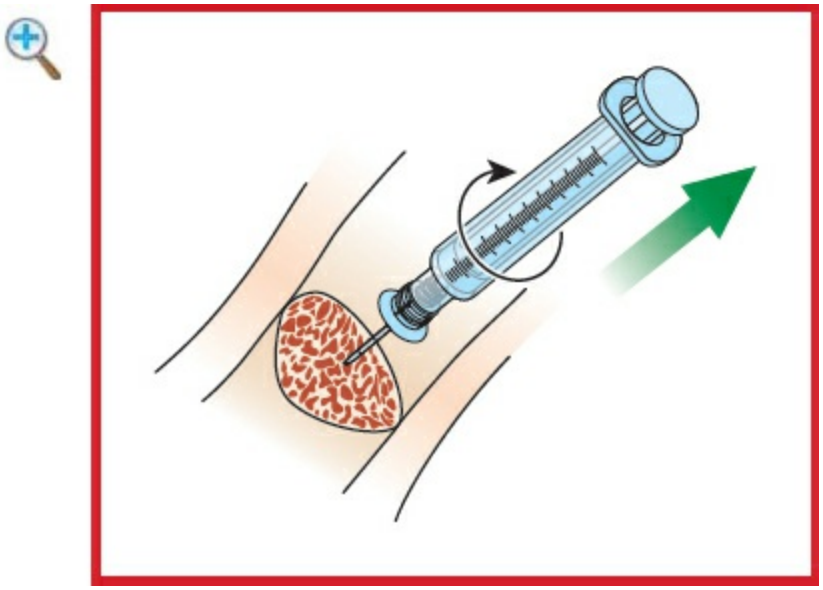

Figure 15.15 To remove EZ-IO catheter, attach Luer-lock syringe. Rotate syringe and catheter clockwise while using traction to withdraw catheter.

SECTION 16.0

REGIONAL BLOCKS—A BRIEF OVERVIEW

ANESTHESIOLOGISTS
Jean-Louis Horn, MD
Mastoora Nasiri, MD

UPPER EXTREMITY BLOCKS

INTERSCALENE

Indications	Shoulder surgery

Anatomy

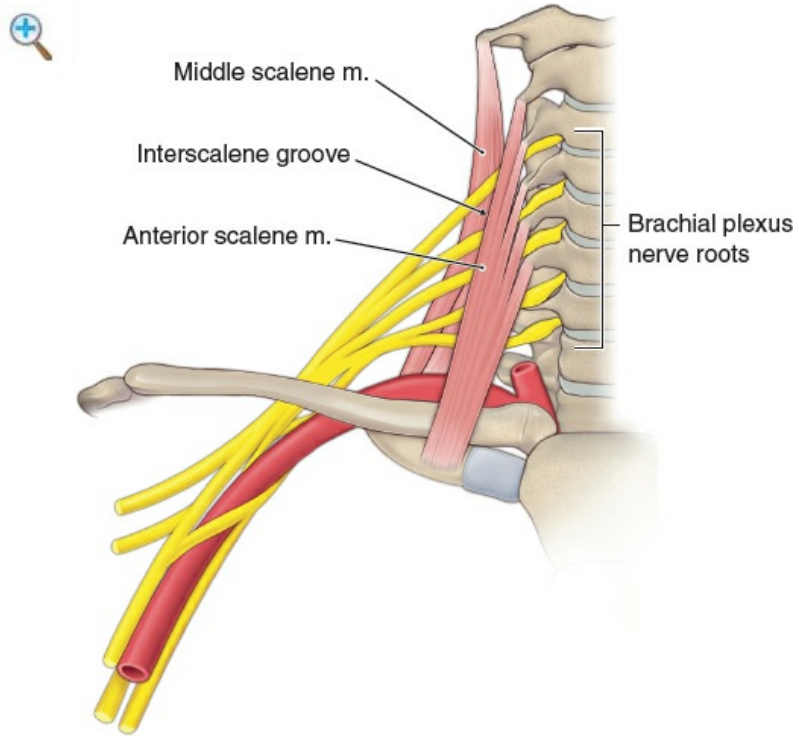

Figure 16.1 Interscalene anatomy. Superior trunk of the brachial plexus (C5-C6).

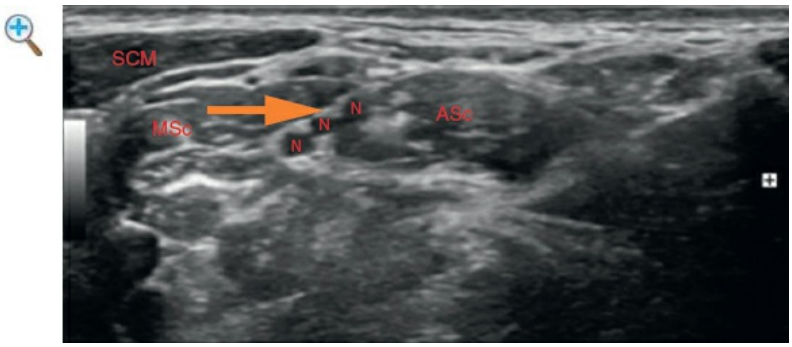

Figure 16.2 Interscalene ultrasound. SCM, sternocleidomastoid; MSc, middle scalene; ASc, anterior scalene; N, nerve.

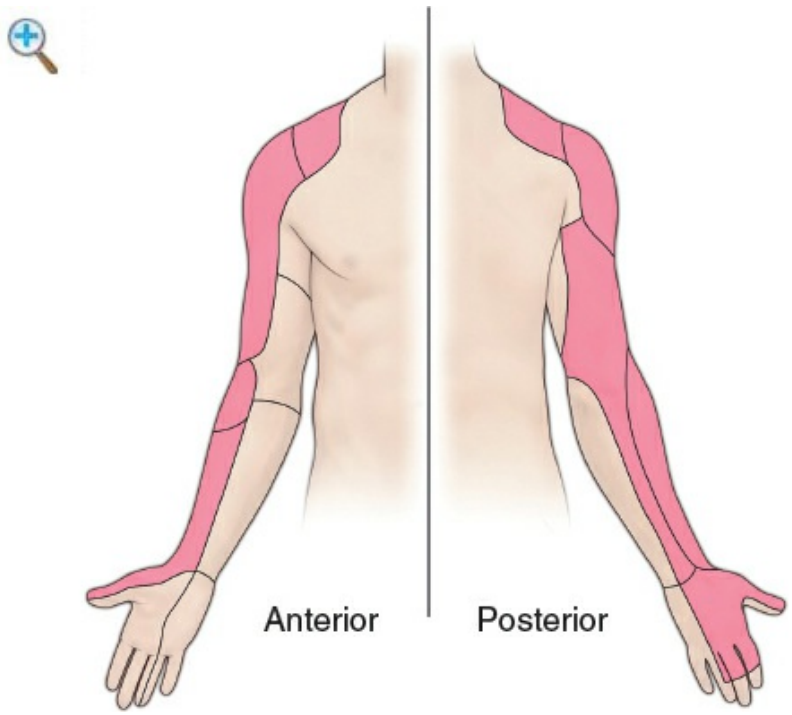

Figure 16.3 Interscalene anatomy.

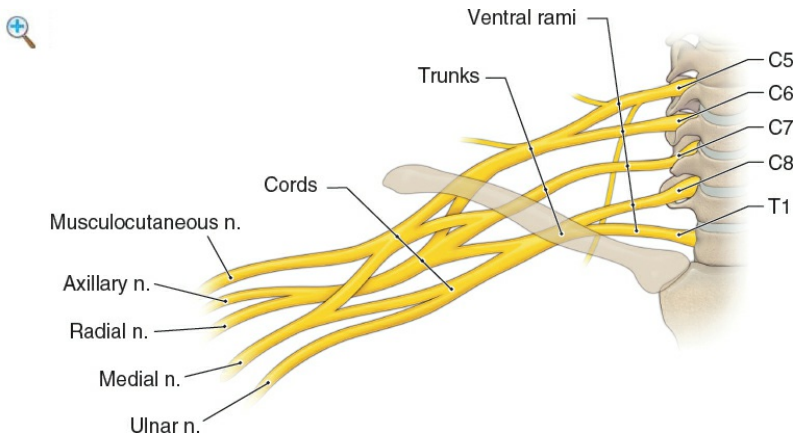

Figure 16.4 Interscalene anatomy.

Dosage	10–20 mL (0.25–0.5% ropivacaine/bupivacaine or 1–1.5% mepivacaine)
Nerve stimulation	Deltoid, distal extensor or lateral flexor
Side effects	Phrenic nerve block (nearly 100% with higher volume local anesthetic) Horner syndrome (rare, risk increases with high volume, fast injection) Recurrent laryngeal nerve block (rare, risk increases with high volume, fast injection) Superficial cervical plexus block extending to the ear

Complications	Permanent phrenic nerve palsy → hemidiaphragm paralysis: very rare Pneumothorax: low risk compared to more distal brachial plexus blocks Dorsal scapular nerve injury → winged scapula Long thoracic nerve injury → both DSN and LTN injury resulted in winged scapula can/or pain
Pearls	• Patient can be placed in the supine or lateral decubitus position • Ultrasound probe placed transversely with a 15–30° caudal angle, 3–4 cm above clavicle (level of cricoid cartilage) over external jugular vein with an in-plane or out-of-plane approach • Avoid injecting between C5 and C6 as this can increase risk of intraneural injection and side effects • Supplement with an intercostobrachial nerve block to cover the medial upper arm when needed (infrequent) • Special contraindications: contralateral phrenic nerve paresis; severe pulmonary disease
Alternative	Combined distal suprascapular and axillary nerve blocks Supraclavicular block Proximal suprascapular nerve block
Further reading	Mian A, et al: Brachial plexus anesthesia: a review of the relevant anatomy, complications, and anatomical variations. Clin Anat 2014; 27(2):210–21.

SUPRACLAVICULAR

Indications	Shoulder, arm, elbow, forearm, and hand surgery
Anatomy	

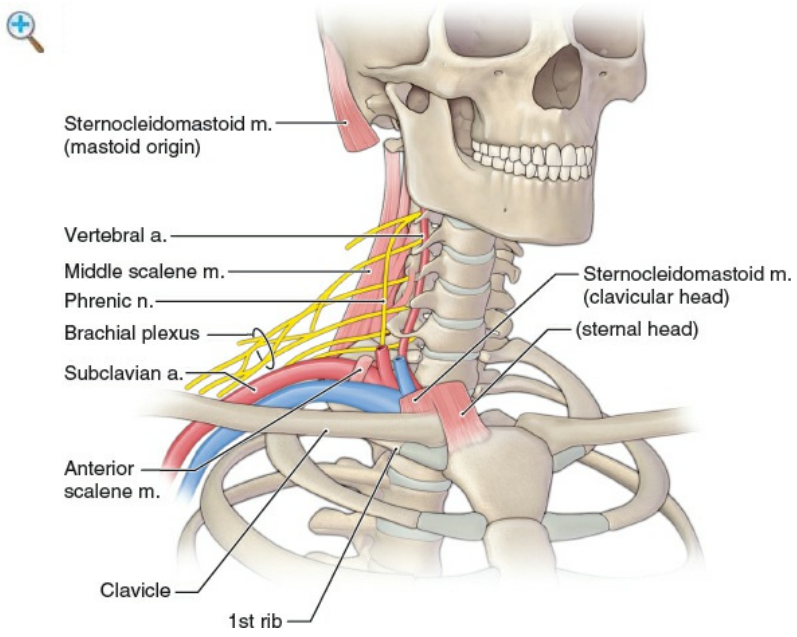

Figure 16.5 Supraclavicular anatomy. Often branches of the thyrocervical trunk cross the divisions creating a fascia preventing spread of local anesthetic. Divisions of the brachial plexus (anterior and posterior) lie mostly posterior to the artery.

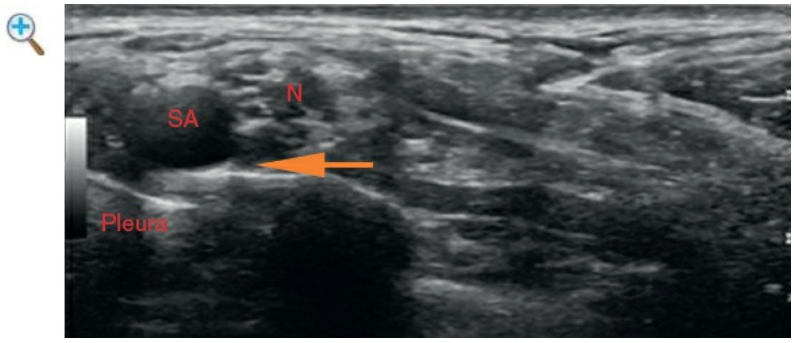

Figure 16.6 Supraclavicular ultrasound. SA, subclavian arter; N, nerve.

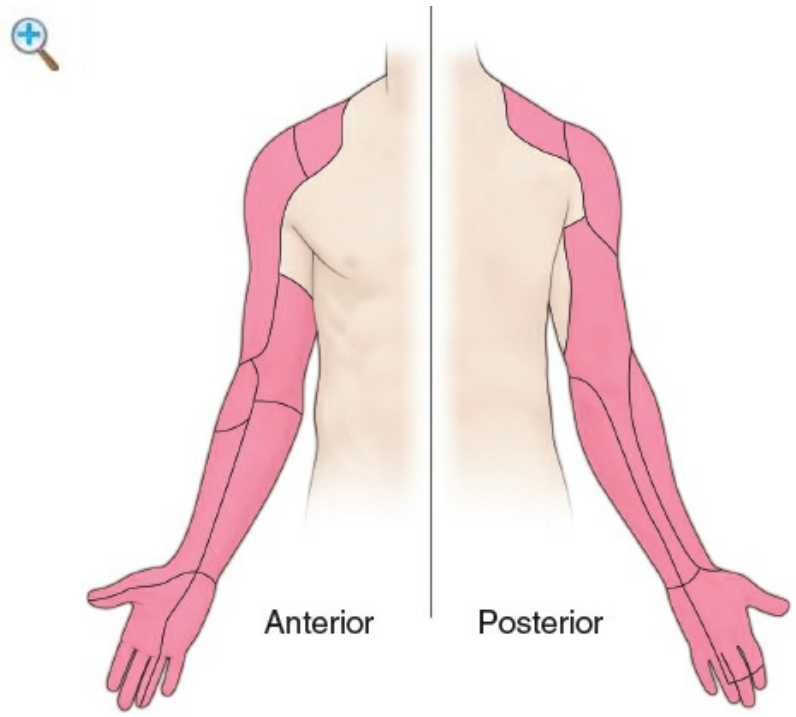

Figure 16.7 Supraclavicular anatomy.

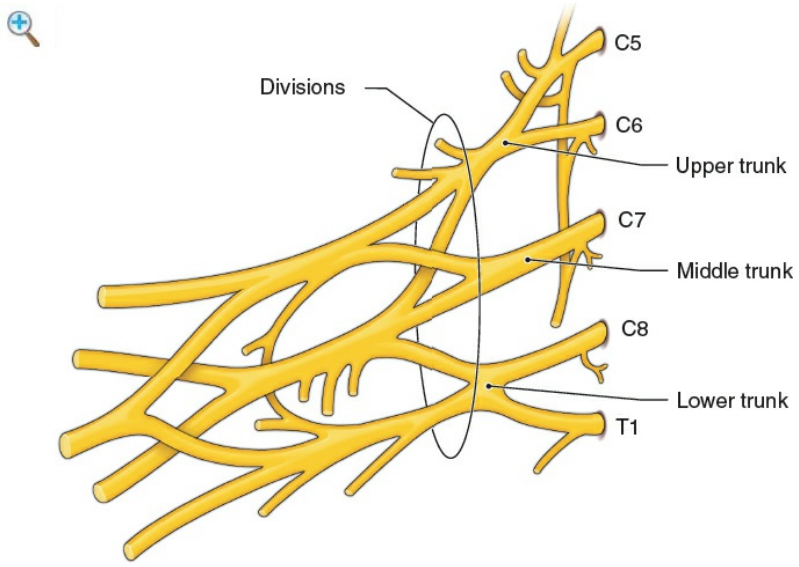

Figure 16.8 Supraclavicular anatomy.

Dosage	15–30 mL (0.5% ropivacaine/bupivacaine or mepivacaine 1–1.5%)
Nerve stimulation	Elbow, forearm, distal arm, hand
Side effects	Phrenic nerve block (40%) → hemidiaphragm paralysis Horner syndrome (very rare)

Complications	Pneumothorax: rare with ultrasound guidance Puncture of overlying vasculature: suprascapular, superficial cervical, transverse cervical, and dorsal scapular arteries (<1%) Suprascapular nerve injury → ↓ abduction and external rotation (supraspinatus + infraspinatus muscles)
Pearls	• Slightly prop the spine up to give space for injection. • Place ultrasound probe immediately parallel to the clavicle in the supraclavicular fossa and adjust the beam to place the target above the first rib to shield the lung. • Use a short needle to minimize chance of pneumothorax. • Success is associated with LA spread under the divisions next to the subclavian artery described as the corner pocket; however, fasciae often present barriers necessitating multiple site injections. • This is not the best site for catheter placement. • Supplement with an intercostobrachial nerve block to cover the medial upper arm when needed (infrequent). • Special contraindications: contralateral phrenic nerve paresis; severe pulmonary disease
Alternative	Axillary or infraclavicular block (especially with significant pulmonary disease to avoid phrenic nerve block)
Further reading	Vermeylen K, et al: Supraclavicular brachial plexus blocks: review and current practice. Acta Anaesthesiol Belg 2012; 63(1):15–21.

INFRACLAVICULAR

Indications	Arm, elbow, forearm, and hand surgery
Anatomy	

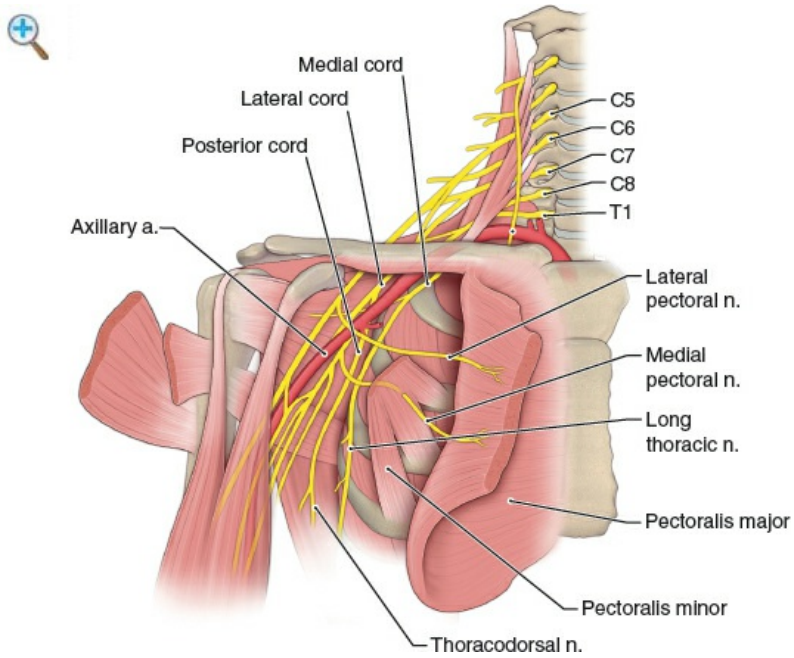

Figure 16.9 Infraclavicular anatomy.

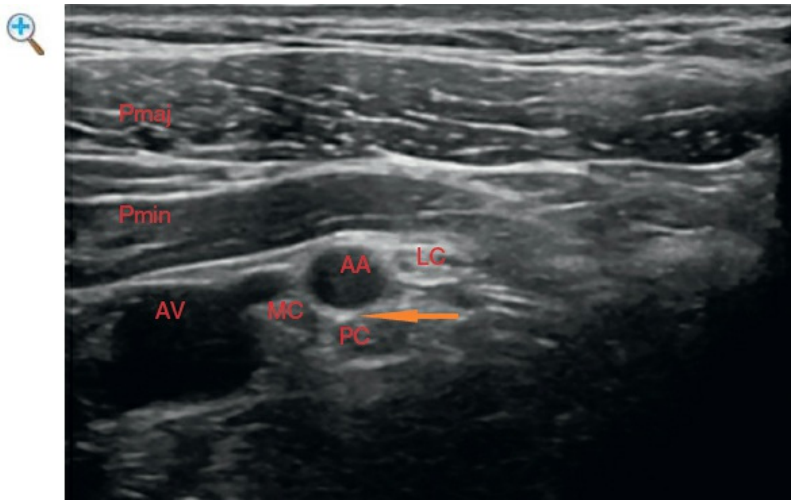

Figure 16.10 Infraclavicular ultrasound. Pmaj, pectoralis major; Pmin, pectoralis minor; AV, axillary vein; AA, axillary artery; LC, lateral cord; PC, posterior cord; MC, medial cord.

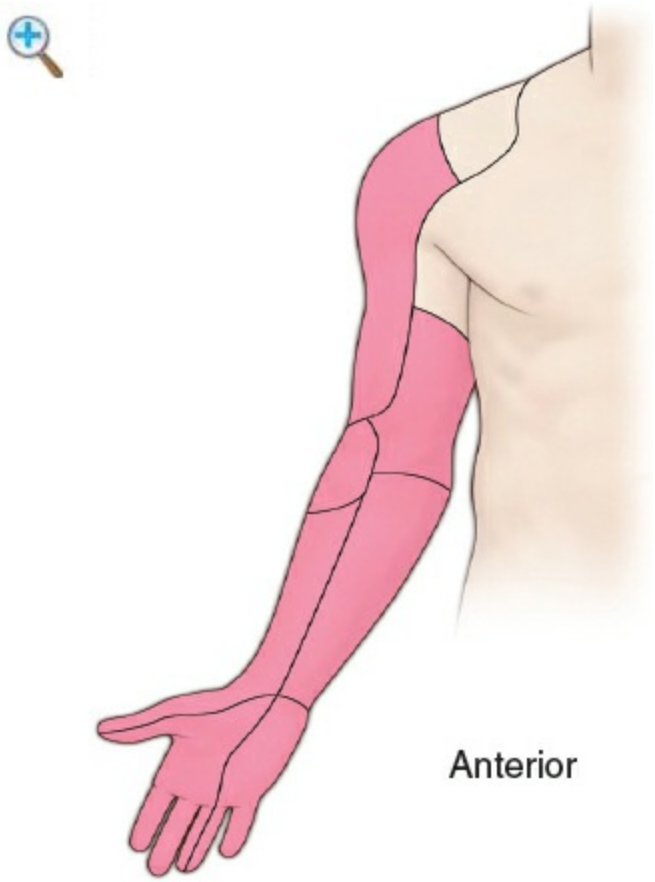

Figure 16.11 Infraclavicular anatomy.

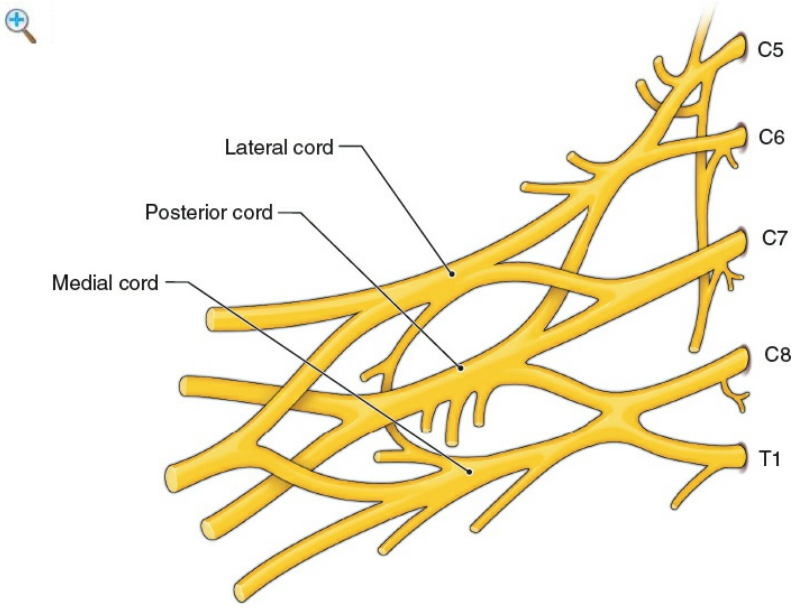

Figure 16.12 Infraclavicular anatomy.

Dosage	20–40 mL (0.5% ropivacaine/bupivacaine or mepivacaine 1–1.5%)
Nerve stimulation	Distal stimulation at the hand

Side effects	Minimal
Complications	Pneumothorax: rare with ultrasound guidance Vascular injury: <1% Lateral pectoralis nerve injury → ↓ pectoralis major muscle strength
Pearls	• Abduct the arm at the shoulder 90° to elevate the clavicle and open access to the cords. Place the probe in a sagittal plane. • For painful shoulder or arm, keep the arm adducted, rotate and translate the probe against the clavicle for a costoclavicular approach. Then tilt the probe slightly under the clavicle. • Success is associated with LA spread under the artery often described as the double bubble or eight ball for the sagittal approach. For the costoclavicular approach, the target is the corner pocket similar to the supraclavicular approach. • Supplement with an intercostobrachial nerve block to cover the medial upper arm when needed (infrequent).
Alternative	Supraclavicular block Axillary block
Further reading	Chin KJ, et al: Infraclavicular brachial plexus block for regional anaesthesia of the lower arm. Anesth Analg 2010; 111(4):1072.

AXILLARY BLOCK

Indications	Forearm and hand surgery
Anatomy	

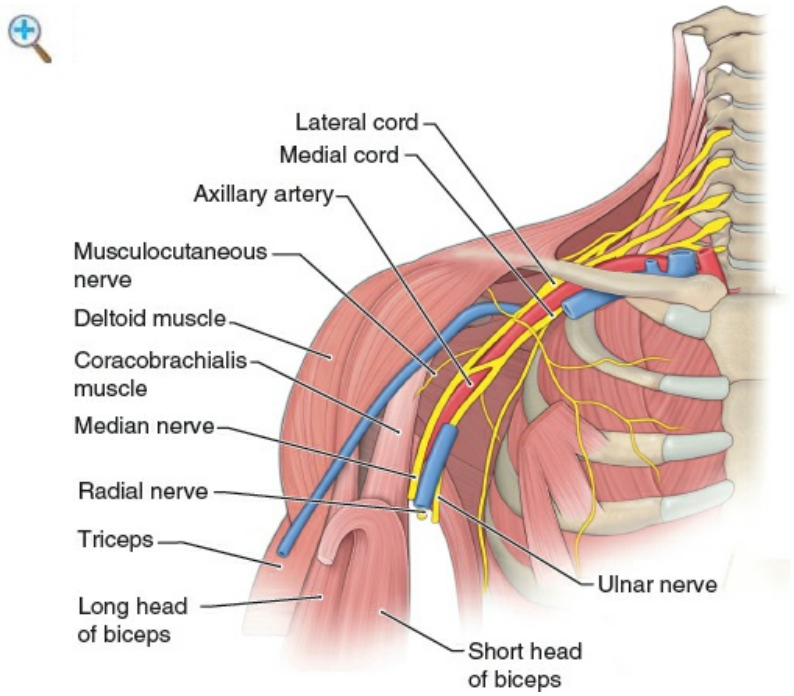

Figure 16.13 Axillary block anatomy. Terminal branches of the brachial plexus (median, ulnar, radial) surround the axillary artery. Musculocutaneous nerve is lateral to the artery and runs through the coracobrachialis muscle and then between the biceps brachialis and coracobrachialis muscles.

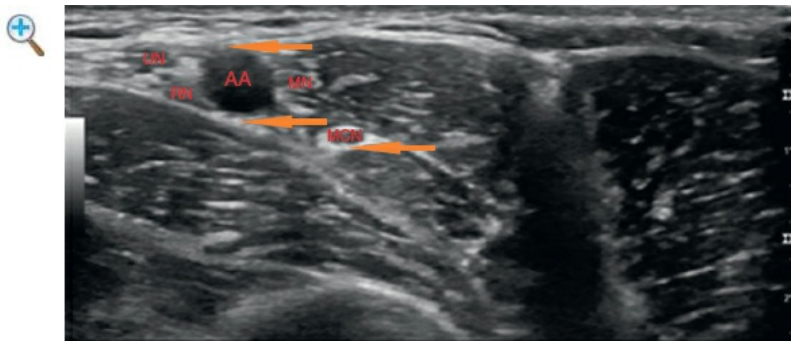

Figure 16.14 Axillary block ultrasound. AA, axillary artery; MCN, musculocutaneous nerve; MN, median nerve; RN, radial nerve; UN, ulnar nerve.

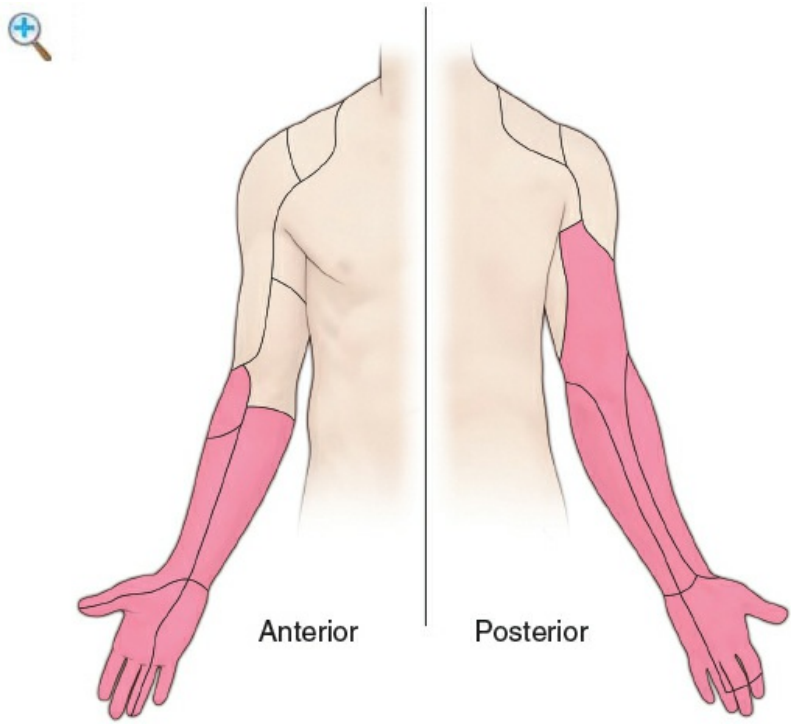

Figure 16.15 Axillary block anatomy.

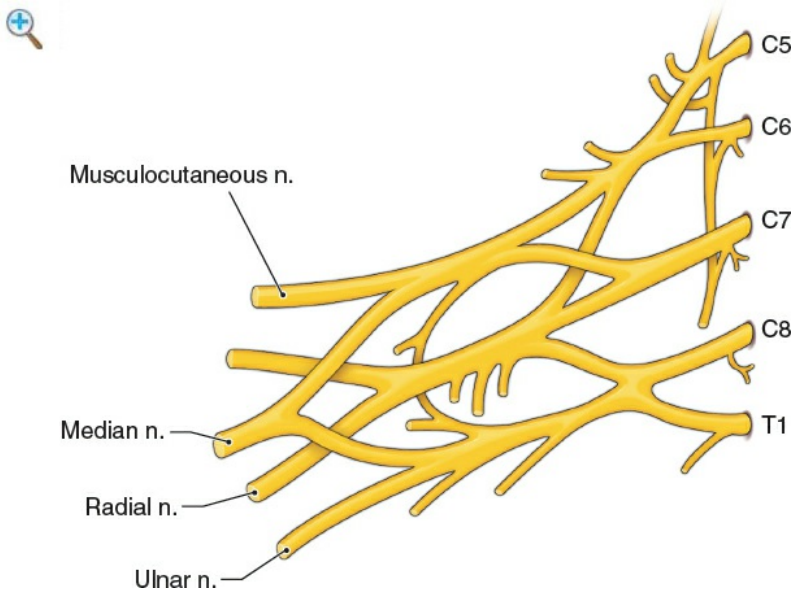

Figure 16.16 Axillary block anatomy.

	Musculocutaneous nerve is lateral to the artery and running through the coracobrachialis muscle and then between the biceps brachialis and coracobrachialis muscles
Dosage	20–40 mL (0.5% ropivacaine/bupivacaine or mepivacaine 1–1.5%)

Nerve stimulation	Distal stimulation at the hand, biceps brachialis stimulation for the musculocutaneous nerve
Side effects	Minimal
Complications	Intravascular injection/injury (<1% with ultrasound guidance)
Pearls	• Supplement with an intercostobrachial nerve block to cover the medial upper arm and improve tourniquet tolerance. • Separate injections for each nerve hasten the onset and increase success. • Catheter will only cover the adjacent nerve and usually provides only partial brachial plexus block. • Special contraindications: infected axillary lymph nodes.
Alternative	Supraclavicular block Infraclavicular block
Further reading	Nowakowski P, Bieryło A: Ultrasound guided axillary brachial plexus block. Part 1 and Part 2. Anaesthesiol Intensive Ther 2015; 47(4):409–24.

LOWER EXTREMITY BLOCKS

FEMORAL NERVE

Indications	Anterior thigh, knee, and medial ankle surgery

Anatomy

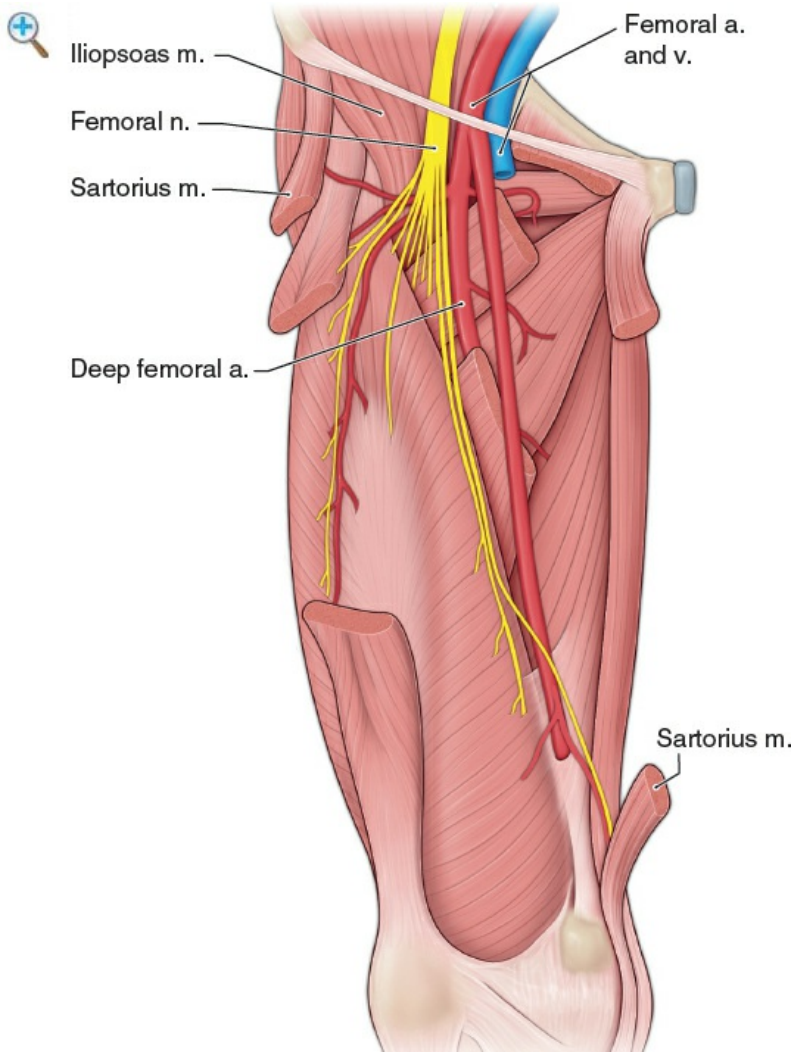

Figure 16.17 Femoral nerve anatomy. Originates from L2 to L4 nerve roots.

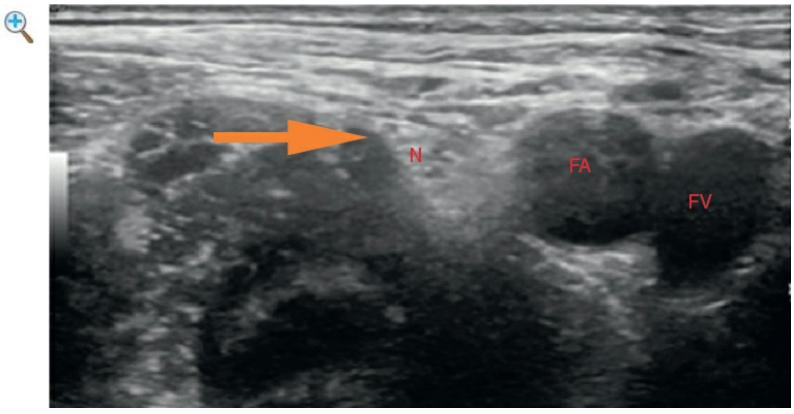

Figure 16.18 Femoral nerve ultrasound. FA, femoral artery; FV, femoral vein; N, nerve.

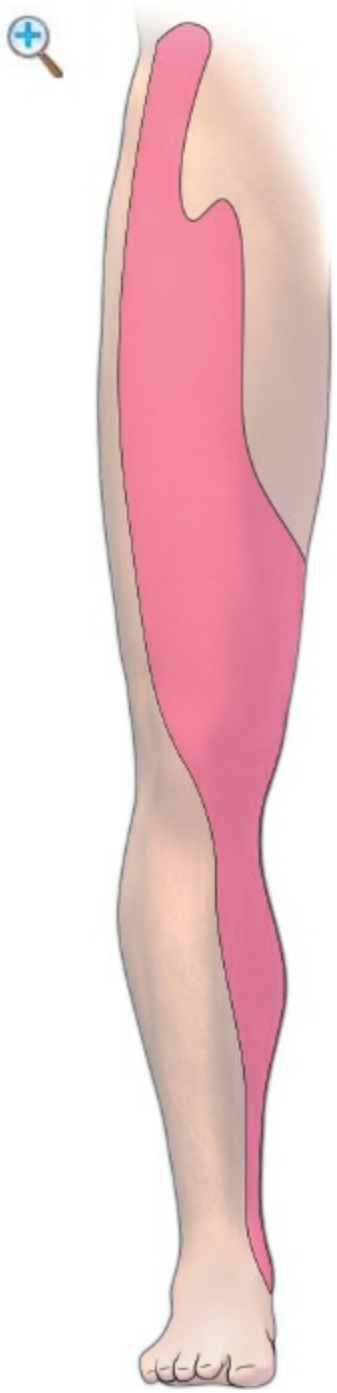

Figure 16.19 Femoral nerve anatomy.

Dosage	15–30 mL (0.25–0.5% ropivacaine/bupivacaine or mepivacaine 1–1.5%)
Nerve stimulation	Quadriceps femoris with patellar twitch
Side effects	Quadriceps weakness with ambulation difficulties
Complications	Vascular injury: <1% using ultrasound guidance
Pearls	• Supine with the leg extended, probe placed transverse for

	an in-plane or out-of-plane approach • The nerve lies deep to the fascia iliaca while the artery is superficial; the fascia iliaca has an S shape placing the nerve in a deeper anatomical plane than the artery.
Alternative	A posterior approach of the lumbar plexus will reliably cover the femoral, obturator, and lateral femoral cutaneous nerves for surgical anesthesia. A fascia iliaca block will reliably cover the femoral, obturator, and lateral femoral cutaneous nerves for analgesia. An adductor canal block or subsartorial distal saphenous block will cover the medial ankle for surgical anesthesia and, partially, the knee for analgesia.
Further reading	Szucs S, et al: Femoral nerve blockade. Med Ultrason 2010; 12(2):139–44.

LUMBAR PLEXUS

Indications	Hip, anterior, medial and lateral thigh, and knee surgery
Anatomy	

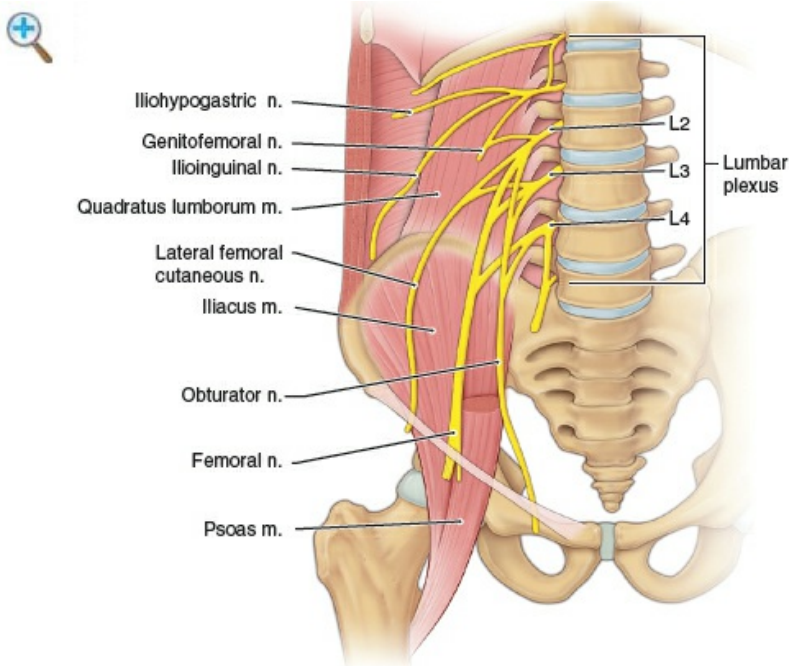

Figure 16.20 Lumbar plexus anatomy. The portion of the

lumbar plexus covering the lower extremity originates from L2 to L4 nerve roots: femoral, lateral femoral cutaneous, and obturator nerves.

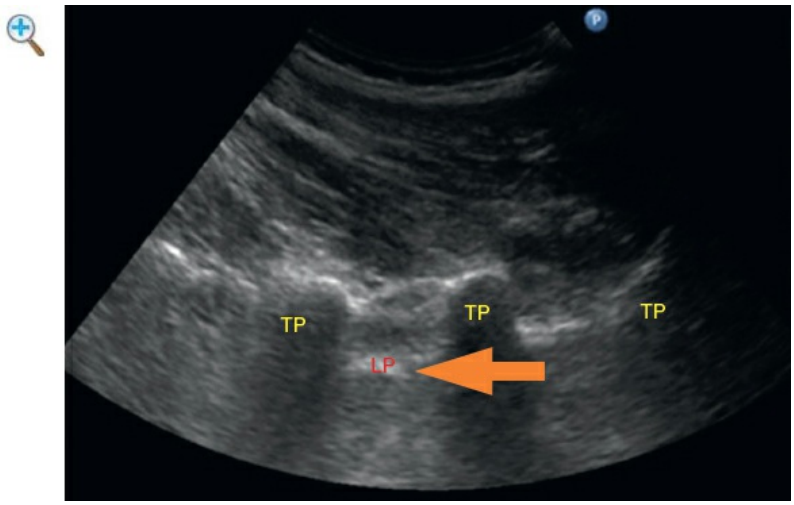

Figure 16.21 Lumbar plexus ultrasound. TP, transverse process; LP, lumbar plexus.

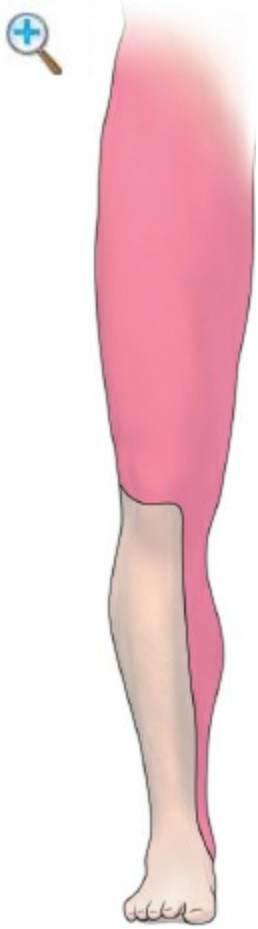

Figure 16.22 Lumbar plexus anatomy.

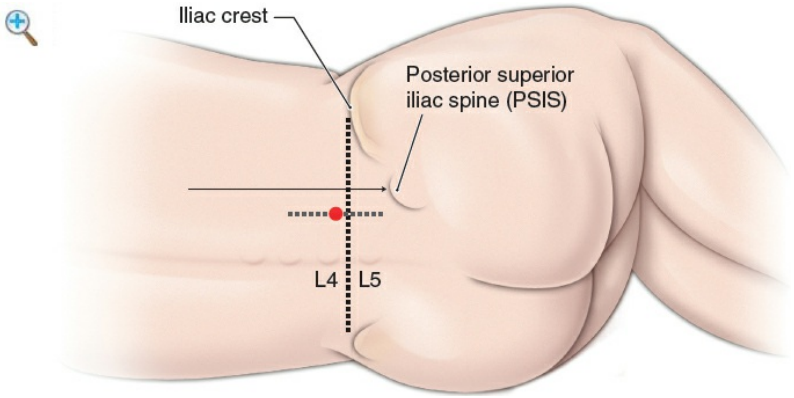

Figure 16.23 Lumbar plexus anatomy.

Dosage	10–20 mL (0.25–0.5% ropivacaine/bupivacaine)
Nerve stimulation	Quadriceps femoris with patellar twitch
Side effects	Quadriceps weakness with ambulation difficulties Epidural spread with partial sympathectomy
Complications	Epidural/bilateral spread (up to 10%) Epidural/intrathecal placement Vascular puncture: <1% Local anesthetic systemic toxicity (LAST): rare Renal puncture/retroperitoneal hematoma: rare
Pearls	• Lateral decubitus with fetal position, i.e., epidural positioning • Prescan with ultrasound to map the area with best angle of approach, angles to avoid, and to estimate depth. • Probe placed transverse and sagittal to create a 3D representation of the target • Direct ultrasound guidance is best in small and lean patients with transverse probe placement in the flank aiming toward the spine. • If hamstring twitch on nerve stimulation, move one level cephalad • Always give a test dose to diagnose intrathecal placement. • Keep volume low to prevent epidural spread.
Alternative	Fascia iliaca block Femoral block
Further reading	Chin KJ, Perlas A. Ultrasonography of the lumbar

spine for neuraxial and lumbar plexus blocks. Curr Opin Anaesthesiol 2011; 24(5):567–72.

FASCIA ILIACA AND LATERAL FEMORAL CUTANEOUS NERVE

Indications	Hip, anterior, medial and lateral thigh, and knee

Anatomy

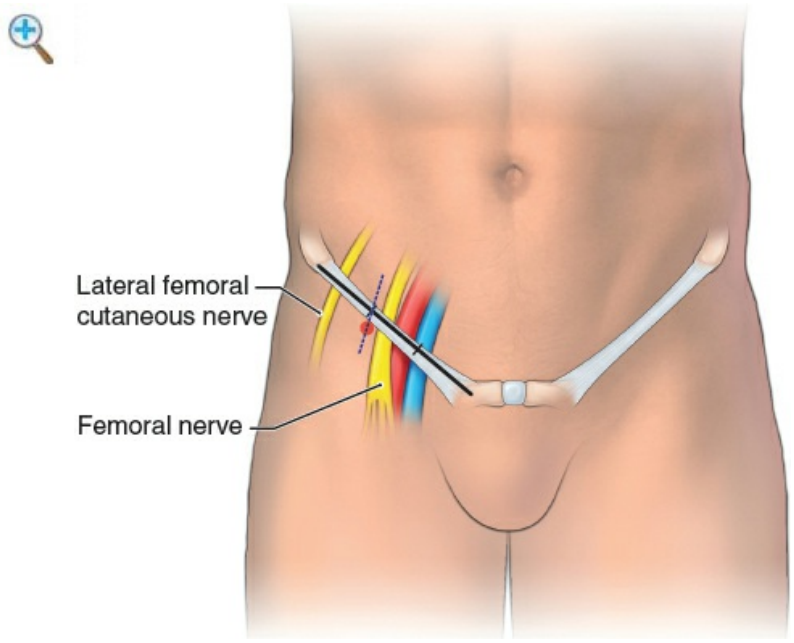

Figure 16.24 Fascia iliaca anatomy. Originates from L2 to L4 nerve roots.

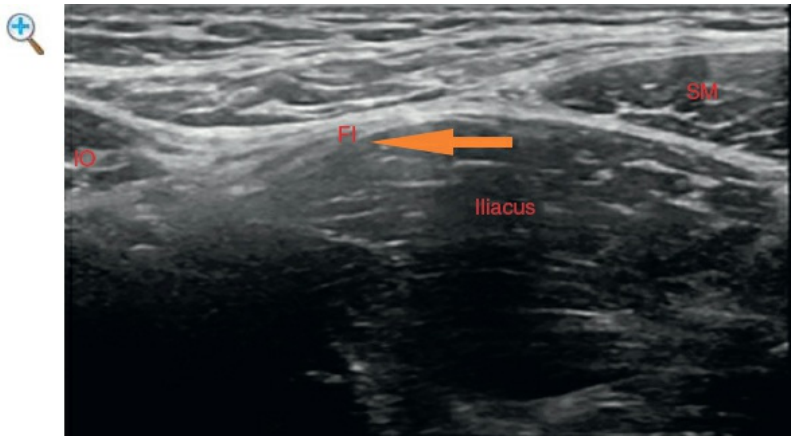

Figure 16.25 Fascia iliaca ultrasound. SM, sartorius muscle; FI, fascia iliaca; IO, internal oblique.

Figure 16.26 Fascia iliaca anatomy.

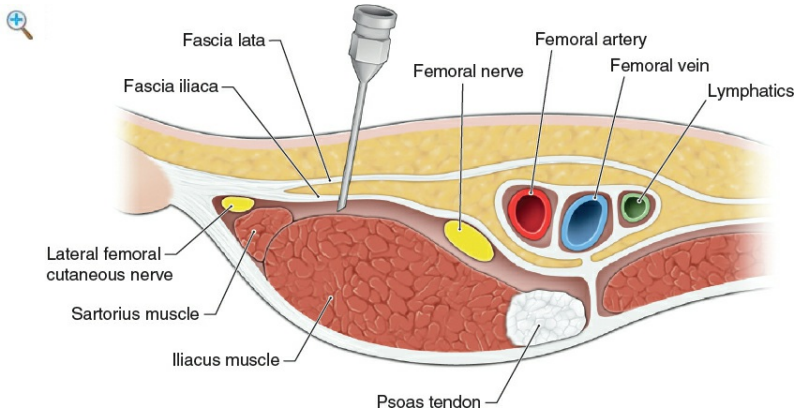

Figure 16.27 Fascia iliaca anatomy.

Dosage	20–60 mL (0.25% ropivacaine/bupivacaine)
Nerve stimulation	None
Side effects	Quadriceps weakness with ambulation difficulties
Complications	Vascular puncture: <1%

	Local anesthetic systemic toxicity (LAST): <0.1% Bowel puncture (rare)
Pearls	• Supine positioning • Position ultrasound transducer transversely near the femoral cease, superficial to the iliopsoas muscle, lateral to femoral vessels and then rotate the probe 90° to drive the needle cephalad under the inguinal ligament. • Use color to avoid the inferior epigastric vessels. • Large-volume dilute local anesthetic allows spread to block both femoral and lateral femoral cutaneous nerves, and sometimes the obturator nerve. • Nonultrasound technique describes the "double pop" as needle traverses the fascia lata and fascia iliaca, but only reliably covers the femoral nerve.
Alternative	Lumbar plexus block Femoral block
Further reading	Steenberg J, et al: Systematic review of the effects of fascia iliaca compartment block on hip fracture patients before operation. Br J Anaesth 2018; 120(6):1368–80.

ADDUCTOR CANAL (SAPHENOUS NERVE)

Indications	Knee and medial ankle surgery
Anatomy	

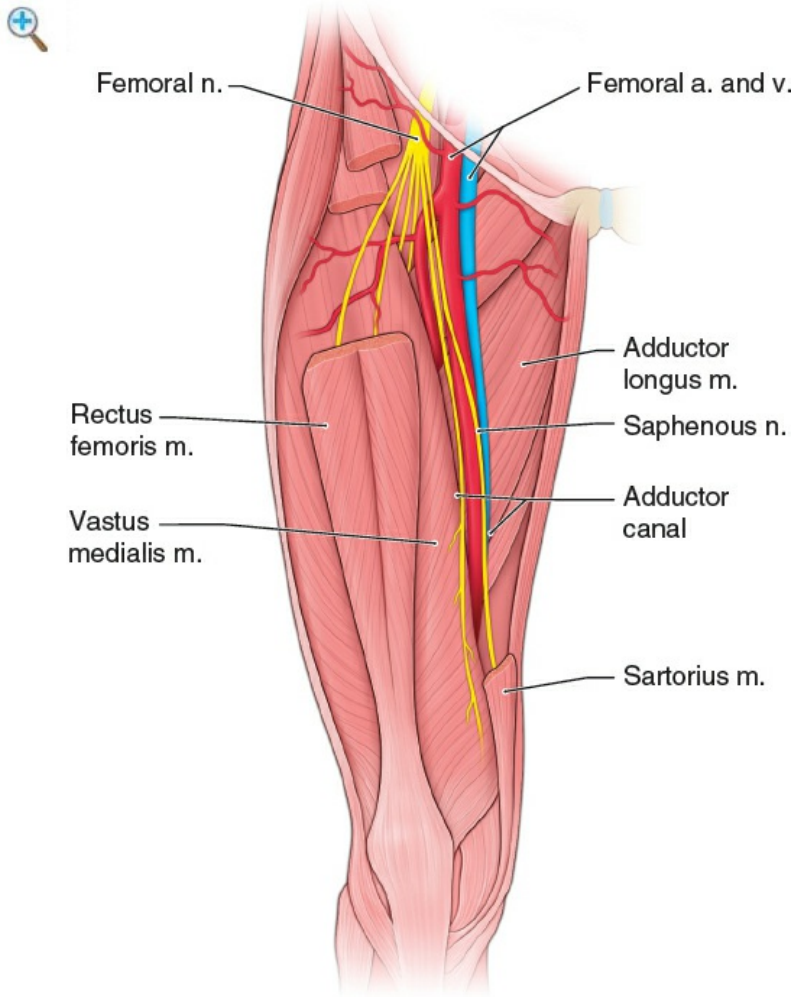

Figure 16.28 Adductor canal anatomy. At the level of the distal femoral triangle, the saphenous nerve runs with the nerve to the vastus medialis. Distal to the adductor hiatus, the nerve runs under the sartorius muscle, with the descending genicular artery.

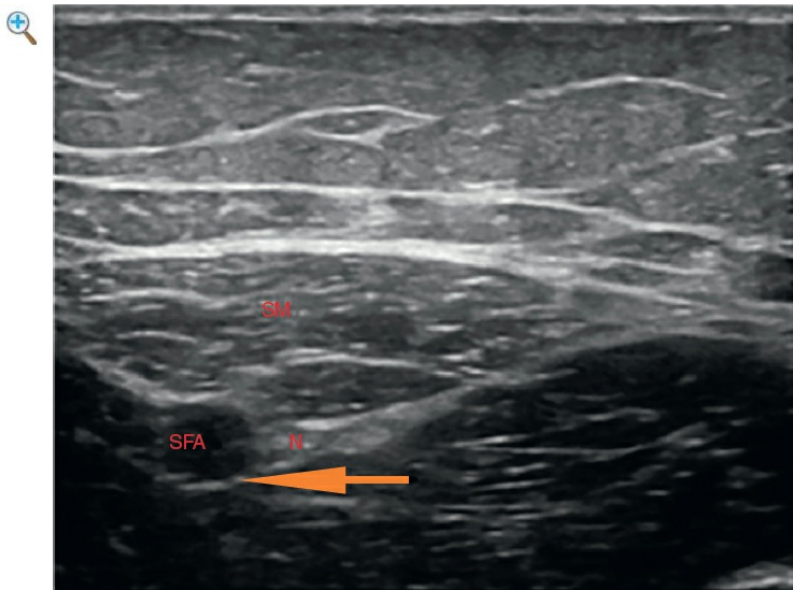

Figure 16.29 Adductor canal ultrasound. SFA, superficial femoral artery; SM, sartorius muscle; N, nerve.

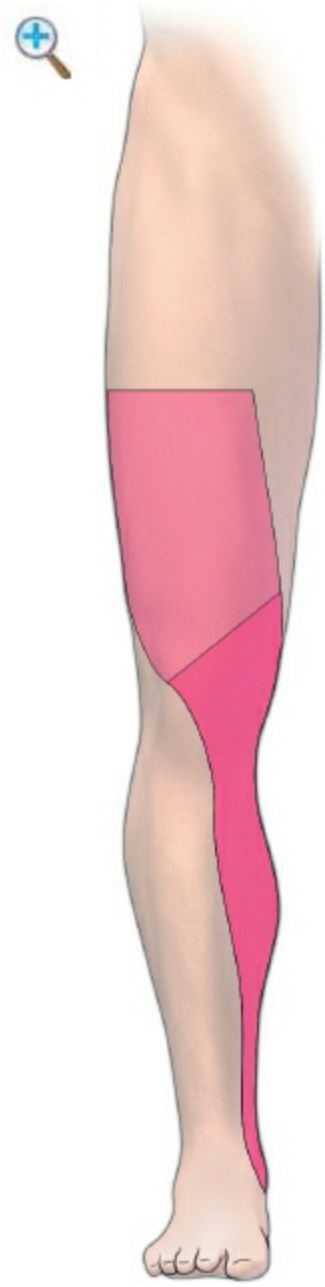

Figure 16.30 Adductor canal anatomy.

Dosage	10–30 mL (0.25–0.5% ropivacaine/bupivacaine or mepivacaine 1–1.5%)
Nerve stimulation	Sensory stimulation at ankle
Side effects	Quadriceps weakness with ambulation difficulties (rare) Infrequent spread to tibial nerve

Complications	Femoral artery injury
Pearls	• Supine with the leg externally rotated, probe placed transverse for an in-plane or out-of-plane approach • The saphenous nerve lies adjacent to the femoral vessels. • A proximal block will provide blockade of both the saphenous nerve and nerve to the vastus medialis. • A block distal to the adductor hiatus will avoid risk of injury to the femoral artery but will only provide appropriate blockade for the ankle/foot. • Despite traditional assumption, the saphenous nerve innervates deep structures of the medial ankle, talocrural joint, and sometimes the first metatarsal.
Alternatives	A posterior approach of the lumbar plexus, a fascia iliaca, or a femoral nerve block will reliably cover all branches of the femoral nerve. For foot surgery, a subcutaneous injection of the saphenous nerve at or above the ankle
Further readings	Eglitis N, et al: The importance of the saphenous nerve in ankle surgery. Anesth Analg 2016; 122(5):1704–6. Horn J-L, et al: Anatomical basis to the ultrasound-guided approach for saphenous nerve blockade. Reg Anesth Pain Med 2009; 34(5):486–9. Vora MU, et al: Adductor canal block for knee surgical procedures: review article. J Clin Anesth 2016; 35:295–303.

POPLITEAL SCIATIC NERVE

Indications	Posterior capsule of the knee and leg, ankle, and foot with the addition of a saphenous nerve block for the medial leg/ankle/forefoot

Anatomy

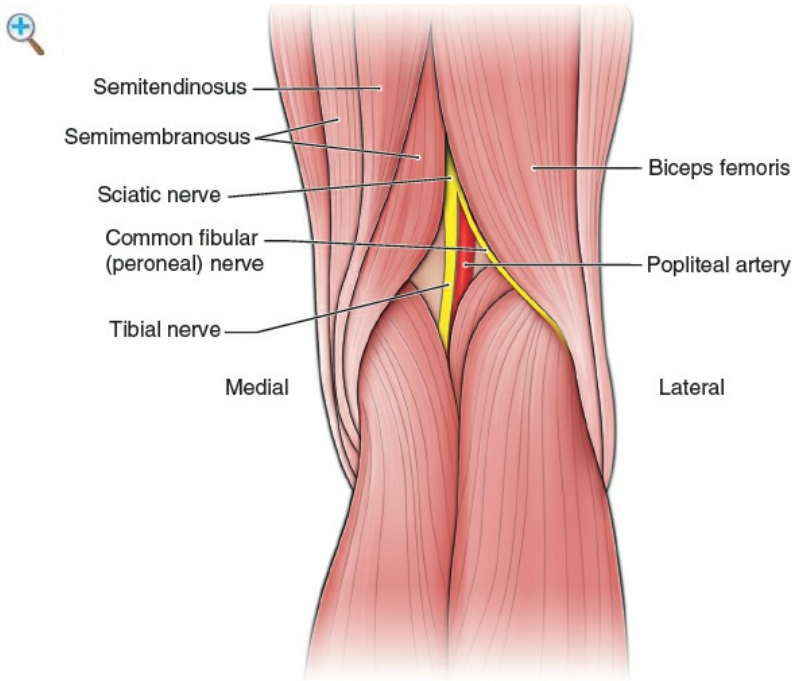

Figure 16.31 Popliteal sciatic anatomy. The sciatic nerve arises from L4 to S3 nerve roots. The level of the split into tibial and common peroneal nerves varies from knee capsule to about 10 cm more proximal.

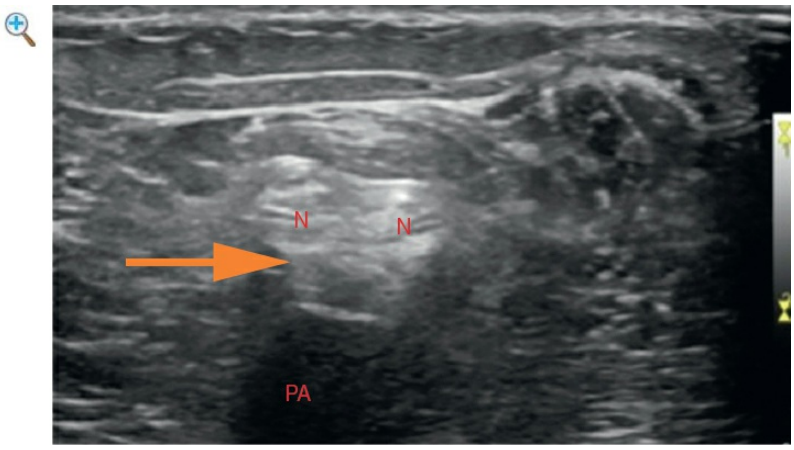

Figure 16.32 Popliteal sciatic ultrasound. PA, popliteal artery; N, nerve.

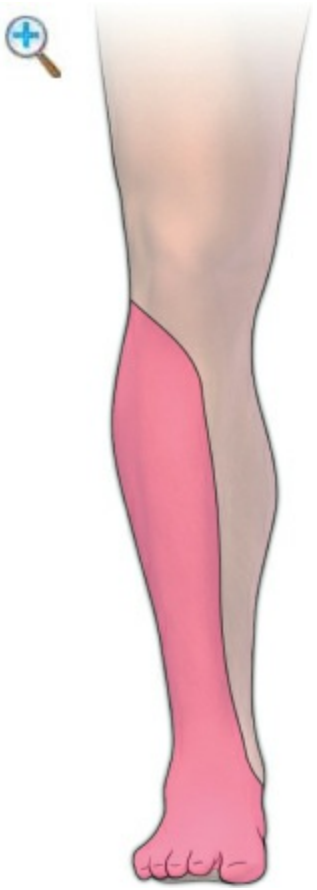

Figure 16.33 Popliteal sciatic anatomy.

	The level of the nerve split into the tibial and common peroneal nerves varies usually from the knee crease to about 10 cm more proximally
Dosage	20–30 mL (0.5% ropivacaine/bupivacaine or mepivacaine 1–1.5%)
Nerve stimulation	Dorsiflexion for common peroneal stimulation, extension for tibial stimulation
Side effects	Complete block of all muscles below the knee with ambulation difficulties
Complications	Vascular injury: <1% Nerve injury: <5%
Pearls	• Prone, lateral decubitus with probe placed transverse for an in-plane or out-of-plane approach. Supine position with elevated leg makes the needle placement more difficult but is more comfortable for the patient. • Adding a saphenous nerve block is essential when the

	medial leg, ankle, and forefoot are involved. • Single shot placed at or just distal to the nerve split speeds the onset. • Catheter placement above the split ensures more reliable results.
Alternative	Higher sciatic approach Ankle block for forefoot and toe surgery
Further reading	Dufour E, et al: Combined ultrasound and neurostimulation guidance for popliteal sciatic nerve block: a prospective, randomized comparison with neurostimulation alone. Anesth Analg 2008; 106:1553–8.

SCIATIC NERVE

Indications	Posterior thigh/knee and ankle/foot with the addition of a saphenous nerve block for the medial ankle/forefoot
Anatomy	

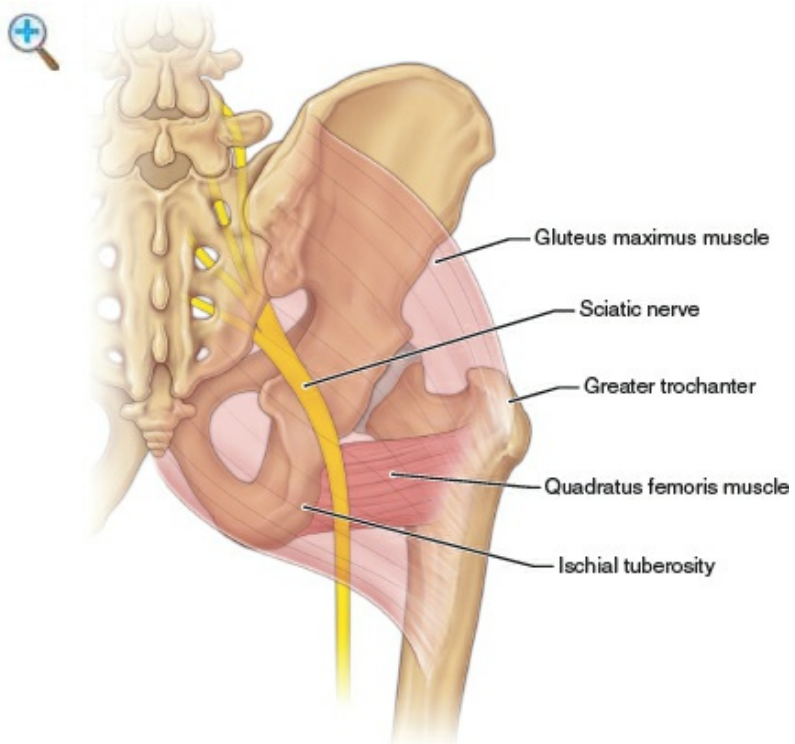

Figure 16.34 Sciatic anatomy—The sciatic nerve arises from L4 to S3 nerve roots.

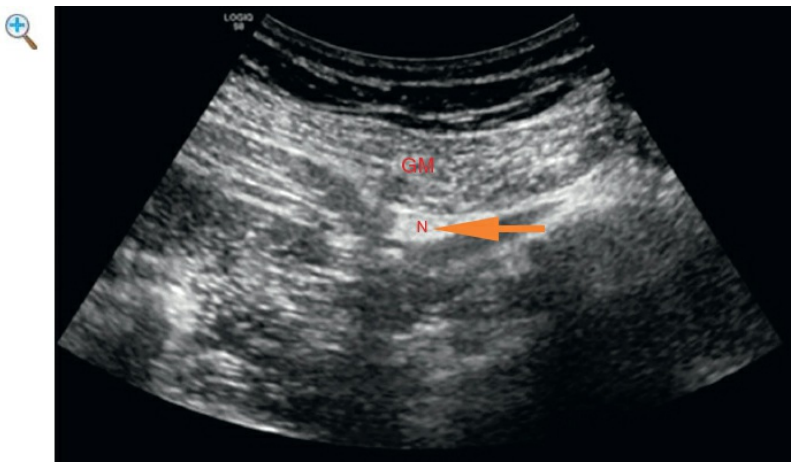

Figure 16.35 Sciatic ultrasound. GM, gluteus muscle; N, nerve.

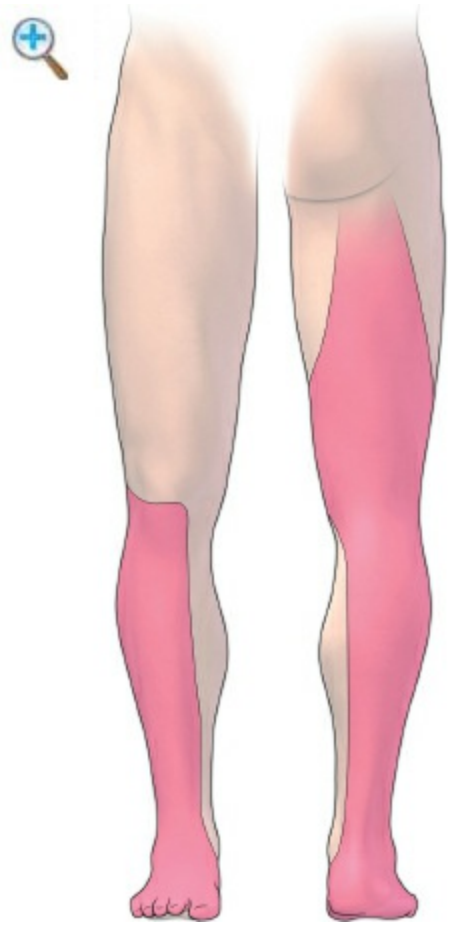

Figure 16.36 Sciatic anatomy.

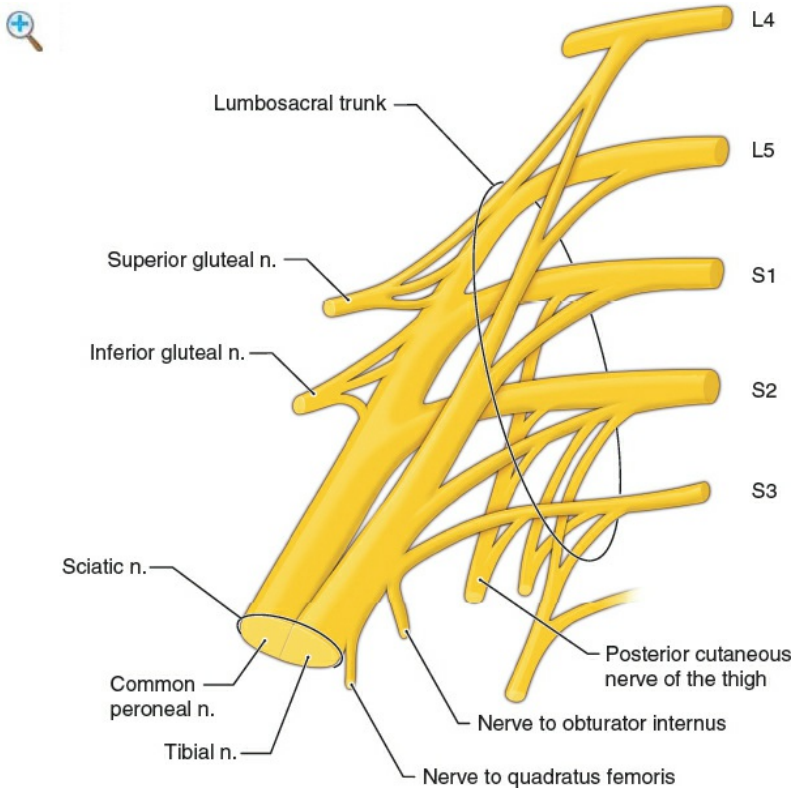

Figure 16.37 Sciatic anatomy.

Dosage	15–30 mL (0.5% ropivacaine/bupivacaine or mepivacaine 1–1.5%)
Nerve stimulation	Dorsiflexion for common peroneal stimulation, extension for tibial stimulation
Side effects	Complete block of all muscles below the knee +/− hamstring muscles with ambulation difficulties
Complications	Vascular injury: <1% Nerve injury: <5%
Pearls	• Lateral decubitus with leg flexed, probe placed transverse for an in-plane or out-of-plane approach • The parasacral approach is the most challenging due to the depth and angle of the nerve entering the sacrum. • A proximal block, parasacral, or subgluteal above the long head of the biceps is necessary to cover the posterior thigh or knee to catch the posterior femoral cutaneous nerve before it branches posterior to the biceps femoris.
Alternative	Anterior approach when the patient cannot be moved

	(but can be challenging due to the depth of the nerve). Popliteal sciatic nerve block is more superficial and works well for structures below the knee, and it may also cover the posterior capsule of the knee joint. Ankle block for forefoot and toe surgery
Further reading	Rodziewicz TL, et al: Sciatic Nerve Block. 2017 Nov 26. StatPearls [Internet]. StatPearls Publishing, Treasure Island: 2018. Available from: http://www.ncbi.nlm.nih.gov/books/NBK470391/

OBTURATOR NERVE

Indications	Medial distal thigh, medial knee, preventing thigh adduction in transurethral bladder surgery, rescue after knee surgery when femoral block is insufficient

Anatomy

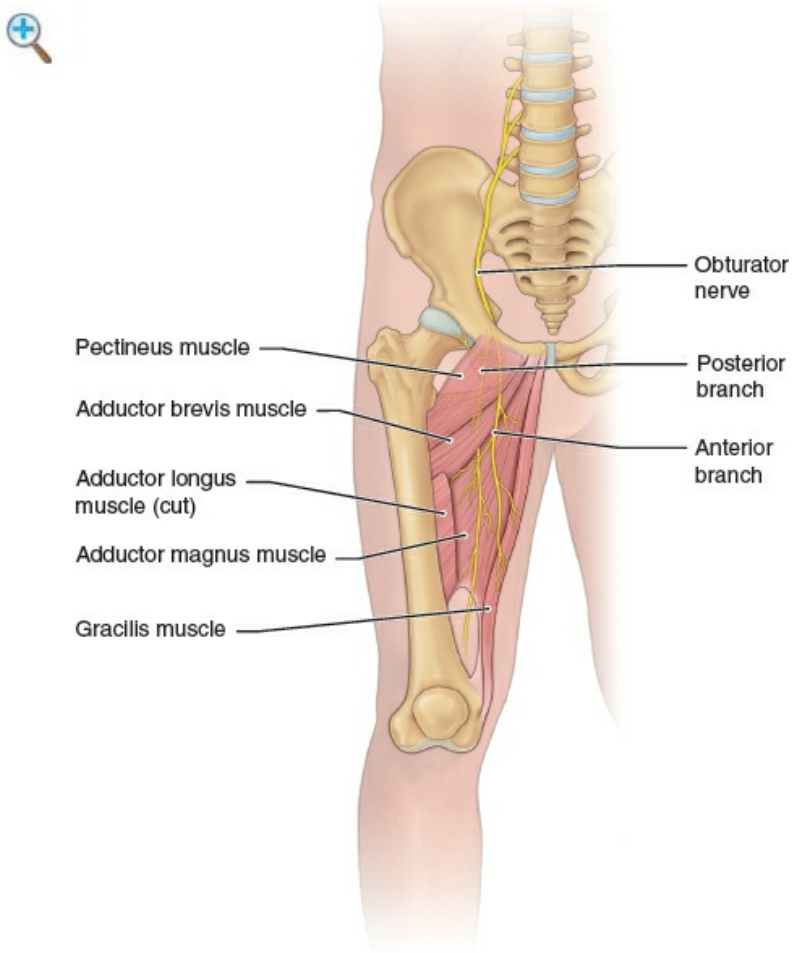

Figure 16.38 Obturator nerve anatomy. Originates from the

lumbar plexus (anterior rami of L2-L4).

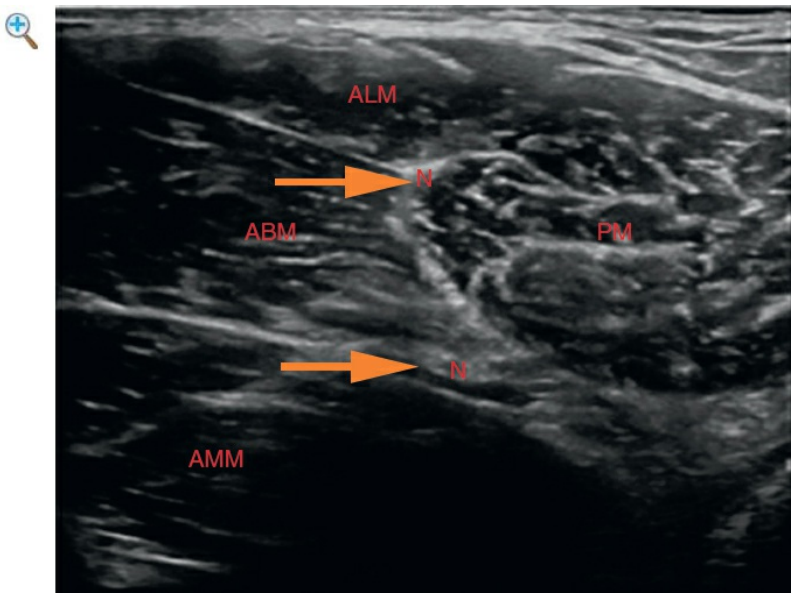

Figure 16.39 Obturator nerve ultrasound. PM, pectineus; ALM, adductor longus muscle; ABM, adductor brevis muscle; AMM, addcutor magnus muscle.

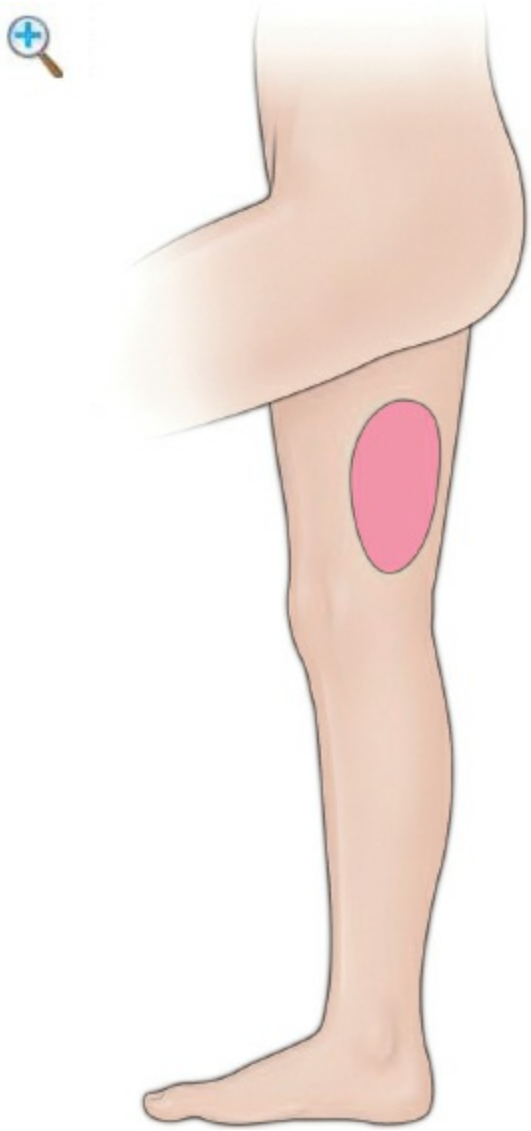

Figure 16.40 Obturator nerve anatomy.

	An interfascial plane block. The anterior branch is between the pectineus, adductor longus, and adductor brevis muscles. The posterior branch is between the adductor brevis and adductor magnus.
Dosage	10 mL (0.25–0.5% ropivacaine/bupivacaine)
Nerve stimulation	Adductor twitch (rarely used)
Side effects	Inability to adduct leg (rarely impairs mobility)
Complications	Vascular injury: rare
Pearls	• Supine with the leg extended, probe placed transversely over the femoral vessels and then slide medially over the pectineus and adductor muscles for an in-plane or out-of-

	plane approach. • The anterior branch is mostly cutaneous, and posterior branch is mostly motor.
Alternative	Lumbar plexus block Fascia iliaca block

ANKLE

Indications	Forefoot or toe surgery

Anatomy

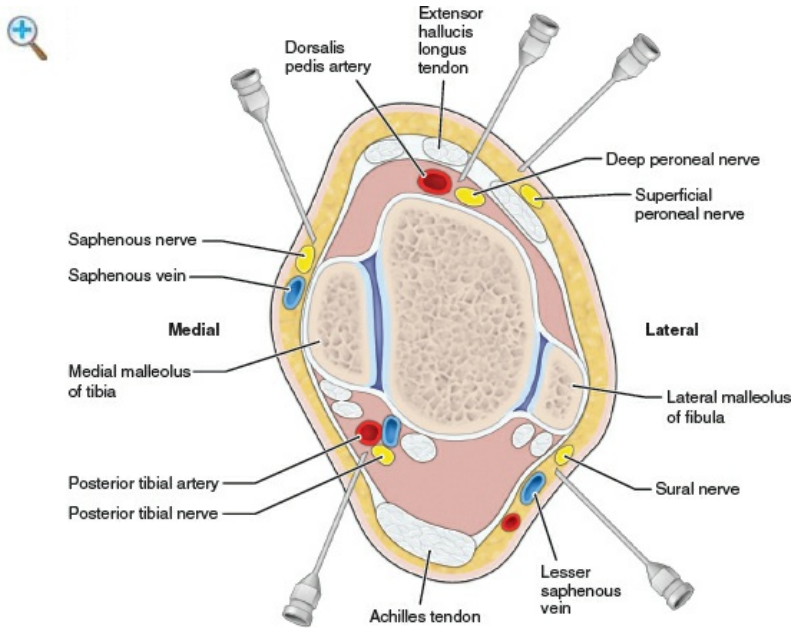

Figure 16.41 Ankle anatomy. The deep peroneal nerve is located lateral to the extensor hallucis longus tendon and dorsalis pedis artery. The posterior tibial nerve is posterior to the distal medial malleolus and posterior tibial artery.

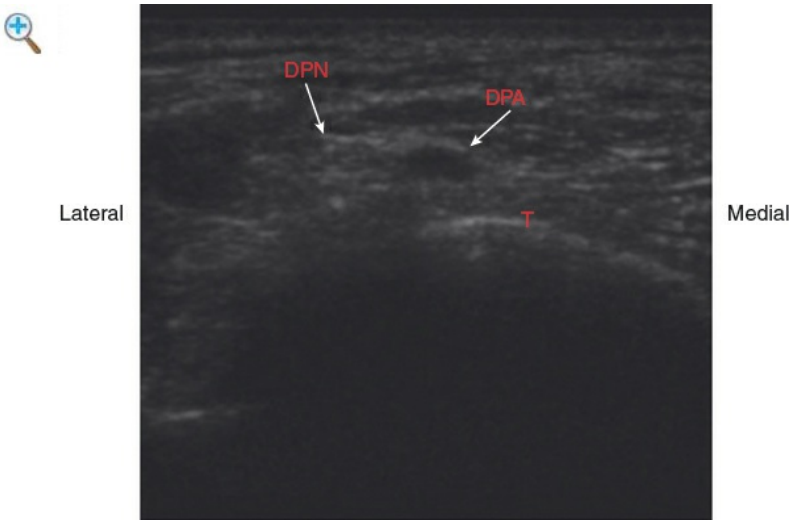

Figure 16.42 Ankle ultrasound. DPN, deep peroneal nerve; DPA, dorsalis pedis artery; T, Tibia.

Figure 16.43 Ankle anatomy.

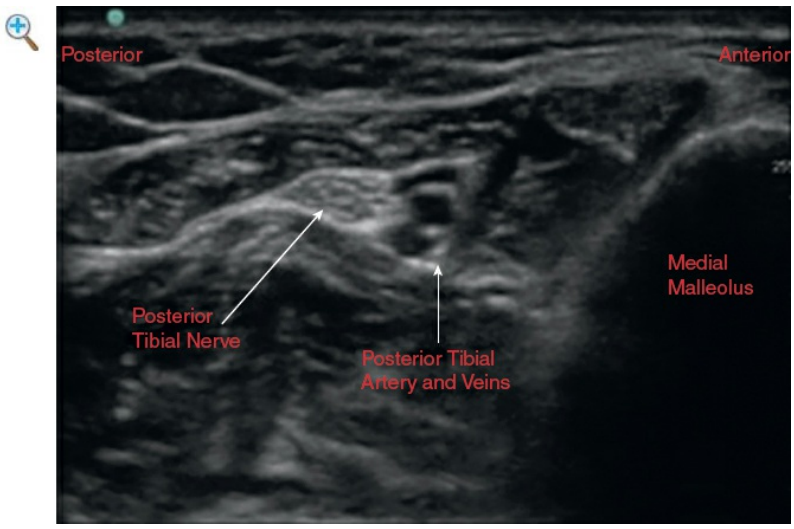

Figure 16.44 Ankle ultrasound.

	Posterior tibial and deep peroneal nerves are targeted individually, and superficial nerves (superficial peroneal, sural, and saphenous) are blocked with a subcutaneous field block. The deep peroneal nerve is located directly lateral to the extensor hallucis longus tendon and the anterior tibial artery. The posterior tibial nerve is located immediately posterior to the distal medial malleolus and the posterior tibial artery. The superficial nerves are targeted with a subcutaneous ring block at the narrowest part of the ankle proximal to the malleoli excluding the tissue overlying the Achilles tendon.
Dosage	5 mL (0.5% ropivacaine or 1.5% mepivacaine) for each nerve
Nerve stimulation	Nerve stimulation is only useful for posterior tibial nerve localization.
Side effects	Discomfort during placement Failure in acidic milieu
Complications	Vascular injury: <1%
Pearls	• Adding sodium bicarbonate (10%) to local anesthetic may correct local acidosis. • Start with the superficial nerves (S), less risk of paresthesia. • Place a circular subcutaneous wheel for the S at the

	narrowest point of the ankle. • Then block the deep peroneal nerve at the distal tibia adjacent to the anterior tibial artery or dorsalis pedis artery more distally. • Lastly, block the posterior tibial nerve behind the medial malleolus next to the posterior tibial artery, as it is the most uncomfortable injection.
Alternative	Combined popliteal and saphenous nerve blocks

THORACOABDOMINAL BLOCKS

TRANSVERSUS ABDOMINIS PLANE (TAP)

Indications	Abdominal surgery

Anatomy

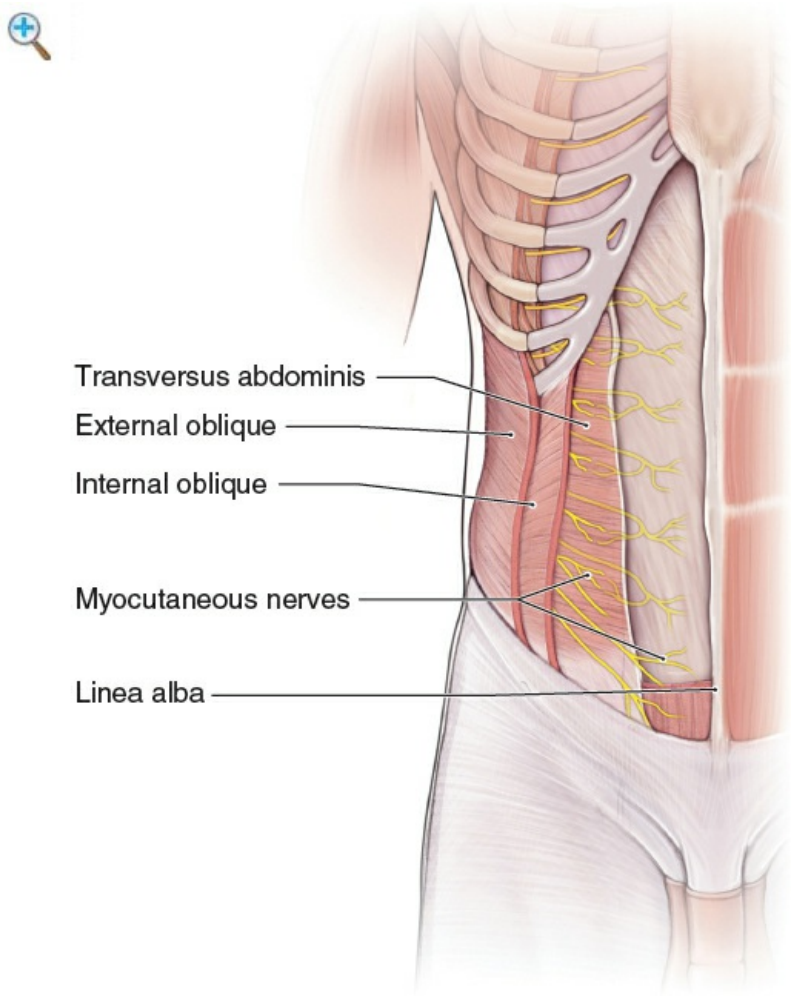

Figure 16.45 Transversus abdominis anatomy. The thoracoabdominal nerves, T6-T12, and the ilioinguinal/iliohypogastric nerves, T12-L1, run in the fascial plane deep to the internal oblique and superficial to the transversus abdominis. The subcostal approach targets higher-level dermatomes (T6-T9), while the lateral approach (mid axillary line) targets lower dermatomes (T10-L1).

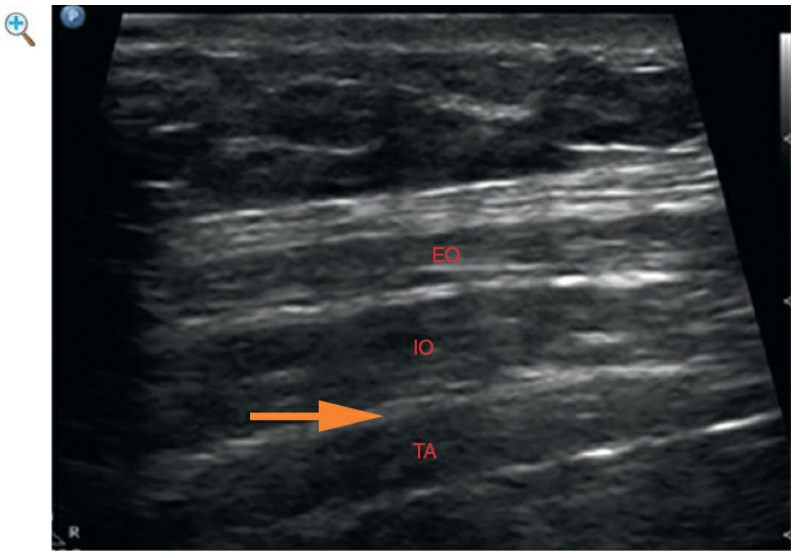

Figure 16.46 Transversus abdominis ultrasound. EO, external oblique; IO, internal oblique; TA, transversus abdominis.

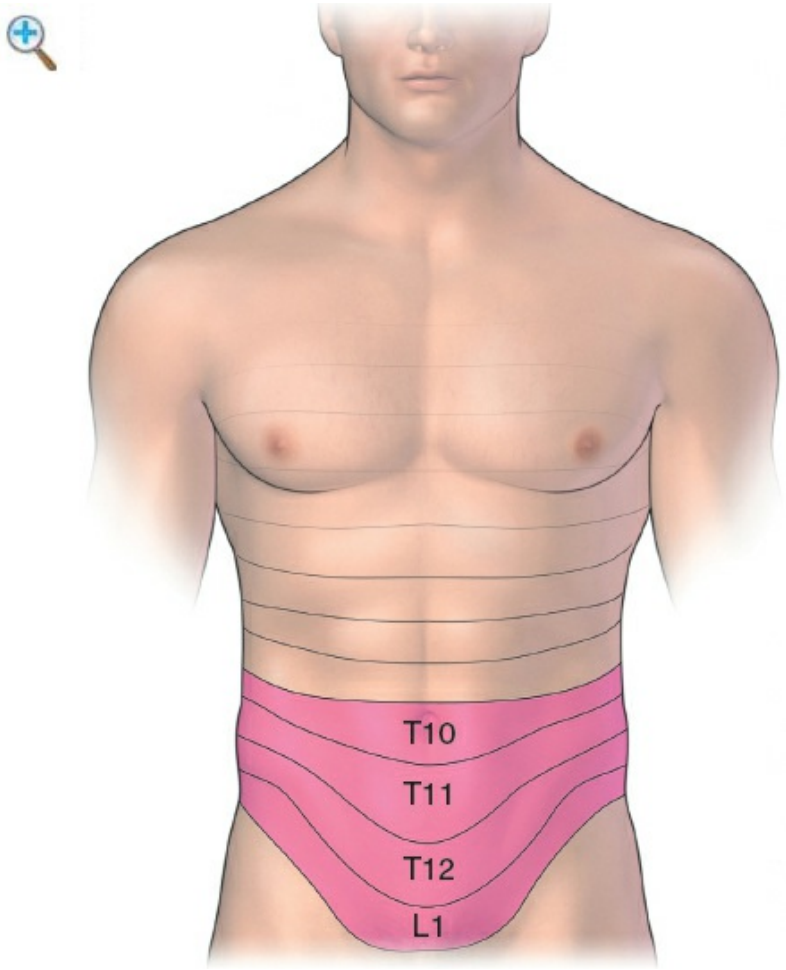

Figure 16.47 Transversus abdominis anatomy.

	The thoracoabdominal nerves, T6-T12, and the ilioinguinal/iliohypogastric nerves, T12-L1, run in the fascial plane deep to the internal oblique and superficial to the transversus abdominis. The subcostal approach targets higher-level dermatomes (T6-T9), while the lateral approach (mid axillary line) targets lower dermatomes (T10-L1).
Dosage	15–30 mL (0.25% ropivacaine)
Nerve stimulation	None
Side effects	Minimal

Complications	Visceral puncture: <0.1% Local anesthetic systemic toxicity (LAST): <0.1% Hematoma: <1%
Pearls	• The posterior approach may extend axially like the blind angle of petit approach. • Large bolus may provide better spread/effect. • Landmarks may be altered by surgery.
Alternative	Local infiltration by the surgeon Epidural Paravertebral block Quadratus lumborum block Rectus sheath block Erector spinae plane block
Further reading	Chin KJ, et al: Essentials of our current understanding: abdominal wall blocks. Reg Anesth Pain Med 2017; 42(2):133–83.

ERECTOR SPINAE PLANE

Indications	Chest wall, abdominal wall, shoulder, and possibly hip
Anatomy	

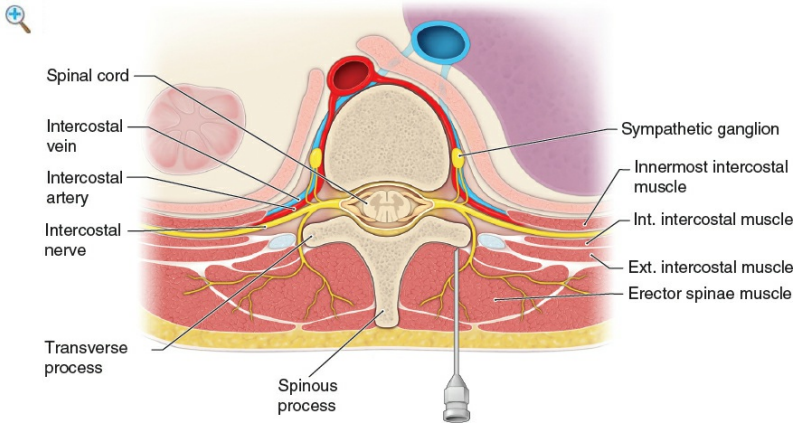

Figure 16.48 Erector spinae anatomy. Potential blockade of dorsal and ventral rami of the thoracic spinal nerves.

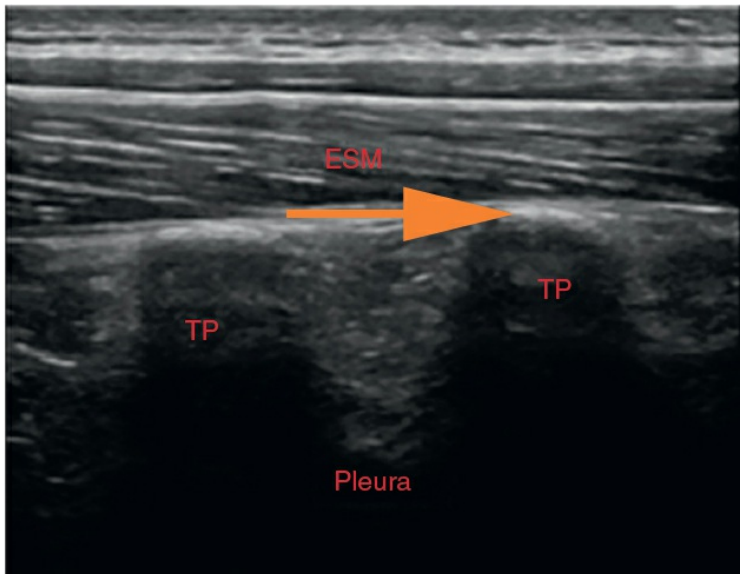

Figure 16.49 Erector spinae ultrasound. ESM, erector spinae muscle; TP, transverse process.

	Fascial plane block. Deposition of local anesthetic deep to the erector spinae muscle along the tip of the transverse processes, potentially blocking dorsal and ventral rami of the thoracic spinal nerves
Dosage	10–20 mL (0.5% ropivacaine or 1.5% mepivacaine)
Nerve stimulation	Not used
Side effects	Minimal
Complications	Paravertebral spread LAST (rare)
Pearls	• Positioning: prone, sitting, or lateral • Ultrasound guided: parasagittal or transverse probe placement with an in- or out-of-plane approach
Alternative	Epidural Intercostal block Paravertebral block
Further reading	Forero M, et al: Erector spinae plane block in the management of post thoracotomy pain syndrome: a case series. Scand J Pain 2017; 17:325–9.

PARAVERTEBRAL

Indications	Thoracic, breast, axillary, abdominal surgeries

Anatomy

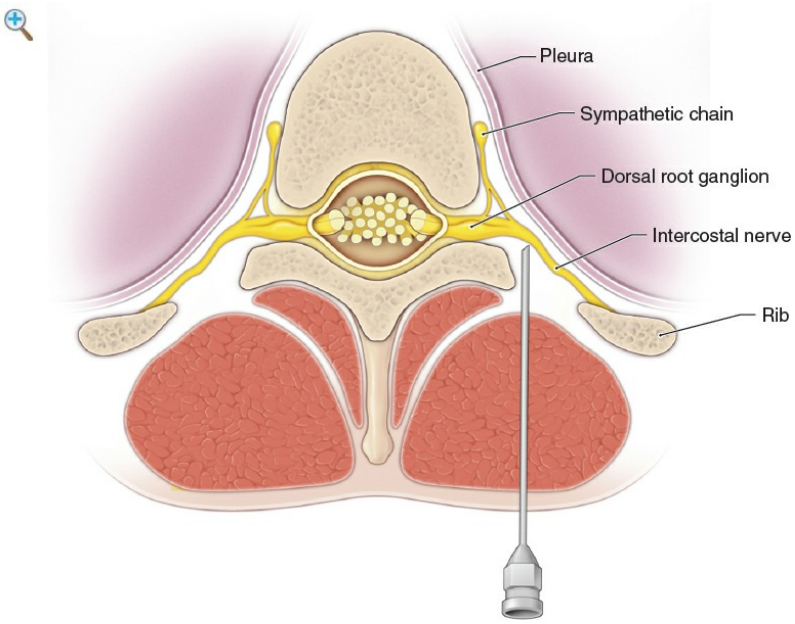

Figure 16.50 Paravertebral anatomy. Triangular spaces lateral to the vertebral column. Bordered anteriorly by the parietal pleura, posteriorly by the superior costotransverse ligament, and medially by the transverse process and foramen. Space contains fat, vessels, intercostal nerves, sympathetic chain, and dorsal rami of the spinal nerves.

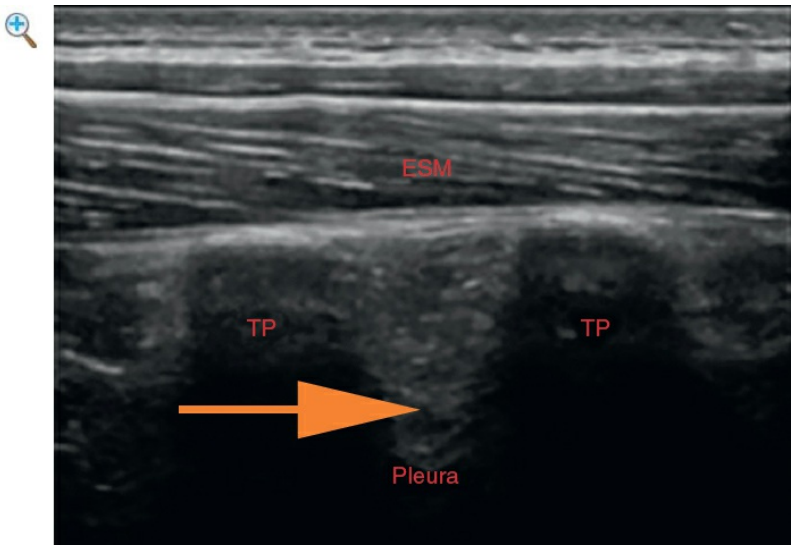

Figure 16.51 Paravertebral ultrasound. ESP, erector spinae muscle; TP, transverse process.

	Target the triangular space lateral to the vertebral column, bordered anterior by the parietal pleura, posteriorly by the superior costotransverse ligament

	and transverse process, and medially by the vertebral body and foramen. The space contains fat, vessels, intercostal nerves, sympathetic chain, and dorsal rami of the spinal nerves.
Dosage	3–5 mL 0.25–0.5% ropivacaine/bupivacaine or 1.5% mepivacaine per level for multiple levels; 15–20 mL 0.25–0.5% ropivacaine/bupivacaine or 1.5% mepivacaine for single level injection
Nerve stimulation	Helpful to confirm level
Side effects	Hypotension Epidural spread
Complications	Epidural or intrathecal injection (~1%) Pneumothorax (~0.5–5%) Hematoma (2.4%)
Pearls	• Positioning: prone, sitting, or lateral • Ultrasound guided: parasagittal probe placement with in- or out-of-plane approach • For parasagittal approach, tilting the probe medial to lateral to obtain a good beam reflection on the pleura • Obtain a "loss of resistance" when passing the posterior border, with depression of the pleura with fluid spread.
Alternative	Epidural Intercostal block Erector spinae plane block
Further reading	Wardhan R: Update on paravertebral blocks. Curr Opin Anaesthesiol 2015; 28(5):588–92.

PECTORALIS PLANE (PECS 1, 2 AND SERRATUS ANTERIOR)

Indications	Breast, anterior chest surgery

Anatomy

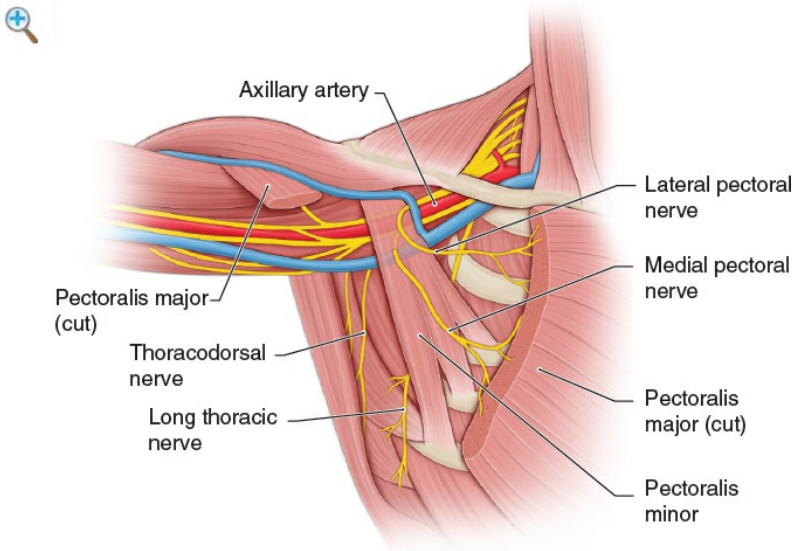

Figure 16.52 Pectoralis plane anatomy.

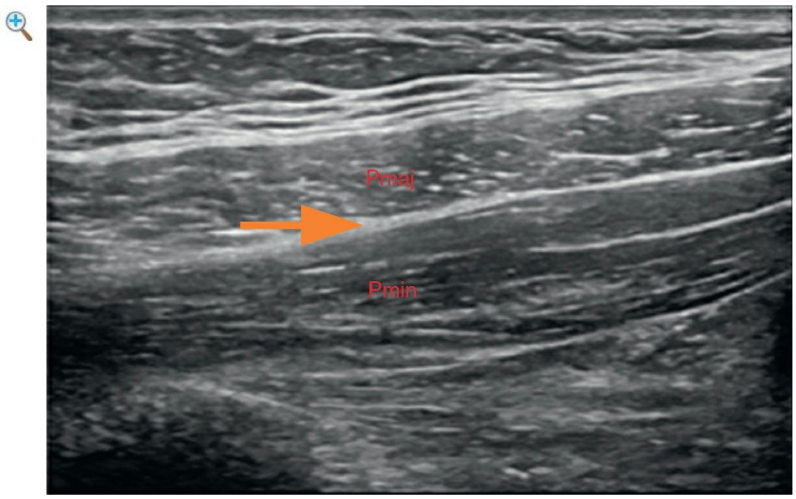

Figure 16.53 Pectoralis plane ultrasound. Pmaj, pectoralis major; Pmin, pectoralis minor.

	PECS I between the pectoralis major and minor muscles targeting the lateral and medial pectoral nerves PECS II under the pectoralis minor muscles and the ribs covering the lateral cutaneous branches of the upper intercostal nerves (T2-T4) PECS III or serratus anterior block covering the lateral cutaneous branches of the mid intercostal nerves (T5-T7). LA is injected either superficial or deep to the serratus anterior muscle
Dosage	10–20 mL (0.25–0.5% ropivacaine or bupivacaine)

Nerve stimulation	Not used
Side effects	Long thoracic nerve block → loss of serratus anterior muscle function
Complications	Local anesthetic systemic toxicity (LAST): <0.1% Vascular puncture: thoracoacromial trunk for PECS I (6.8%) Pneumothorax (0.5%)
Pearls	• Supine positioning with arm abducted or at side • PECS I: ultrasound probe parasagittal, midclavicular line below clavicle, identify the thoracoacromial trunk adjacent to the lateral pectoralis nerve • PECS II: move the probe laterally at an angle along breast contour directing the probe to the anterior axillary line • PECS III: continue to slide the probe caudate over the serratus anterior muscle
Alternative	Epidural Intercostal block Paravertebral block Erector spinae plane block
Further reading	O'Scanaill P, et al: Single-shot pectoral plane (PECs I and PECs II) blocks versus continuous local anaesthetic infusion analgesia or both after non-ambulatory breast-cancer surgery: a prospective, randomized, double-blind trial. Br J Anaesth 2018; 120(4):846–53.

RECTUS SHEATH

Indications	Abdominal midline/umbilical surgery
Anatomy	

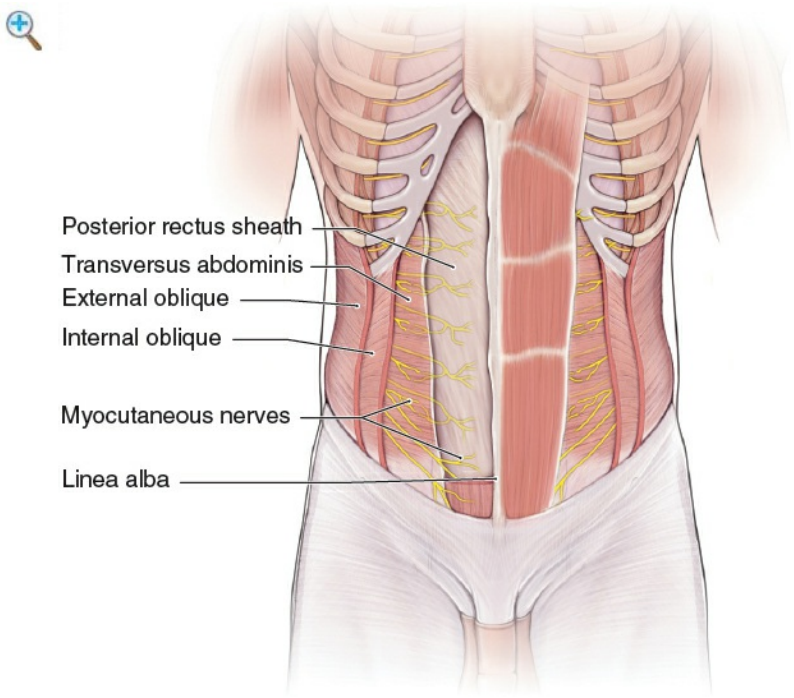

Figure 16.54 Rectus sheath anatomy. Local spread between the oval-shaped rectus muscle and its posterior fascia with blockade of T6-T11.

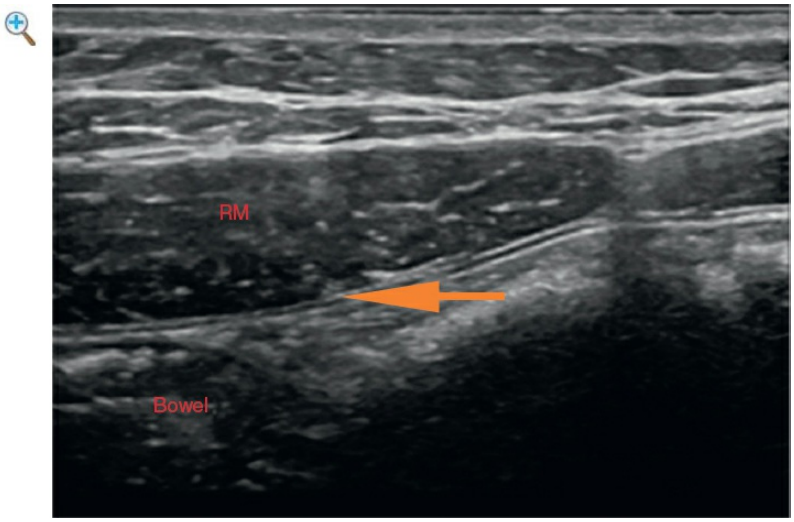

Figure 16.55 Rectus sheath ultrasound. RM, rectus muscle.

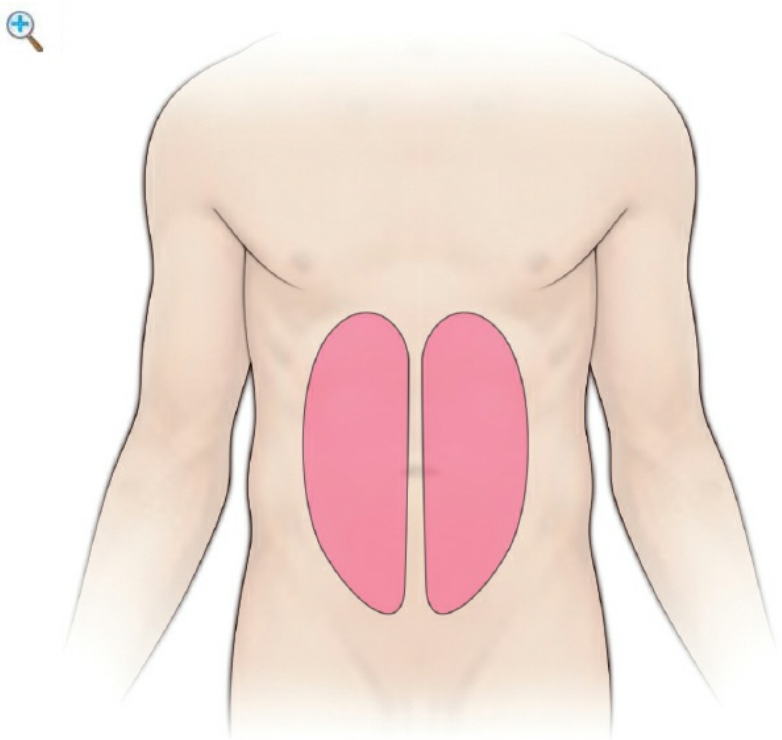

Figure 16.56 Rectus sheath anatomy.

Dosage	10–30 mL (0.25–0.5% ropivacaine or bupivacaine)
Nerve stimulation	Not used
Side effects	Minimal
Complications	Local anesthetic systemic toxicity (LAST): <0.1% Vascular puncture: epigastric artery: <1% Visceral puncture: <1%
Pearls	• Supine positioning • Ultrasound probe placed in the transverse position at the level of the desired injection site • Look for the superior epigastric at medial part of the rectus muscle, stay lateral to the artery • Injection posterior to the muscle fascicles but anterior to the posterior rectus sheath
Alternative	Epidural Transversus abdominis plane block Paravertebral block
Further reading	Chin KJ, et al: Essentials of our current understanding: abdominal wall blocks. Reg Anesth

Pain Med 2017; 42(2):133–83.

QUADRATUS LUMBORUM (QL)

Indications	Abdominal surgery, possibly useful for hip surgery

Anatomy

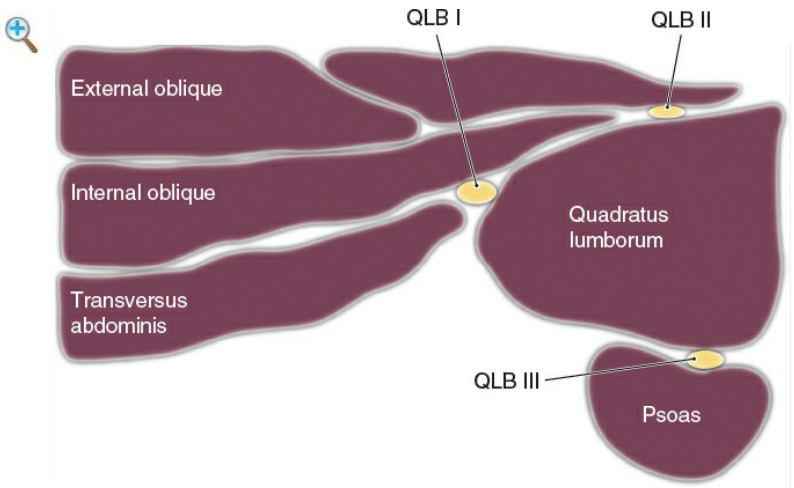

Figure 16.57 Quadratus lumborum anatomy. The quadratus lumborum lies deep and posterior to the aponeurosis of the abdominal wall musculature and is covered by the thoracoabdominal fascia.

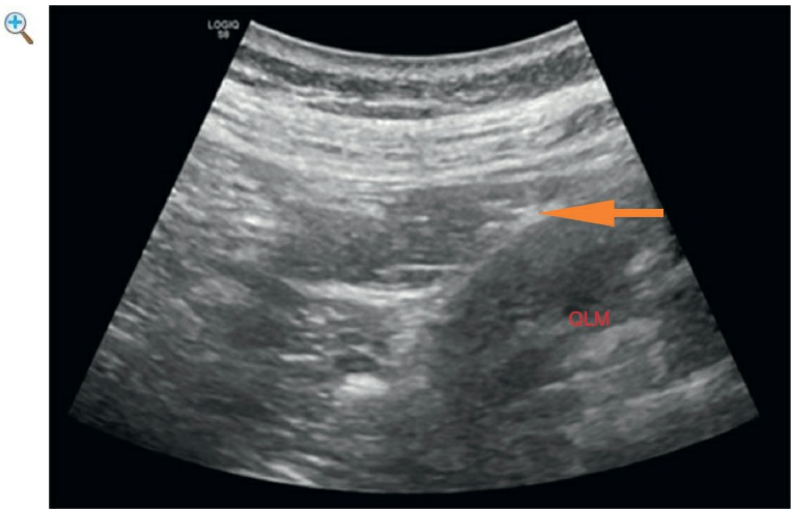

Figure 16.58 Quadratus lumborum ultrasound. QLM, quadratus lumborum muscle.

The quadratus lumborum lies deep and posterior to the aponeurosis of the abdominal wall musculature and is covered by the thoracoabdominal fascia. LA is injected either lateral, posterior, or anterior to the

	QL muscle defined as QL 1, 2, or 3 (transmuscular), respectively. All injection sites have spread of LA into the space under the transversus abdominis muscle aponeurosis with spread along the thoracoabdominal fascia with possible paravertebral space spread.
Dosage	20–30 mL (0.25% ropivacaine or bupivacaine)
Nerve stimulation	Not used
Side effects	Minimal
Complications	Local anesthetic systemic toxicity (LAST): <0.1% Vascular puncture: epigastric artery: <1% Visceral puncture: <1%
Pearls	• QL1, lateral, is close to a posterior TAP and the key landmark is a thick fascia: the lumbar interfascial triangle (LIFT). • QL2, posterior, is between the latissimus dorsi and the QL. • QL3, transmuscular, injection adjacent to the psoas muscle • Large bolus may be better.
Alternative	TAP block Epidural Erector spinae plane block Paravertebral block
Further reading	Chin KJ, et al: Essentials of our current understanding: abdominal wall blocks. Reg Anesth Pain Med 2017; 42(2):133–83.

APPENDIX A: PREOPERATIVE CONSIDERATIONS

PREOPERATIVE LABORATORY TESTING AND DIAGNOSTIC STUDIES

Clifford A. Schmiesing, MD

The value and utility of preop diagnostic studies have become central issues in evaluating cost-effective health care in the surgical patient. Approximately $3 billion is spent in the United States annually on preop laboratory and diagnostic studies. Unnecessary testing is inefficient and expensive, and it requires additional technical resources. Inappropriate studies may lead to evaluation of "borderline" or false-positive laboratory abnormalities. This may result in unnecessary OR delays, cancelations, and potential patient risk through additional testing and follow-up.

Surgical patients require preop lab and diagnostic studies that are consistent with their medical conditions, the proposed operative procedures, and the potential for blood loss. Preop lab and diagnostic testing should be ordered for specific clinical indications rather than just because the patient is about to undergo a particular surgical procedure.

The following preop diagnostic guidelines provide basic recommendations. They are not absolute or standard requirements. Practice guidelines should be modified based on clinical needs and individual practice to ensure the highest quality of anesthesia and surgical patient care.

SUMMARY OF PREOP STUDIES

Chest x-ray (CXR)	**Overview**: A preop CXR should be used to assess the presence of acute, progressive, or chronic changes in cardiac/pulmonary disease. The decision to obtain a preop CXR should be individualized and based on clinical indications (see Table A-1). CXRs should not be part of a routine preop screening protocol. **Clinical indications**: Pneumonia; pulmonary edema; atelectasis; aortic aneurysm; mediastinal or pulmonary masses; tracheal deviation; pulmonary HTN; cardiomegaly; advanced COPD and blebs;

	dextrocardia; pulmonary embolism
Electrocardiogram (ECG)	**Overview**: ECGs evaluate cardiac rhythm/conduction disturbances, ischemia, myocardial infarction, hypertrophy, and metabolic and electrolyte disorders. **Clinical indications**: Patients with suspected or known Hx of CAD; patient age >60; HTN; Hx of dysrhythmias, chest pain; CHF; diabetes; OSA, cerebrovascular disease, and PVD; syncope or presyncope; dizziness; SOB; DOE; PND; palpitations; leg/ankle edema; abnormal valvular murmurs
Liver function test (LFT)	**Overview**: LFTs establish the absence or presence of hepatic injury and the degree of hepatic reserve in disease states. LFTs consist of AST (SGOT), ALT (SGPT), GGTP, alkaline phosphatase, serum albumin, and bilirubin. **Clinical indications**: Patients with suspected or known Hx of hepatitis (viral, alcohol, drugs, high BMI); infiltration (tumor, immunologic); cirrhosis; portal HTN; gallbladder or biliary tract disease; jaundice; intravascular hemolysis
Renal function testing	**Overview**: Renal function testing measures glomerular filtration and the magnitude of renal tubular dysfunction. These tests include serum creatinine and BUN. **Clinical indications**: Renal function testing is indicated for patients with HTN; increased fluid overload (CHF/peripheral edema/ascites) associated with cardiac or hepatic disease or dehydration; diabetes; nausea, emesis, or anorexia; polyuria; nocturia; oliguria; anuria; high-risk surgery in patients with low-CO syndrome; hematuria; costovertebral angle pain: renal transplant Hx; acute and chronic kidney disease; and dialysis.
Hemoglobin (Hgb),	**Overview**: The decision to obtain a preop Hgb, Hct,

hematocrit (Hct), CBC	or CBC should be individualized and based on clinical indications, medical Hx, and the proposed surgical procedure. Hgb/Hct or CBC should not be part of a routine preop screening protocol. **Clinical indications**: Hematologic disorder; bleeding/coagulopathy Hx; malignancy; chemotherapy; radiation therapy (CBC); renal disease; anticoagulant and steroid therapy; surgical procedures with high blood loss (>1500 mL); highly invasive or trauma surgery; malabsorption/poor nutrition status; CNS disease
Pregnancy testing	**Overview**: The decision to obtain a preop pregnancy test may be based on clinical Hx and examination or OR policy. Several assays are available (serum hCG, urine hCG); β-hCG is detectable in maternal urine and blood 8–9 d postconception. **Clinical indications**: Sexually active; time of last menstrual period; presence or absence of birth control method; patient intuition. OR policy may require pregnancy testing based on specific criteria including age and ability to become pregnant (i.e., no Hx of hysterectomy).
Coagulation testing	**Overview**: Coagulation testing, or clotting function studies, should be considered in patients with known or suspected coagulopathies as indicated from H&P and drug therapies. Tests include PT, PTT, INR, and platelet count. **Clinical indications**: Bleeding disorder Hx; anticoagulants or other drugs affecting coagulation; critical-risk surgeries with significant blood loss expected; hepatic disease: malabsorption/poor nutrition
Urinalysis	**Overview**: Assessment of renal function, infection, intravascular volume status, and metabolic disorders **Clinical indications**: There are no routine anesthesia preop requirements for a urinalysis.

We gratefully acknowledge the past contributions of Stephen P. Fischer, MD.

PREOPERATIVE EVALUATION OF PATIENTS WITH A CARDIAC RHYTHM MANAGEMENT DEVICE

Preoperative evaluation should include at least the following:

Device-Specific Considerations	• Date of most recent device interrogation (preferably <6 mo) • Type of device, manufacturer, model number, implant date (information typically on "pacemaker card" carried by patient) • Indication (including underlying dysrhythmia) for pacemaker or ICD. Include whether patient is "pacemaker dependent." • Determine underlying rate and rhythm. • Confirm adequate battery life. • Presence of freshly implanted leads (<3 mo old) → ↑ risk of dislodgement • Programming information including pacing mode, lower rate, pacer/ICD thresholds, and the response to magnet placement (asynchronous mode, ICD inactivation) • If any questions or concerns arise during evaluation, contact patient's cardiologist. Pacemaker companies can be contacted through 24-h service centers.
Patient-Specific Considerations	• Determine if patient has developed new symptoms possibly related to pacemaker dysfunction since last interrogation, including dizziness, syncope, fatigue, dyspnea, chest pain, or palpitations. • Review status of any associated cardiac disease (CAD, cardiomyopathy, valvular lesions). • Obtain 12-lead electrocardiogram; consider rhythm strip as needed. • If patient is pacemaker-dependent, consider placing magnet for procedures above T10. • If ICD/CRT, consider placing magnet for procedures above T10.

	• Advise surgeon to use short electrocautery applications (<5 sec). • External defibrillation equipment should be immediately available. • Consider placement of external pacer pads. • Use caution when placing upper body central lines with a guidewire. • A magnet should be immediately available.
Procedure-Specific Considerations	• Anatomical location of the surgery and patient position during surgery • Is monopolar cautery necessary? • Will there be other sources of electromagnetic interference (e.g., IORT, ECT, SSEP, MEP, RF ablation, or resection). • Will cardioversion or defibrillation be used during the procedure?

A complete discussion of this topic can be found in the following consensus statement

Grossley GH, Poole JE, Rozner MA, et al: The Heart Rhythm Society (HRS)/Americ Society of Anesthesiologists (ASA) Expert consensus statement on the perioperative management of patients with implantable defibrillators, pacemakers, and arrhythmia monitors: facilities and patient management: this document was developed as a joint project with the ASA, and in collaboration with the American Heart Association (AHA), and the Society of Thoracic Surgeons (STS)Heart Rhythm 2011; 8(7):1114–54.

ASA PHYSICAL STATUS CLASSIFICATION SYSTEM

ASA Physical Status	Preop Health Status	Examples Include
1	A healthy patient	No Hx acute illness or chronic medical conditions, no meds, no significant substance abuse, negative ROS
2	A patient with mild	No functional limitations: mild obesity,

	systemic disease	pregnancy, smoking, well-controlled hypertension or diabetes
3	A patient with significant systemic disease	Functionally limited: morbid obesity with comorbidities, CHF, COPD, poorly controlled HTN or diabetes, stable angina or old MI, renal failure on dialysis, stable cerebrovascular disease, unruptured aneurysm
4	A patient with severe systemic disease that is a constant threat to life	Severe functional limitations: unstable angina, unstable cerebrovascular disease, symptomatic CHF or COPD, ruptured aneurysm
5	A moribund patient who is not expected to survive without the operation	Not expected to survive >24 h without surgery; severe sepsis, multiorgan failure, severe coagulopathy, or intracranial hemorrhage
6	A declared brain-dead patient whose organs are being removed for donor purposes	

PERIOPERATIVE BETA-BLOCKER THERAPY

Clifford A. Schmiesing, MD

In the absence of new data showing benefit and safety of perioperative beta-blockers (PBB), published guidelines have tempered their support for starting therapy before surgery. Although PBB decreases the risk of cardiac complications, it increases the risk of stroke. The current ACC/AHA updated report continues to give a class recommendation (should be performed) to continue beta-blockers in patients undergoing surgery who are already receiving the drugs for management of other conditions including but not limited to HTN, afib, heart failure, and coronary artery disease. The report recommends against starting beta-blockers on the day of surgery due to the risk of bradycardia, hypotension, and stroke. Specific recommendations are listed in Table A-2 below.

When starting PBB therapy before surgery, consider the following general

recommendations. “Start low and go slow.” Initiate therapy days to weeks in advance of surgery and titrate to a heart rate of 60–80 beats per minute (assuming not hypotensive), maintain a systolic blood pressure of >100 mm Hg, and monitor vigilantly. Choose medications that are beta-1 selective (e.g., atenolol, metoprolol, and bisoprolol). Consider contraindications before initiating PBB therapy and how it will interact with other medications, medical conditions, and other surgical and anesthetic factors (Table A-3).

Table A-2. Guidelines for Perioperative Beta-Blocker (PBB) Therapy (Adapted from current ACC/AHA Guideline)

Recommendation	Recommendation Class	Level of Evidence
Continue BBs for patients taking them chronically.	Should be performed (1)	Limited (B)
Guide management of BB after surgery by clinical circumstances, independent of when the agent was started.	Reasonable to perform (2a)	Limited (B)
It may be reasonable to begin PBB Rx in patients with intermediate- or high-risk myocardial ischemia noted in preop risk stratification tests.	Reasonable to perform (2a)	Very limited (C)
It may be reasonable to begin PBB Rx in patients ≥3 RCRI risk factors (high-risk surgery, diabetes mellitus, heart failure, CAD, CKD, or stroke).	Reasonable to perform (2a)	Limited (B)
Uncertain benefit to begin PBB Rx in patients with a compelling long-term indication for beta-blocker therapy but no other RCRI risk factors	Reasonable to perform (2a)	Limited (B)
If beginning PBB Rx, it may be reasonable to start long enough in advance to assess effect and safety, preferably >1 d before surgery.	Reasonable to perform (2a)	Limited (B)

PBB Rx should not be started on the day of surgery.	Harmful (3)	Limited (B)

Table A-3. Recommendations for Perioperative Beta-Blocker Therapy (Adapted from the Focused AHA/ACC Recommendations for Perioperative Beta-Blocker Therapy Based on Published Randomized Clinical Trials)

Surgery Type	≤1 Risk Factor	>1 Risk Factor	CHD or Finding of Ischemia on Preop Testing	Taking β-Blocker
Vascular	Usefulness β-blocker uncertain*,†	Reasonable to give β-blocker‡,§	Probably give β-blocker	Continue β-blocker‖
Intermediate risk	Usefulness β-blocker uncertain	Reasonable to give β-blocker	Reasonable to give β-blocker	Continue β-blocker
Low risk	Usefulness β-blocker uncertain	Usefulness β-blocker uncertain	Usefulness β-blocker uncertain	Continue β-blocker

*In patients who are not currently taking β-blockers.
†β-blockers should not be given to patients undergoing surgery who have absolute contraindications to β-blockade.
‡Titrated to heart rate and blood pressure.
§Routine administration of high-dose β-blockers in the absence of dose titration is not useful and may be harmful to patients not currently taking β-blockers who are undergoing noncardiac surgery.
‖β-blockers should be continued in patients undergoing surgery who are receiving β-blockers for treatment of conditions with ACA/AHA class I guideline indications for the drugs.

PREOPERATIVE MEDICATION MANAGEMENT

Preop medication management is a crucial step in patient preparation for surgery. It is made challenging by several factors. Input from the surgeon and other consultants may

be needed. Patients often take a large number of medications, and many require active and deliberate management before surgery, including stopping and starting, dose adjustment, and conversion to other medications, and these adjustments often require different timing. Patients frequently find it challenging to follow these medication instructions. Many EHR systems do not provide robust support for this complex workflow. Medication management before surgery must be individualized, thorough, thoughtful, and transparent—a tall order. The following is intended as general recommendations and considerations. Specific management of preop medications must be based on a detailed assessment of the patient's medical history including a current and accurate medication list, planned surgery, and anesthetic plan.

Preoperative Medication Management Considerations			
Medication	**Day Before Surgery**	**Day of Surgery (DOS)**	**Other Management Considerations**
Antihypertensives	Take*	Take*	*Hold ACE, ARBs ≥ 24 h. Hold diuretics DOS unless indicated for management of CHF. Note: hemodialysis (HD) may completely filter off ACE/ARB and lead to rebound HTN. Consider timing of HD and ACE/ARB cessation after HD.
Oral antidiabetics	Take	Hold	Include many antidiabetic medication classes including sulfonylureas, meglitinides, and metformin. Consider holding metformin ≥24 h inpatient with CKD and those who will receive IV contrast.
Insulin, long-acting	No change	Consider 50–100% a.m.	Consider ↓ p.m. dose day before surgery if patient is

(peakless)		dose.	prone to nighttime or morning hypoglycemia.
Insulin, intermediate-acting	No change daytime dosing 50–75% of p.m. dose	50–75% a.m. dose	Consider ↓ p.m. dose day before surgery if patient is prone to nighttime or morning hypoglycemia.
Insulin, short-acting	No change	Hold	
Antiplatelet agents (APA)	Risk dependent →	→	Consider risk of thrombosis vs. risk of hemorrhage. Need to individualize based on indication and duration for therapy and surgical urgency and risk of bleeding. Consider carefully before stopping or adjusting antiplatelet therapy, especially dual therapies (DAPT). It is often helpful to consult with the clinician who manages antiplatelet therapy and surgeon to ensure optimal periop management. Guidelines exist for a variety of antiplatelet agent regimens (see Suggested Reading). Consider other hemostatic defects when formulating optimal plan.
NSAIDs	**Risk dependent** →	→	Consider holding NSAID 3 d before surgery unless the anticipated benefit of pain relief outweighs the

		risk of bleeding. Ibuprofen's effect on platelet function is shorter, and it can often be held for as little as 24 h. Selective COX-2 inhibitors have limited antiplatelet effect and are often continued and even initiated preoperatively. Consider other hemostatic defects (CKD, liver disease, thrombocytopenia) when formulating optimal plan.
Anticoagulants	Risk dependent →	Consider risk of thrombosis vs. risk of hemorrhage. Need to individualize based on the indication for anticoagulation, surgical urgency, and risk of bleeding. Thoughtful and timely planning is crucial. It is often helpful to consult with clinician who manages anticoagulant therapy and surgeon to ensure optimal periop management that may include cessation up to a week in advance or bridging strategies. Guidelines exist for periop anticoagulant Rx. (See Suggested Reading.) Consider other hemostatic defects (CKD, liver

			disease, thrombocytopenia, etc.) when formulating optimal plan.
Pure opiate agonists	Take	Take	Consider both fixed dose and PRN use. Helpful to calculate an MME score to determine overall opiate use and the potential effect on periop dosing. Anticipate tolerance when MME is significant.
Partial and complete opiate antagonists	Individualized →	→	Partial opiate agonists, especially buprenorphine, are increasingly used to manage opiate use disorder and chronic pain conditions. Preop management needs to be individualized and may include continuation with or without weaning to lower dose. See suggested readings. Full antagonists, especially naltrexone, are being increasingly used for indications including alcohol use disorder. It should usually be held 3–4 d before surgery that is painful, especially postop pain. Depot naltrexone use is on the rise and lasts up to 40 d. Recognition and management well in advance of surgery are necessary.

Antirejection medications	Take	Take	
Psychiatric medications	Take	Take if helpful	Consider drug-drug interactions, especially for MAOI inhibitors.
Acid-lowering	Take	Take	
Statins	Take	Take	
Corticosteroids	Take	Take or ± stress dose	
Dietary supplements	Consider holding supplements 7 d before, especially if constituents are hard to identify. Vitamins generally can be continued up to the day before surgery.		
Preemptive analgesia	Consider a multimodal approach that may include acetaminophen, gabapentin or pregabalin, and COX-2 inhibitors.

APPENDIX B: STANDARD ADULT ANESTHETIC PROTOCOLS

Richard A. Jaffe, MD, PhD, Clifford A. Schmiesing, MD, and Steven L. Shafer, MD

STANDARD MONITORS (NONINVASIVE)	
Blood pressure (BP)	Usually noninvasive (oscillometric) technique. Match cuff width to arm size to avoid inaccurate BP.
Capnometry/capnography	Measurement of $ETCO_2$/display of waveform
Gas analyzer (e.g., IR, mass spectrometry)	Measurement of respired gases including end-tidal CO_2 and inhaled anesthetics
Electrocardiogram (ECG)	5-Lead preferred. Usual display: lead II and $V_{4\text{ or }5}$. EASI lead system can be used to derive a 12-lead ECG that may improve detection of intraop ischemia.
Esophageal or precordial stethoscope	Breath and heart sounds are monitored; dysrhythmias and pulmonary system changes may be quickly detected. Seldom used today.
Nerve stimulator	Monitor status of neuromuscular blockade usually by stimulating the ulnar nerve. Automated systems to measure TOF ratio are more accurate than visual assessment but still may fail to detect residual blockade.
Oxygen analyzer	Measurement of FiO_2
Pulse oximetry	Measurement of O_2 saturation of arterial hemoglobin; also gives a pulse sound that indicates heart rate, rhythm, and change in saturation
Temperature	Nasal, esophageal, bladder, rectal, tympanic, or skin (deep esophageal best approximates core

	temperature)
Visual observation of patient	Skin color, pupils, edema, sweating, movement
Ventilator function monitors	PIP, TV, disconnect alarm, pressure-volume/flow-volume loops, etc.

STANDARD ANESTHETIC MANAGEMENT (ADULT ASA 1 AND 2)

NB: The following sections are guidelines only (for an otherwise healthy 70-kg adult). Specific drugs and drug dosages should be individualized, based on the physiologic and pharmacologic status of the patient, including factors such as age, weight, concurrent medication, and comorbidities.

PREMEDICATION FOR ANXIOLYSIS ± ANALGESIA

Light	Midazolam 1–2 mg iv- or- Lorazepam 1–2 mg - or- Hydroxyzine 25–100 mg	Before induction or transport to OR po 1 h preop po 1 h preop
Moderate	Midazolam 2–3 mg iv ± Fentanyl 25–100 mcg iv	Prior to transport to OR Monitor for respiratory depression or apnea.
Heavy	Lorazepam 1–2 mg Midazolam titrated to effect	PO the night before surgery Before transport to OR. May require >10 mg iv. **NB:** severe respiratory depression when combined with opiates. Flumazenil should be available.

PREINDUCTION CHECKLIST

Anesthesia machine	Complete ASA preanesthesia checkout procedures. Sample procedures for specific

	machines/workstations are on the ASA Web site: http://www.asahq.org/For-Members/Clinical-Information/2008-ASA-Recommendations-for-PreAnesthesia-Checkout/Sample-Procedures.aspx.
Airway management	Appropriate-sized face masks Working laryngoscope and blade Working backup laryngoscope and blade Working suction ETT with nonleaking cuff + backup ETTs in other sizes ETT stylet and bougie available Oral and nasal airways available McGill forceps available Ambu® bag or equivalent self-inflating resuscitator available Unexpected difficult airway plan and equipment available
Monitoring	Standard monitors (see section above) Invasive monitoring if necessary, before induction
Patient	Working IV access Verify status of regional blocks (if in use). Positioning plans discussed with surgeon Fire risk assessment (especially if open O_2 delivery is planned)
Medication	Emergency drugs available Infusions prepared and pump function verified Anesthetic plan and drugs reviewed

INDUCTION TECHNIQUES

Preinduction	1. Administer 100% O_2 by mask × 3 min (ideally ETO_2 should be >90%). 2. Administer supplemental sedation/analgesia (as appropriate). e.g., fentanyl 1–3 mcg/kg iv			
Induction agents	Propofol	1.5–2.5 mg/kg iv (in increments) **NB:** pain on injection may be lessened by prior administration of lidocaine 1% 5–10 mL in conjunction with temporary venous occlusion.		
	Thiopental	3–5 mg/kg iv (still unavailable in the United States)		
	Etomidate	0.2–0.4 mg/kg iv **NB:** pain on injection; myoclonus		
Muscle relaxants for intubation	**Drugs**	**Doses**	**Onset**	**Duration**
	Vecuronium	0.1 mg/kg	2–3 min	24–30 min
		0.2 mg/kg (rapid onset)	<2 min	45–90 min
	Rocuronium	0.6 mg/kg	90–120 sec	30–45 min
		1.2 mg/kg	60–90 sec	60–120 min
	Pancuronium	0.1 mg/kg	3–4 min	40–65 min
	Gantacurium*	0.2–0.5 mg/kg	1–2 min	5–10 min
	Cisatracurium	0.2 mg/kg	2 min	40–80 min
	Succinylcholine	1.0 mg/kg	30–60 sec	4–8 min
	If given after defasciculating dose of NMR	1.5 mg/kg	30–60 sec	4–8 min
	Infusion	1 g/250–500 NS: 50–100 mcg/kg/min (titrated to effect)	+60 sec	While infusing +5–8 min (phase II block possible)
	*Gantacurium is not yet (2019) available in the United States.			

MAINTENANCE TECHNIQUES

Inhalational anesthesia	30–100% O_2 (NB: absorption atelectasis rapid above 80% O_2) + 0–70% N_2O + Sevoflurane (MAC = 2.0%) or isoflurane (MAC in 100% O_2 = 1.2%) or titrated to effect. Desflurane (MAC = 6.6%) may be useful for rapid recovery in morbidly obese patients.
Balanced anesthesia	30–100% O_2 (NB: absorption atelectasis rapid above 80% O_2) + 0–70% N_2O + Hydromorphone 3–10 mcg/kg/3–4 h (intermittent bolus) or fentanyl 1–10 mcg/kg prn response to surgical stimulation or remifentanil 0.05–2 mcg/kg/min prn response to surgical stimulation (no residual analgesia)

	+ Isoflurane or sevoflurane titrated to effect or propofol 50–200 mcg/kg/min (titrated to effect)		
Total intravenous anesthesia (TIVA)*	Oxygen usually mixed with air to a final concentration of 30–50%		
	Remifentanil†	Induction infusion	@ 0.5–1 mcg/kg/min × 1–2 min
		Maintenance infusion	@ 0.1–0.35 mcg/kg/min
		10 min before end of surgery, reduce infusion rate	@ 0.05–0.1 mcg/kg/min
		5 min before end of surgery	Infusion off
	Propofol	Induction bolus Maintenance infusion 10 min before end of surgery, reduce infusion rate 3 min before end of surgery	1–1.5 mg/kg @ 60–90 mcg/kg/min @ 20–40 mcg/kg/min Infusion off
	*Steven Shafer, MD. †No residual analgesia: Postop pain management depends on the type of surgery, and analgesic requirements may be substantial. Recommend having fentanyl or meperidine for quick pain relief followed by hydromorphone as a component of multimodal analgesia for prolonged pain relief.		

If **continued muscle relaxation** is required during the above maintenance techniques, several options are available. Always use a nerve stimulator to assess block before bolus redosing.

Short-acting	Gantacurium*	0.2 mg/kg/10–20 min
	Rocuronium	Rocuronium can be rapidly reversed shortly (3 min) after administration (1.2 mg/kg bolus) by using

		sugammadex (16 mg/kg iv).
Intermediate	Vecuronium	0.025 mg/kg/30 min; 1–2 mcg/kg/min infusion
	Rocuronium	0.6 mg/kg/30 min; 5–12 mcg/kg/min infusion
	Cisatracurium	0.2 mg/kg/40 min; 1–2 mcg/kg/min infusion
Long-acting	Pancuronium	0.02 mg/kg/60–90 min

*Not yet (2019) available in the United States.

EMERGENCE

1. Reversal of muscle relaxant	As surgical conditions permit, reverse residual muscle relaxant (when at least one twitch is present in train-of-four) with one of the following: Sugammadex 2 mg/kg actual body weight if twitch 2 in TOF has reappeared, otherwise 4 mg/kg Neostigmine 0.05–0.07 (maximum dose) mg/kg iv + glycopyrrolate 0.01 mg/kg iv Edrophonium 0.5–1.0 (maximum dose) mg/kg iv + atropine 0.015 mg/kg iv
2. Analgesia	If remifentanil was used during surgery, supplemental analgesics will be necessary and should be given promptly after emergence.
3. Nausea prophylaxis	Ondansetron (4 mg iv before emergence) or granisetron (1 mg iv for a longer duration effect). Also, consider adding dexamethasone 4 mg at induction, metoclopramide (20 mg iv before emergence), or aprepitant (40 mg po 1–3 h before induction). The use of droperidol (0.625 mg iv) is unfortunately controversial because of QT prolongation at higher doses. Consider OG tube suction to empty stomach. See Prevention of PONV (below).
4. O_2	d/c N_2O/volatile agents and administer 100% O_2.

5. Suction	Suction oropharynx thoroughly.
6. Extubation	Extubate after protective airway reflexes have returned and the patient is breathing spontaneously and ideally (with adequate analgesia) can follow commands.

LUNG PROTECTIVE VENTILATION

The traditional use of high tidal volume (10–15 mL/kg) mechanical ventilation has been associated with alveolar overdistension → ventilator-associated lung injury → release of inflammatory mediators → pneumonia and multiorgan dysfunction in ICU patients. Recent studies have suggested that a strategy of lung-protective ventilation using a pressure-controlled, volume-directed ventilator mode may improve postop outcomes in a variety of surgical patient populations. The types of surgery most commonly associated with postop pulmonary dysfunction include thoracic abdominal aortic aneurysm, neurosurgery, upper abdominal surgery, and emergency surgery.

Recommendations for lung-protective ventilation in hemodynamically stable patients (without ARDS) at risk for adverse postop pulmonary complications include:

- FiO_2 titrated to keep $SpO_2 > 92\%$ (optimal PaO_2 is patient dependent)
- Tidal volume = 6–8 mL/kg predicted body weight (see Table B-1)
- PEEP = 4–8 cm H_2O (less if venous return is impaired)
- Recruitment maneuvers (CPAP of 30 cm H_2O × 30 sec, prn atelectasis)

In the IMPROVE trial, recruitment maneuvers started immediately after intubation and were standardized as follows:

1. Pressure support ventilation mode
2. PEEP set to 30 cm of water
3. Inspiratory gas flow set to the highest value
4. Duration of the maneuver = 30 sec

Table B-1. Duration of the maneuver = 30 sec

Height (inches)	Female Predicted Body Weight (kg)	Female Tidal Volume (mL) (@6–8 mL/kg)	Male Predicted Body Weight (kg)	Male Tidal Volume (mL) (@6–8 mL/kg)
5′ 0″	45.5	273–364	50	300–400
5′ 1″	47.8	287–382	52.3	314–418
5′ 2″	50.1	301–401	54.6	328–437
5′ 3″	52.4	314–419	56.9	341–455
5′ 4″	54.7	328–438	59.2	355–474
5′ 5″	57	342–456	61.5	369–492
5′ 6″	59.3	356–474	63.8	383–510
5′ 7″	61.6	370–493	66.1	397–529
5′ 8″	63.9	383–511	68.4	410–547
5′ 9″	66.2	397–530	70.7	424–566
5′ 10″	68.5	411–548	73	438–584
5′ 11″	70.8	425–566	75.3	452–602
6′ 0″	73.1	439–585	77.6	466–621

Formula: males, PBW (kg) = 50 + 2.3 (height [inches] – 60); females, PBW (kg) = 45.5 + 2.3 (height [inches] – 60)

Suggested Readings

1. Futier E, Constantin JM, Paugam-Burtz C, et al; IMPROVE Study Group: A trial intraoperative low-tidal-volume ventilation in abdominal surgery. N Engl J Mec 2013; 369(5):428–37.
2. Mills GH: Respiratory complications of anaesthesia.Anaesthesia 2018; 73(Suppl 1):25–33.

MONITORED ANESTHESIA CARE (MAC)

1. Standard monitoring with regular verbal contact.
2. Nasal O_2 (qualitative measurement of respiratory rate, and $ETCO_2$ can be obtained by attaching a sampling catheter to the nasal cannula). The open administration of O_2 should be limited to a maximum concentration of 30% O_2 for procedures above T4 to minimize fire risk.
3. Light-to-moderate levels of sedation (±analgesia) can be maintained using a propofol (25–100 mcg/kg/min) or dexmedetomidine (see below) infusions, with PRN intermittent bolus injections of midazolam (1 mg) or propofol (20–30 mg), or with a remifentanil infusion (0.025–0.07 mcg/kg/min), titrated to effect. Monitor closely for respiratory depression.

4. Alternatively, dexmedetomidine (a α-2 agonist) can produce excellent sedation and analgesia without respiratory depression. The loading dose is typically 1 mcg/kg iv over ~10 min (↓ BP may occur) followed by an infusion of 0.2–0.7 mcg/kg/h.
5. If the initial local anesthetic injection is painful (e.g., retrobulbar block), then a brief period of analgesia, sedation, and amnesia can be induced with

	Advantages	**Disadvantages**
A. Midazolam (0.5–2 mg) ± ketamine (10–20 mg) ± alfentanil 3–7 mcg/kg or remifentanil 0.5 mcg/kg all injected 2–3 min before acute pain	Profound amnesia and analgesia. Usually no apnea, and airway reflexes are maintained. The patient is usually able to cooperate.	Patient not "asleep" Possible ↑ BP and HR
B. Propofol (0.5–1 mg/kg) ± fentanyl (25–50 mcg/kg)	Patient "asleep"	Possible apnea with loss of airway. ↓ BP may occur; patient may become unresponsive.

RAPID-SEQUENCE INDUCTION OF ANESTHESIA (FULL-STOMACH PRECAUTIONS)[1]

1. ↓ Gastric volume/acidity	Ranitidine 50 mg iv at least 30–60 min before induction if possible Metoclopramide 10 mg iv 30–60 min before induction if possible 0.3 M sodium citrate 30 mL po within 15 min of induction
2. Induction	Preoxygenation × 3 min (or until ETO_2 > 90%). Suction must be readily available. Stylet ETT. ± Defasciculate, e.g., rocuronium 3–4 mg iv 1.5–3 min before using succinylcholine. Cricoid pressure (Sellick maneuver) by an assistant (8–10 lb; beware of force transfer to C6 vertebra). Effective cricoid pressure makes laryngoscopy, mask ventilation, and LMA insertion difficult and will not

	eliminate the risk of aspiration. Choice of induction agent depends on patient condition including hemodynamic stability. Options include Etomidate 0.1–0.4 mg/kg (minimal hemodynamic effects) or Ketamine 1 mg/kg (usually ↑BP and HR) For patients better able to tolerate ↓ BP: Propofol 1–2.5 mg/kg + succinylcholine 1.5 mg/kg or rocuronium 1.2 mg/kg (slightly slower but <2 min) for intubation (sugammadex 16 mg/kg can be used for rapid reversal) Lungs may be ventilated while waiting for NMB—avoid airway pressure >20 cm H_2O (to reduce stomach insufflation).
3. Intubation	Intubate only when the patient is fully relaxed. After intubation, watch chest movement and auscultate for equal BBS. ✓ expired CO_2 on monitor. Listen over the stomach. Secure ETT and release cricoid pressure. Pass NG/OG tube and suction stomach contents.
4. Failed intubation protocol	[See Anesthetic Considerations for Cesarean Section, Obstetric Surgery, p. 297]
5. Maintenance	As indicated by patient's condition and type of surgery
6. Extubation	Repeating NG/OG suction is often useful before emergence and extubation. Extubate when patient is awake and has active laryngeal protective reflexes. Postop ICU care may be necessary until safe extubation can be assured.

[1]SPECIAL PEDIATRIC CONSIDERATIONS

1. The same principles apply in children requiring surgery and in those who may have

full stomachs. Consider emptying the stomach with an OG tube before induction ir patients with pyloric stenosis or with high-grade intestinal obstruction following po barium. If iv is placed, continue as indicated previously. If iv access is difficult, O_2/sevoflurane induction with cricoid pressure, and succinylcholine (2–4 mg/kg im) will permit intubation and minimize risks of gastric aspiration.

2. Awake intubation in neonates and sick infants may be the safest method.

PREVENTION OF PONV (ADAPTED FROM GAN ET AL., 2014)

Clifford A. Schmiesing, MD

PONV Risk Factors	Patient-related Anesthetic-related Surgical-related	Female gender Nonsmoking status Hx PONV or motion sickness Volatile anesthetics Nitrous oxide Intra-/postop opiates High-dose neostigmine Duration of surgery Type of surgery	Simple risk score for PONV in adults: assign 1 point for each of the following risk factors—female gender, nonsmoker, hx of PONV, and postop opioids. Risk of PONV: point sum 0 = 10%; 1 = 20%; 2 = 40%; 3 = 60%, and 4 = 80%.
Antiemetics	**Pharmacologic Agents** Serotonin blockers Dexamethasone 4–8 mg iv Droperidol 0.625–1.25 mg iv or Haloperidol 1 mg iv Metoclopramide 10–25 mg iv	**Timing of Administration** End of surgery Postinduction 30 min before end of surgery 30 min before end of surgery 30 min before end of surgery 2–4 h before surgery	Ondansetron 4–8 mg iv or po, granisetron 0.35–1.5 mg iv, dolasetron 12.5 mg iv, palonosetron 0.075 mg iv (long-acting) Adverse effects not seen with single-bolus dose.

	Promethazine 6.25–25 mg iv Scopolamine transdermal patch Neurokinin-1 receptor antagonists	Before surgery	May cause perianal pruritus when given iv to awake patient Minimal risk of QT prolongation, cardiac dysrhythmias, or extrapyramidal reactions at these low doses Can cause anxiety, confusion, or visual changes. 20–25 mg more effective than lower doses Sedating and may cause local tissue damage if iv catheter infiltration occurs May cause sedation, dry mouth, dilated pupils, visual changes, and confusion, especially in the elderly Aprepitant 40–80 mg po. Long-acting
Nonpharmacologic PONV prevention	Acupuncture, acupressure	Before or after surgery	
PONV prevention strategies	↓ Anesthesia-related RFs	Consider regional anesthesia where	

		appropriate. Propofol for induction and maintenance where appropriate ↓ N_2O and volatile agents ↓ Intraop and postop opioids ↓ Neostigmine	
PONV risk stratification and management	Low risk Intermediate risk High risk Very high risk	No prophylaxis → treat PONV when it occurs Choose 1–2 interventions Choose 2 interventions Consider 3–4 interventions	Consider including both short- and long-lasting antiemetics that will be effective post PACU discharge.

VENOUS THROMBOEMBOLISM (VTE) PROPHYLAXIS

Clifford A. Schmiesing, MD

Common patient risk factors for VTE	• Increasing age • Previous VTE or family h/o VTE • Pregnancy and the postpartum period • Obesity • Inherited or acquired thrombophilia • Immobility, lower extremity paresis
Common disease-related risk factors for VTE	• Estrogen-containing oral contraceptives or hormone replacement therapy • Major surgery trauma (major trauma or lower extremity injury) • Cancer (known or occult) • Inflammatory bowel disease • Nephrotic syndrome • Myeloproliferative disorders • Paroxysmal nocturnal hemoglobinuria

VTE Risk Factor Assessment: Caprini Score Worksheet

Venous Thromboembolism Risk Factor Assessment Please Choose All That Apply				
Each Risk Factor Represents 1 Point	**Each Risk Factor Represents 2 Points**	**Each Risk Factor Represents 3 Points**	**Each Risk Factor Represents 5 Points**	**Women Only: Each Risk Factor Represents 1 Point**
☐ Ages 41–60 y ☐ Minor surgery planned (<45 min) ☐ History of prior major surgery (>1 mo) ☐ Varicose veins ☐ History of inflammatory bowel disease ☐ Swollen legs (current) ☐ Obesity (BMI > 25) ☐ Acute myocardial infarction (<1 mo) ☐ Congestive heart failure (<1 mo) ☐ Sepsis (<1 mo) ☐ Serious lung disease including pneumonia (<1 mo) ☐ Abnormal pulmonary function (COPD) ☐ Medical patient currently at bed rest ☐ Other risk factors: _____	☐ Ages 61–74 y ☐ Major surgery (>45 min) ☐ Arthroscopic surgery (>45 min) ☐ Laparoscopic surgery (>45 min) ☐ Previous or present malignancy ☐ Central venous access ☐ Immobilizing leg plaster cast (<1 mo) ☐ Patient confined to bed (>72 h)	☐ Age 75 y or more ☐ History of DVT/PE ☐ Family history of DVT/PE ☐ Positive factor V Leiden ☐ Positive prothrombin 20210A ☐ Elevated serum homocysteine ☐ Positive lupus anticoagulant ☐ Elevated anticardiolipin antibodies ☐ Heparin-induced thrombocytopenia (HIT) ☐ Other congenital or acquired thrombophilia ☐ If yes: Type_____	☐ Elective major lower extremity arthroplasty ☐ Hip, pelvis, or leg fracture (<1 mo) ☐ Stroke (<1 mo) ☐ Multiple trauma (<1 mo) ☐ Acute spinal cord injury (paralysis) (<1 mo)	☐ Oral contraceptives or hormone replacement therapy ☐ Pregnancy or postpartum (<1 mo) ☐ History of unexplained stillborn infant, recurrent spontaneous abortion (≥3), premature birth with toxemia, or growth-restricted infant

POSTOPERATIVE DELIRIUM: PRACTICAL GUIDELINES

Postoperative delirium (POD) can occur in any patient. DSM-5 criteria define delirium as "a disturbance in attention (i.e., reduced ability to direct, focus, sustain, and shift attention) and awareness (reduced orientation to the environment)" that develops over a short period of time and includes impaired cognition not explained by preexisting conditions. POD may be characterized as hyperactive or hypoactive, the latter being more difficult to diagnose. POD has been associated with long-term morbidity including POCD (postoperative cognitive dysfunction) and PTSD (posttraumatic stress disorder). POD usually starts in the recovery room and may persist for several days postop. The complex and often unpredictable interactions of both predisposing and precipitating factors make an accurate preop risk assessment for POD difficult.

RISK FACTORS ASSOCIATED WITH POD INCLUDE:

Preop	• Cognitive impairment • Patient self-assessment of health if fair, poor, or very poor (compared to good or very good) • Functional age greater than 65 years

	• Functional impairments • Dehydration/malnutrition • Significant comorbidities (e.g., CVD, CAD, PVD, DM, PD, anemia, depression/anxiety disorders) • Vision or hearing impairments • Polypharmacy or h/o substance abuse • Emergency surgery
Intraop	• Surgery of long duration • General anesthesia or deep sedation • Hypo or hyperglycemia • Hypotension (SBP < 90 mm Hg)
Postop	• Surgical complications • Hypothermia on arrival in recovery • Poorly controlled pain

Prevention should include when possible the use of fast-track (ERAS) protocols, preop Midazolam for significant anxiety, intraop dexmedetomidine, perioperative multimodal analgesia, and avoidance of deep anesthesia/sedation.

Treatment should include the return of any hearing or vision aids, minimal restraint, frequent reassurance and reorientation, supplemented (if necessary) with low-dose dexmedetomidine (e.g., 0.2 mcg/kg over 2 minutes followed by 0.2 mcg/kg/h infusion) or haloperidol (e.g., 0.25 mg titrated up to 2 mg iv at 30-minute intervals).

In recovery, patients should be screened for POD and if confirmed, treated before discharge. The Nursing Delirium Screening Scale (Nu-DESC) is often used for POD diagnosis (see Fig. B-1 below), but like similar screening tests, its reported sensitivity (32–95%) is quite variable. As usual, other potentially treatable explanations for POD-like Sx (e.g., electrolytes, ventilation, temperature, Sz, stroke, central cholinergic syndrome) should be ruled out.

Features and descriptions	Symptoms Rating (0-2)		
Symptom / Time Period	Midnight - 8 AM	8 AM - 4 PM	4 PM - Midnight
I. Disorientation Verbal or behavioural manifestation of not being oriented to time or place or misperceiving persons in the environment			
II. Inappropriate behaviour Behaviour inappropriate to place and/or for the person; e.g., pulling at tubes or dressings, attempting to get out of bed when that is contraindicated, and the like.			
III. Inappropriate communication Communication inappropriate to place and/or for the person; e.g., incoherence, noncommunicativeness, nonsensical or unintelligible speech.			
IV. Illusions/Hallucinations Seeing or hearing things that are not there; distortions of visual objects.			
V. Psychomotor retardation Delayed responsiveness, few or no spontaneous actions/words; e.g., when the patient is prodded, reaction is deferred and/or the patient is unarousable.			
Total score			

Fig. B-1. The Nursing Delirium Screening Scale (Nu-DESC). Symptoms are rated from 0 to 2 based on the presence and intensity of each symptom, and individual ratings are added to obtain a total score per shift. A score of 2 or more is strongly correlated with the presence of postop delirium.

APPENDIX C: MULTIMODAL PERIOPERATIVE PAIN MANAGEMENT

Roya Saffary, MD and Einar Ottestad, MD

INTRODUCTION

Periop pain management continues to be a challenging aspect of anesthesiology with significant effects on patient satisfaction and clinical outcomes. According to the Centers for Disease Control and Prevention (CDC), about 48 million surgical and nonsurgical procedures were performed in the United States in 2010. A large survey of periop pain management revealed that ~80% of patients experienced acute pain postop, with 86% of those patients characterizing their pain as ranging from moderately to extremely painful. Furthermore, postop pain management was the most common concern of the patients surveyed. Expertise in neuraxial and regional anesthesia, as well as analgesic pharmacology, makes the anesthesiologist the ideal advocate for improving periop pain management.

The Joint Commission has recognized the importance of pain management in reducing periop pain while facilitating improvements in functionality. Poor pain control leads to adverse clinical outcomes, including decreased ability to ambulate with increased risk for thromboembolic events and fatal pulmonary embolism. Inadequate pain control following abdominal and thoracic surgeries may → splinting, atelectasis, and pneumonia.

The neuroendocrine stress response to surgery involves the release of stress hormones and catecholamines, which lead to many deleterious clinical effects and outcomes. These include weight loss, fatigue, immunosuppression, thromboembolism, hypercoagulability, dysrhythmias, urinary retention, and impaired pulmonary function. Furthermore, ongoing, uncontrolled pain in the postop period is a risk factor for chronic postsurgical pain. The continuous nociceptive barrage to the spinal cord and brain can lead to central sensitization, or "windup," which is thought to result in persistent pain beyond the acute recovery period. As we learn more about periop pain management, we can minimize pain while reducing morbidity and mortality in our surgical patients.

Opioids remain the primary treatment for postop pain. However, the recent opioid epidemic and the clinical application of enhanced recovery after surgery (ERAS) protocols have emphasized the potential risks and weaknesses of opioid-dominated

treatment. In addition to respiratory depression, opioids can lead to dependence, opioid-induced hyperalgesia, decreased testosterone levels, depressed immune function, lack of functionality, slowed recovery, and morphologic brain changes, particularly in patients with a preexisting chronic pain condition and/or opioid tolerance. In contrast to traditional pain management, ERAS protocols utilize an opioid-sparing approach by incorporating other medication families. Initially introduced to standardize key aspects of periop management including pain management for colorectal surgery, ERAS has since been applied to other surgical subspecialties, including gynecologic and orthopedic surgeries. Studies have shown that this approach significantly improves patient comfort and overall recovery and may even decrease hospital stay.

MULTIMODAL ANALGESIA

The concept of multimodal analgesia is based on the understanding that no single analgesic medication targeted to one receptor system allows for sufficient postop pain control. Therefore, rather than relying solely on opioids, ERAS protocols utilize agents that act on several receptor systems in the nociceptive pathway often combined with neuraxial or regional techniques to provide more effective postop analgesia. A number of medication classes have been effectively used for this purpose throughout the periop period. Please refer to Table C-1 for an outline of medication classes and examples.

Table C-1. Pain Medication Classes

Class	Examples
Mu opioid receptor agonists	IV or po morphine; sublingual sufentanil
Mixed COX inhibitors	IV or po ketorolac
COX-2 inhibitors	PO celecoxib
Central COX inhibitors	IV or po acetaminophen
Sodium channel blockers	IV lidocaine; po mexiletine
Multisite effects including Ca^{++} channel modulation	PO gabapentin or pregabalin
SNRIs	PO duloxetine or venlafaxine
TCAs	PO desipramine or nortriptyline

Alpha-2 agonists	Patch clonidine or IV dexmedetomidine
NMDA antagonists	IV ketamine; magnesium
Inhaled low-dose anesthetic	Methoxyflurane (experimental)

Postop pain management and patient recovery are most successful when an integrated, multispecialty, rehabilitation-orientated approach is utilized. Input from surgeons, anesthesiologists, rehabilitation specialists, nursing, pharmacy, and other key health care providers is necessary for this to occur. Best outcomes require that the patient be given appropriate preop education, excellent periop nociceptive blockade, attenuation of the neuroendocrine stress response, postop exercise, and early enteral nutrition.

PREEMPTIVE ANALGESIA

Preemptive analgesia refers to the administration of antinociceptive agents especially during the pre- and intraop periods to prevent the formation of central sensitization caused by incisional and inflammatory injuries. The benefit of preventing sensitization is a reduction in the patient's risk of developing chronic pain after surgery. It has been demonstrated clinically that preincisional analgesics help improve postop pain control. A number of agents have been studied in this context with promising results, including lidocaine, ketamine, neuraxial anesthesia, peripheral nerve blockade, topical anesthetics, peripheral opioid, gabapentin, and central opioid agonists. ERAS protocols often recommend oral administration of nonopioid analgesics in the preop area, including NSAIDs, gabapentin, and acetaminophen.

THE NEW ANALGESIA PARADIGM

This new paradigm, with ERAS at the forefront, emphasizes the preemptive and multimodal administration of a variety of analgesic classes through various routes of administration, including iv, po, neuraxial, peripheral nerve exposure, and topical agents. The traditional approach using mainly short-duration opiates has been shown to be suboptimal and inferior to providing the patient with a more comprehensive periop pain management regimen. In addition to improved pain control, this approach leads to less reliance on opioids and their associated side effects, as well as reduced risk of sensitization and development of chronic postop pain. When used in conjunction with a structured postop rehabilitation program, these techniques can lead to decreased patient morbidity and mortality, increased patient satisfaction, decreased recovery time, and shorter hospitalization (Table C-2).

Table C-2. An Example of Multimodal Analgesia for a 70-kg Patient Without Specific Drug Contraindications, Undergoing Major Surgery		
Preinduction	Systemic	Ibuprofen 800 mg or celecoxib 200 mg (decreased bleeding risk) po 30–60 min before induction and/or acetaminophen 1000 mg po 30–60 min before induction and/or gabapentin* 600–1200 mg or pregabalin* 150–300 mg po 60 min before induction
	Regional	Neuraxial analgesia (e.g., epidural or spinal opiates) or regional/peripheral nerve blocks
Preincision	Systemic	Fentanyl 100–250 mcg iv and/or ketamine 0.5 mg/kg iv bolus + 0.25 mg/kg/h infusion during surgery (especially useful in opioid-dependent patients)
	Local	Incision-site local anesthetic infiltration
Intraop	Systemic	IV opiates (e.g., fentanyl, hydromorphone)
		Lidocaine infusion 1–3 mg/kg/h
		Acetaminophen 1000 mg IV if not given preop
		Magnesium sulfate infusion 1 g/h
		Continuous regional anesthetic
Postop	Systemic	IV opiates (e.g., fentanyl, hydromorphone) bolus and PCA
		Ketorolac 15 mg iv q6h or ibuprofen 200–800 mg po q8h or celecoxib 100 mg bid
		Acetaminophen 650–1000 mg q6–8h

*Recent meta-analyses suggest that gabapentinoids may be associated with an increased incidence of adverse events (e.g. sedation, respiratory depression) while providing minimal opioid-sparing effects.

STANDARD ADULT POSTOP PCA ORDER

Typical orders	1. Call anesthesiologist with any questions about PCA. 2. Check respiratory rate q1h while PCA is in use. 3. Call anesthesiologist if respiratory rate <10/min. If rate <6/min, treat with naloxone 0.4–0.8 mg iv push (may repeat q2–3min to 2 mg), and assist ventilation while waiting for anesthesiologist. 4. Encourage patient to ambulate 4–6 h after surgery (unless contraindicated).

	5. After PCA d/c'd, start po pain medications (per surgeon). 6. If patient required a large loading dose, the PCA lockout dose may need to be increased. Expect patient to need about 1/3 loading dose q h. Change PCA dose or lockout time to permit this dosing.	
Analgesics	Morphine	1–2 mg q10–15min
	Hydromorphone	0.2–0.4 mg q10–12min
	Fentanyl	10–25 μg q8–10min*
*Very short-acting might need small basal infusion dose.		

Epidural Analgesia*

Lumbar Epidural		Thoracic Epidural	
Morphine Bolus	**Hydromorphone Bolus**	**Morphine Bolus**	**Hydromorphone Bolus**
2–4 mg	0.4–0.8 mg	1–2 mg	0.1–0.4 mg
Morphine infusion	**Hydromorphone infusion**	**Morphine infusion**	**Hydromorphone infusion**
0.5–1 mg/h	0.05–0.2 mg/h	0.25–0.5 mg/h	0.1–0.2 mg/h
*Age <65 consider half dosing.			

Special considerations

1. Concentrations of opioids used for epidural infusions (in preservative-free solution):
   - Morphine, 0.15 mg/mL
   - Hydromorphone, 0.05 mg/mL

Epidural Anesthesia/Postop Analgesia*

Surgical Site	Epidural Catheter Location	Initial Bolus of 0.5% Bupivacaine	Infusion Rate of 0.125% Bupivacaine
Thoracic or upper abdomen	T6-T8	4–6 mL	4–8 mL/h

Lower abdomen	T10	10 mL	6–10 mL/h
Hip or knee	L2-L3	8 mL	6–10 mL/h
*Divided doses.			

Special considerations

1. iGve initial bolus dose before incision. Then, if patient is hemodynamically stable, give 1/2 bolus dose 30 min before end of surgery.
2. In recovery room, ✓ sensory level. If no sensory block, ✓ whether catheter is functioning with 5–10 mL 2% lidocaine bolus. (✓ vital signs.) If thoracic epidural starts with 2–3 mL, redose with 2 mL q5–10min, up to 10 mL.
3. Start infusions: If catheter is functional, as evidenced by loss of sensation, start local anesthetic + opioid infusions (see table, above).
4. Best results: Local anesthetics and opioids are mixed in line using two separate infusion pumps. Thus, if either causes side effects, one can be stopped without affecting the other.

PATIENT-CONTROLLED EPIDURAL ANALGESIA (PCEA)

Bupivacaine	0.125–0.25% with 3–5 mL bolus q12–20min
Fentanyl	2–4 mcg/mL

Special considerations

1. For thoracic epidural, decrease all doses by one-third; if high thoracic, decrease by one-half.

TYPICAL ORDERS FOR POSTOP EPIDURAL/SPINAL ANALGESIA

I. EPIDURAL MEDICATIONS

_____ **1. Epidural Infusion—Opiate**

- ❑ Hydromorphone (Dilaudid) 0.05 mg/mL concentration @_____mg/h =_____mL/h
- ❑ Morphine sulfate 0.15 mg/mL concentration @_____mg/h =_____mL/h
- ❑ Fentanyl (Sublimaze) 10 mcg/mL concentration @_____mcg/h =_____mL/h
- ❑ Range: May vary infusion between_____/h and_____/h prn pain.

_____ **2. Epidural Infusion—Anesthetic**

- ❑ Bupivacaine 0.125% concentration @_____mL/h
- ❑ Bupivacaine 0.25% concentration @_____mL/h
- ❑ Turn off bupivacaine on POD # 1 @ 5 a.m.

_____ **3 Epidural Bolus—Opiate**

- ❑ Hydromorphone (Dilaudid)_____mg q_____h in 10 mL preservative-free NS (PFNS)
- ❑ Morphine sulfate_____mg q_____h in 10 mL PFNS

_____ **4. Breakthrough Pain**

- ❑ Fentanyl PCEA 10–20 mcg q10min or Bupi 0.125% with fentanyl 4 mcg/mL 3 mL bolus q10min
- ❑ Call MD if > 2 doses in [2] h.
- ❑ Ketorolac (Toradol) [15] mg iv q6h × [3] d (for a maximum of 12 doses)

II. NURSING CARE

_____ **1. Vital Signs**

- ❑ For opiates: T, P, BP q4h; RR q2h; then q8h, if stable.
  Continuous O_2 sats × 24 h; then d/c if O_2 sats >90% on room air.
- ❑ For anesthetics: BP & P q2h; then q4h, if stable.
  Orthostatic BP before ambulation × 24 h.

_____ **2.** Label tubing, pump, infusion as "epidural." Place sign over bed; cover "Y" ports on tubing.

_____ **3.** Place naloxone (Narcan) and syringe at bedside.

_____ **4.** Administration of any additional opiates, sedatives, or antiemetics must be approved by anesthesiologist.

_____ **5.** Assess patient's pain (0–10 scale: 0 = no pain; 10 = worst pain imaginable) and level of sedation (awake, drowsy, asleep, unresponsive), along with VS.

_____ **6.** d/c Epidural Protocol when epidural d/c'd.

III. SIDE EFFECTS MANAGEMENT

_____ **1. Respiratory depression:** For RR < 6 or O_2 sat <86% (on two separate occasions <5 min apart):
Administer naloxone (Narcan) 0.1–0.2 mg iv STAT; may repeat, to total of 0.6 mg.
Administer O_2 10 L/min via nonrebreathing mask. TURN OFF INFUSION. CALL ON-CALL MD STAT.

_____ **2. Excessive somnolence/sedation:**
Administer naloxone (Narcan) 0.1–0.2 mg iv STAT; may repeat, to total of 0.6 mg.
Administer O_2 10 L/min via nonrebreathing mask. TURN OFF INFUSION. CALL ON-CALL MD STAT.

_____ **3. Nausea/Vomiting:**

- ❑ Metoclopramide (Reglan) [*10 mg*] iv q4–6h prn
- ❑ Ondansetron [*4 mg*] q6h prn
- ❑ Nalbuphine (Nubain) [*2.5–5.0 mg*] iv q4h prn

_____ **4. Pruritus:**

- ❑ Nalbuphine (Nubain) [*2.5–5.0 mg*] iv q2–4h prn
- ❑ Diphenhydramine (Benadryl) [*10–25 mg*] iv q4h prn

Suggested dosage shown in brackets [–]

APPENDIX D: STANDARD PEDIATRIC ANESTHETIC MANAGEMENT

Birgit Maass, MD, and Brenda Golianu, MD

Standard Pediatric Monitors (Noninvasive)	
Blood pressure (BP)	
Capnometry/capnography	Measurement of $ETCO_2$ display of waveform
Gas analyzer (e.g., Raman, IR, or mass spectroscopy)	Measurement of respired gases and anesthetics
Electrocardiogram (ECG)	5-lead preferred
Esophageal or precordial stethoscope	Breath and heart sounds monitored; dysrhythmias detected
Nerve stimulator	Monitor status of neuromuscular blockade.
Oxygen analyzer	Measurement of FiO_2
Pulse oximetry	Measurement of O_2 saturation; two pulse oximeters in neonates—one preductal; one postductal
Temperature	Nasal, esophageal, rectal, skin, or Foley
Visual observation of patient	Skin color, pupils, temperature, edema, sweating, movement
Ventilator function monitors	PIP, TV, disconnect alarm, etc.

Standard Preop Fasting (NPO) Guidelines
• All solid foods should be withheld after midnight or 6–8 h before procedure. Fatty (fried) solids, 8 h • Nonclear liquids (e.g., milk, infant formula, orange juice) should be withheld 6 h prior to surgery. • Breast milk has a relatively short transit time through the stomach and may be given up to 4 h prior to surgery.

• All clear liquids should be discontinued 2 h prior to scheduled surgery.

⋆NB: the following sections are guidelines only. Specific drugs and drug dosages should be individualized, based on the physiologic and pharmacologic status of the patient, including factors such as age, weight, medication, and concurrent diseases.

ASSESSMENT OF FLUID STATUS

Preop fluid management is essential and includes assessment of preexisting dehydration before fasting, minimization of NPO status, and estimation of any ongoing fluid or blood losses before surgery.

In addition to an historical assessment of recent oral intake, enteral nutrition, iv or other source of fluid administration, and recent urine output, a physical examination will include evaluation of vital signs, level of alertness, skin turgor, and the fontanelle status in infants. Laboratory analysis (e.g. electrolytes, Hb) may be useful.

Dehydration can be classified as mild (50 ml/kg, 5% body weight loss), moderate (100 ml/kg, 10% body weight loss) and severe (150 ml/kg, 15% body weight loss). For severe dehydration, it may be difficult to obtain iv access, and intraosseous access may be needed. In emergency surgery, optimizing fluid status will need to occur concurrently with surgery. For neonates and some infants, concurrent administration of dextrose may be needed.

Intraop volume management is guided by several parameters: preop fluid status, maintenance requirements during surgery, "third-space" fluid loss, urine output, and blood loss. Alterations in body temperature, patient positioning, and the use of vasopressors, vasodilators or other agents will affect assessment of volume status.

Positioning of the patient.

Surgical requirements (e.g. volume loading before reperfusion of transplanted organ) must also be considered

Postop volume management requires assessment of any ongoing bleeding, extracellular fluid shifts, and urine output. Volume assessment can be affected by administration of opioids, regional anesthesia, and patient comfort.

PREMEDICATION

- In general, patients <8 mo of age do not need sedative premedication. Infants <1 mo

and premature infants may require atropine 10–20 mcg/kg iv or 20 mcg/kg im or glycopyrrolate 5–10 mcg/kg iv before intubation. Older children (8 mo to 10 yr) can be premedicated successfully by using po midazolam (0.5–0.75 mg/kg with maximum of 20 mg) in syrup, grape Kool-Aid, or cherry-flavored acetaminophen elixir (10–15 mg/kg po) 20–30 min before surgery.

- Another option for premedication is intranasal dexmedetomidine 1–2 mg/kg or intranasal midazolam 0.2–0.4 mg/kg via atomizer.
- For patients >35 kg, po lorazepam (0.03–0.05 mg/kg) or diazepam (0.1–0.15 mg/kg) may be given 60 min before surgery with a sip of water if needed. Distraction with computer games, movies, and interaction with child life personnel has been used successfully.

Parental presence may not decrease the need for premedication but has been shown to increase parental satisfaction.

INDUCTION TECHNIQUES

Preinduction	1. ✓ anesthesia machine, suction, airway equipment, drugs 2. Attach monitors and verify function. 3. Premedication: <6 mo—consider atropine 0.01–0.02 mg/kg iv or glycopyrrolate 5–10 mcg/kg iv before laryngoscopy to prevent vagally mediated bradycardia.
IV induction	Indicated in cases with a difficult airway, in full-stomach considerations, in complex medical conditions, and in older children (>10). If iv induction is planned, topical anesthesia, such as Synera® (lidocaine/tetracaine) patch (30 min), EMLA® (lidocaine/prilocaine, 1 h), and ELA-Max® (liposomal lidocaine, 20 min), may be applied prior to iv placement.
Induction	**Routes of administration:** 1. IM: ketamine hydrochloride 3–5 mg/kg (with atropine 0.02 mg/kg or glycopyrrolate 0.01/mg/kg and 0.05–0.1 mg/kg midazolam) 2. IV: propofol 2–3 mg/kg 3. Inhalational: sevoflurane (MAC = 3.3% for neonates and younger infants, 2.5% for older infants and children) in N_2O (up to 70%)/O_2. Increase inspired concentration of

	sevoflurane incrementally every three breaths (up to 8%). Monitor BP and HR closely.
Muscle relaxation	1. Rocuronium: 0.6–1 mg/kg iv; 1 mg/kg recommended for rapid-sequence induction. If airway concerns exist, consider awake intubation and use of succinylcholine. 2. Succinylcholine: 1–2 mg/kg iv. May be useful for rapid-sequence intubations, especially if airway concerns exist. Succinylcholine 2–4 mg/kg im should always be available for urgent administration if needed for treatment of laryngospasm during induction that has not responded to CPAP and deepening of inhalational anesthesia. It may cause bradycardia; consider concomitant atropine (20 mcg/kg). 3. Vecuronium: 0.1 mg/kg iv 4. Deep sevoflurane anesthesia
Laryngoscope	**Blade** — **Age** Miller 0 — Neonate Miller 1 — 6–9 mo Wis-Hipple 1.5 — 9 mo–3 yr Macintosh 2 — 1–5 yr Macintosh 3 or Miller 2 — >5 yr
	*Succinylcholine may trigger MH or hyperkalemia with cardiac arrest in susceptible patients; therefore, many pediatric anesthesiologists avoid the use of succinylcholine especially in male patients under 6 yr unless airway concerns exist. Sugammadex is able to reverse paralysis with rocuronium at any time; rocuronium is becoming more popular as an agent for a rapid-sequence induction in pediatric patients.

TYPICAL ETT SIZE AT DIFFERENT AGES

Age	Wt	Uncuffed ETT Size	Cuffed ETT Size	LMA Size
Premature Newborn	1–3 kg 3–4 kg	2.5 or 3.0 3.5	n/a 3.0	1 (<5 kg)
≤6–8 mo	6–8 kg	3.5 or 4.0	3.0 or 3.5	1.5 (5–10 kg)
≤8–16 mo	10–12 kg	4.0 or 4.5	3.5 or 4.0	2 (10–20 kg)
2–3 yr	13–15 kg	4.5	4.0 or 4.5	2 (10–20 kg)
6 yr	20	Formula (uncuffed tubes): 4+ (age/4) = ETT size (to allow for a slight leak when positive pressure is applied). For cuffed tubes, use 0.5 size smaller and inflate as necessary to attain leak of 20–30 cm H_2O.		2.5 (20–30 kg)
9 yr	30 kg			3 (30–50 kg)
12 yr	40 kg			3 (30–50 kg)

NB: these ETT sizes are guidance only. ✓ ET placement of tube by auscultation of breath sounds bilaterally. ✓ depth of carina by auscultation over left axilla as ETT is slowly advanced. Withdraw and secure ETT 2 cm from carina. Positive pressure leak between 20 and 30 cm H_2O is desirable to prevent airway tissue necrosis due to inadequate perfusion. Leaks <20 cm may result in volume loss and difficulty in providing appropriate ventilation during critical phases intraop or postop. Conversely, leaks >30 cm H_2O may carry a higher risk of subglottic edema and/or stenosis. Consider length of case, difficulty of placing ETT, and adequacy of ventilation. A throat pack may assist in decreasing the leak if tube exchange is not desired.

In the past few years, mostly cuffed ETT are used in the OR in order to minimize need for tube exchange and optimize ventilation. This has not been associated with an increased risk of stridor; however, care should be exercised if N_2O is utilized in long cases, as it will cause an increase in cuff inflation pressure.

MAINTENANCE TECHNIQUES

Inhalational anesthesia only	30–100% O_2 + 0–70% N_2O. In preemies and for cases where N_2O is contraindicated, air should be used to lower FiO_2. + Sevoflurane or isoflurane, titrated to effect Consider warming and humidifying all gases for long cases. Warm room to 75–80°F for infants, 70–75°F

	for children.	
Balanced anesthesia	30–100% O_2 + 0–70% N_2O + ~0.5% isoflurane or propofol (50–250 mcg/kg/min) **TIVA**—propofol 100–250 mcg/kg/min, + remifentanil 0.05–0.2 mcg/kg/min. Consider including amnestic agents: midazolam and low-dose inhalational agents (e.g., sevoflurane, isoflurane). Dexmedetomidine 0.5–2 mcg/kg/h + remifentanil 0.05–0.1 mcg/kg/min Ketamine 0.2–1.5 mg/kg/h + Morphine (0.05 mg/kg/h) or fentanyl (1–3 mcg/kg/h) + hydromorphone 2 mcg/kg/h + Consider acetaminophen PR 30–40 mg/kg or iv 10–15 mg/kg for pain control. Temperature monitoring; forced-air warming; fluid warming if volume/blood/resuscitation is expected Fluid requirements LR/NS at maintenance: 0–10 kg = 4 mL/kg/h +11–20 kg = 2 mL/kg/h +>20 kg = 1 mL/kg/h (e.g., 25 kg = 65 mL/h) If continued muscle relaxation is required during the above maintenance techniques, several options are available. Always use a nerve stimulator to assess block before redosing. Neonates may demonstrate delayed return of neuromuscular function.	
Intermediate	Rocuronium (most commonly used)	0.6 mg/kg → 30 min 1 mg/kg for rapid-sequence induction → onset in 1 min, lasts 45–60 min
Vecuronium	0.1 mg/kg → 25–30 min	

EMERGENCE

1. Reverse muscle relaxant	As surgical conditions permit, reverse residual muscle relaxant (when at least one twitch is present in train-of-four) with one of the following: • Neostigmine 0.05–0.07 (maximum dose) mg/kg iv + glycopyrrolate 0.01 mg/kg iv or sugammadex: for rocuronium and vecuronium • A dose of 4 mg/kg is recommended if spontaneous recovery of the twitch response has reached 1–2 posttetanic counts (PTC) and there are no twitch responses to train-of-four (TOF) stimulation. • A dose of 2 mg/kg is recommended if spontaneous recovery has reached the reappearance of the second twitch (T2) in response to TOF stimulation for rocuronium only. • A dose of 16 mg/kg is recommended if there is a clinical need to reverse neuromuscular blockade soon (~3 min) after administration of a single dose of 1.2 mg/kg of rocuronium. • The efficacy of the 16-mg/kg dose following administration of vecuronium has not been studied. • NB: Sugammadex may decrease the effectiveness of hormonal contraceptives for up to 7 d.
2. Nausea prophylaxis	Ondansetron 0.1 mg/kg iv and/or metoclopramide 0.1 mg/kg iv (~1 h before emergence). Dexamethasone 0.1 mg/kg can be considered (avoid in oncology patients due to special protocols). TIVA. A scopolamine patch (e.g., one patch if >15 kg) may be useful in selected patients with h/o severe PONV although no safe/effective dose has been established by the manufacturer.
3. O_2	d/c N_2O/volatile agents and administer 100% O_2.
4. Suction	Suction oropharynx thoroughly.
5. Extubation	Laryngeal spasm is common in children; therefore, it is common practice to extubate them when they are awake, moving all limbs, and breathing adequately. Infants and children with full stomachs or difficult airways must be extubated when they are fully

awake. Deep extubation on 1.5–2 MAC sevoflurane or on propofol infusion is also common, except in patients <1 yr, moderate to severe sleep apnea, full stomach, or difficult airway. The pharynx and stomach should be suctioned thoroughly prior to extubation. If laryngeal spasm occurs, Rx with 100% O_2 and CPAP or PPV. If spasm fails to resolve and hypoxemia occurs, give succinylcholine 0.1–0.5 mg/kg and administer PPV. Consider reintubation if hypoxemia fails to resolve quickly. Consider atropine 0.01–0.02 mg/kg before succinylcholine, to preempt bradycardia.

PEDIATRIC EPIDURAL ANESTHESIA

Epidural anesthesia may be combined with GA for infants and children undergoing surgery involving the lower extremities, abdomen, chest, or spine. Single-dose ("single-shot") techniques may be used, or epidural catheters may be placed for longer procedures and to facilitate postop epidural analgesia (see below). Ropivacaine 0.1–0.2% ± 1:200K epinephrine or bupivacaine 0.25% ± 1:200K epinephrine is most commonly used intraop. For patients admitted following surgery, opioids (e.g., hydromorphone) are generally added, together with ropivacaine or bupivacaine 0.1% (see Appendix E). Use saline-filled syringe for loss of resistance to minimize chances of VAE.

TECHNIQUES AND DOSAGES

1. Caudal

- Single shot: 22-ga iv catheter is inserted via sacrococcygeal membrane. Usually only performed for age <6 yr.
- A test dose with 0.1 mL/kg (max 3 mL) lidocaine or bupivacaine + epinephrine 1:100K or 1:200K is given. (If epidural catheter is used, add 0.8 mL to test dose volume due to dead space volume of catheter.)
- Initial dose: 0.5 mL/kg for lower extremity/perineal/genital procedures, 1.0 mL/kg for abdominal procedures (max 15 mL).
- Catheter technique: 18-ga iv catheter is used; in patients <10 kg, first dilate the epidural space with 5–10 mL NS; then, a 20-ga epidural catheter may be inserted through 18-ga iv catheter and advanced so that the tip is located near the level of incision (e.g., ~17 cm from the skin to T4 in infant). If resistance is met, it may be necessary to pull the catheter back slightly, together with the needle (to avoid

shearing catheter), or repeat procedure. The tip of the catheter should be visualized with ultrasound or via x-ray with 0.5–1 mL of contrast. (If epidural catheter is used, add 0.8 mL to test dose volume due to dead space of catheter.)

2. LUMBAR

- 18-ga epidural needle is inserted via L3-L4 or L4-L5 interspace for single-sho injection or placement of 20-ga epidural catheter.
- Use loss-of-resistance technique with fluid-filled syringe (air may cause VAE).
- Good estimate of depth to epidural space is 1 mm/kg, up to ~30 kg.
- Catheter should be threaded 3–4 cm beyond the tip of needle.
- A test dose with 0.1 mL/kg lidocaine or bupivacaine + epinephrine 1:200K is given, max 3 mL. (If epidural catheter is used, add 0.8 mL to test dose volume due to dead space of catheter.)
- Initial dose: 0.5 mL/kg for lower abdominal procedures, 1.0 mL/kg for upper abdominal and thoracic procedures

3. THORACIC

- The technique described for lumbar epidural catheter placement may be used between T6 and T12 in children.
- A test dose with 0.1 mL/kg lidocaine or bupivacaine + epinephrine 1:100K or 1:200K is given, max 3 mL. (If epidural catheter is used, add 0.8 mL to test dose volume due to dead space of catheter.)
- Initial dose: 0.5 mL/kg
- Local anesthetic–dosing guidelines same as above (note that volume will be ~1/3 less than with caudal approach).
- Erector spinae plane block:

Most recently, erector spinae catheters have emerged at a safe alternative to central neuraxial blockade for major pediatric surgeries. Though still described primarily via case studies, these catheters hold promise as a simpler and safer alternative to thoracic epidural or paravertebral blocks, as the site can be easily visualized with sonography and is distant from the neuraxis, pleura, and major vascular structures. Catheter placement may be bilateral if warranted by the surgical incision. Dosing is accomplished by alternating hourly boluses via R and L catheters.

For indwelling catheter techniques, hourly maintenance doses of half the initial dose may be given. For continuous infusion, maximum rate for ropivacaine and bupivacaine is 0.5 mg/kg/h (0.3 mg/kg/h for neonates).

PEDIATRIC SPINAL ANESTHESIA AND ANALGESIA

Spinal anesthesia is used primarily for procedures such as inguinal herniorrhaphy in former preterm infants at risk for postop apnea following GA. By avoiding GA, the incidence of postop apnea is reduced, but not eliminated.

After standard monitors are applied, the infant is placed in a supine or lateral decubitus position. Care is taken to avoid neck flexion, which may cause airway obstruction. The skin is infiltrated with 1% lidocaine using a 27- or 30-ga needle. Lumbar puncture is performed with a 22-ga 1.5-inch spinal needle to an average depth of 1.5 cm from the skin. The most commonly used local anesthetic for spinal anesthesia in infants is tetracaine 1.0%, mixed with an equal volume of 10% dextrose in a dose of 0.8–1.0 mg/kg. Epinephrine 1:1000 0.01 mL/kg is added. This dose usually provides adequate anesthesia for 90–120 min for inguinal herniorrhaphy. Little change in BP or HR occurs in infants <6 mo of age.

Complications include high spinal anesthesia requiring tracheal intubation. PDPH is very uncommon in children <12 yr of age and probably rare in infants.

APPENDIX E: MULTIMODAL PEDIATRIC POSTOPERATIVE PAIN MANAGEMENT

Genevieve D'Souza, MD, Julie Good, MD, and Brenda Golianu, MD

INTRODUCTION

Traditionally, children have been undermedicated for their pain because of difficulty with assessment, concerns for safety, and lack of understanding of the physiologic consequences of untreated pain. There is now strong evidence that it is not only safe but also beneficial to treat children's procedural pain. For example, infants have adverse behavioral cardiorespiratory and neuroendocrine responses to pain, which improve when appropriate analgesia is administered.

Pain assessment	Unlike most adults, infants and children <7 yr have difficulty understanding and using a Visual Analog Scale (VAS). A frequently used tool for assessing pain in children 3–7 yr old is the Wong-Baker Faces Scale (Fig. E.1). For infants and nonverbal children, observational scales that rely on behavioral and/or physiologic parameters are often used (e.g., the FLACC Pain Scale, Table E.1, PIPP, NIPS, CHEOPS, CRIES, as well as appropriate translations). The "gold standard" of pain measurement is to solicit a direct subjective report from the child whenever possible.
Oral medications	For simple outpatient procedures, such as hernia repair, circumcision, or closed reduction of a fracture, a weak oral opioid, in combination with acetaminophen, is appropriate. Care must be exercised in the use of opioids for management of pain in outpatients following tonsillectomy due to risk of hypoventilation and airway obstruction, especially in patients with severe sleep apnea.
Intravenous medications	**Patient-controlled analgesia (PCA)** can be considered in patients >5 yr who are expected to

	remain hospitalized overnight, especially in those who are unlikely to tolerate oral intake during the initial hours after surgery. For younger children, a **nurse-controlled analgesia (NCA)** can be employed. When the patient begins oral medications, d/c the basal rate but continue to provide the lockout dose for several more hours to be sure that the child is tolerating the oral medication. For opioid-related side effects such as nausea and vomiting, ondansetron can be added (0.1 mg/kg q6h to maximum of 4 mg q6h), and for pruritus, diphenhydramine (0.5 mg/kg q6h max 50 mg), or nalbuphine (0.05 mg/kg q6h max 20 mg), especially effective for epidural opioid-related pruritus. For respiratory depression, naloxone can be carefully titrated beginning at 0.001 mg/kg q1–2min as needed to restore adequate respiratory effort and wakefulness. Care must be taken, as naloxone will have a short half-life (10–15 min), and respiratory depression may recur. Reversal of analgesia may also occur if naloxone is administered for treatment of pruritus or respiratory depression.
Adjuvant medications	In addition to opioids, several adjuvant medications are useful in the periop period. **Lorazepam** (Ativan) 0.001 mg/kg iv q6h is useful in preventing spasms and lessening fear in an unfamiliar environment. It is important to remember that lorazepam has a half-life of up to 16 h, and doses can be additive. Another useful adjuvant is **ketorolac** 0.5 mg/kg, up to a maximum of 30 mg loading dose, followed by 0.5 mg/kg (up to 15 mg) q6h, up to 72 h. Ketorolac is not recommended in patients with poor renal function or following surgeries where there is a large bleeding surface or complex bone repair. Ketorolac has been shown to cause delay in bony fusion in animal models, but conflicting information has been presented in humans. It also has been reported to cause acute renal failure with prolonged use and is not recommended for use in bariatric patients due to

	its potential adverse impact on renal function. Given these concerns, it is helpful to observe hydration status, plt count, and Cr, and discuss the use of this medication with the surgical team. Other adjuvants to consider include **acetaminophen** iv or po (10–15 mg/kg/dose q6h, maximum 650 mg). Medications to manage side effects, such as pruritus, N/V, constipation, and respiratory depression, are presented in detail on the PCA order form. **Gabapentin** (15 mg/kg po, maximum 300 mg po tid) or pregabalin (2 mg/kg po) preop, followed by gabapentin 5 mg/kg po postop 3×/day for 5 days or **pregabalin** 1 mg/kg po, maximum 150 mg po bid postop for 5 days has been shown to decrease opioid requirement postop and should be considered for major surgeries. **Celecoxib** (2 mg/kg/dose, maximum 100 mg po bid twice a day for 5 days) can also be considered instead of ketorolac if the surgeon allows. Ketamine (0.1–0.3 mg/kg/h iv) may also be used as an adjuvant, though studies have not found a postop opioid-sparing effect.

Figure E.1 Wong-Baker Faces Scale used in pain assessment in children (and other patients developmentally from 3 to 7 years old). The higher the score, the greater the child's pain. (Courtesy of the Wong-Baker FACES Foundation (2019). Wong-Baker FACES® Pain Rating Scale. Retrieved Aug 7, 2019 with permission from http://www.WongBakerFACES.org. Originally published in Whaley & Wong's Nursing Care of Infants and Children. © Elsevier Inc.)

Epidural pain management	In children, it is generally considered safer to place epidurals after induction of GA to avoid movement

during placement. For children 0–12 mo, a **caudal technique** can be used. The patient is placed in the lateral decubitus position, the caudal anatomy is identified, and an 18-ga iv catheter is used to enter the caudal space. The catheter is advanced and aspirated. The space is then dilated with 5–8 mL of preservative-free NS. A 20-ga epidural catheter is then advanced to the desired location or until obstruction is felt (~10–15 cm). The catheter tip may be visualized using ultrasound or nerve stimulation, if available. The catheter is taped securely with a moisture-resistant dressing, as it can easily become dislodged with regular activity. A test dose is given (lidocaine 1.5% with 1:200,000 epinephrine 0.1 mL/kg + 0.8 mL for the dead space of the catheter). **Lumbar** and **thoracic epidurals** can be placed in children >10–12 mo or earlier in experienced hands. **Contraindications** for epidural catheters include infection at the local site, coagulopathy, low plt, sepsis, progressive neurologic deficit, and refusal of patient or parent.

Epidural placement should be checked by syringe aspiration before starting the infusion. Return of any bloody fluid or >0.5 mL clear aspirant necessitates further evaluation before use of the catheter for pain control. Patients with indwelling epidural catheters may receive postop analgesia with either continuous infusion or automatic programmed intermittent epidural bolus (PIEB), which delivers the full hourly rate at once each hour on schedule.

Continuous infusion can be used alone or with intermittent bolus dosing (**patient-controlled epidural analgesia** [PCEA]). Similar to PCA, PCEA can be used in ages = 5–7 yr. Typical starting infusions are described in the table below.

Medication dosage will depend on patient's age, location of surgical pain, catheter insertion level, and catheter tip location. If the patient has an extra-wide

	incision or other areas of discomfort, or if tolerant to opioids, the anesthesiologist may choose to run the epidural infusion at a fixed rate with local anesthetic alone (ropivacaine 0.1% or bupivacaine 0.1%) and provide the patient with an IV PCA with bolus (lockout) dose only (i.e., no continuous or basal rate). A bolus dose equivalent to the hourly volume of infusion may be given when a patient is uncomfortable. Increase the infusion by 10% to maintain the new level of analgesia. Infusion should not exceed 0.3 mg/kg/h in infants under 6 mo or 0.5 mg/kg/h in older patients. If inadequate analgesia persists after two dosing increases, it may be appropriate to abandon this form of treatment in favor of systemic analgesia. Do not leave a patient in pain for an extended period of time trying to "fix" an epidural catheter. If in doubt, check catheter placement, then bolus catheter with 2% lidocaine w/ 1:200,000 epi 0.1 mL/kg to determine if a level is able to be obtained.
Erector spinae catheters	When epidural infusions are not desired, or if there are concerns related to increased risk of bleeding, such as thrombocytopenia, coagulopathy, or need for intraop anticoagulation, erector spinae catheters may be an effective alternative to epidural catheter insertion. Catheters may be placed unilaterally or bilaterally, depending on surgical intervention. If unilateral, an hourly bolus dose can be administered. If bilateral, a bolus dose can be administered alternately to each side every 2 h, taking care not to exceed the maximum hourly dose of local anesthetic noted above.
Peripheral nerve catheters	Increasingly, peripheral nerve catheters are being employed for periop pain control. Local anesthetic infusions (ropivacaine 0.1% or bupivacaine 0.1%) are continued for 3–5 d postop.

Table E-1. FLACC Pain Scale for Pain Assessment in Nonverbal Patients			
	FLACC Pain Scale (For Nonverbal Patients)		
	Scoring		
Categories	**0**	**1**	**2**
Face	No particular expression or smile	Occasional grimace or frown, withdrawn, disinterested	Frequent-to-constant quivering chin, clenched jaw
Legs	Normal position or relaxed	Uneasy, restless, tense	Kicking, or legs drawn up
Activity	Lying quietly, normal position, moves easily	Squirming, shifting back and forth, tense	Arched, rigid, or jerking
Cry	No cry (awake or asleep)	Moans and whimpers; occasional complaint	Crying steadily, screams or sobs, frequent complaints
Consolability	Content, relaxed	Reassured by occasional touching, hugging, or being talked to; distractible	Difficult to console or comfort

Each of the five categories (F) Face, (L) Legs, (A) Activity, (C) Cry, and Consolability is scored from 0 to 2, which results in a total score between 0 and 10.

From Merkel SI, Voepel-Lewis T, Shayevitz JR, Malviya S. The FLACC: a behavioral scale for scoring postoperative pain in young children. Pediatr Nurs. 1997 May–Jun;23(3):293–7. The FLACC scale was developed by Sandra Merkel, MS, RN; Terri Voepel-Lewis, MS, RN; and Shobha Malviya, MD at C.S. Mott Children's Hospital, University of Michigan Health System, Ann Arbor, MI.

STANDARD PEDIATRIC INTRAOP EPIDURAL/CAUDAL DOSING

	Ropivacaine 0.2% ± epi	**Bupivacaine 0.25% ± epi**	**Lidocaine**
Caudal	0.25 mL/kg	0.25 mL/kg	0.25 mL/kg
Lumbar	0.5 mL/kg	0.5 mL/kg	0.5 mL/kg
Thoracic	0.3 mL/kg	0.3 mL/kg	0.3 mL/kg

Maximum LA dosage: bupivacaine/ropivacaine/lidocaine 3 mg/kg.

Common additives for single dose administration

1. Preservative-free morphine: 30–50 mcg/kg
2. Hydromorphone 3–5 mcg/kg (commonly 3 mcg/kg in younger children, 5 mcg/kg in older children and teenagers)
3. Fentanyl 0.25–0.5 mcg/kg

l. Clonidine 0.5–2 mcg/kg (commonly 1 mcg/kg)

Lumbar epidural space depth (mm): ≈18 + 1.5 × age (yr)

STANDARD PEDIATRIC POSTOP ANALGESICS AND ANTIEMETICS

Analgesics	Acetaminophen	10 mg/kg po iv q6h 20 mg/kg po pr q6h	Max: 30–45 mg/kg/24 h (neo); 60 mg/kg/24 h (infants); max 80 mg/kg/24h pr (children>1)
	Hydrocodone/Acetaminophen Liquid or Tablet	0.15 mg/kg po iv q6h	Dose based on maximum acetaminophen allowed for weight (up to 10 mg/kg/dose) q4–6h, but not to exceed 60 mg/kg/d
	Oxycodone/Acetaminophen	0.1 mg/kg po q6h Oxycodone may also be prescribed without acetaminophen, and doses may be increased as needed, commonly 0.15 mg/kg po q6h	Dose should also be based on maximum acetaminophen allowed for weight (up to 10 mg/kg/dose) q4–6h, but not to exceed 60 mg/kg/d)
	*__NB__: Codeine is not recommended in pediatrics. Patients with CXP2D6 polymorphism may be ultrarapid metabolizers of		

	codeine, leading to oversedation and in some cases to fatalities in patients with OSA following tonsillectomy. In addition, 16% of people cannot metabolize codeine and thus may have suboptimal analgesia.		
Antiemetics	Metoclopramide* Ondansetron	0.1 mg/kg, may repeat × 1 iv 0.1 mg/kg iv	May increase risk of extrapyramidal reactions

Notes: To prevent irreversible liver damage, it is important to d/c or supervise all other use of acetaminophen when prescribing the above medications, so as not to exceed the maximum dose of 60 mg/kg/d (40 mg/kg/d in neonates) of acetaminophen.

Hydro, hydrocodone; APAP, acetaminophen; Cod, codeine.

PATIENT-CONTROLLED IV ANALGESIA (PCA)

In a setting with trained nursing supervision, PCA can be used safely by children <5 yr old (about the age they are able to play video games). The lockout time usually is set at 10 min but can be as short as 5 min for fentanyl. Common PCA medications and recommended starting doses in opiate-naive patients are listed below, followed by typical order for iv PCA.

Common PCA Medications

Medication	Loading Dose	Basal Rate	Patient-Controlled Bolus
Morphine (1 or 5 mg/mL)	0.03 mg/kg	0.01 mg/kg/h	0.02–0.03 mg/kg
Hydromorphone (100 mcg/mL)	3–5 mcg/kg	1 mcg/kg/h	2 mcg/kg
Fentanyl (50 mcg/mL)	0.3 mcg/kg	0.1 mcg/kg/h	0.2–0.3 mcg/kg

Continuous iv infusion

When PCA is not practical (e.g., in children unable to understand PCA), continuous iv infusion of opiates may be used. Morphine infusion of 10–30 mcg/kg/h results in serum concentrations of 10–22 ng/mL and provides adequate analgesia. A common technique is to initiate iv morphine infusion with 1 mg/kg of morphine in 100 mL of D5W at 1 mL/h (the effective infusion rate is 10 mcg/kg/h). The infusion rate is slowly increased

to provide adequate pain relief.

TYPICAL ORDERS FOR PATIENT-CONTROLLED IV ANALGESIA (PCA)

Patient's Name:_____ Medical Record No.:_____

Weight (kg):_____ Allergies:_____

Drug	Recommended Concentration	Loading Dose	Mode (*select one*)			PCA Dose	Lockout Interval	Basal Rate
			PCA Only	Continuous	PCA + Continuous			
Morphine	1 mg/mL	30 mcg/kg*				20–30 mcg/kg*	8–10 min	10 mg/kg/h*
Hydromorphoine	100 mcg/mL	5 mcg/kg*				2 mcg/kg*	8–10 min	1 mcg/kg/h*
Fentanyl	50 mcg/mL	0.3 mcg/kg*				0.2–0.3 mcg/kg*	8–10 min	0.1 mcg/kg/h*

Physician: Check all orders that apply: **Recommended starting dose for opiate-naive patients.*

Nursing Care:

- ❑ 1. For renewed or changed PCA orders only, continue PCA nursing are as previously ordered.
- ❑ 2. Do not administer any other opioids, benzodiazepines, sedatives, or antiemetics unless approved by:
  Service Pager No.:
- ❑ 3. Continuous O_2 sat monitor. For $SaO_2 < 94\%$, place order for and administer O_2 per nasal cannula to maintain $SaO_2 \geq 94\%$ and re-evaluate PCA doses.
- ❑ 4. Assess and record at least q2h: RR, O_2 sat, and level of pain, using appropriate tool.
  (*0–10 Scale, Wong-Baker Faces Scale, FLACC Scale, or PIPP Scale*)
- ❑ 5. Assess and record at least q4h: HR, BP, and T. Spot-check SaO_2 with vitals.
- ❑ 6. Bag and mask at bedside.
- ❑ 7. Assess for bladder retention. If no void for_____ h (since surgery or last void), may straight cath prn × 2.

Medications:

- ❑ 1. For renewed or changed PCA orders only, continue prn medications for PCA as previously ordered.
- ❑ 2. Metoclopramide (Reglan)_____mg iv q6h prn N/V (0.1 mg/kg/dose; max 15 mg).
- ❑ 3. Ondansetron (Zofran)_____mg iv q8h prn N/V (0.1 mg/kg/dose; max 4 mg).
- ❑ 4. Diphenhydramine (Benadryl)_____mg iv q6h prn pruritus (0.5 mg/kg/dose; max 50 mg).
- ❑ 5. Nalbuphine (Nubain)_____mg iv q4 prn pruritus (0.05 mg/kg/dose; max 20 mg).
- ❑ 6. Polyethylene glycol (Miralax) T packet po bid.
- ❑ 7. If no stool by_____(POD 3), administer:
  - ❑ 1 pediatric glycerin suppository pr 1 or 2 × daily prn (ages 2–6 yr).
  - ❑ Bisacodyl 5 mg (½ suppository) pr daily prn (ages 6–11 yr).
  - ❑ Bisacodyl 10 mg (1 suppository) pr daily prn (ages >11 yr).
  - ❑ Senna (Senokot) 8.6 mg tablet po bid prn.
  - ❑ If no stool within 24 h of beginning treatment, notify physician listed above.
- ❑ 8. If unable to arouse or SaO_2 < 90%, turn off PCA pump, administer O_2 and/or ambu-bag, stimulate patient, administer naloxone_____mg (0.001 mg/kg) q1–2min (obtain naloxone from floor stock) as needed to restore consciousness, and STAT page physician.
- ❑ 9. Other medications:_____

POSTOPERATIVE EPIDURAL ANALGESIA

Patients with indwelling epidural catheters may receive postop analgesia with either continuous infusion alone or continuous infusion with intermittent bolus dosing (PCEA or PIEB). The infusate may be either local anesthetic with an opioid, local anesthetic alone, or opioid alone. At Stanford, the most commonly used epidural infusate for continuous infusion or PIEB is ropivacaine 0.1% with hydromorphone 3 mcg/mL. In patients receiving PCEA, ropivacaine 0.1% with hydromorphone 25 mcg/mL is often used.

At Stanford, patients receiving epidural analgesia are managed by the Pediatric Pain Service.

Hydromorphone (Dilaudid): May bolus dose 5–10 mcg/kg or just add to continuous infusion. Reduced dose for thoracic catheters.

When opioid epidural analgesia is indicated, hydromorphone is most commonly used because

a. It causes less itching and nausea, compared with morphine.
b. It is more water soluble than fentanyl (decreased systemic absorption, spread over

more dermatomes).

2. It is less water soluble than morphine (thereby minimizing late respiratory depression).

STARTING DOSES FOR EPIDURAL INFUSION

Age	Starting Dose
0–6 mo	Hydromorphone 3 mcg/mL + 0.1% ropivacaine @ 0.1–0.15 mL/kg/h (max ropi 0.3 mg/kg/h); for neonates, consider 0.1% ropivacaine infusion only
6 mo to 3 yr	Hydromorphone 3 mcg/mL + 0.1% ropivacaine @ 0.1–0.15 mL/kg/h (max ropi 0.5 mg/kg/h)
3–7 yr	Hydromorphone 3–5 mcg/mL + 0.1% ropivacaine @ 0.1–0.15 mL/kg/h (max ropi 0.5 mg/kg/h)
>7 yr	Hydromorphone 5–10 mcg/mL + 0.1% ropivacaine @ 0.1–0.15 mL/kg/h + 0.05 mL/kg/h PCEA dose q30min lockout (max ropi 0.5 mg/kg/h)

Notes: In general, use a lower concentration of opiate infusion for neonates. When spread is needed (for surgeries with incisions that cross multiple dermatomes or when catheter placement is below the level of anticipated pain), a lower concentration and higher volume infusion may be desired.

TYPICAL ORDERS FOR CONTINUOUS EPIDURAL ANALGESIA
(may also be utilized for Peripheral Nerve Blockade)

Patient's Name:_____ Medical Record No.:_____

Weight (kg):_____ Allergies:_____

Drug and Concentration (*Check one*)	**Basal Rate** (0.15 mL/kg/h) (maximum 0.3 mL/kg/h for 0–6 mo)
❑ Hydromorphone 3 mcg/mL with bupivacaine 0.1% →	Epidural infusion rate_____ mL/h
❑ Hydromorphone 3 mcg/mL with bupivacaine 0.1% → **and** Clonidine 0.2 mcg/mL	Epidural infusion rate_____ mL/h
❑ Hydromorphone 3 mcg/mL with levobupivacaine 0.1% →	Epidural infusion rate_____ mL/h

Physician: Check all orders that apply:

Nursing Care:

❑ 1. Do not administer any other opioids, benzodiazepines, sedatives, or antiemetics unless first approved by Pain Management Service.

❑ 2. Maintain iv access until epidural catheter d/c'd.

❑ 3. Check epidural site qd and notify Pain Management Service if site is soiled, red, or tender.

❑ 4. Check lower extremities q8h while awake, and notify Pain Management if numbness or weakness exist.

❑ 5. Continuous O_2 sat monitor. For $SaO_2 < 94\%$, administer O_2 per nasal cannula to maintain $SaO_2 \geq 94\%$.

❑ 6. Assess and record at least q4h: RR, O_2 sat, and level of pain, using appropriate tool. (0–10/*Numeric Scale, Wong-Baker Faces Scale, FLACC Scale, or PIPP Scale*)

❑ 7. Assess and record at least q4h: HR, BP. Confirm absence of postural hypotension before ambulating for the first time.

❑ 8. Assess for bladder retention. If no void for 8 h (since surgery or last void), may straight cath prn × 2.

❑ 9. Bag and mask at bedside.

❑ 10. Check catheter entry site q8h and notify Pain Management Service if soiled, red, or tender

Medications:

- ❑ 1. Metoclopramide (Reglan)_____mg iv q6h prn N/V (0.1 mg/kg/dose; max 15 mg).
- ❑ 2. Ondansetron (Zofran)_____mg iv q6h prn N/V (0.1 mg/kg/dose; max 4 mg).
- ❑ 3. Diphenhydramine (Benadryl)_____mg iv q6h prn pruritus (0.5 mg/kg/dose; max 50 mg).
- ❑ 4. Nalbuphine (Nubain)_____mg iv q4 prn pruritus (0.05 mg/kg/dose; max 20 mg).
- ❑ 5. Polyethylene glycol (Miralax) 1 packet po bid
- ❑ 6. If no stool by_____(POD 3), administer:
  - ❑ 1 pediatric glycerin suppository pr 1–2 × daily prn (2–6 yr).
  - ❑ Bisacodyl 5 mg (½ suppository) pr daily prn (6–11 yr).
  - ❑ Bisacodyl 10 mg (1 suppository) pr daily prn (> 11 yr).
  - ❑ Senna (Senokot) 8.6 mg tablet T po bid prn
  - ❑ If no stool within 24 h of beginning treatment, notify physician listed above.
- ❑ 6. If unable to arouse or SaO_2 is <85%, turn off PCA pump, administer O_2 and/or ambu-bag, stimulate patient, administer naloxone (Narcan)_____ mg (0.001 mg/kg) q1–2min (obtain naloxone from floor stock) as needed to restore LOC, and STAT page pain Management Service.
- ❑ 7. Other medications:_____

Electronic Order Sets for Epidural and Regional Block Infusions in Pediatrics

Pump type : _____ CADD—On-Q—Nimbus—Other

Local anesthetic Infusion:

Bupivacaine _____% 0.05%; 0.0625%; 0.08%; 0.1%; 0.125% 0.2% 0.25% **(Usually 0.1%)**

Lidocaine _____% 0.25%; 0.5%; 1%

Ropivacaine _____% 0.05%; 0.08%; 0.1%; 0.2%; 0.25%(Usually 0.1% or 0.2%)

Adjuvants

Clonidine _____ mcg/mL 0.1 mcg/mL; 0.2 mcg/mL; 0.5 mcg/mL; 1 mcg/mL (**Usually 0.2 mcg/mL)—decrease for sedation—higher doses may be used if not using opioid)**

Fentanyl _____ mcg/mL 0.5 mcg/mL; 1 mcg/mL; 2 mcg/mL; 5 mcg/mL

Hydromorphone _____ mcg/mL 3 mcg/mL; 5 mcg/mL; 10 mcg/mL; 20 mcg/mL **(Usually 3 mcg/mL)**

Morphine (Preservative free) _____ mcg/mL

Example of frequently utilized infusions:

Immediately postoperatively: Ropivacaine 0.2% (or bupivacaine 0.1%) with clonidine 0.1 or 0.2 mcg/mL (depending on possible concerns of postoperative hypotension), hydromorphone 3 mcg/mL

Run infusion at 0.2–0.3mL/kg; check anesthetic level.

For thoracic infusions, reduce dose to 0.15–0.2 mL/kg. Check anesthetic level and assess for hypotension.

It can be particularly effective to administer the hourly dose of anesthetic as an hourly bolus—e.g., 8 cc delivered in one bolus, and the subsequent bolus is delivered in 1 h. This can be accomplished with the CADD and Nimbus devices but not with On-Q.

Maximum local anesthetic dose infusion: neonates–9 months 0.3 mg/kg/h; > 9 mo 0.5 mg/kg/h

When ambulation is being considered, reduce ropivacaine concentration to 0.1%. Verify orthostatic vital signs, lower extremity strength. Patient should always ambulate with assistance.

PCEA (patients >12 yr old): Local anesthetic and adjuvant mixture as above.

Begin Basal infusions at 0.1 – 0.15 mL/kg/h, and epidural bolus at 0.05 mL/kg/h q30min. Thus to total volume in the epidural will not exceed 0.25 mL/kg/h. This can be adjusted as needed for patient comfort to not exceed the above noted 0.3 mL/kg inepidural volume, or 0.5 mg/kg/h of local anesthetic.

Vital sign parameters for regional block infusions in pediatrics:

Age Group	1–9 mo	9 mo–3 yr	3–6 yr	6–15 yr	>15 yr

APPENDIX F: TABLES OF DRUG INTERACTIONS AND RECOMMENDATIONS FOR PREOP MANAGEMENT

Carolyn Nguyen, PharmD

These tables are intended only as an advisory overview of potential interactions between various drug classes or herbals that patients may be taking preop and the drugs used in anesthetic practice. They are not intended to be comprehensive lists. Drug interactions are dynamic and depend on a variety of circumstances including dosage, duration of administration, as well as the patient's genetics and current physiologic state. An excellent source for the predictive values of drug interactions due to altered metabolism can also be found in references for inhibitors, inducers, and substrates of the cytochrome P450 enzymes. In view of the constant flow of new drug information, the reader is strongly encouraged to check the primary literature of each drug or online resources, such as DRUG-REAX, Lexi-Interact, and Facts and Comparisons for dru interactions, and then tailor drug usage to the patient-specific clinical situation.

TABLE F-2 HERBAL AGENTS

It may be difficult to accurately predict the potential for drug interactions, because the majority of people neglect to inform health care providers of their consumption of herbal agents, natural remedies, alternative or complementary medicines, nutritional supplements, and illicit substances. The significance of the potential interaction is also difficult to assess due to variations of botanical species, the different parts of plants that are used, assay of active ingredient(s), and product formulation. Herbs that alter hemostasis should be discontinued 14 d before surgical, dental, or invasive procedures.

TABLE F-1 DRUG-DRUG INTERACTIONS

Preop Drug or Drug Class	Anesthetic Drug or Drug Class	Interaction	Clini Man
Acetylcholinesterase inhibitors (neostigmine, pyridostigmine, donepezil, rivastigmine)	Nondepolarizing neuromuscular blockers (NMBs)	↓ blockade	Titra thera

TABLE F-2 HERBAL AGENTS

Plant	Precautions for Anesthesia and Surgery
Aloe vera	May impair hemostasis
Bilberry (Vaccinium myrtillus)	May impair hemostasis
Black cohosh (Cimicifuga racemosa)	Potential for hypotension and bradycardia
Bladderwrack (Fucus vesiculosus)	May impair hemostasis
Cat's claw (Uncaria tomentosa)	May impair hemostasis (inhibit platelet aggregation)
Cayenne (Capsicum annuum)	May impair hemostasis (inhibit platelet aggregation). Has biologic effect of increased catecholamine secretion. Overdose may cause hypothermia.
Chamomile. German (Matricaria chamomilla)	May enhance CNS depression
Coleus (Coleus forskohlii)	May impair hemostasis. Has antithrombotic effects and potential for hypotension
Devil's claw (Harpagophytum	May have chronotropic and inotropic effects.

procumbens)	May impair hemostasis
Dong quai (Angelica sinensis)	Has anticoagulant effects. May impair hemostasis. May cause vasodilation
Echinacea	May increase the sedative effect of midazolam
Ephedra (ma huang) (Ephedra sinica)	Potent sympathomimetic may cause cardiac arrhythmias, heart failure, and stroke.
Evening primrose (Oenothera biennis)	May impair hemostasis (inhibit platelet aggregation)
Fenugreek (Trigonella foenum-graecum L.)	May impair hemostasis. Contains coumarin
Feverfew (Tanacetum parthenium)	May impair hemostasis (inhibit platelet aggregation). Increase risk of serotonin syndrome
Fish oils	May impair hemostasis (inhibit platelet aggregation). Potential prolonging bleeding during and after surgery
Garlic (Allium sativum L.)	May impair hemostasis. May inhibit platelet aggregation; potential for enhanced ↓ BP. May ↓ blood glucose
Ginger (Zingiber officinale)	May → prolonged bleeding time (irreversible platelet inhibition); possible ↓ catecholamine secretion; cardioactive in large and prolonged doses
Ginkgo (Ginkgo biloba)	Selective antagonist of platelet aggregation; may cause vasodilation. Antithrombotic effect
Ginseng, American (Panax quinquefolius)	May impair hemostasis (possibly irreversible platelet inhibitor)
Ginseng, Panax (Panax ginseng) root	Dose-dependent effects on BP. May cause tachycardia. May impair hemostasis
Ginseng, Siberian (Eleutherococcus senticosus)	May impair hemostasis. Use barbiturates with caution. May affect BP.

Goldenseal (Hydrastis canadensis)	May impair hemostasis. Potential for hypotension and bradycardia. May alter liver enzymes
Grapefruit	Cytochrome P450 (CYP3A4) inhibition. Onset of midazolam may be delayed and action increased.
Grape seed (Vitis vinifera)	May impair hemostasis
Green tea (Camellia sinensis)	May impair hemostasis
Guggul (Commiphora mukul)	May impair hemostasis
Hawthorn (Crataegus oxyacantha)	High doses may cause hypotension + CNS depression. May ↑ digoxin and ACE inhibition.
Horse chestnut (Aesculus hippocastanum)	May impair hemostasis (contains coumarin). Has cholinergic properties
Kava kava (Piper methysticum)	Synergy with midazolam and anesthetic drugs. Chronic use may ↑ anesthetic requirements. Antagonizes dopamine
Licorice (Glycyrrhiza glabra)	May impair hemostasis. Mineralocorticoid effect ↓ K^+
Melatonin	May enhance CNS depressants
Passion flower (Passiflora spp.)	Synergy with CNS depressants. Avoid combination with MAOI.
Red clover (Trifolium pratense)	May impair hemostasis. Contains coumarins
Reishi (Ganoderma lucidum)	May impair hemostasis
Saw palmetto (Serenoa repens)	May cause ↑ BP. Antiestrogen effect
Schisandra (Schisandra chinensis)	Inducer of cytochrome P450 enzyme system
St. John's wort (Hypericum perforatum)	May have some MAOI activity. May reduce midazolam levels due to enzyme induction. Delayed emergence from anesthesia. Avoid meperidine.

Turmeric (Curcuma longa)	May impair hemostasis
Valerian (Valeriana officinalis)	Potentially synergistic with opiates and CNS depressants, including anesthetics
White willow (Salix alba)	Salicylate, may impair hemostasis
Yohimbe (Corynanthe yohimbe) (Pausinystalia yohimbe)	May cause CNS stimulation. May have cardiovascular effects

TABLE F-3 PREOPERATIVE MANAGEMENT OF PATIE MEDICATIONS

Drug/Drug Class	Continue to Time of Surgery?	Otherwise d/c Before Surgery
Aliskiren (renin inhibitor)	Do not continue unless essential for BP control (consult prescribing MD).	At least 2 d and preferably 7–10 d before lengthy or high blood loss surgery in patients taking other renin/angiotensin system drugs.
Alpha- and alpha-beta-blockers	Continue except for tamsulosin in cataract surgery.	Stop tamsulosin several days prior to cataract surgery to prevent floppy iris syndrome. Consider use of labetalol for intraop blood pressure control.
Amiodarone	Continue (long elimination half-life).	
Angiotensin-converting enzyme (ACE) inhibitors		May intensify hypotension in anesthesia—ensure adequate intravascular volume d/c 24 h prior to surgery.
Angiotensin receptor blockers (ARB)		May intensify hypotension in anesthesia. Hypotension may be less responsive to vasopressors—ensure

		adequate intravascular volume d/c 24 h prior to surgery.
Anticytokines in general	Consider consult.	
Anticytokines, adalimumab		d/c 1–2 wk prior to surgery. Restart 1–2 wk after surgery.
Anticytokines, anakinra		d/c 1–2 wk prior to surgery. Restart 1–2 wk after surgery.
Anticytokines, etanercept		d/c 1–2 wk prior to surgery. Restart 1–2 wk after surgery.
Anticytokines, infliximab	May continue if indication is inflammatory bowel disease	
Anticytokines, rituximab		d/c 1–2 wk prior to surgery. Restart 1–2 wk after surgery.
Antigout medications in general	Continue.	Monitor for fluid and electrolyte shift leading to changes in uric acid levels. Treat flares with NSAIDs or corticosteroids.
Antiparkinsonian medications	Continue prior to surgery as prescribed to prevent relapse.	
Antiparkinsonian medications, levodopa/carbidopa	Give dose evening before surgery.	
Antiparkinsonian medications, entacapone		Hold 24 h before surgery.

Antiparkinsonian medications, tolcapone		Hold 24 h before surgery. Resume when the patient is taking po and stable.
Antiparkinsonian medications, bromocriptine		Hold 24 h before surgery. Resume when the patient is taking po and stable.
Antiparkinsonian medications, pergolide		Hold 24 h before surgery. Resume when patient is taking po and stable.
Antiparkinsonian medications, ropinirole	Administer morning of surgery to avoid precipitating neuroleptic malignant syndrome.	Resume when the patient is taking po.
Antiparkinsonian medications, pramipexole	Administer morning of surgery to avoid precipitating neuroleptic malignant syndrome (NMS).	Resume when the patient is taking po.
Antiparkinsonian medications, selegiline		d/c 3 d before surgery because it is a MAOI type B.
Antiparkinsonian medications, anticholinergic agents		Parenteral diphenhydramine and benztropine can be used to control symptoms in patients who cannot take po medications.
Antipsychotic medications	Continue.	Haloperidol, olanzapine, and ziprasidone are available parenterally.
Antiseizure medications (AEDs)	Continue. Anesthesia, metabolic changes, ethanol withdrawal, and neurosurgical procedures may increase risk of seizures.	Check drug levels. Substitute iv alternatives.

Antithyroid medications	Continue antithyroid medications and beta-blockers.	
Apixaban		d/c 24 h before minor surgery and 48 h before any surgery with a moderate or higher bleeding risk.
Aspirin	Continue in vascular surgery or stents. Secondary prophylaxis in patients at high risk	d/c 5–7 d (up to 10 d) before surgery if risk or consequences of bleed are high or if taken only for primary prophylaxis.
Benzodiazepines	Continue to prevent development of withdrawal symptoms.	Support with iv preparations if necessary.
Beta-adrenergic blockers	Continue because abrupt discontinuation is associated with rebound ischemia, hypertension, and tachycardia.	If d/c prior to surgery, consider use of esmolol intraop for pressure and rate control.
Buspirone	Continue to prevent development of withdrawal symptoms.	
Calcium channel blockers	Continue in patients with normal or slightly impaired heart function. Continue with caution in patients with LV dysfunction.	
Cholestyramine, colestipol		d/c day before surgery.
Cilostazol		d/c 3–5 d before surgery.
Clonidine	Continue to prevent withdrawal symptoms	Consider use of transdermal system 3–4 d

	such as rebound hypertension, tachycardia, tremors, and anxiety.	before surgery with overlap oral dose for 2–3 d if the patient is NPO perioperatively. Observe for hypotension and bradycardia. Resume oral dose 8 h after transdermal patch removal.
Clopidogrel	In patients with: Drug-eluting stents <12 mo Bare metal stents <1 mo if asymptomatic Bare metal stents <12 mo if symptomatic + any others	d/c 5–10 d before surgery. d/c at least 24 h before urgent on-pump CABG if possible, and urgent off-pump CABG may be considered within 24 h of clopidogrel administration.
Clozapine	Continue to prevent withdrawal symptoms and disease relapse. May need psychiatric consult	
Corticosteroids	Continue. May need to supplement due to surgical stress.	
Dabigatran		d/c 1–2 d prior to surgery in patients with good renal function and 3–5 d prior to surgery in patients with CrCl < 50 mL/min. Consider d/c earlier for patients undergoing major surgery or neuraxial anesthesia. Check aPTT morning of surgery. Reversible with idarucizumab
Digoxin	Continue (long half-life).	

Dipyridamole		d/c 2–3 d before surgery
Diuretics (thiazides, loop)	Continue but monitor for volume depletion and ↓ K.	
DMARDs (disease-modifying antirheumatic drugs)	Consider consult.	May increase immunosuppression and increase the risk of wound infection
DMARDs, methotrexate	Continue in patients with normal renal function.	
DMARDs, leflunomide		d/c 2 wk prior to surgery (long half-life)
DMARDs, sulfasalazine	Continue.	
DMARDs, azathioprine	Continue.	
DMARDs, hydroxychloroquine	Continue.	
Ezetimibe		d/c day before surgery.
Fibric acid derivatives (gemfibrozil, fenofibrate)		d/c day before surgery.
Fondaparinux		d/c 24 h prior to surgery. Start no sooner than 6 h postop. Not reversible with protamine
H2-blockers	Continue.	Consider iv formulations.
Heparin		d/c 4–6 h before surgery. Reversible with protamine. Restart postop 12–24 h after procedures with low risk of postop bleeding. Restart postop 48–72 h after procedures with high risk of postop bleeding.

		Monitor for HIT (heparin-induced thrombocytopenia).
Herbals		d/c at least 14 d prior to elective surgery due to potential CV effects and/or bleeding.
HIV therapy	Be cognizant of drug interactions between HIV medications and anesthetic agents.	
HMG Co-A reductase inhibitors (“statins”)	Continue—may be cardioprotective and anti-inflammatory	
HRT (e.g., estrogen)	Balance risk of VTE with risks of stopping HRT.	Consider VTE prophylaxis.
Inhaled pulmonary medications including beta-agonists, ipratropium, and steroids	Continue.	
Insulin		Reduce evening dose of insulin (give about 2/3 dose). Adjust or omit morning dose of insulin. Use a sliding scale replacement.
Insulin pump		Decrease dose on evening of surgery. Switch to insulin infusion except for short, simple cases.
Leukotriene inhibitors (montelukast, zafirlukast)	Continue.	
Lipid-controlling		d/c day before surgery

agents (cholestyramine, colestipol, gemfibrozil, niacin)		
Lithium	Continue with caution. May prolong blockade of NMBs	Monitor sodium and fluid status.
LMWH		d/c 12–24 h prior to surgery; 24 h if planning neuraxial anesthesia. Partially reversible with protamine. Restart 4 h after epidural catheter is removed.
MAOIs		d/c 10–14 d prior to surgery. Use MAOI-safe anesthetic agents.
Meds for myasthenia gravis	Risk for respiratory insufficiency. Use pyridostigmine evening before surgery.	Postop management with pyridostigmine im 1/10th dose and iv 1/30th dose continuous infusion at 2 mg/h.
Niacin		d/c day before surgery
Nitrates	Continue.	May use nitroglycerin 2% ointment to substitute for po nitrates
NSAIDs		Usually d/c 1–3 d before surgery depending on the medication
Opioids, chronic use	Continue to avoid withdrawal and pain exacerbation.	Review equianalgesic substitutions. Patient may need multimodal approach to temporarily control the surgical pain.
Oral antidiabetic		Hold sulfonylureas and

agents (in general)		nonsulfonylurea secretagogues evening before surgery. Short procedures—delay morning doses until po intake. Monitor for hypoglycemia especially in the longer-acting sulfonylureas.
Oral antidiabetic agents: metformin		Risk of lactic acidosis (rare). Recommendations vary from holding 48 h prior to surgery to continuing (in patients with normal renal function).
Oral contraceptives	Balance risk of VTE with risks of d/c.	Consider VTE prophylaxis.
Pentoxifylline		d/c at least 8 h prior to surgery
PPIs	Continue.	Consider iv formulation.
Prasugrel		d/c 7 d before surgery
Rivaroxaban		d/c at least 24 h prior to surgery or longer (3 d in patients with CrCl < 50 mL/min) if bleeding risk is of primary importance. Nonreversible with protamine. Check aPTT morning of surgery.
Selective estrogen receptor modulators (SERM)	Balance risk of VTE with risks of d/c.	Consider VTE prophylaxis.
SSRIs	Continue.	If it is decided to d/c, taper for 3 wk prior to surgery.

TCAs	Long half-life	If it is decided to d/c, taper for 3 wk prior to surgery. Norepinephrine is pressor of choice.
Theophylline		Hold morning of surgery. Toxic levels are associated with arrhythmias.
Thyroid medication	Medication has long half-life, so omitting a dose is unlikely to have clinical effect.	
Ticagrelor		d/c 5 d before surgery
Ticlopidine		d/c 10–14 d before surgery
Valproic acid	Continue.	Consider iv formulation.
Warfarin	Assess bleeding risk of procedure compared with risk of thromboembolism. Consider bridging therapy.	Hold warfarin 3–5 d prior to surgery and consider bridging therapy. Check INR morning of surgery. Consider low dose of vitamin K on day of surgery if INR remains above surgeon's target INR. If INR is significantly elevated and surgery is immediately necessary, consider a warfarin reversal protocol, which includes vitamin K, FFP, PCC, and factors.

APPENDIX G: SPECIAL CONSIDERATIONS FOR LATEX ALLERGY

Andrew J. Giustini, MD, PhD, Rebecca E. Claure, MD, Anita Honkanen, MD and Brenda Golianu, MD

Latex is the second most common cause of anaphylactic reactions under anesthesia (20%) after neuromuscular blocking agents. The incidence of intraop latex reactions has declined significantly as latex-containing materials have been removed from the OR. Latex gloves were the major source of latex proteins and were implicated in most cases of latex-mediated reactions. Latex exposure may occur through skin contact, mucous membrane exposure, inhalation of glove powder, ingestion, or parenteral injection. Reactions to latex are divided into three types: irritant contact dermatitis, type IV hypersensitivity (skin reaction similar to poison ivy), and type I, IgE-mediated hypersensitivity, which can lead to life-threatening anaphylaxis.

Populations at risk

- Patients with history of multiple surgical procedures, including those with myelomeningocele, spina bifida, and congenital genito-urinary tract anomalies.
- Patients with a history of myelomeningocele and spina bifida should be treated with a "latex precaution" regimen from birth, regardless of prior history of exposure or latex reactivity.
- Health care personnel with occupational exposure.
- Other individuals with occupational exposure such as rubber industry workers and hairdressers.
- Patients with history of atopy, hay fever, asthma, or eczema.
- Patients with history of food allergy to tropical fruits (such as avocado, kiwi, banana, mango) and chestnuts, which contain cross-reacting proteins with latex.
- Patients with history of rash or swelling following contact with balloons, rubber bands, erasers, gloves or other products which may contain latex.

It is currently estimated that as many as 17% of health care workers have been sensitized to latex. Occupational exposure can be minimized by avoiding powdered latex gloves and limiting the use of latex-containing gloves. Applying lotion to hands before using latex gloves facilitates the transfer of latex proteins to hands, and should be avoided.

In high-risk patients, latex-avoidance protocols are recommended as this may decrease

the incidence of subsequent intraop allergic reactions. Hospitals and ORs have decreased the use of products that contain latex to the extent that many are essentially latex free. Anesthesia carts can be assembled with latex-free products, reducing the risk of latex sensitization for all patients and negating the need for a special "latex-free cart." The latex content of commonly used materials can be identified from external labeling, from package inserts, or directly from the manufacturers. Even minimal latex exposure (e.g., an injection through a latex port of iv tubing or opening a package of powdered latex gloves) has resulted in anaphylaxis.

Diagnosis of latex allergy is based on a focused history and physical examination with positive in vivo or in vitro test. In vitro serum tests for latex-specific IgE such as RAST are highly specific but have a high false-negative rate, up to 30%. Skin testing identifies patients with a high titer of IgE to latex but must be performed with appropriate safeguards because it may induce systemic anaphylaxis.

Pharmacologic prophylaxis in the acute setting is controversial for patients with documented latex allergy. Prophylaxis medications, such as diphenhydramine, ranitidine, and hydrocortisone, are not universally successful in preventing latex anaphylaxis. Some authors have argued that pretreatment may mask the early immune responses, leaving anaphylaxis as the first evidence of an allergic reaction.

To prepare a latex-safe environment

- Notify OR nurses, anesthesia technicians, and surgical staff of the need for a latex-free room.
- Place a sign on the door stating: "LATEX-FREE ROOM."
- Schedule the latex-allergic patient as the first case of the day to minimize the presence of airborne latex particles.
- Set up the room with latex-free materials (e.g., bag, bellows, ECG electrodes, pulse oximeter clip, iv tubing without latex ports, vinyl gloves, vinyl BP cuffs, clear micropore tape).
- Avoid bouffant surgical hair caps and shoe covers that contain latex bands.
- Wrap Webril™ around latex tubing on stethoscope, BP cuff, or tourniquet with Webril™ or cotton gauze if they contain latex derivatives.
- Removal of rubber stoppers from drug vials (instead of withdrawing through the stopper) is controversial.

Diagnosis of anaphylaxis or latex allergy

- **Early Manifestation** Skin: hives or urticaria at site of contact with latex product, red eyes, angioedema of eyelids, nasal congestion, GI cramping, headache, anxiety.
- **Late Manifestation** Respiratory: bronchospasm, wheezing, ↑ PIP, ↓ O_2 sat,

upsloping of $ETCO_2$ tracing.

- Intraop cardiac: ↓ BP, ↑ HR, cardiac arrest. Generally, type I hypersensitivity may not occur immediately at the beginning of a surgical procedure but after exposure of peritoneum or mucous membranes to latex.

Treatment of anaphylaxis

- Remove latex.
- Notify surgical team.
- Call for help.
- 100% O_2; secure airway; manually ventilate if needed.
- Discontinue all anesthetic agents, ± Trendelenburg's.
- Epinephrine 0.1–1 mcg/kg iv initially, increasing to 10 mcg/kg; repeated boluses may be needed to support BP; may require an epinephrine infusion (0.05–0.1 mcg/kg/min) and may be increased up to 1 mcg/kg/min in severe cases. IM dose of epinephrine is 0.01 mg/kg (maximum dose of 0.5 mg). If hypotension is refractory to epinephrine, consider the use of a vasopressin bolus of 0.01-0.05 units/kg iv; repeated boluses may be necessary. The use of an infusion can be considered after blood pressure is stabilized: 0.3 milliunits/kg/min to 2 milliunits/kg/min iv with a maximum of 40 milliunits/min (0.04 units/min).
- Administer iv fluid to ↑ preload and support BP.
- Review field to ensure all possible latex-containing equipment has been removed. (Instruct surgical staff to change to nonlatex gloves and scrutinize all equipment.)
- Administer steroids (hydrocortisone 100 mg iv or methylprednisolone 0.5 mg/kg iv (max 125 mg)), antihistamine (diphenhydramine 50 mg or 0.5 mg/kg iv; max = 50 mg), and H-2 blockers (ranitidine 1 mg/kg; max = 50 mg).
- Administer bronchodilators (albuterol) via nebulizer for bronchospasm.
- Continue steroids and diphenhydramine for 24–48 h or until symptoms resolve.
- Collect blood for mast cell tryptase (peaks at 30–60 min, $t_{1/2}$ is 2 h) and histamine (peaks at <30 min).
- Inform pharmacy of latex sensitivity to ensure all products are prepared latex free.
- Refer patient to allergist for follow-up. Skin prick test or RAST can be performed (4–6 wk after the acute reaction resolves) to specifically test for latex allergy.
- Patients with a history of latex anaphylaxis should be advised to wear a Medic Alert bracelet.

APPENDIX H: PERIOPERATIVE ACUPUNCTURE

Brenda Golianu, MD, and Jeannie Seybold, MD

We gratefully acknowledge the past contributions of Emily F. Ratner, MD

INTRODUCTION

Acupuncture is a treatment modality that has been practiced in China for over 3 millennia. Initially transmitted as an oral tradition, it was first described in written form in the Huangdi Neijing or the Yellow Emperor's Inner Canon, the seminal text of ancient Chinese medicine dating back to the 3rd century BC. Acupuncture involves placing very thin needles in the skin to stimulate the flow of qi (pronounced "chee") in a complex network of meridians in the body. There are 12 principal and 8 curious acupuncture meridians that correspond to physiologic and anatomical organ functions. Qi is a dynamic form of physical and spiritual energy that flows within the universe and in all organisms. One of the basic tenets of Chinese medicine is that illness and pain are caused by the stagnation or blockage of qi flow and/or the invasion of pathologic influences—traditionally known as wind, heat, cold, dampness, dryness, or fire—that result in imbalances of yin and yang. When a point is needled, a heavy sensation known as "deqi," or a mild paresthesia, may be experienced by the patient. The practitioner may sense a gentle contraction of the connective tissue surrounding the needle or may observe a flare developing around the needle. Needling, electrical and laser stimulation, acupressure, or even herbal therapies (moxibustion or capsicum plaster) over specific points have all been documented to alleviate pain and pathologic states. In addition to body acupuncture, which developed in China, Japan, and Korea, many different traditions have been developed that focus on needling specific body parts, that is, the ear, scalp, or hand, as microsystems representing the entire body. Acupuncture has been used to provide analgesia during surgery since the 1950s in China. However, it was little more than a curiosity in the United States before 1971, when reporter James Reston went to China to report on the diplomatic efforts of Henry Kissinger and President Richard Nixon. While in Beijing, Reston required an emergency appendectomy and received acupuncture for postoperative ileus and pain control. The popularity of acupuncture in the United States exploded after he published his experiences in the New York Times. In 1997, the NIH released a consensus statement supporting the use of acupuncture for adult postoperative and chemotherapy-induced nausea and vomiting and postoperative dental pain. It also stated that acupuncture may

be a useful adjunctive treatment in addiction, stroke rehabilitation, headache, menstrual cramps, tennis elbow, fibromyalgia, myofascial pain, osteoarthritis, low back pain, carpal tunnel syndrome, and asthma. During the last 10 years, acupuncture has been increasingly studied and used to treat acute postoperative pain as well as in chronic pain clinics throughout the United States.

MECHANISMS

Several mechanisms for acupuncture analgesia have been proposed. The gate control theory by Melzack and Wall in 1965 postulated that stimulation of a-beta fibers inhibits a-delta and c-fiber transmission of pain signals. This may be a local mechanism of action. Other studies have shown that electroacupuncture at low (2–4 Hz) and high frequencies (100 Hz and greater) selectively induces endorphin and enkephalin release, respectively. Conflicting evidence exists regarding the ability of naloxone to antagonize the analgesic effects of acupuncture. Some studies show that naloxone reverses acupuncture-induced analgesia, while others dispute this. This suggests the analgesic mechanisms of acupuncture are more complex than the release of endorphins. Additional evidence suggests that the frequency and intensity of stimulation determine the degree of naloxone reversibility. A review of functional MRI and positron emission tomography studies has shown that electroacupuncture exerts effects over the hypothalamus, somatosensory motor cortex, and rostral anterior cingulate cortex, with nonspecific modulation of the limbic system and hypothalamus. Other mechanisms of action may include the local generation of plasma and nitric oxide and release of adenosine. Acupuncture may also have anti-inflammatory properties.

PERIOPERATIVE USE

Acupuncture is effective for reducing PONV. P6 (Neiguan), the most thoroughly studied acupoint, is located three fingerbreadths proximal to the wrist crease, between the flexor carpi radialis and palmaris longus tendons and directly over the median nerve. A Cochrane review of 26 randomized trials noted significant reduction in nausea and the need for rescue antiemetics with the use of P6 acupoint stimulation (Fig. H-1). Direct electrical stimulation of this point was shown to be as efficacious as a standard dose of ondansetron for PONV in adults and resulted in a 37% reduction in nausea in children after tonsillectomy. There is evidence that transcutaneous electrical acupoint stimulation is also effective in reducing PONV. Stimulation of P6 by twitch monitoring using a standard nerve stimulator (at 1 Hz, 0.2 ms, 50 mA) during general anesthesia for laparoscopic surgery significantly reduced PONV for 24 h with an efficacy similar to that of commonly used antiemetic drugs. A trained medical acupuncture practitioner

would likely integrate P6 with a combination of body and ear acupuncture points to minimize PONV. Acupuncture has not been shown to eliminate the need for anesthetic medications during surgery, but it may be a useful adjuvant for perioperative analgesia and anxiolysis. In a randomized controlled trial of perioperative acupuncture for abdominal surgery, Kotani et al. showed 50% reduction in postoperative morphine use, 20–30% reduction in postop nausea, and 30–50% reduction in plasma cortisol and epinephrine levels. A reduction in postoperative pain and analgesic requirements was also seen in studies of acupuncture in patients having gynecologic, abdominal, thoracic, and orthopedic surgeries. Acupuncture is known to produce deep relaxation and sedation and may be useful for preoperative anxiolysis or for postoperative weaning of opioid medications in opioid-tolerant patients. Two recent studies demonstrated cardioprotective effects of electrical acupuncture in adult and pediatric cardiac surgical patients, as indicated by decreased postoperative serum cTn1 (cardiac troponin 1), decreased duration of postoperative mechanical ventilation, and shorter ICU stay. The risks of acupuncture are rare. The most common are minor bruising, limited capillary bleeding, pain, or local infection at the needling site. Anesthesiologists can be trained to provide acupuncture treatment for PONV and anxiolysis. More comprehensive perioperative treatment should be performed by or under the supervision of a trained medical acupuncturist.

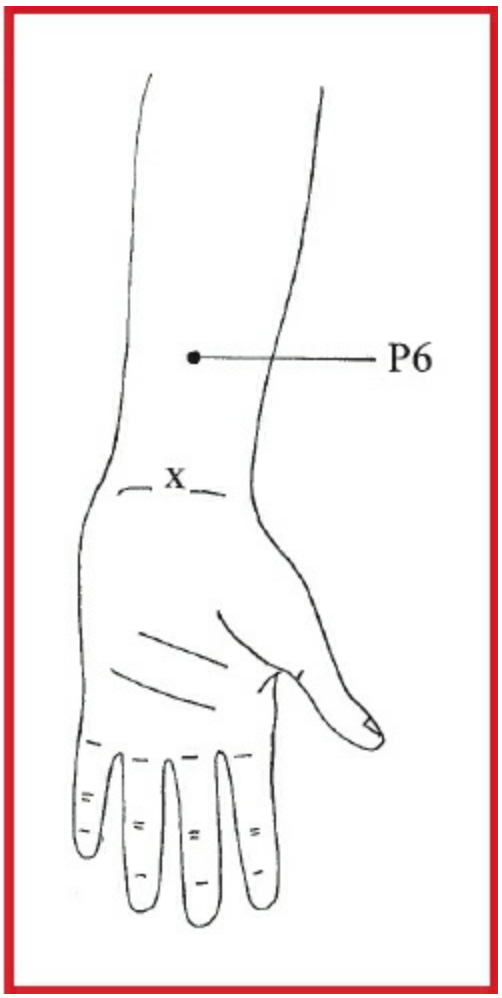

Figure H-1 P6 acupoint. P6 is located three fingerbreadths proximal to the wrist crease directly over the median nerve and between the tendons of palmaris longus and flexor carpi radialis. For PONV prophylaxis, the two nerve stimulator electrodes can be placed over the median nerve (1) at a point proximal to the wrist crease (marked with an x) 2 cm proximal to P6 and (2) on P6 or 1 cm distal to the P6 point. Stimulus parameters: 1 Hz, 0.2 ms, 50 mA during anesthesia.

APPENDIX I: MANAGEMENT OF THE DIFFICULT AIRWAY

C. Philip Larson Jr., MD, CM

Management of the airway, particularly the difficult airway, effectively and safely is a skill that every anesthesia provider must have to be qualified to provide clinical anesthesia. Competency in airway management is mandatory before undertaking independent clinical practice of anesthesia.

DIFFICULT AIRWAY VERSUS DIFFICULT VENTILATION

Difficult airway	5–10% of patients depending on type of practice Tip-offs include prior history of difficult airway/intubation, small mouth opening, large tongue, prominent teeth, large neck, limited range of motion of head, short thyromental distance (<3 cm), Mallampati grade >2, upper-lip bite test below vermilion. Management: multiple options (see below)
Difficult ventilation	Rare, <1% of patients Causes obvious: large beard, thick redundant jowls, oropharyngeal mass, fractured larynx, mediastinal mass compressing trachea, lingual tonsillar hyperplasia (easily ventilated with LMA) Management: Consider LMA and Plan C (see below) or awake fiberoptic intubation (FOI).

MANAGEMENT OF DIFFICULT AIRWAY

Caution

Always determine that ventilation is possible with bag-mask or LMA before inducing full general anesthesia and paralysis. If it is not possible and ET tube is needed, consider awake intubation.

Patient positioning	Have head at top edge of table; bed height at umbilical level of operator. Do not bend over. Can

	reposition patient for surgical needs after airway established.
Direct laryngoscopy (plan A)[1]	Stand sideways facing right wall; keep left arm at side with ET tube in the left axilla (the only place where operator does not have to look away once the glottis identified). Put patient's head in sniff position by directing laryngoscope along the plane of handle (do not lift or pull handle toward oneself). With proper positioning, intubation should be a leg activity with the arm only acting as a fulcrum. Do not do more than two direct laryngoscopies. Multiple laryngoscopies result in inability to ventilate as well as intubate.
Endotracheal tube selection	Always use the smallest appropriate tube (7.0 men, 6.5–7.0 women). Small tubes are easier to insert than large tubes. If larger tube needed later, can always change tube using airway exchange catheter (AEC). Choice of tubes: standard, wire-reinforced (for prone surgery), EMG no. 6 (for nerve monitoring), laser, MLT tube (for microlaryngeal surgery)
Choice of LMAs	Many choices available, each with specific benefits/problems. Either classic or disposable suitable for routine care. Use classic when using as a conduit for FOI or Aintree catheter. Use LMA no. 4 for men and no. 3 or no. 4 for women. Avoid no. 5 when doing FOI as it blocks the glottic opening by invaginating the epiglottis. Intubation LMA; success rate 90–95%; less when intubation difficult. Make certain balloon on reusable silicone tube does not leak. Loosen 15-mm connector before inserting tube. Determine that tube is in trachea. Do not drop 15-mm connector while inserting tube holder and removing LMA. Fix connector firmly before utilizing ET tube.
Video laryngoscopes (plan B)[3]	GlideScope™ or C-MAC™ gives the best picture. Use the largest blade for most adults. Use either special rigid stylet provided or shape another stylet to same

	curvature as blade. Watch the tube enter the mouth before looking at the screen to avoid soft tissue trauma. Extract stylet slightly once tube at glottis opening if tube does not advance easily.
Intubating catheters (plan B)[1]	Cook (Frova) catheters: two types, styleted and unstyleted. 70-cm long and styleted has two adaptors (15 mm for O_2 insufflation, one for attaching syringe or gas sampling line). Tip rounded so it will not perforate soft tissue. Needs some shaping before use. Must see the epiglottis to use effectively; cannot be advanced beyond the carina. Use ET tube that closely approximates catheter size (6.5–7.5). Can use intubating catheter together with video laryngoscope if catheter bent to conform to the shape of the laryngoscope blade. Eschmann: 60 cm long, easily wound in circle for transport. Loses shape and stiffness after a few washings Aintree: 60-cm-long, hollow tube blunt at both ends; has snap-on 15-mm adaptor for O_2 insufflation. Use classic LMA or Tudor-Williams airway as conduit for insertion; may not advance through disposable LMAs. Must be experienced at FOI as all control and direction done with handle. Use. 7.0–7.5 tube for insertions (6.5 will not advance).

FIBEROPTIC INTUBATION PROTOCOL; AWAKE AND ASLEEP[2–4]

Awake	Preferred technique when ventilation by bag-mask or LMA not possible
Premedication	If not contraindicated, patients should receive mild-to-moderate sedation with dexmedetomidine 1 mcg/kg over 10 min or fentanyl 0.3–0.5 mcg/kg and/or midazolam 2–4 mg iv.
Topical anesthesia	When premedication has been established, for awake FOI, the oropharynx is sprayed vigorously ~6

	times over a span of 10 min with lidocaine 4% solution using a disposable EZ spray unit powered with oxygen. Initially, the spray is directed at the front of the tongue; gradually, it is directed further back in the throat, until the entire oropharynx is numb. Having the patient inhale deeply while spraying enhances anesthetic spread into the airway. In reality, the lateral recesses of the oropharynx need not be anesthetized topically because both fiberoptic laryngoscope (FOL) and ETT are confined to the midline of the mouth.
Tracheal anesthesia	With patient breathing oxygen from anesthesia circuit or transport mask, transtracheal injection of cocaine or lidocaine 4% (4 mL) is made through the cricothyroid membrane, using a 5-mL syringe and a 23-ga, 3/4-inch needle. So that this injection can be made as rapidly as possible, it is important to use a small syringe, making certain that the connection between syringe and needle is tight. It is important that operator's hand be fixed firmly against the patient's upper chest to assure that needle movement is minimized should the patient start to cough and that the full injection is made into the trachea. When the injection is complete, the patient is urged to cough vigorously.
Laryngoscopy	After the mouth and trachea are anesthetized with local anesthetic, an oral airway with a central orifice (e.g., Tudor-Williams, Patel, Ovassapian airway) is placed in the midline of the mouth. A 7-mm orotracheal tube, without connector attached, is placed over an FOL. With the operator at the patient's side near the waist, the FOL is introduced through the hole in the airway and advanced to the end of the airway. At this point, the epiglottis should be visible. The tip of the fiberoptic scope is flexed toward the operator about 15–20°, which should bring arytenoid cartilages and laryngeal opening into view. The scope is advanced into the larynx so that

	tracheal rings can be visualized. Often, the carina also can be visualized. The laryngoscopist also can place the scope in the airway by darkening the room and using the scope as a light wand, directing the light externally to the sternal notch and advancing it down the trachea. If a wire-reinforced tube is desired, use a Patel or Ovassapian airway instead of the Tudor-Williams airway for guidance, because these airways can be removed with the tube connector in place.
Intubation	The scope is placed on the patient's chest and, holding it so that it not advanced further, the orotracheal tube is advanced gently into the trachea. To facilitate passage of the orotracheal tube past the arytenoid cartilages and into the larynx, it is necessary to rotate the tube counterclockwise 90°—or even as much as 180°—several times as it is being advanced. Using rotational movement, the operator should never need to push hard on the tube to position it in the larynx. After the tube is in place, the FOL and oral airway are removed, and the 15-mm connector is reattached to the tube. $ETCO_2$ confirms proper placement. The orotracheal tube is then firmly taped in place at one side of the mouth. If manual ventilation of the lungs is possible, it is often beneficial for both patient and anesthesiologist to perform FOI with the patient anesthetized. This is particularly true for patients with cervical spine injuries where manipulation of the head during direct laryngoscopy or coughing during topicalization of the airway or insertion of the tube during awake FOI may aggravate the spinal cord injury. Asleep FOI involves inducing GA, inserting an LMA, and placing the patient on controlled ventilation. Then, proceed with plan C (see Ref 6). In brief, a 6.0 uncuffed tube is mounted on the FOI, the FOI is inserted into the trachea using the LMA as a guide, and the 6.0 tube is

	lubricated and inserted into the laryngeal opening. The FOI is removed and the lungs are ventilated via the 6.0 tube. A medium-sized airway exchange catheter (AEC) is lubricated on one end and inserted into the trachea via the 6.0 tube. The AEC usually meets resistance at the distal end of the 6.0 tube. If this occurs, rotate the 6.0 tube while pushing on the AEC. Once the AEC is a few centimeters beyond the tip of the 6.0 tube, the tube and LMA are removed en bloc leaving the AEC in the airway. With the AEC in the far right corner of the mouth, thread the final endotracheal tube on the AEC and gently advance it through the mouth into the larynx, rotating it counterclockwise to avoid obstruction from the right arytenoid cartilage. Then, remove the AEC and connect the ETT to the anesthetic circuit.
Asleep (plan C)[1]	Preferred technique when ventilation possible by bag-mask or LMA. Easy to determine by administering very low-dose propofol and initiating assisted/controlled ventilation with sevoflurane. Major induction agent is sevoflurane. Establish excellent anesthesia and paralysis. Insert classic LMA. Disposable LMAs have internal ridge that makes advancement of scope and/or tube impossible. In emergency, ridge can be cut out before insertion in the mouth. Mount 6.0 uncuffed ET tube with very tight 15-mm connector onto the scope. Focus FOL, maximize light source, minimize room light, and insert FOL via center struts of LMA into the glottis and trachea. Lubricate no. 6 tube and advance into the trachea; remove FOL; attach tube to circuit and ventilate lungs. Need high gas flow because of leak between the tube and LMA. Lubricate medium airway exchange catheter (AEC) and insert via no. 6 tube about 35–37 cm (5–7 cm beyond tube tip); remove ET tube and LMA together; insert final tube (6.5 or 7.0) rotating gently counterclockwise; remove AEC

	and palpate balloon on tube for final positioning above the sternal notch. Technique can be practiced safely in normal patient so, when needed, operator is comfortable and confident performing it.
Failed plans A–C (plan D)[1]	Plans A–C very rarely fail, but if they should, plan D would present two choices: Proceed with a surgical airway (cricothyrotomy, tracheostomy) or awaken patient and bring back another day for awake FOI.

NASAL FIBEROPTIC

Awake	Requires adequate sedation and excellent topical anesthesia of the nose preferably with cocaine 4% pledgets or cotton applicators and oral spray with lidocaine 4% via EZ spray. Dilate nasal cavity with progressively larger nasal airways. Mount the smallest acceptable nasal RAE on the scope, insert the scope in the nose keeping it in the midline and asking an assistant to pull up on the jaw to open the oropharynx. Do not advance nasal RAE until the scope is well into the trachea.
Asleep	Preferred to awake as it is much more pleasant for both patient and anesthesia provider. Despite general anesthesia and paralysis, topical anesthesia of the nose with cocaine 4% and gradual nasal dilation are essential to avoid nasal bleeding. Have assistant do jaw thrust to open oropharynx.

CERVICAL SPINE INJURY: INTUBATION OPTIONS

Awake FOL	Preferred technique by many despite serious drawbacks: namely, coughing and bucking during oropharyngeal topicalization; during transtracheal injection (if used); and during insertion of fiberoptic scope and/or tube into the trachea. Should rarely be used now, and only in circumstance where bag-mask

	ventilation is not possible.
In-line traction	Commonly used in emergency rooms in combination with direct laryngoscopy with patient either sedated or anesthetized. Multiple problems with this technique: (1) There is no established standard for how in-line traction should be applied, and no documentation of its effectiveness or safety. (2) In-line traction requires the use of excessive leverage on the laryngoscope to visualize the laryngeal opening. (3) In-line traction greatly compromises operator's ability to visualize glottis opening, even in patients who are not classified as difficult airways on preop assessment.[5,6]
Plan C (asleep)	Strongly preferred technique since there is no movement of the head during the procedure and there is no coughing/bucking since the patient is anesthetized and paralyzed. The only prerequisite for use is that bag-mask or LMA ventilation is possible. This is easily determined by administering a sedative dose of propofol in conjunction with low-dose inhaled sevoflurane and seeing if assisted ventilation is possible. If as the depth of anesthesia is increased with sevoflurane the patient becomes more difficult to ventilate, administration of a neuromuscular blocking drug and insertion of an LMA will usually resolve the problem. This technique can be used with a patient in a cervical collar or halo traction.
Difficult pediatric airway	Airway difficulties in infants and small children are generally due to congenital abnormalities of the face, mouth, chin, or upper airway. These can usually be handled effectively and safely by a combination of sedation or GA and insertion of a fiberoptic scope directly into the mouth or via a conduit such as an LMA.
Intubation	The scope is placed on the patient's chest, and, holding it so that it is not advanced further, the orotracheal tube is advanced gently into the trachea.

	To facilitate passage of the orotracheal tube past the arytenoid cartilages and into the larynx, it is necessary to rotate the tube counterclockwise 90°—or even as much as 180°—several times as it is being advanced.

EXTUBATION STRATEGY

Delayed extubation	Always have an extubation strategy. Delaying extubation and mechanically ventilating the lungs for a time postop is frequently a good option.
Postoperative extubation	Establish full recovery from GA and paralysis, with sustained, spontaneous ventilation. Consider deflating the balloon on the tube, occluding the ET tube and determining if ventilation is possible around the tube. This finding is reassuring but no guarantee of sustained airway patency when the tube is removed. Consider inserting an LTA spray down the tube to prolong tolerance to the tube. If there is any question regarding airway patency, insert an AEC 5–7 cm beyond the tube before removing it. As long as it does not touch the carina and is not moved, it will not cause coughing and will not affect voice. Remove AEC when sustained ventilation is evident. If reintubation is necessary, use a tube that closely approximates the AEC in diameter.

MANAGEMENT OF LARYNGOSPASM

Standard technique	Positive pressure ventilation with oxygen along with jaw thrust. Technique may not work until patient is sufficiently hypoxic that vocal cords relax. May need to administer succinylcholine 20–50 mg iv or im. If this fails and ET intubation is not possible, consider immediate cricothyrotomy.
Best technique	Learn to do the laryngospasm maneuver[2] and apply

	it immediately after every removal of ETT or LMA. Should be standard of care because if done correctly, it always relieves laryngospasm within 15–20 sec. Find "laryngospasm notch," which is behind the pinna of the ears. It is bounded by the coronoid process of the mandible anteriorly, the mastoid process posteriorly, and the base of the skull superiorly. To be effective, operator must feel the base of the skull. With patient lying supine, very firm pressure is directed inward bilaterally and at the same time pulling upward (skyward) on the coronoid process. Place transport mask with oxygen flowing on patient's face prior to starting laryngospasm maneuver. Continue maneuver until patient moves arms up toward head (Larson reflex). Once the patient can do this, laryngospasm will not recur. The maneuver corrects airway obstruction from the tongue because the forward displacement of the mandible pulls the tongue forward. Why it corrects laryngospasm is not known. It is not due to pain because pain elsewhere does not resolve laryngospasm.

CRICOTHYROTOMY

Indications	Every anesthesia provider should be trained to perform a cricothyrotomy and be prepared to do it when needed. The risks associated with doing it are minimal and the benefit is lifesaving. Indications: partial or complete airway obstruction and inability to ventilate lungs or perform tracheal intubation; massive oral/tracheal bleeding making mask ventilation or tracheal intubation impossible, combined with rapidly decreasing SaO_2
Technique	Identify cricothyroid membrane between the thyroid cartilage superiorly and cricoid cartilage (round, signet ring shape) inferiorly. With scalpel, penknife,

	or scissors, make 1–1.5 inches horizontal or vertical incision at the level of the cricoid. Cut down quickly to the cricoid cartilage, cut through it, and insert a small tube (no. 4–6F) or an AEC followed by a small tube in the opening. One generally has little time before the patient goes into cardiac arrest from hypoxia, so the maneuver must be done quickly. There are no structures in the midline of the neck that will be harmed by the incision, and bleeding from the incision is generally minimal. Reluctance to perform the maneuver when indicated generally results in patient death. Needle cricothyrotomies are not recommended. They are harder and more time consuming to perform and far less effective in establishing an airway.

APPENDIX K: ENHANCED RECOVERY AFTER SURGERY

Richard A. Jaffe, MD, PhD, Andrew J. Giustini, MD, PhD, and Brenda Golianu, MD

GENERAL CONSIDERATIONS

Enhanced recovery after surgery (ERAS) was conceived as an enhanced fast-track approach to the management of patients undergoing colorectal surgery that incorporated the additional goals of improving postop functional status and decreasing morbidity. ERAS principles have since been expanded both in scope and in application to many other types of surgery. Studies have demonstrated significant benefits of ERAS protocols including decreased length of stay, improved patient satisfaction, decreased morbidity, and cost reduction. ERAS works best as a multispecialty team approach to perioperative patient care. Even in the absence of a formal team, the application of individual elements of ERAS (e.g., limiting NPO duration, multimodal pain management, etc.) is likely to be beneficial for most patients undergoing anesthesia and elective surgery. Importantly, the unique combination of elements most beneficial for any specific surgical procedure and patient cannot be arbitrarily defined.

In the following table, many of the individual elements of enhanced recovery protocols are briefly presented (further details can be found in the Suggested Reading list below). ERAS protocols continue to evolve as the relative importance of the individual elements of enhanced recovery are studied. When considering individual elements, it is essential to appreciate their interdependence. For example, reducing the NPO interval and achieving adequate preop hydration will facilitate intraop fluid management. Obviously, the implementation of any ERAS element must take into consideration patient condition, co-morbidities, and surgical requirements that could affect applicability.

Element	Recommendations
Preop counseling/education	Patients should be routinely counseled regarding what to expect from their surgical and anesthetic experience and be given ample opportunity to have their questions answered in appropriate detail. Discussion should include lines, drains and urinary catheters, along with plans for postop pain

	management emphasizing the use of regional analgesia along with peripheral nerve blocks where possible. Postop wound care, activity limitations, and physiotherapy plans should also be discussed. A procedure-specific enhanced recovery handout with preop checklist should be given to patients.
Prehabilitation program	A program of preop exercise activities designed to increase aerobic capacity may improve recovery in selected patients. For obese patients with time permitting, the benefits of weight loss to a BMI < 30 may be beneficial. For elective major surgery, consider preop physical therapy for patients with significant deconditioning. More generally, prehabilitation refers to any preop intervention that can improve postop recovery including the optimization of any comorbid conditions, and implementation of the interventions listed below.
Preop smoking and alcohol cessation	Abstinence from both alcohol and smoking should be recommended in preparation for surgery. Chronic alcoholics may require withdrawal precautions.
Preop nutritional status	The patient's nutritional status should be assessed in advance of the surgery and optimized if possible. Immunonutrients (most trials have used some combination of arginine, glutamine, omega-3 fatty acids, and ribonucleic acid as a dietary supplement) may have anti-inflammatory effects, boost immune function, and improve outcome in surgical patients. Further study will be necessary to identify effective formulations and specific patient populations most likely to benefit. Impact Advanced Recovery® immunonutrition drink (Nestlé Health Science) is an example of a commercially available preop supplement that has been shown to improve some surgery outcome measures.

Preop fasting and carbohydrate loading	For most procedures, preop fasting should be limited to 2 h for clear (see-through) liquids and 6 h for solid foods or opaque liquids. Preop carbohydrate loading should be encouraged and can be accomplished using oral rehydration sports drinks (e.g., regular Gatorade™ or equivalent) 2 h before surgery.
Antithrombotic prophylaxis	Assess VTE risk. The use of sequential pneumatic compression sleeves is recommended to prevent venous thromboembolism. The addition of anticoagulants (e.g. heparin 5000u sc 30–60 min preop) should be discussed with the surgeon and should take into account patient risk factors for VTE.
Antimicrobial prophylaxis, bowel prep, and skin cleansing	Patients will often be provided with an antimicrobial skin cleanser to use before surgery. Minimize surgical site shaving. Bowel prep is now rarely indicated. Prophylaxis with iv cefazolin 30–60 min before skin incision is recommended.
Regional anesthesia and nerve blocks	When possible, the use of bolus or continuous regional anesthesia and/or specific nerve blocks should be encouraged as a component of anesthetic and analgesic management, particularly for major open surgical procedures.
Surgical approach	Although not always an option, minimally invasive and endoscopic approaches are associated with less postop pain, improved recovery, and patient satisfaction.
Anesthetic protocol	There is insufficient evidence of improved recovery to support the use of TIVA vs. inhalational anesthesia or to support the choice of specific anesthetic agents for most surgical procedures. When appropriate, the use of N_2O will reduce the need for other anesthetics and facilitate rapid recovery from anesthesia. PONV concerns can be eliminated with prophylactic antiemetics, and

	effects on intraop bowel distention appear to be minimal. Optimal ventilation can usually be achieved using volume controlled, pressure mode with TV = 8 ml/kg IBW, PEEP at least 5 cmH_2O, and $ETCO_2$ = 40mmHg (mild permissive hypercapnia).
Fluid management	Fluid balance can be assessed by PPV (if art line in place), TEE (if available), or PVI especially when used in combination with small-volume (100–250 mL) bolus tests. Noninvasive cardiac output monitoring may also be useful. For most minor surgeries, a restrictive (**zero balance**) strategy is appropriate (see section below). A **goal-directed** fluid management strategy is useful for many major surgeries (see section below). Vasopressors should be used in preference to volume in euvolemic patients to maintain MAP unless otherwise contraindicated.
Multimodal pain management emphasizing nonopioid analgesia **(see p. K-5)**	PO or IV acetaminophen (e.g., 1 g) is a useful component of multimodal analgesia. PO celecoxib (COX-2 inhibitor; 200–400 mg po qd) or ketorolac (COX-1 inhibitor; 15–30 mg iv q6h) can provide other modes of analgesia (although some surgeons may be concerned about impaired hemostasis). A ketamine bolus (0.5 mg/kg) and subsequent infusion (5–10 mcg/kg/min) after induction may be a useful intraop analgesic supplement in select patient populations. Gabapentin (300–600 mg po preop) and tramadol (50 mg po postop) have side effects (e.g., prolonged sedation, N/V, pruritus, respiratory depression) that may be unfavorable in some patients or following some surgical procedures. Regional analgesia should be used when possible.
PONV	Routine use of 5-HT3 antagonists (e.g., ondansetron 4 mg iv) and dexamethasone (4–8 mg) is recommended. The addition of preop

	aprepitant (40 mg po qd) is often reserved for procedures or patients with a high risk of PONV. Scopolamine and promethazine have side effects (e.g., sedation, dysrhythmias) that may make them undesirable as primary agents especially in older patients.
Avoiding hypothermia	In general, active heating (e.g., forced-air blanket, circulating water blanket, airway humidifier) should be used to maintain core normothermia.
Oxygenation	Liberal oxygen administration (resulting in SpO_2 > 95%) may be detrimental (e.g., ↑mortality, absorption atelectasis, acute lung injury, etc.) and should be avoided throughout the postop period if possible.
Urinary drainage	Bladder catheters should be removed as early as possible (usually POD 0–1).
Chest tube and other surgical drainage	Active management is required to avoid retention of fluids. Drainage tubes should be removed as soon as it can be safely accomplished.
Postop delirium management	Postop delirium is thought to be underdiagnosed and may result in delayed recovery, extended hospital stay, and cognitive impairment. Medical, metabolic, and medication etiologies should be excluded or treated. Effective pain management, along with nonpharmacologic interventions (return of hearing aids/eyeglasses, reassurance/reorientation, minimizing physical restraints, presence of family/friends, etc.) should be emphasized. Avoiding ketamine and high-dose benzodiazepines in older adults may be helpful. If nonpharmacologic treatment has failed, consider treating hyperactive delirium with low-dose haloperidol (0.5–1 mg iv) if not otherwise contraindicated (onset of beneficial effects may require >15 min). A dexmedetomidine infusion (e.g., 0.1 mcg/kg/h) should be considered in patients for whom haloperidol has failed or is

	contraindicated (see section on Postoperative Delirium in Appendix B for more details).
Postop nutrition	Postop enteral nutrition should be initiated as soon as possible. Chewing gum (30 min tid) may speed up the return of postop bowel function.
Early mobilization	Extubate as soon as criteria are met. Encourage early mobilization, at least sitting up in chair starting POD1 if possible.
Physiotherapy	Immediate pulmonary physiotherapy is often beneficial after long GETA. A physical therapist may be needed to assist with early mobilization following major surgery.

ENHANCED RECOVERY AFTER SURGERY: FLUID MANAGEMENT

Intraoperative fluid management strategies for enhanced recovery

Intraop fluid management can be significantly affected by the patient's adherence to liberal NPO instructions including preop hydration. In the past, "NPO after midnight" ensured that patients would be dehydrated, uncomfortable, and in a catabolic state before surgery. The typical 70-kg healthy adult will have lost >800 mL of primarily extracellular fluid volume by the end of an 8-h fast (Fig. K-1). As a general rule, deep levels of anesthesia (e.g. BIS <40) should be avoided, and vasopressors should be used to treat anesthesia-related hypotension.

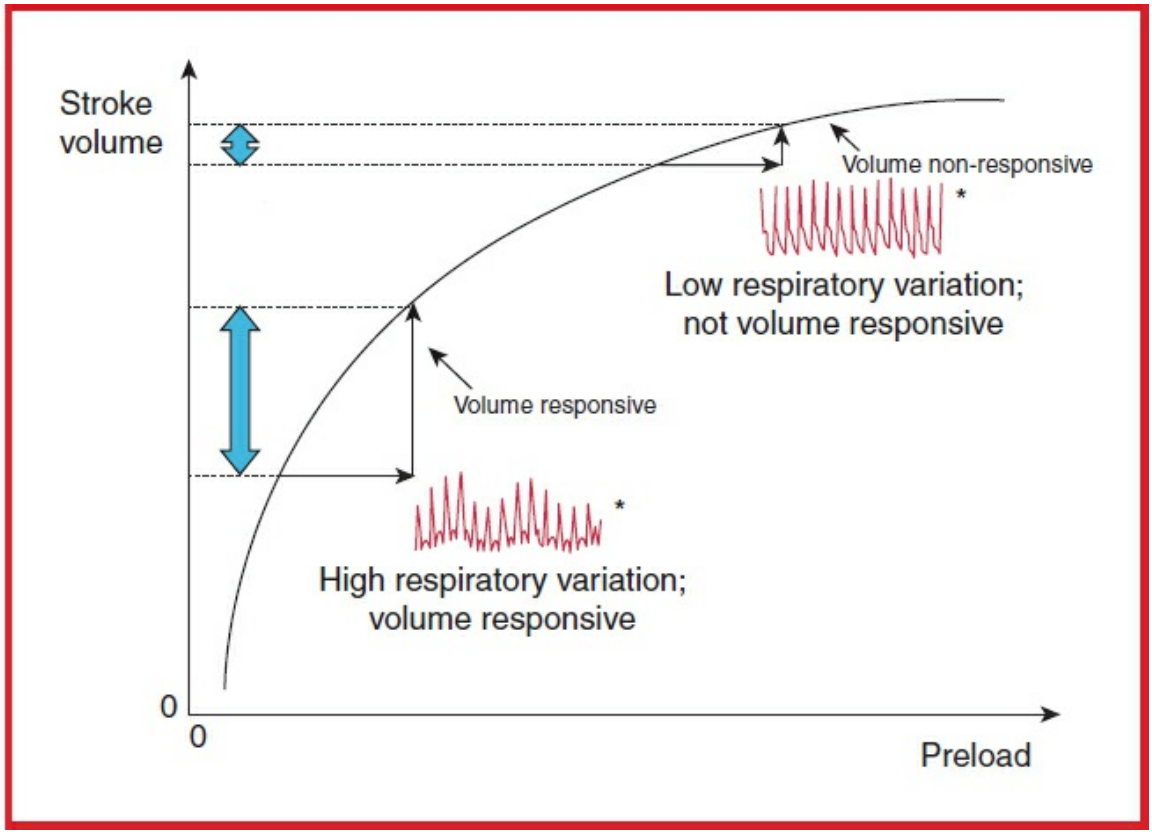

Figure K-1 Frank-Starling relationship with corresponding respiratory variations in the arterial pressure waveform. High respiratory variation in the arterial pressure or in the plethysmographic oximeter waveforms indicates that the patient is on the steep portion of the Frank-Starling relationship. Low

variation indicates that the patient is on the plateau. Cardiac output maximization concepts aim at increasing cardiac output until it reaches the plateau of the Frank-Starling relationship. This goal, as demonstrated on this figure, could be achieved by minimizing respiratory variation in arterial pressure or plethysmographic waveform. (Modified from Rinehart J, Liu N, Alexander B, et al: Closed-loop systems in anesthesia: is there a potential for closed-loop fluid management and hemodynamic optimization? Anesth Analg 2012; 114(1):130–43.)

Parameter	Goal-Directed Strategy	Restrictive (Zero Balance) Strategy
Patient population	Major surgery with potential for EBL ≥ 500 cc or significant fluid shift	Surgery in low-risk patient. EBL < 500 cc
IV fluids*	BSS @ 1–3 mL/kg/h + UO + 1.5 × EBL (or 1 × EBL if colloid used)	BSS @ 1–3 mL/kg/h + 1.5 × EBL
PPV (or SVV)	Give volume if PPV > 10–15% (TV: 8 cc/kg). Use 100–250 cc BSS bolus; repeat prn to keep PPV <11%.	PPV usually not available (no art line)
PVI	May substitute for PPV (less reliable?)	← but probably better than nothing
TEE	Transgastric two-chamber (or midpapillary) view to assess LV cavity size. Normal end diastolic diameter = 45–50 mm ± 4 mm (F < M). Rx small EDV with 100–250 cc BSS bolus prn	Usually not necessary
CO/SV estimating devices	May substitute for PPV when PPV cannot be used	Usually not necessary
HR	Poor predictor of volume status	←
BP	Poor predictor of volume status; Rx ↓ BP 2° anesthesia	←

	with phenylephrine or ephedrine prn	
Urine output	Poor predictor of volume status Goal UO ≥ 0.3 mL/kg/h to avoid AKI	← expect/accept mild oliguria
CVP or PAOP	Poor predictor of volume status	← and usually not available
SvO_2 or $ScvO_2$	Poor predictor of volume status	← and usually not available

*assuming adequate preop hydration.

BSS, balanced salt solution (e.g., LR, Normosol®, PlasmaLyte®). Patients should be euvolemic and carb loaded preop per ERAS guidelines.

ENHANCED RECOVERY AFTER SURGERY: MULTIMODAL ANALGESIA

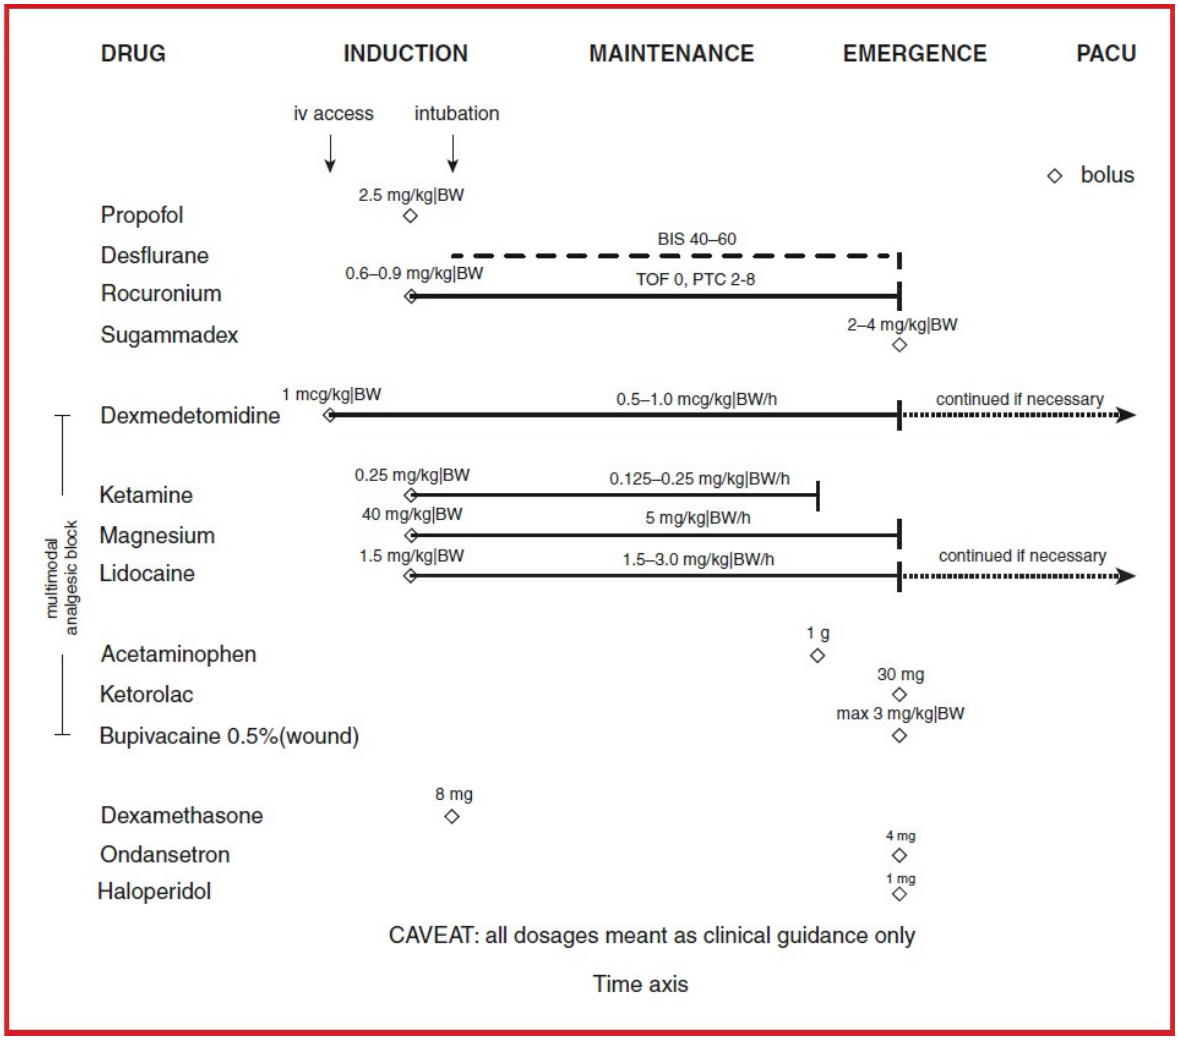

Figure K-2 An example of nonopiate multimodal analgesia/anesthesia. (Adapted from Mauermann E, Ruppen W, Bandschapp O. Different protocols used today to achieve total opioid-free general anesthesia without locoregional blocks. Best Pract Res Clin Anaesthesiol2017; 31(4):533–45. Copyright © 2017 Elsevier. With permission.)

Multimodal analgesia options for a 70-kg patient without specific drug contraindications, undergoing major surgery (see Fig. K-2). Specific analgesic components and doses must be individualized for each patient. (See Appendix C for additional information on perioperative pain management.)

Multimodal Analgesia Options to Consider		
Preinduction	Systemic	Acetaminophen 1000 mg PO Celecoxib 200 mg PO Ibuprofen* 800 mg PO Gabapentin 300–600 mg PO

	Regional	Neuraxial analgesia (e.g., epidural or spinal opiates) or regional/peripheral nerve block
Preincision	Systemic	Ketamine 50 mg iv (especially in opioid-dependent patients) Fentanyl 100–250+ mcg iv
	Local	Local anesthetic infiltration of incision site
Intraop	Systemic	IV opiates (e.g., fentanyl, hydromorphone [low-dose], remifentanil infusion @ 0.05–0.2 mcg/kg/min) Lidocaine infusion 1–2 mg/kg/h and/or ketamine infusion 0.25 mg/kg/h ± $MgSO_4$ 2 g iv (may enhance opiate analgesia) ± Acetaminophen 1000 mg iv q6h
	Regional/local	Whenever possible: continuous regional anesthesia/analgesia Local anesthetic infiltration of incision at closing
Postop	Systemic	Acetaminophen 1000 mg PO q6h Ketorolac* 15–30 mg IV q6h or ibuprofen* 200–800 mg PO q6h or celecoxib 200 mg PO IV opiates (e.g., fentanyl)

	Regional/local	bolus and PCA Tramadol 50 mg PO q4h for breakthrough pain Continuous regional analgesia

*May interfere with platelet function.

ENHANCED RECOVERY AFTER SURGERY: PEDIATRIC SURGERY

ERAS pathways have become common for adult surgical procedures, especially in bowel, breast, and joint surgeries. These pathways typically employ standardized preop, intraop, and postop medications, fluid management strategies, surgical approaches, patient mobilization, and nutrition optimization to facilitate patient recovery, decrease morbidity, and decrease time to discharge from the hospital. ERAS pathways use opioid-sparing multimodal analgesics, antiemetics, optimal intraop fluid management, and preferred anesthetic method (including neuraxial and regional anesthetic techniques). In randomized controlled trials, these interventions have been shown to decrease morbidity, shorten length of stay, and reduce costs of care after various types of surgeries in adults. ERAS pathways have slowly become more common in pediatric surgical practice, with recent articles detailing their benefits.

Principles of ERAS can be applied to most types of surgical cases. While providing a very hemodynamically stable profile intraop, high-dose intraop and postop opioids represent one of the primary causes of prolonged hospital courses, including postop nausea and delayed return of bowel function after surgery. Therefore, many ERAS protocols emphasize the use of opioid-sparing techniques, including thoracic, lumbar and caudal epidurals; paravertebral catheters; and erector spinae plane catheters for thoracic and abdominal procedures. For unilateral upper and lower extremity procedures, single-shot or continuous nerve catheters are also often used. The use of adjuvants to intravenous opioids is also encouraged, including (when appropriate) intraop ketamine; preop or intraop acetaminophen that is continued postop; preop and

postop use of pregabalin or gabapentin; postop use of NSAIDS including ketorolac ibuprofen, or celecoxib; and the use of low-dose lorazepam or diazepam to treat agitation or for muscle spasm after surgeries likely to cause spasm. When opioids are used, the goal should be to use the lowest effective dose of opioids to adequately control pain and to transition to oral analgesics as soon as the patient can tolerate.

The use of nonpharmacologic therapies at all phases of care, including child life consultation, distraction therapies, preop counseling where appropriate, and parental presence at induction, may help to decrease perioperative anxiety, decrease the patient's stress response, and reduce perioperative opioid requirements. Perioperative acupuncture has been shown to decrease postop pain, nausea, and vomiting and may help to decrease the inflammatory response perioperatively and thereby facilitate patient recovery.

Other principles of ERAS that are applicable to most pediatric surgeries include the optimization of nutrition and of fluid management. Nutrition is optimized by prescribing patients evidence-based diets before surgery or admitting patients the night before surgery to follow a standard feeding protocol, and then encouraging early enteral nutrition and discontinuation of parenteral fluids as soon as practical after surgery. Along with early feeding, it is especially important in postsurgical, hospitalized pediatric patients to start medications to reduce the risk of opioid-induced constipation, especially medications such as senna, bisacodyl, docusate, or polyethylene glycol. To prevent intravascular depletion as well as unnecessary fluids that can cause total body and bowel edema, careful assessment of the patient's fluid status is necessary before and during surgery, and general guidelines for fluid requirements for each surgery should be considered. Some pathways combine these aims by encouraging patients, for example, to continue drinking clear fluids containing electrolytes up until two hours prior to surgery and to minimize fasting to as little as is required for the safe performance of general anesthesia.

An evidence-based guide to antiemetic management is also important, as the two primary causes of unplanned admission after outpatient surgeries are uncontrolled pain and uncontrolled nausea.

The creation of ERAS pathways for specific types of surgery is typically done at each operating site by a careful review of the literature and then collaboration and agreement between surgeons, anesthesiologists, and other stakeholders including nursing staff, nutritionists, physical and occupational therapists, and patients. Inclusion and exclusion criteria of patients for each surgery are created, as are guidelines for both the anesthesiologist and surgeon, and perioperative counseling strategies for patients and

families. ERAS pathways include recommendations for preferred minimally invasive surgical techniques, multimodal analgesics, anesthetic techniques, protocols for maintenance of normothermia, hemodynamic goals, choice of antibiotics, fluid optimization, nutritional management, antiemetic choice, time to mobilization, and goals for discharge of patients. Another necessary part of ERAS pathways is the monitoring of metrics associated with surgical recovery to ensure that the ERAS pathway is enhancing recovery and to allow for further improvements.

Typical ERAS Elements Applicable to Pediatric Anesthetic Care	

Preop	• Allow patients to drink clear, electrolyte-containing fluids until 2 h before surgery.
	• Consider preop administration of oral acetaminophen, celecoxib, and/or gabapentin or pregabalin (see doses in table below).
	• Assess volume status.
	• Discuss with surgeon the use of neuraxial and regional techniques, when appropriate.
	• Assess for how patient comorbidities will affect anesthetic and analgesic choices.
	• Pharmacologic anxiolysis
	  • Midazolam 0.5 mg/kg po (maximum 20 mg) or 0.05–0.1 mg/kg iv (maximum 2 mg)
	  • Intranasal dexmedetomidine (2 mcg/kg)
	• Nonpharmacologic anxiolysis options
	  • Child life consultation
	  • Distraction with music, videos, virtual reality
	  • Preop psychological counseling
	  • Perioperative acupuncture
	  • Parental presence for induction

Intraop	• Attempt to maintain euvolemia with appropriate use of crystalloids and colloids.
	• Use multimodal pain control. Can include the following:
	  • Acetaminophen iv 10 mg/kg (<1 yr old) or 15 mg/kg (1 yr or older)
	  • Dexmedetomidine iv (1 mcg/kg over 15 min if not used preop) or clonidine 1–2 mcg/kg
	  • Ketamine iv (0.5 mg/kg at beginning of anesthetic and then additional 0.25 mg/kg every hour)

	• Ketorolac 0.5 mg/kg at end of surgery • Employ neuraxial and regional techniques when appropriate. • Use appropriate antiemetic treatments. • Employ techniques to maintain normothermia. • Change anesthetic plan based on best management of patient comorbidities.
Postop	• Continue multimodal analgesia. • Use medications to prevent constipation. • Encourage early enteral nutrition and patient mobilization, as appropriate.

Analgesic Adjuvants to Opioids		
Indication or Category	**Medication and Dosage**	**Maximum per Dose**
Skeletal muscle spasm or anxiety. Use only one at a time.	Lorazepam (0.01 mg/kg) q6h iv/po	0.5 mg
	Diazepam (0.1 mg/kg) q8h po	5 mg
Neuropathic pain. Use only one at a time.	Pregabalin (1 mg/kg) q12h po	75 mg
	Gabapentin (5 mg/kg) tid po	300 mg
NSAIDs for general pain (do not use any of these in children <6 mo old). Use only one at a time.	Ibuprofen (10 mg/kg) q6h po	600 mg
	Ketorolac (0.5 mg/kg) q6h iv	15 mg. Do not use for more than 3 d.
	Celecoxib (2 mg/kg) q12h po	100 mg
Acetaminophen	Acetaminophen 10 mg/kg (<1 yr old) or 15 mg/kg (1 yr or older) q6h po/iv	650 mg
Opioid-induced pruritus	Nalbuphine (0.05 mg/kg) q4h iv prn	2.5 mg
Nausea (typically ondansetron as first-line therapy with one	Ondansetron (0.1 mg/kg) q8h iv/po prn	4 mg
	Metoclopramide (0.1	10 mg

alternative medication)	mg/kg) q6h iv/po prn Promethazine (0.25 mg/kg) q6h iv/po/pr prn 25 mg
Constipation treatment and prevention	Bisacodyl 5 mg (3–11 yr old) or 10 mg (>11 yr old) qd pr prn Docusate 10 mg (<3 yr old), 25 mg (3–5 yr old), 50 mg (6–12 yr old), 100 mg (>12 yr old) bid po scheduled or prn Senna 4.3 mg (half tablet, for 2–5 yr old), 8.6 mg (one tablet, for 6–11 yr old), 19.2 mg (two tables, for >12 yr old) qd po scheduled or prn Polyethylene glycol 3350: 4.25 g (<5 yr old), 8.5 g (5–12 yr old), 17 g (>12 yr old) bid po

APPENDIX L: HIGH-FLOW NASAL CANNULA (HFNC) AND TRANSNASAL HUMIDIFIED RAPID-INSUFFLATION VENTILATORY EXCHANGE (THRIVE)

Erin Bushell, MD

Background	1. Heated and humidified high-flow nasal cannulae (HFNC) have been employed in critical care areas for some time. 2. Use in the OR with apneic, anesthetized patients is more recent. Patel and Nouraei coined the acronym THRIVE when they began using the device in the OR on anesthetized patients and discovered that it significantly extended the safe apnea period. 3. HFNC may be delivered by the ventilator in the ICU or by a stand-alone device. When stand-alone devices such as the Optiflow® (Fisher & Paykel Healthcare) and the Hi-VNI® (Vapotherm®) are used on spontaneously breathing patients, this is usually referred to as HFNC, and when used on apneic patients, this is usually referred to as THRIVE. 4. Blenders are available for these devices and an $FiO_2 < 1$ may be used in spontaneously ventilating patients, but for apneic patients, an FiO_2 of 1 is standard. 5. The devices deliver a totally conditioned gas (37° at 44 mg H_2O/L = 100% saturation), which allows patients to tolerate high flows. 6. Flows can be titrated from 10 to 70 lpm. Even in dyspneic spontaneously breathing patients, this usually exceeds the peak inspiratory flow rate and thus provides noninvasive support for patients with hypoxemic respiratory failure.
Physiologic Principles	Five physiologic mechanisms are involved. 1. Apneic oxygenation:

- First described by Volhard in 1908 as diffusion ventilation, the mechanisms were expanded upon by Draper's notion of a "hemoglobin-oxygen pump" in 1947.
- Given an oxygen consumption of ~200–250 mL/min, this amount of oxygen will move from the alveolus into the blood. However, due to buffering and the high solubility of carbon dioxide, only about 8–20 mL/min of additional CO_2 enter the alveoli. This results in a slight negative pressure in the alveoli and, provided the patient has a patent airway, net movement of oxygen (or whatever gas is in the pharynx) into the alveoli.

2. Positive airway pressure: When the mouth is closed, these devices provide ~1 cm H_2O of positive pressure for every 10 L of flow.
3. Maintenance of FRC: The replacement of alveolar oxygen combined with positive airway pressure maintains FRC, thereby reducing atelectasis and minimizing desaturation due to shunting.
4. Ventilatory exchange: In contrast to true apneic oxygenation where the PCO_2 rises ~2–3 mm Hg per min of apnea, when THRIVE is used, the observed increase in PCO_2 is only about 1 mm Hg per min of apnea. This may be due to synergy between high flow washout and cardiogenic oscillations.
5. Dead space washout: The high flows employed wash out the pharyngeal space, effectively removing all supraglottic CO_2 and thus eliminating this dead space.

Applications/Indications

Included here is a list of the common current applications:

1. Preoxygenation of patients prior to intubation or induction of anesthesia and while securing difficult airways:
   - Three minutes of preoxygenation with HFNC has been shown to be as effective as 10 L via face

	mask. • In obese patients undergoing bariatric surgery, 8 ½ min of preoxygenation with HFNC was superior to face mask and equivalent (with a trend toward superior) to preoxygenation with 7 cm H_2O of CPAP. • In patients undergoing rapid sequence intubation, it allowed for longer apnea time. • It has been demonstrated to significantly improve oxygenation during intubation in the ICU and to optimize oxygenation and intubation conditions during awake fiberoptic intubation. • In contrast to face mask ventilation, it may be continued during efforts to secure an airway, thus further extending the safe apnea time. There are case reports in which it has provided lifesaving maintenance of oxygenation during 30-min periods of apnea while emergency surgical airways were secured. 2. During general anesthesia: • THRIVE has been successfully used as the sole means of oxygenation during general anesthesia for oral and laryngeal surgeries and ECT. 3. During monitored anesthesia care: • The use of HFNC has been described for various procedures such as endoscopy, awake tracheostomies, and awake craniotomies. 4. In critically ill patients: • HFNC has been employed in patients with stridor, acute epiglottitis, hypoxemic and hypercapneic respiratory failure, and heart failure. • HFNC has been used to prevent postextubation respiratory failure and reintubation.
Contraindications	1. Fire risk: THRIVE has been used successfully with laryngeal laser surgery as long as care is exercised to ensure all fuel sources are protected from the laser. THRIVE with an FiO_2 of 1 should not be used in areas near electrocautery. Instead, an FiO_2 of 0.3

	or lower should be used to reduce the risk of fire. 2. Recent sinus surgery or recent transsphenoidal hypophysectomy. 3. Patients who would not tolerate even a modest rise in PCO_2 (e.g., pulmonary hypertensives) should not undergo apneic oxygenation with THRIVE.
Other Considerations	1. Airway patency must be maintained: Laryngeal suspension, jaw thrust, or oral/nasal airways should be used to maintain oxygenation and allow for some ventilatory exchange. 2. Must have sufficient FRC at outset: THRIVE will maintain FRC but cannot expand atelectatic lungs. Therefore, it is best to use in slight head-up position. 3. Use in children: Although THRIVE is effective in extending the safe apneic period in children, early data indicate it may not offer the same degree of ventilatory exchange because the rate of rise of PCO_2 does not appear to be as reduced as it is in adults.

EMLA	eutectic mixture of local anesthetic
ENT	ear-nose-throat
EP	evoked potentials
EPS	electrophysiologic studies

EPV	endopulmonary vent
ER	emergency room
ERCP	endoscopic retrograde cholangiopancreatography
ERV	expiratory reserve volume
ESC	endocoronary sinus catheter
ESLD	end-stage liver disease
ESRD	end-stage renal disease
ESS	endoscopic sinus surgery
ET	endotracheal
$ETCO_2$	end-tidal CO_2
ETN_2	end-tidal N_2
ETOH	alcohol
ETT	endotracheal tube
EVAR	endovascular aneurysm repair
EVD	endovascular drain (extraventricular catheter)
FAP	familial adenomatous polyposis
FAST	focused assessment with sonography for trauma
FB	foreign bodies
FDP	flexor digitorum profundus (tendon)
FDS	flexor digitorum superficialis (tendon)
FDT	forced duction test
FEIBA	factor B inhibitor bypass activity
FESS	functional endoscopic sinus surgery
FEV_1	forced expiratory volume (in 1 sec)
FFP	fresh-frozen plasma
FHR	fetal heart rate
FIGO	International Federation of Gynecology and Obstetrics
FiO_2	fraction of inspired oxygen
FNA	fine needle aspiration
FOB	fiberoptic bronchoscopy
FOI	fiberoptic intubation
FOL	fiberoptic laryngoscopy

Fr	French (size)
FRC	functional residual capacity
FSP	fibrin-split products
FTSG	full-thickness skin graft
FTT	failure to thrive
FVC	forced vital capacity
g	gram(s)
ga	gauge
GA	general anesthesia
GCS	Glasgow Coma Scale
GDT	goal-directed therapy
GE	gastroesophageal
GERD	gastroesophageal reflux disease
GETA	general endotracheal anesthesia
GFR	glomerular filtration rate
GGTP	gamma-glutamyl transpeptidase (liver enzyme)
GH	growth hormone
GI	gastrointestinal
GIA	gastrointestinal anastomosis
GIFT	gamete intrafallopian transfer
GM-CSF	granulocyte-macrophage colony-stimulating factor
Gn-RH	gonadotropin-releasing hormone
GSW	gunshot wound
GT	gastric tube
GTD	gestational trophoblastic disease
GU	genitourinary
h	hour(s)
HA	headache
H&P	history and physical examination
Hb	hemoglobin
Hb/Hct	hemoglobin/hematocrit

HbA	adult hemoglobin
HbF	fetal hemoglobin
HCC	hepatocellular carcinoma
HCG	human chorionic gonadotropin
HCO_3	bicarbonate
Hct	hematocrit
HELLP	hemolysis, elevated liver enzymes, and low platelet count
HFNC	high-flow nasal cannula
HFV	high-frequency ventilation
Hg	mercury
HIV	human immunodeficiency virus
HLHS	hypoplastic left heart syndrome
HM	hyoid myotomy
Ho	holmium-YAG laser
HPV	hypoxic pulmonary vasoconstrictive (reflex)
HR	heart rate
HSV	highly selective vagotomy
HTN	hypertension
HVA	homovanillic acid
Hx	history
IABP	intra-aortic balloon pump
IBD	inflammatory bowel disease
IC	inspiratory capacity
ICD	implantable cardioverter-defibrillator
ICP	intracranial pressure
ICU	intensive care unit
ID	inside diameter
IE	inspiratory/expiratory
IgE	immunoglobulin E
IHSS	idiopathic hypertrophic subaortic stenosis
II	image intensifier
IIC	intermediate intensive care

IJ	internal jugular (vein)
im	intramuscular
IMA	internal mammary artery
IMF	intermaxillary fixation
iMRI	interventional magnetic resonance imaging
INH	isonicotinic acid hydrazide (isoniazid)
INR	international normalized ratio
IOFB	intraocular foreign body
IOL	intraocular lens
IOP	intraocular pressure
IORT	intraoperative radiation therapy
IPAA	ileal pouch and anastomosis
IPG	implantable generator
IPPV	intermittent positive pressure ventilation
IRDS	infant respiratory distress syndrome
ISS	injury severity score
IT	iliotibial
ITP	idiopathic thrombocytopenic purpura
IUP	intrauterine pressure
iv or IV	intravenous
IVC	inferior vena cava
IVF	in vitro fertilization
IVH	intraventricular hemorrhage
IVP	intravenous pyelogram
IVS	intact ventricular septum
J	Joule
JET	junctional ectopic tachycardia
JI	jejunoileal
JVD	jugular venous distension
K^+	potassium
KCl	potassium chloride

kg	kilogram(s)
KVO	keep vein open
L	liter
LA	left atrium or local anesthetic
LAD	left anterior descending
LAE	left atrial enlargement
LAP	left atrial pressure
LAVH	laparoscopy-assisted vaginal hysterectomy
LBBB	left bundle branch block
LDH	lactate dehydrogenase
LE	lower extremity
LEEP	loop electrosurgical excision procedure
LFT	liver function test
LGL	Lown-Ganong-Levine (syndrome)
LH-RH	luteinizing hormone–releasing hormone
LHSV	laparoscopic highly selective vagotomy
LIMA	left internal mammary artery
LINAC	linear accelerator
LLETZ	large loop excision of the transformation zone
LLD	left lateral decubitus
LLQ	left lower quadrant
LMA	laryngeal mask airway
LMG	laser midline glossectomy
LMP	last menstrual period
LMWH	low molecular weight heparin
LP	lumbar puncture
LR	lactated Ringer (solution)
LRD	living related donor
LSC	laparoscope approach
LTA	lidocaine tracheal anesthesia
LUQ	left upper quadrant
LV	left ventricle/ventricular

LVAD	left ventricular assist device
LVEDP	left ventricular end diastolic pressure
LVEF	left ventricular ejection fraction
LVH	left ventricular hypertrophy
LVOT	left ventricular outflow tract
LVOTO	left ventricular outflow tract obstruction
LVRS	lung volume reduction surgery
m	meter(s)
M	molar
MAC	monitored anesthesia care
MAGPI	meatal advancement glanuloplasty
MAO-B	monoamine oxidase-B
MAOI	monoamine oxidase inhibitor (antidepressant)
MAP	mean arterial pressure
MAPCAs	major aortopulmonary collaterals
MCA	middle cerebral artery
MCKD	medullary cystic kidney disease
MDI	multidirectional instability
MEA	multiple endocrine adenopathy
MED	microendoscopic lumbar discectomy
MEN	multiple endocrine neoplasia
MEP	motor-evoked potential
mEq	milliequivalent
mEqK^+	milliequivalency of potassium
metHb	methemoglobin
mg	milligram(s)
Mg^{++}	magnesium
$MgSO_4$	magnesium sulfate
MH	malignant hyperthermia
MI	myocardial infarction
MICAB	minimally invasive coronary artery bypass
MICABG	minimally invasive coronary artery bypass graft(ing)

µg	microgram(s)
MIDCAB	minimally invasive direct coronary artery bypass
MIDCABG	minimally invasive direct coronary artery bypass graft(ing)
MIF	maximum inspiratory flow
min	minute(s)
mL	milliliter(s)
MLT	microlaryngeal tube
mm	millimeter(s)
$MMEF_{25–75}$	maximum midexpiratory flow
mm Hg	millimeters of mercury
MMPM	multimodal pain management
mo	month(s)
MOGA	mandibular osteotomy and genioglossal advancement
MR	mitral regurgitation
MRA	magnetic resonance angiography
MRI	magnetic resonance imaging
MRSA	methicillin-resistant Staphylococcus aureus
MRT	magnetic resonance–guided therapy
MS	mitral stenosis
MTP	massive transfusion protocol
MUF	modified ultrafiltration
MUGA	multigated acquisition (scan)
MUPIT	Martinez Universal Perineal Interstitial Template
MV	minute ventilation; mitral valve
MVA	motor vehicle accident
MVC	motor vehicle collision
MVD	microvascular decompression
MVO_2	mixed venous oxygen content
MVP	mitral valve prolapse
Na^+	sodium
$NaHCO_3$	sodium bicarbonate
NB	nota bene (note well)

NDMR	nondepolarizing muscle relaxant
Nd:YAG	neodymium-YAG laser
NEC	necrotizing enterocolitis
ng	nanogram(s)
NG	nasogastric (tube)
NIBP	noninvasive blood pressure
NICU	neonatal intensive care unit
NIF	negative inspiratory force
nl	normal
NLD	nasolacrimal duct
NMB	neuromuscular blocker
NMR	nondepolarizing muscle relaxant
NO	nitric oxide
NOAC	new oral anticoagulants
NOE	naso-orbital ethmoid
NORA	non–operating room anesthesia
NPH	neutral protamine Hagedorn (insulin)
npo	nothing by mouth
NS	normal saline
NSAID	nonsteroidal anti-inflammatory drug
NS/LR	normal saline/lactated Ringer (solution)
NSR	normal sinus rhythm
NTE	not to exceed
NTG	nitroglycerin
NTP	nitroprusside
N_2O	nitrous oxide
N/V	nausea and vomiting
OA	osteoarthritis
OATS	osteochondral autograft transfer system
OCR	oculocardiac reflex
OD	outside diameter
OEIS	omphalocele exstrophy imperforate anus spinal defect

OG	orogastric (tube)
OLV	one-lung ventilation
OPCAB	off-pump coronary artery bypass
OPCABG	off-pump coronary artery bypass graft(ing)
OPLL	ossification of the posterior longitudinal ligament
OR	operating room
ORIF	open reduction and internal fixation
ORR	oculorespiratory reflex
OSA	obstructive sleep apnea
O_2	oxygen
O_2 sat	oxygen saturation
P	pulse
PA	pulmonary artery
$PaCO_2$	partial pressure of CO_2 (arterial)
PACU	postanesthesia care unit
PAD	pulmonary artery diastolic
PADP	pulmonary artery diastolic pressure
PAK	pancreas after kidney (transplant)
PAOP	pulmonary artery occlusion pressure
PaO_2	partial pressure of oxygen (arterial)
PAP	pulmonary artery pressure
PAR	postanesthesia room
PAWP	pulmonary artery wedge pressure
PCA	patient-controlled analgesia
PCC	prothrombin complex concentrate
PCEA	patient-controlled epidural analgesia
PCL	posterior cruciate ligament
PCO_2	partial pressure of carbon dioxide
PCV	parietal cell vagotomy
PCWP	pulmonary capillary wedge pressure
PDA	patent ductus arteriosus
PDE	phosphodiesterase

PDPH	postdural puncture headache
PE	pulmonary embolus
PEEP	positive end-expiratory pressure
PEF	peak expiratory flow
PET	positron emission tomography
$PetCO_2$	end-tidal CO_2 partial pressure
PFNS	preservative-free normal saline
PFO	patent foramen ovale
PFT	pulmonary function test
PGE	prostaglandin E
PICC	peripherally inserted central catheter
PICU	pediatric intensive care unit
PID	pelvic inflammatory disease
PIH	pregnancy-induced hypertension
PIP	peak inspiratory pressure
PKP	penetrating keratoplasty
PLIF	posterior lumbar interbody fusion
Plt	platelet
PND	paroxysmal nocturnal dyspnea
po	by mouth
POC	product of conception
POD	postoperative day
POEM	peroral endoscopic myotomy
PONV	postoperative nausea and vomiting
POOP	perineal one-stage operative pull-through
POPE	postobstructive pulmonary edema
PO_2	partial pressure of oxygen
PPH	postpartum hemorrhage
PPI	proton pump inhibitor
ppm	parts per million
PPTL	postpartum tubal ligation
PPV	positive pressure ventilation or pulse pressure variation
pr	per rectum

PRBC	packed red blood cell
prn	as needed
PS	pulmonic stenosis
PSARP	perineal sagittal anorectoplasty
PSSD	postsurgical stress disorder
PT	prothrombin time
PTCA	percutaneous transluminal coronary angioplasty
PTM	posterior tibial muscle
PTS	posttourniquet syndrome
PTSD	posttraumatic stress disorder
PTT	partial thromboplastin time
PUD	peptic ulcer disease
PUV	posterior urethral valve
PVA	polyvinyl alcohol
PVB	paravertebral block
PVC	premature ventricular contraction
PVD	peripheral vascular disease
PVI	pleth variability index
PVOD	pulmonary vascular occlusive disease
PVR	pulmonary vascular resistance
q	query
qd	every day
Q_P/Q_S	pulmonary-to-systemic flow ratio
QRS	QRS complex of ECG
qs	quantum satis (sufficient quantity)
RA	radial artery
RAD	right axis deviation
RAE	right atrial enlargement
RAP	right atrial pressure
RAST	radioallergosorbent test
RBBB	right bundle branch block

RBC	red blood cell
RC	rotator cuff
RCA	right coronary artery
RCP	retrograde cerebral perfusion
RCT	randomized controlled trial
RDS	respiratory distress syndrome
RF	radiofrequency
RFA	radiofrequency ablation
RFT	renal function test
RIND	reversible ischemic neurologic deficit
RLD	right lateral decubitus
RLQ	right lower quadrant
r/o	rule out
ROM	range of motion
ROP	retinopathy of prematurity
RR	respiratory rate
RSD	reflex sympathetic dystrophy (obsolete)
RSI	rapid-sequence induction
RSV	respiratory syncytial virus
RUE	right upper extremity
RUQ	right upper quadrant
RV	right ventricle
RVE	right ventricular enlargement
RVEDP	right ventricular end-diastolic pressure
RVESV	right ventricular end-systolic volume
RVH	right ventricular hypertrophy
RVOT	right ventricular outflow tract
RVOTO	right ventricular outflow tract obstruction
Rx	treatment
SA	sinoatrial (node)
SAB	subarachnoid block
SAD	subacromial decompression

SAH	subarachnoid hemorrhage
SAM	systolic anterior motion
SBE	subacute bacterial endocarditis
SBO	small bowel obstruction
SBP	systolic blood pressure
sc	subcutaneous
SCD	sequential compression device
SCFE	slipped capital femoral epiphysis
SCT	sacrococcygeal teratoma
sec	second(s)
SGOT	serum glutamic-oxaloacetic transaminase
SGPT	serum glutamate-pyruvate transaminase
SI	sacroiliac
SIADH	syndrome of inappropriate antidiuretic hormone
SICU	surgical intensive care unit
sl	sublingual
SLAP	superior labral anterior to posterior
SLE	systemic lupus erythematosus
SLH	subtotal laparoscopic hysterectomy
SLT	single-lung transplant or single-lumen tube
SMA	superior mesenteric artery
SMV	superior mesenteric vein
SNP	sodium nitroprusside
SOB	short(ness) of breath
S/P	status post
SPK	simultaneous kidney/pancreas (transplant)
SpO_2	oxygen saturation measured by pulse oximetry
SPV	systolic pressure variation
SSA	sickle cell anemia
SSEP	somatosensory evoked potential
SSI	surgical site infection
SSRI	selective serotonin reuptake inhibitor
SSS	sick sinus syndrome

S-T	wave of ECG
ST-T	ST-T wave of ECG
STA	superficial temporal artery
STP	sodium thiopental
STSG	split-thickness skin graft
SV	stroke volume
SVC	superior vena cava
S_vO_2	venous O_2 saturation
SVR	systemic vascular resistance
SVT	supraventricular tachycardia
Sx	signs and symptoms
Sz	seizure
T	temperature
T&C	type and cross-match
T&S	type and screen
T/A	tonsillectomy/adenoidectomy
TAAA	thoracoabdominal aortic aneurysm
TAB	therapeutic abortion
TACO	transfusion-associated circulatory overload
TAH	total abdominal hysterectomy
TAPVC	total anomalous pulmonary venous connection
TB	tuberculosis
TBI	total body irradiation
TBSA	total body surface area
TCA	tricyclic antidepressant
TCD	transcranial Doppler
TE	tangential excision
TEA	thromboendarterectomy
TECAB	totally endoscopic coronary artery bypass
TEE	transesophageal echocardiogram (graphy)
TEF	tracheoesophageal fistula
TEG	thromboelastogram

TET	tubal embryo transfer
TEVAR	thoracic endovascular aortic repair
TGA	transposition of the great arteries
TGV	transposition of the great veins
THRIVE	transnasal humidified rapid-insufflation ventilatory exchange
TIA	transient ischemic attach
tid	3 times per day
TIPS	transjugular intrahepatic portosystemic shunt
TIVA	total intravenous anesthesia
TKO	to keep open
TL	thoracolumbar
TLC	total lung capacity
TLH	total laparoscopic hysterectomy
TLIF	transforaminal lumbar interbody fusion
TMJ	temporomandibular joint
TMJD	temporomandibular joint dysfunction
TOF	tetralogy of Fallot, train of force
tPA	tissue plasminogen activator
TPN	total parenteral nutrition
TR	tricuspid regurgitation
TRALI	transfusion-related acute lung injury
TRAM	transverse rectus abdominis muscle (flap)
TSA	total shoulder arthroplasty
TSC	tethered spinal cord
TSH	thyroid-stimulating hormone
TT	thrombin time
TTE	transthoracic echocardiography
TTP	thrombotic thrombocytopenic purpura
TUMT	transurethral microwave thermotherapy
TUNA	transurethral needle ablation
TUR	transurethral resection
TURBT	transurethral resection of bladder tumor
TURP	transurethral resection of the prostate

TUVP	transurethral vaporization of the prostate
TV	tidal volume
TVOR	transvaginal oocyte retrieval
TVT	tension-free vaginal tape procedure
TW airway	Tudor-Williams airway
TWR	total wrist replacement
Tx	transplant
U	unit(s)
UA	urinalysis
UAC	umbilical artery catheter
UBC	unicameral bone cyst
UC	ulcerative colitis
UE	upper extremity
UO	urine output
UPJ	ureteropelvic junction
UPPP	uvulopalatopharyngoplasty
URI	upper respiratory infection
US	ultrasound
UTI	urinary tract infection
UVC	umbilical vein catheter
UW	University of Wisconsin (solution)
V&A	vagotomy and antrectomy
V&P	vagotomy and pyloroplasty
VA	ventriculoatrial
VAE	venous air embolism
VAGM	vein of Galen malformation
VALH	vaginally assisted laparoscopic hysterectomy
VAT	video-assisted thoracoscopy
VATS	video-assisted thoracoscopic surgery
VBG	vertical banded gastroplasty
VC	vital capacity

Vd	volume of distribution
VF	ventricular fibrillation
VIP	vasoactive intestinal peptide
VIPoma	vasoactive intestinal peptide-secreting tumor
VLAP	visual laser ablation of the prostate
VMA	vanillylmandelic acid
VO_2	oxygen consumption
VP	ventriculoperitoneal
VPI	velopharyngeal insufficiency
V/Q	ventilation-perfusion ratio
VRE	vancomycin-resistant enterococci
VS	vital signs
VSD	ventricular septal defect
VT	ventricular tachycardia
VUR	vesicoureteral reflux
WBC	white blood cell
WPW	Wolff-Parkinson-White (syndrome)
W/U	workup
XRT	x-ray therapy
yr	year(s)

SUBJECT INDEX

INDEX

Note: Page numbers followed by f indicate figures; page numbers followed by t indicate tabular material.

A

- AAA (abdominal aortic aneurysm)
  - endovascular stent-grafting, 459–465, 461f, 462t–464t
  - surgery of, 479–485, 480f, 481t–485t
- Abbe–Estlander flap, 1620, 1621f
- Abdnominal nerve block
  - quadratus lumborum, 1798–1799, 1798f, 1798t–1799t
  - rectus sheath, 1796–1797, 1796t–1797t, 1796f–1797f
  - transversus abdominis plane, 1788–1789, 1788t–1789t, 1788f–1789f
- Abdominal aortic aneurysm (AAA)
  - endovascular stent-grafting, 459–465, 461f, 462t–464t
  - surgery of, 479–485, 480f, 481t–485t
- Abdominal approach, rectal prolapse, 607–609, 608t, 618–620, 618t–620t
- Abdominal colpopexy, 901t–902t
- Abdominal compartment syndrome, 828
- Abdominal dehiscence, repair of, 724–727, 724t–727t
- Abdominal hysterectomy, 909–914, 911f, 911t–912t, 912b, 912t–914t

- Abdominal, laparoscopic, or robotic colpopexy, 900
- Abdominal sacrocolpopexy or sacrocervicopexy, 915–916
- Abdominal surgery, 1235–1240, 1236f–1239f
- Abdominal suspension procedures, 919
- Abdominal trauma
  - anesthetic considerations for, 833, 833f, 835–837, 835t–837t
  - hepatic and splenic injuries, 829–831, 830f, 831t
  - laparotomy, exploratory/staging, 708–714, 708f
  - surgery for damage control, 828–829, 828t–829t, 829b
  - vascular injuries, 832–837, 834t
- Abdominal tumors, pediatric, 1465–1469, 1466f
- Abdominal vessels, injuries to, 832
- Abdominal wall defects, 1477–1481, 1478f
- Abdominoplasty, 1235–1240, 1236f, 1237t, 1238t, 1239t
- Abortion
  - dilatation and curettage, 890–891, 890t, 891f, 891t, 893–896, 894t–895t
  - therapeutic, dilatation, and evacuation, 891–896, 892t–893t, 892f, 893b
- Abscess
  - biopsy/drainage of, 1197–1201
  - drainage of subphrenic, 717–719, 718t, 718f, 719t
  - incision/drainage of neck, pediatric, 1357–1359
- ACE (angiotensin-converting enzyme) inhibitor, 677t–679t
  - drug interactions, F–10t–F–14t
- Acetabular augmentation, 1561–1563, 1562f, 1587–1591
- Acetabular dysplasia, 1117, 1117f
- Acetabulum fractures, open reduction and internal, 1110–1112, 1114–1116, 1114f–1115f
- Acetaminophen, E–1t–E–3t, 654t–655t, 670t, 673t, 683t–684t, 686t, 711, 735t, 739t, 740t, 749t–751t, 757t–758t, 764t, 768t, 784t, 857t, 858t, 861t, 862t, 863t, 866t–867t, 868t, 872t, 874t, 877t, 878t, 882t, 883t, 887t–888t, 894t, 895t, 898t, 899t, 903t, 904t, 906t, 909t, 928t, 932t–933t, 938t–939t, 946t, 948t, 978t–979t, 982t, 983t–984t, 987t, 995t–996t, 997t, 1001t–1002t, 1003t–1004t, 1008t, 1011t, 1014t, 1015t, 1017t, 1018t, 1021t
  - abdominal dehiscence, repair of, 725t, 726t–727t
  - exploratory/staging laparotomy, 710t, 711t–713t
  - pancreatic surgery, 699t–700t, 700–701, 701t–703t
  - pediatric use of, E–1t–E–3t
- Acetylcholine antagonists, 81
- Acetylcholinesterase inhibitors, drug interactions, F–1t–F–8t
- Achalasia, 652t

- esophagomyotomy, 542–544, 543f, 543t–544t, 550–554, 550t–554t
- laparoscopic Heller's myotomy, antireflux, 648–649, 652, 652t
- video-assisted thoracic surgery, 309–313, 310t, 311f, 311t–313t

Achilles tendon
- lengthening, 1184
- repair, 1158–1163

Achondroplasia, anesthesia issues, 1587t
Acoustic neuromas, 276
Acromegaly, transsphenoidal resection, 60–65, 61b, 61f, 62b, 63t–65t
Acromial impingement, 1063–1066, 1063f, 1064f
Acromioclavicular joint
- arthritis, 1063–1066, 1063f, 1064f
- separation, 1065, 1076

Actinomycin D, 851t
Acupuncture, H–1–H–3, H–2f
Acute airway obstruction, 752t
Acute appendicitis, 683
Acute hypocalcemia, 752t
Acute pancreatitis, 699, 699t–700t
Acute stroke, cerebral revascularization, 1654
Acute testicular torsion, 1013
Addison's disease, 750t–751t
Adductor canal (saphenous nerve), 1778–1779
- anatomy, 1778f–1779f
- indications, 1778t–1779t
- ultrasound imaging, 1778f

Adductor release/transfer, 1567–1568, 1587–1591
Adenoidectomy, 228–232, 228f, 230t–232t
- pediatric, 1345–1349

Adenoma
- laparoscopic adrenalectomy, 660–663, 660f
- rectal surgery, 609–612, 610f, 611t, 612t, 618–620, 618t–620t

Adenomyosis, laparoscopic hysterectomy, 965–972
Adenosine, 10t–12t
Adjustable gastric banding, 674
Adjustable strabismus surgery, 1328
Adjustable suture technique, 1328
Adnexal mass, 960–962
Adrenalectomy, 762t
- adrenal glands, anatomy, 759f–760f

- intraoperative, anesthetic considerations, 764, 764t
- laparoscopic, 660–663, 660f, 661t–662t
  - anterior transperitoneal approach, 759
  - lateral transperitoneal approach, 759, 760f
- laparoscopic retroperitoneal approach, 760–761
- open extraperitoneal approach (flank), 758
- open transperitoneal approach, 758, 760f
- postoperative, anesthetic considerations, 765
- preoperative, anesthetic considerations
  - Conn's syndrome, 763–764, 763t–764t
  - Cushing's syndrome, 763, 763t
- procedures, 758–769, 759f–760f
- robot-assisted approach, 761

Adrenergics/sympathomimetics, drug interactions, F–1t–F–8t
Adrenocortical carcinoma, 761
Adrenocorticotropic hormone-secreting tumor, transsphenoidal resection, 60–65, 61b, 61f, 62b, 63t–65t
Advanced Trauma Life-Support (ATLS) Program, 808
AEDs (antiseizure medications), F–10t–F–14t
Aganglionosis, congenital, 1481–1485, 1482f
aHUS (atypical hemolytic uremic syndrome), 1636
Airway
- control, ABC's of, 808
- fire, 206
- laser surgery, 363–366, 364t–365t
- and lung access conflicts, 306
- management and assessment
  - cricothyrotomy, 808–811
  - initial, 808, 809f
  - in-line stabilization, 808–809
  - nasotracheal intubation, 809
  - orotracheal intubation, 808
  - pediatric, 838–840, 839f
  - surgical airway, 809
  - tracheostomy, 810–811
- obstruction, 1351–1355
- otolaryngology management, 196

Alanine aminotransferase (ALT), 677t–679t
Alar reduction, 1220
Alcohol-mediated cirrhosis, 784–785

- Alfentanil, drug interactions, F–1t– F–8t
- ALIF (anterior lumbar interbody fusion), 134–135
- Aliskiren, drug interactions, F–1t– F–8t, F–10t– F–14t
- All-arterial revascularization, 390
- Allopurinol, 804t–806t
- Alpha blockers, drug interactions, 765, F–10t– F–14t
- Alpha-beta blockers, drug interactions, F–10t– F–14t
- Alpingo-oophorectomy, 965
- ALT (alanine aminotransferase), 677t–679t
- Altemeier procedure, rectal prolapse, 607–609, 608t, 618–620, 618t–620t
- Alteplase, drug interactions, 1t–2t
- Alveolar microlithiasis, 350–353, 350t–353t
- Alveolar proteinosis, pulmonary, 350–353, 350t–353t
- Amantadine, 81
- American Society of Anesthesiologists (ASA) concensus statement, A–5
- Aminoglycosides, drug interactions, F–1t– F–8t
- Amiodarone, 766t–768t
  - drug interactions, F–1t– F–8t, F–10t– F–14t
- Amphetamines, drug interactions, F–1t– F–8t
- Ampicillin, 799t, 800t–801t
- Ampullary hepaticojejunostomy, 696–697
- Amputations
  - above the knee, 1185–1186
  - ankle, 1180–1182, 1180f–1181f
  - around hip and pelvis, 1120–1124
  - below the knee, 1186–1190, 1187f
  - common areas for lower leg, 1181f
  - Guillotine, 1185, 1187
  - Syme, 1180–1182, 1180f–1181f
  - transmetatarsal, 1182–1183
- Anal fistulotomy/fistulectomy/fistula plug, 612–614, 613t–614t, 618–620, 618t–620t
- Analgesia
  - emergence, B–3–B–4, B–3t–B–4t
  - epidural, C–4t
  - multimodality, C–1– C–2, C–2t
  - new paradigm, C–2– C–6, C–3t
  - pediatric, E–4, E–4t
  - preemptive, C–2
- Anastomosis
  - choledochal cyst with, 637–641, 638t, 639t, 640t

- end-to-end, 1002
- small bowel resection with, 585–586, 585f, 586t, 588–591, 588t–591t

Anatomic pulmonary resections, 823–824

Anderson–Heinz (Hynes) pyeloplasty, 993

Anemia, laparoscopic splenectomy for hemolytic, 655–659, 656f

Anesthetic management protocols
- adult, B–1–B–9
- pediatric, B–2–B–6

Aneurysmectomy, left ventricular, 397–398, 397t, 398t

Aneurysms
- abdominal aorta, surgery of, 479–485, 480f, 481t–485t
- dissecting, 465
- endovascular stent-grafting aortic aneurysm, 459–465, 461f, 462t–464t
- giant intracranial, 13–17, 14t–16t
- intracranial, 4–17
- therapy, 1653, 1654f
- thoracic aortic, repair of, 455–459, 456t–458t
- thoracoabdominal aorta, repair of, 472–479, 473f–474f, 474t–476t, 478t

Angiographically occult vascular malformations (AOVMs), 20–26

Angiography, 832–833, 1712

Angioplasty
- balloon, 1711–1713
- cerebral revascularization, 1654–1655

Angiotensin II receptor blocker (ARB), 677t–679t

Angiotensin-converting enzyme (ACE) inhibitor, 677t–679t
- drug interactions, F–10t–F–14t

Angiotensin-receptor-blockers, drug interactions, F–10t–F–14t

Anhepatic phase, 784–785

Anisomelia, congenital/acquired, 1577–1579, 1578f, 1587–1591

Ankle, 1786–1787
- amputation, 1180–1182, 1180f–1181f
- anatomy, 1786f–1787f
- arthrodesis, 1175–1177, 1176f
- arthroscopy, 1172–1174, 1173f
- arthrotomy, 1174–1175
- capsulotomy, 1184
- fractures, open reduction and internal fixation of, 1169–1171
- indications, 1786t–1787t
- ligaments, repair/reconstruction of, 1179–1180
- total replacement, 1177–1178

- ultrasound imaging, 1786f, 1787f

Annuloplasty, 408–409
Anorectal surgery, 612
Anorexia, 676–677
Antecolic approach, laparoscopic bariatric surgery, 674–675
Anterior and posterior colporrhaphy, 915–918
Anterior approach, indirect/direct inguinal hernia, 719
Anterior capsule-labral repair, 1060, 1067
Anterior cervical discectomy, 114–115
Anterior cervicothoracic spinal surgery, 122–129, 123t–129t
Anterior colporrhaphy, 915
Anterior cranial base surgery, 261
Anterior extraperitoneal approach, 717
Anterior fusion/fixation
- of mid and lower cervical spine, 114–117, 115f–116f, 117t
- of upper cervical spine, 108–111, 109f, 110t, 110f, 111t

Anterior horizontal partial laryngectomy, 223–225, 224f
Anterior instrumentation, 134
Anterior lumbar interbody fusion (ALIF), 134–135
Anterior lumbar/lumbosacral spinal surgery, 134–136, 134f, 136t
Anterior mediastinotomy procedure, 372
Anterior orbitotomy, 186
Anterior pelvic exenteration, 870. See also Pelvic exenteration
Anterior screw-plate fixation, 115
Anterior spinal reconstruction and fusion of thoracic and thoracolumbar spine, 1100–1107
Anterior transperitoneal route, 717
Anterolateral retroperitoneal approach, lumbar sympathectomy, 491
Anthracyclines, drug interactions, F–1t–F–8t
Antibiotic therapy, permanent vascular access, 505–509
Anticoagulation guidelines, for neuraxial procedures, J–1–J–2
Anticytokines, drug interactions, F–10t–F–14t
Antiemetics
- pediatric, E–4, E–4t
- prophylaxis, 199

Antigout agents, drug interactions, F–10t–F–14t
Antineoplastic chemotherapeutic agents, 851t
Anti-Parkinsonian medications, drug interactions, F–10t–F–14t
Antipsychotic agents, drug interactions, F–10t–F–14t
Antireflux, laparoscopic Heller's myotomy, 648–649, 652

- Antiseizure medications (AEDs), F–10t–F–14t
- Anus, imperforate, 1481
- Aorta
  - arch, 455
  - ascending, 455, 465–466
  - chest trauma and repair of, 821–823

Colporrhaphy, 900, 909–910, 915–918
Colpotomy, 966
Columellar strut, 1219t
Combined anterior and posterior instrumentation, 141–146, 141t
- anesthetic issues, 142–146, 142t–145t

Combined spinal/epidural (CSE)
- cesarean section, 929t
- dilatation and evacuation and dilatation and curettage, 890–896, 891f, 892f, 890t–895t, 893b
- hysteroscopy, 896–899, 896f, 897b, 897t–899t
- infertility operations and, 907
- stress urinary incontinence, operations for, 919–923, 920t–923t
- vaginal, abdominal, laparoscopic/robotic-assisted hysterectomy, 909–914

Compartment syndrome of thigh, 1190–1192, 1191f
Complete A-V canal defects, 1373
Complete inversion, 950
Completion axillary dissection, 733
Composite resection with marginal/segmental mandibulectomy, 240–241, 241t
Computed tomography (CT) procedures, 1684–1690, 1731–1733
Congenital abnormalities, lung resection, 313–322, 314f, 315f, 315t–322t
Congenital cystic adenomatoid alformations (CCAM), 1443–1447
Congenital diaphragmatic hernia (CDH), 1443–1447, 1444f
- repair of, 1457–1461

Congenital lobar overdistention (CLO), 1443–1447, 1444f
Congenital muscular torticollis, 1545–1547
Congenital pseudarthrosis of tibia, 1575–1577, 1587–1591
Congestive heart disease (CHD), heart transplant, 516–522, 517f, 517t–522t
Congestive heart failure (CHF), 1671–1673
- aortic valve replacement, 398–402, 399t–402t
- asymmetric septal hypertrophy, 413–416, 413t–415t
- implantation of cardioverterdefibrillator, 1662–1666, 1665f–1666f
- left ventricular aneurysmectomy, 397–398, 397t, 398t

- mitral valve repair/replacement, 403–408, 404t–408t
- morbid obesity, 563–569, 564f–566f, 565t–569t

Conivaptan, drug interactions, F–1t–F–8t
Conization of cervix, 859–862, 859f, 860t–862t
Conjunctival transposition, 172
Conn's disease, laparoscopic adrenalectomy, 660–663, 660f
Conn's syndrome, 763–764, 763t–764t
Constrictive pericarditis, 420–425, 421t–424t
Continent catheterizable stoma, 1523
Continent ileostomy pouch (Kock), 583–585, 583t, 584f, 584t
- proctocolectomy, total, 595–599, 596f, 597t–599t, 598f, 604–607, 604t–606t

Continent/incontinent urinary diversion, 869
Continuous venovenous hemofiltration (CVVH), 791t–792t
COPD (chronic obstructive pulmonary disease), 650
- lung transplant, 378–379
- lung-volume reduction surgery, 346–350, 346t–349t

Corneal transplant, 160–162
Coronary artery bypass graft (CABG)
- grafting, 428–434, 429f–430f, 432t–433t
- minimally invasive, 390–397, 391t–396t, 428–434, 429f–430f, 432t–433t
- off-pump, 390–397, 391t–396t, 428–434, 429f–430f, 432t–433t
- procedures, 390–397, 391t–396t, 391f

Coronary artery disease (CAD)
- heart transplant, 516–522, 517f, 517t–522t
- infrainguinal arterial bypass, 485–489
- morbid obesity, 563–569, 564f–566f, 565t–569t

Coronary artery revascularization, port access, 390–397, 391f, 391t–396t
Coronary vein ligation, 499
Corpus callosotomy, 92
Cortical stimulation, 84–87, 85t–87t
Corticosteroids, 665t
- drug interactions, F–1t–F–8t, F–10t–F–14t

Costotransversectomy, 131–132
Cotrel–Duboussett rods, 1553–1557, 1554f
CPB. See Cardiopulmonary bypass (CPB)
Crafoord aortic coarctation, 1386
Cranial nerve, microvascular decompression of, 50–54, 51b, 51f, 52t–54t, 52b
Cranial spinal irradiation (CSI), 1706
Cranial vault reconstructive surgery (CCVR), 1302–1305
Craniectomy for craniosynostosis, 1302–1307, 1302f

- Craniocervical decompression, 70–72, 71b, 71f, 72b
- Craniocervical (occipitocervical, craniovertebral) fusion/fixation, 111
- Craniofacial malformations
  - cleft lip repair, alveolar with bone graft, 1618–1620, 1618f, 1622–1625
  - cleft lip repair, secondary, 1620–1625, 1620f–1621f
  - cleft lip repair, unilateral and bilateral, 1609–1612, 1609f–1610f, 1622–1625
  - craniosynostosis, 1598–1604, 1598f
  - otoplasty, 1625–1627, 1626f
  - palatoplasty, 1612–1615, 1613f, 1614f, 1622–1625
  - pharyngoplasty, 1615–1618, 1615f, 1616f, 1622–1625
- Craniofacial surgery, 1302–1307
  - facial fractures, repair of, 1248–1256, 1249f–1252f
  - LeFort osteotomies, 1248, 1264
  - mandibular osteotomies, 1260–1265, 1261f, 1262f
  - procedure, 1604–1609, 1605f
- Craniopharyngioma, transsphenoidal resection, 60–65, 61b, 61f, 62b, 63t–65t
- Cranioplasty, 41
- Craniosynostosis, 1598–1604, 1598f
  - craniectomy for, 1302–1307, 1302f
- Craniotomy
  - for awake, 39–41, 40t–41t
  - bifrontal for CSF leak, 54–57, 55f, 56b
  - for brain tumors, 33–39, 33t, 34t, 35b, 36t–38t
  - for cerebral embolectomy, 17–19, 18f, 19b
  - definition, 5
  - for epilepsy, 92
  - for extracranial-intracranial revascularization, 26–33, 27f–28f, 28b, 29t, 29b, 30t–32t
  - frontal, temporal, and occipital, 92
  - frontotemporal (pterional), 5
  - for giant intracranial aneurysms, 13–17, 14t–16t
  - for intracranial aneurysms, 4–17, 4f, 5t, 6f, 7b, 8t–13t
  - for intracranial vascular malformations, 20–26, 20t–25t, 21b, 21f–22f
  - middle fossa, 280f
  - operating room setup, 280f
  - posterior fossa, 280f
  - for skull tumor, 41–42, 42t
  - stereotactic, 20
  - suboccipital, 5
  - subtemporal, 5

- transjugular, 279f
- for trauma, 43–50, 43f–44f, 45b, 46t–49t
- for tumor, 33–39, 33t, 34t, 35b, 36f–39f
- vein of galen malformation, 1322–1325

Crawford classification of thoracoabdominal aorta aneurysms and inclusion technique, 472f, 473
Crawford procedure for clubfoot, 1585–1591
Crawford's classification, 472f, 473
- inclusion technique, 473, 474f

Cricoid split, 1360
Cricothyroidotomy
- percutaneous, 810
- procedures, 209–213, 210t–213t

Cricothyrotomy, 810–811, 1750–1751, 1750f–1752f
- needle, 838
- surgical in children, 838

Cricotracheal resection, 221–223, 222t
- pediatric, 1359–1362

Crizotinib, drug interactions, F–1t–F–8t
Crohn's disease, 665t
- anal fistulotomy/fistulectomy/fistula plug, 612–614, 613t–614t, 618–620, 618t–620t
- colectomy, segmental/partial, 599–602, 601t, 604–607, 604t–606t
- proctocolectomy, total, 595–599, 596f, 597t–599t, 598f, 604–607, 604t–606t
- small bowel resection with anastomosis, 585–586, 585f, 586t, 588–591, 588t–591t

Cross-sectional imaging, 1731–1733
Crouzon syndrome, 1598
CRT (cardiac resynchronization therapy), 1663
Cruciate ligament, arthroscopy, 1151, 1156
Cryoballoon ablation, 1667, 1668f
Cryotherapy, 188
- for hemorrhoids, 614–615

Cryptorchidism, 1491–1493
CSF leaks. See Cerebrospinal fluid (CSF) leaks
C-spine injuries, 817, 817t, 818t
CTS (carpal tunnel syndrome), 1049
Culdoplasty, 966
Culdoplasty, McCall's, 917
Culdotomy, posterior, 963
Curettage, 947
Curvilinear/horseshoe-shaped incisions, 33–34

- Cushing's disease
  - laparoscopic adrenalectomy, 660–663, 660f
  - transsphenoidal resection, 60–65, 61b, 61f, 62b, 63t–65t
- Cushing's syndrome, 763, 763t
- Cyclophosphamide, 850, 851t
  - drug interactions, F–1t–F–8t
- Cyclosporine, drug interactions, F–1t–F–8t
- Cyst
  - choledochal, excision/anastomosis, 637–641, 638t–640t
  - choledochal, pediatric repair, 1473–1477, 1474f
  - drainage, stereotactic neurosurgery, 72–76, 74f, 75b
  - epididymal, 1013
  - fenestration of, 1314–1317, 1314f
  - pediatric resection of branchial cleft/thyroglossal duct, 1424–1427
  - removal of branchial cleft/thyroglossal duct, 1356
  - skull base surgery and epidermoid/arachnoid, 275–284, 278f–279f, 281t–284t
  - thyroglossal duct, excision of, 744–746, 745f, 748–753
- Cystectomy, 997, 999t–1002t
  - anesthetic issues, 1000–1002, 1000t, 1001t
  - bladder substitution, 998–999, 999f
  - ileal conduit, 998–999, 998f–999f
  - ovarian, 900–902
  - partial, 997
  - pelvis with tissue, anatomy of, 998f
  - radical, 998
  - simple, 997
  - urinary diversion, 998–999
- Cystic fibrosis
  - bronchopulmonary lavage, 350–353, 350t–353t
  - heart/lung transplant, 522–532, 523t–532t
  - lung transplant, 378–379
- Cystic hygroma, 1424–1427
- Cystic neoplasms, 695
- Cystic neoplasms, pancreatectomy, 693–696, 694f, 695f, 699–705
- Cystitis, hemorrhagic/interstitial
  - cystectomy, 997, 999t–1002t
  - cystoscopy, 974, 977–979
  - transurethral resection, 976–979, 976t–979t, 977b
- Cystocele
  - anatomy of, 916f

- repair of, 1020
- Cystolitholapaxy, 1518
- Cystoplasty, augmentation, 1002
- Cystoscopy, 974, 975f, 977–979
  - with ureteral stenting, 966
- Cystourethroscopy, 915–917
- Cytopenia, 710t
- Cytoreductive laparotomy, for ovarian cancer, 850
- Cytotec (misoprostol), 952t

D

- da Vinci robotic system, 985
- Dabigatran, drug interactions, F–1t–F–8t
- Dacron graft, 821
- Dacryocystorhinostomy (DCR), 181–184, 182f, 183t, 183f
- Dandy–Walker malformation, 67
- Darrach procedure, 1028–1029, 1028f
  - modified, 1029–1030
- Dasatinib, drug interactions, F–1t–F–8t
- Daunorubicin, 850, 851t
- Davies lip repair, 1610
- DBS (deep brain stimulation), 79–80
- DeBastiani limb lengthening, 1577–1579, 1578f, 1587–1591
- Debridement, 1060–1061, 1156, 1172–1173, 1192
- Decadron, 35b
- Decompressive laminectomy, 118, 137
- Deep brain stimulation (DBS), 79–80
- Deep inferior epigastric artery perforator (DIEP) flaps, 737
- Deep pelvic lymphadenectomy, 853
- Deep venous insufficiency, 493–496, 494f
- Deep venous thrombosis (DVT) prophylaxis, 644, 688
- Deformational plagiocephaly, 1302
- Delayed extubation, I–4–I–5
- Deliberate relative hypotensive anesthesia, 196
- Delorme procedure, rectal prolapse, 607–609, 608t, 618–620, 618t–620t
- Deltoid-splitting approach, 1064–1065
- Deltopectoral incision, 1072, 1082
- Dental/oral surgery, 300–301
  - anesthetic issues, 302–304

- bone grafting, 1745–1747
- extractions and implants, 300
- implants, 1745–1747
- preoperative preparation, 1743–1744
- restorative dentistry, 301–304
- sedation, deep IV, in office, 1742–1745
- temporomandibular joint arthroscopy/arthrotomy, 298, 298f

Dentoalveolar fractures, 1248
Dentoskeletal dysplasia, 1258
Depression, 89
- electroconvulsive therapy, 1646–1652
- medications used to treat, 1649t

Dermoid tumor, 42
Descending thoracic aorta, 822
Desflurane, 952t
Deviated septum, nasal surgery, 262
Dexamethasone, 14t–16t, 669t–670t, 681t–682t, 749t–750t, 777t–778t, 857t, 1001t
- pancreatic surgery, 701t–703t

Dexmedetomidine, 40t–41t, 679t–682t
Dextrose, 726t
Diabetes, 929t
Diabetes insipidus (DI), 802t–806t
Diabetes mellitus (DM)
- infrainguinal arterial bypass, 485–489
- kidney/pancreas transplant, 774–779, 775f
- morbid obesity, 563–569, 564f, 565f, 565t–569t

Diagnostic laparoscopy, 965
Diagnostic transurethral (endoscopic) procedures, 974–975, 974t, 975f, 975t
Dial osteotomy, 1559–1561, 1560f, 1587–1591
Diaphragmatic hernia, 1733–1735
Difficult airway management, I–1–I–5
Digit replantation, 1054–1058
- microsurgery replantation, 1272–1276

Digital fasciectomy, 1041–1042
Digitalis, 982t
Digoxin, drug interactions, F–1t–F–8t
Dilatation and curettage (D&C), 890–891, 890t, 891f, 891t, 893–896, 894t–895t
Dilatation, and evacuation (D&E), 891–896, 892f, 893b, 892t–895t
Dilated pancreatic duct pancreaticojejunostomy, longitudinal, 692
Diltiazem, 755t–756t

- DIP (distal interphalangeal)
  - arthrodesis, 1043–1044
  - arthroplasty, 1031–1032
- DIPS (direct IVC-to-portal shunt), 1677
- Dipyridamole, drug interactions, F–1t–F–8t
- Direct current (DC) cardioversion, 1658–1662, 1659f
- Direct hernias, 719
- Direct IVC-to-portal shunt (DIPS), 1677
- Direct lateral open approach, 1064–1065
- Direct/extreme lateral interbody fusion (DLIF/XLIF), 139
- Discectomy, minimally invasive posterior lumbar, 1088–1089
- Dismembered pyeloplasty, 993, 994f
- Displaced lateral condyle humerus fracture, 1542–1543, 1550–1553
- Dissecting aneurysms, 465
- Distal clavicle resection (Mumford procedure), 1060–1061, 1064
- Distal femur fractures, open reduction and internal fixation, 1137–1138
- Distal interphalangeal (DIP)
  - arthrodesis, 1043–1044
  - arthroplasty, 1031–1032
- Distal pancreatectomy, 693, 695t–696t
  - resection of distal, 694f
- Distal tibia, open reduction and internal fixation of, 1169–1171
- Distal ureteral trauma, 1510–1516, 1511f
- Distraction osteogenesis, 1257f–1258f, 1258, 1261
- Disulfiram, drug interactions, F–1t–F–8t
- Diuretics, drug interactions, F–10t–F–14t
- Diverticula, colectomy, segmental/partial, 599–602, 601t, 604–607, 604t–606t
- Diverticulectomy, esophageal, 537–541, 538f, 539f, 540t, 550–554, 550t–554t
- DLT (double lumen tube), 648
  - one-lung ventilation, pediatric, 1445
- DMARDS, drug interactions, F–10t–F–14t
- Dobutamine, 802t–804t
  - drug interactions, F–1t–F–8t
- Docetaxel, 851t
- Dofetilide, drug interactions, F–1t–F–8t
- Dohlman procedure, 538
- Dolstad modified hysterectomy, 880
- Donation after Cardiac Death (DCD), 802
- Dopamine, 777t–778t, 802t–806t, 826, 827t
  - drug interactions, F–1t–F–8t

- Dor fundoplication, 646–648
- DORV (double-outlet right ventricle), 1414–1417, 1415f
- Double lumen tube (DLT), 648
  - one-lung ventilation, pediatric, 1445
- Double-outlet right ventricle (DORV), 1414–1417, 1415f
- Doxorubicin, 710t, 850, 851t
- Doxycycline, 890t
- Drug interaction table, F–1t–8t, F–1b
- Ductal carcinoma in situ (DCIS), 730
  - mastectomy for, 732
- Duhamel pull-through for Hirschsprung's disease, 1481–1485, 1482f
- Duodenal hepatic ojejunostomy, 696–697
- Duodenal mobilization, 832
- Duodenotomy, 574–575, 574t, 575f
- Duodenum
  - gastric resection, 556–559, 557f, 558t, 561–563, 561t, 561t–562t
  - perforation, 559–563, 559f, 560t, 561t, 561t–562t, 562t–563t
- Dupuytren's contracture, 1041
- Dural arteriovenous fistulas, 1653
- DVT (deep venous thrombosis) prophylaxis, 644
- Dysplasia
  - dentoskeletal, 1258
  - fibrous, 41–42
  - hip, 1117, 1117f
  - Zenker's diverticulectomy, 206, 215–217
- Dysrhythmias, 653t–654t, 666t, 669t–670t, 804t–806t
  - implantation of cardioverter-defibrillator, 1662–1666, 1665f–1666f

- usual preopeative diagnosis, 254

Endoscopic third ventriculostomy (ETV), 67, 1314–1317, 1314f
Endoscopically assisted strip craniectomy (EASC), 1302–1303
Endoscopy, 644
Endovascular stent
- grafting of aortic aneurysms, 459–465, 461f, 462t–464t
- placement, 1713

Endstage liver disease (ESLD), 1634
End-stage renal disease (ESRD), kidney/pancreas transplant, 772, 784–785
End-to-end anastomosis, 1002
End-to-side shunt, 496, 497f
Enhanced recovery after surgery (ERAS), K–1–K–8, 594, 594t
Enteric fistulae, closure of, 588–591, 588t–591t
Enterocele, 915
Enterocele repair, 915–918
Enterocystoplasty, 1002
Enterolysis, 587–588, 587t
Enterostomy, 580–583, 580f, 581t–582t
Enterovesical fistulas, bladder operations, open, 1002–1005, 1003t–1005t
Entropion repair, 167–168, 167t, 168t
Enucleation, 184–185, 184f, 185t
Enzalutamide, drug interactions, F–1t–F–8t
Eosinophilic granuloma, 41
Ephedrine, 826, 861, 930, 988t–989t, 1021t
- exploratory/staging laparotomy, 711t–713t

Ephedrine, bolus, 30t–32t
Epidermoid, 41
- cyst, skull base surgery, 276

Epidermolysis bullosa, 1592–1595, 1727–1731
Epididymal cyst, 1013
Epidural analgesic techniques, 703t–704t
Epidural anesthesia, 945
- pediatric, D–4–D–5

Epidural anesthetic techniques, 700, 711, 713t
Epidural infusion, E–6, E–6t, E–7f–E–8f
Epidural motor cortex stimulation, 84
Epiglottitis, intubation for, 214–215, 214t–215t
Epilepsy
- asleep-awake-asleep technique, 95

- surgery, 92–96, 93t–96t
- vagal nerve stimulation, 88–91, 88f, 89t, 90t–91t

Epinephrine, 726t, 740, 766, 802t–804t, 826, 852t, 858t, 863t–864t, 867t–868t, 878t, 894t, 898t, 900, 907t, 930, 930t–931t, 939t, 949t, 988t, 1001t, 1004t, 1008t, 1011t, 1015t, 1021t

Epiphrenic diverticulectomy, 537–541, 538f, 539f, 540t, 550–554, 550t–554t

Epiphysiodesis, 1573–1575, 1574f, 1587–1591

Epistaxis, 257

Eppright osteotomy, 1559–1561, 1560f, 1587–1591

ERCP. See Endoscopic retrograde cholangiopancreatogram (ERCP)

Erector spinae plane block, 1790–1791
- anatomy, 1790f
- indications, 1790t–1791t
- ultrasound imaging, 1790f

Esmolol, 749t–750t, 766t–768t, 929t

Esophageal atresia (EA), repair of, 1434–1438

Esophageal diverticulectomy, 537–541, 538f, 539f, 540t, 550–554, 550t–554t

Esophageal fundoplication, laparoscopic, 645–648, 646f, 647t, 652

Esophageal (Heller) myotomy, 309–310

Esophageal myotomy, anesthetic issues, 550–554, 550t–554t

Esophageal perforation
- anesthetic issues, 550–554, 550t–554t
- esophagostomy, 536–537, 536f, 537t
- management of, 541–542, 541t–542t, 542t

Esophageal replacement, 1453–1456, 1454f

Esophageal spasm, 542–544, 543f, 543t–544t, 550–554, 550t–554t

Esophageal surgery, 535–554
- anesthetic issues, 550–554, 550t–554t

Esophageal transection with stapling, 498

Esophagectomy, 309–310, 547–554, 547f, 548f, 549t
- gastric resection, 556–559, 557f, 558t, 561–563, 561t–562t

Esophagogastric fundoplasty, 544–546, 545f, 546t, 550–554, 550t–554t

Esophagogastroduodenoscopy, 1424–1427

Esophagomyotomy, 542–544, 543f, 543t–544t, 550–554, 550t–554t

Esophagoscopy, 648
- flexible, 205
- flexible fiberoptic, 201, 1350
- pediatric, 1349–1351, 1427–1430
- rigid, 205, 1350

Esophagostomy

- anesthetic issues, 550–554, 550t–554t
- esophageal perforation, 536–537, 536f, 537t

Etomidate, 152t–154t, 669t–670t, 792t–796t, 818t, 826, 836t–837t, 929t, 931t–932t, 943t, 952t
- induction, B–2, B–2t
- pancreatic surgery, 701t–703t

ETT sizes, D–3
Euvolemia, 749t–750t, 755t–756t
Evisceration, 185
Ex utero intrapartum treatment (EXIT), 1498–1502
Excisional biopsy, 730
Exenteration, 185
- pelvic, 869–875, 869f, 870f, 871t–874t

Exostoses resection, 272
Exploratory laparotomy, 708–714, 708f, 709t–713t, 819, 869
Exploratory laparotomy/laparoscopy and hysterectomy/BSO for uterine cancer, 875–879, 876t–878t
Exploratory tympanotomy, 271–272
Exstrophy cloaca, 1478f, 1477–1481
Extended Focused Assessment with Sonography for Trauma (eFAST), 808, 809f
Extended iliofemoral approach, 1115f
External beam therapy, 885
External ventricular drain (EVD), 1314
Extracapsular approach, 781–782
Extracapsular technique, 158
Extracorporeal membrane oxygenation (ECMO), 1733–1736, 1734f
Extracorporeal shock wave lithotripsy (ESWL), 1517
Extracranial-intracranial revascularization, craniotomy for, 26–33, 27f–28f, 28b, 29b, 29t–32t
Extrapleural-retroperitoneal approach, 130
Extratemporal epilepsy, 88
Extreme lateral interbody fusion (XLIF), 139
Extrinsic disease, 956
Eye injury, endoscopic sinus surgery complications in, 255
Eyelids
- ectropion repair, 165–193, 165f, 166t
- entropion repair, 167–168, 167t, 168t
- lift, 1214–1218, 1215f, 1216t–1218t
- ptosis repair, 168–170, 169f, 169t

- Hemorrhoids, 614–616, 615t–616t, 618–620, 618t–620t
- Hemostasis, 650
- Hemostatic uterine stapling device, 1498–1499
- Hemothorax, 812
- Heparin

- drug interactions, F–10t–F–14t
- pancreatic surgery, 689t, 695t–696t, 698t

Heparinization, 14t–16t
Hepatectomy, 784–785
Hepatic injuries, 829–831, 830f, 831t
Hepatic surgery
- hepatorrhaphy, 625–628, 625t– 628t
- resection, 622–628, 623f, 623t–624t, 626t–628t

Hepaticojejunostomy, 633
Hepatoblastoma, pediatric, 1465–1469, 1466f
Hepatoduodenal ligament, temporary occlusion, 622
Hepatorrhaphy, 625–628, 625t–628t
Herbal agents, F–8t–F–10t, F–8b
Hereditary spherocytosis, 715
Hernia
- groin, 1006f–1007f
- incisional hernia, repair of, 722–724
- inguinal operations, 1005, 1006f–1007f
- laparoscopic inguinal hernia repair, 671–674, 671f
- repair of inguinal and umbilical, 1488–1491
- small bowel resection with anastomosis, 585–586, 585f, 586t, 588–591, 588t–591t
- stoma closure/peristomal hernia repair, 602–607, 603t–606t

Herniorrhaphy, 1005
- femoral, 721–722, 721t, 722t, 722f, 725–727
- inguinal, 719–721, 720t, 725–727, 1005, 1006f–1007f

Hess and Hunt clinical grading system, 4, 5t
Hickman catheters, 505–509
High cervical anterior retropharyngeal approach, 109
High Mallampati score, 677t–679t, 679
High McCall's culdoplasty, 917
High transthoracic thoracotomy, 122
Hill procedure, esophagogastric fundoplasty, 545, 545f, 550–554, 550t–554t
Hindquarter amputation, 1120–1124
Hip
- amputations around, 1120–1124
- arthrodesis, 1128–1129, 1128f
- arthroplasty, 1125–1128, 1125f
- disarticulation, 1120–1124
- femoral osteotomy, 1572–1573, 1587–1591
- fractures, 1135f

- open reduction and femoral shortening, 1565–1566, 1565f, 1587–1591
- synovectomy, 1130–1134

Hirschsprung's disease, 1481–1485, 1482f
HMG Co-A reductase inhibitors, drug interactions, F–10t–F–14t
Hodgkin's disease, laparotomy, exploratory/staging, 708–714
Horner's syndrome, 740t
Horseshoe-shaped incisions, 33–34
HRT, drug interactions, F–10t–F–14t
Human immunodeficiency virus (HIV) therapy, drug interactions, F–10t–F–14t
Huntington procedure, uterine inversion, 950–951
Hydralazine, 929t
Hydrocele, 1013
- repair of, 1488–1491

Hydrocelectomy, 1012
Hydrocephalus, stereotactic neurosurgery, 75
Hydrocortisone, 749t–750t, 764t, 850, 877t
Hydrodissection, 957–958, 965, 968
Hydromorphone, 679t–681t, 740t, 766, 848t, 852t–853t, 858t, 863t–864t, 873t–874t, 878t, 883t, 888t, 931t–932t, 940t, 943t, 946t, 997t, 1012t, 1015t, 1018t, 1022t
- exploratory/staging laparotomy, 711t–713t
- pancreatic surgery, 701t–703t

Hydromorphone, postop, C–4t
Hydronephrosis, nephrectomy, 989, 990f, 991f, 992t–993t, 992f, 993
Hydrophilic opioids, 701t–703t
Hydrosalpinx, ectopic pregnancy/adnexal mass, 961
Hydroxyzine, premedication, B–1t
Hygroma, subdural, 67
Hyoid myotomy and suspension (HM), 286, 288f
Hyperadrenocorticism, 763
Hyperaldosteronism, 763
Hypercalcemia, 755
Hypercarbia, 653t–654t
Hyperglycemia, 703t–704t, 804t–806t
Hyperhidrosis, video-assisted thoracic surgery, 309–313, 310t, 311f, 311t–313t
Hyperlipidemia, morbid obesity, 563–569, 564f–566f, 565t–569t
Hypernatremia, 792t–796t
Hyperparathyroidism, 699t–700t, 755t–756t
Hyperplasia
- laparoscopic adrenalectomy, 660–663, 660f
- vaginal, abdominal, laparoscopic/robotic-assisted hysterectomy, 909–914

- Hypersplenism, portal hypertension, 496
- Hypertension (HTN). See also Portal hypertension

  - total abdominal, 844–848, 844f, 845t–848t, 846b, 936
  - for uterine cancer, 875–879, 876t–878t
  - vaginal, abdominal, laparoscopic/robotic, 909–914, 911f, 912b, 911t–914t
- Hysteroscopy, 896–899, 896f, 897b, 897t–899t
- Hysterotomy, 1498

I

- Iatrogenic injury, biliary drainage, 632–635, 634t, 635t, 638–641, 639t, 640t
- Ibuprofen, 686t, 740t, 852t–853t, 858t, 868t, 874t, 883t, 888t, 940t
- Idiopathic thrombocytopenic purpura (ITP), laparoscopic splenectomy, 655–659, 656f
- Ileal conduit, 998–999, 998f–999f
- Ileal pouch anal anastomosis (IPAA), 596–597
- Ileostomy
  - Brooke, 580–583, 580f, 581t–582t
  - continent (Kock, Barnett), 583–585, 583t, 584f, 584t
  - proctocolectomy, total, 595–599, 596f, 597t–598t, 598f, 599t, 604–607, 604t–606t
- Iliac crest bone
  - biopsy of, 708f
  - grafting from, 1166
- Iliac thrombosis, 493–496, 494f, 495t
- Ilioinguinal approach, 1114f–1115f
- Ilizarov limb lengthening, 1577–1579, 1578f, 1587–1591
- Image-guided frameless stereotaxy, 73, 74f
- Image-guided navigation, 34
- Image-guided radiation therapy (IGRT), 1707
- Image-guided/wire-localized breast biopsies, 730
- Imaging procedures, 1684–1690, 1685f
- Imatinib, drug interactions, F–1t–F–8t
- Immediate reconstruction, 737
- Immune thrombocytopenic purpura, 715
- Imperforate anus, 1485–1488
- Implantable medication delivery system, 85
- Implantable pulse generator (IPG), 80
- Implantation of cardioverter-defibrillator (ICD), 1662–1666, 1665f–1666f
- Implant-based reconstruction, 737
- Implants, dental, 1745–1747
- Impotence and insertion of penile prosthesis, 1009, 1010f
- IMRT (intensity-modulated radiation therapy), 885–886
- In situ breast cancer, 737
- In vitro fertilization (IVF), 905
- Incarcerated hernias, 719
- Incisional hernia, repair of, 722–724, 723t
- Inclusion technique, thoracoabdominal aorta aneurysms and Crawford's, 473, 474f
- Incompletely inverted uterus, 950
- Indirect revascularization, 28
- Induction techniques, 818t

- adult, B–2, B–2t
- pediatric, D–2, D–2t

Inferior pedicle technique, 1228–1229

Infertility
- assisted reproductive technologies, 904–909, 905t, 908t–909t
- hysteroscopy, 896–899, 896f, 897b, 897t–899t
- transvaginal oocyte retrieval, 902–904, 903t, 904t

Infertility operations, 904–909, 905t–908t

Inflammatory bowel disease (IBD), 665t
- continent ileostomy pouch (Kock), 583–585, 583t, 584f, 584t
- proctocolectomy, total, 595–599, 596f, 597t–599t, 598f, 604–607, 604t–606t

Infraclavicular block, 1768–1769
- anatomy, 1768f–1769f
- indications, 1768t–1769t
- ultrasound imaging, 1768f

Infracolic omentectomy, 844–845

Infrainguinal arterial bypass, 485–489, 486t– 489t

Inguinal anatomy, 720f

Inguinal hernia repair, 1007f
- inguinal operations, 1005, 1006f–1007f, 1007t–1009t, 1008–1009
- laparoscopic, 666, 671–674, 671f, 672t, 673t
- pediatric, 1488–1491

Inguinal herniorrhaphy, 719–721, 720f, 720t, 725–727, 1005

Inguinal lymph node biopsy, 1009

Inguinal operations, 1005, 1006f–1007f, 1007t–1009t, 1008–1009

Inguinal region, 671f

Inguinofemoral lymphadenectomy, 1007

Inguinoscrotal procedures, pediatric

Inhalation anesthesia
- adult, maintenance techniques, B–3, B–3t
- drug interactions, F–1t–F–8t
- pediatric, maintenance techniques, D–3–D–4, D–3t–D–4t

Injection laryngoplasty, 217–218, 218t, 219t

Innominate artery, 821

Instability
- shoulder, 1066–1071, 1067f
- surgery, 1067

Instrumental perforation, 541

Insulin, drug interactions, F–10t–F–14t

Insulinoma, 699t–700t

- Intensity-modulated radiation therapy (IMRT), 885–886
- Intercarpal arthrodeses, 1033
- Intermittent apnea technique, 206
- Interphalangeal joint arthroplasty, proximal, 1031–1032
- Interscalene block, 1764–1765
  - anatomy, 1764f–1765f
  - indications, 1764t–1765t
  - ultrasound imaging, 1764f
- Interspinous wiring, 118
- Interstitial chemotherapy, 34
- Interstitial perineal implants, 885–888, 886f, 886t–888t, 887b
- Interstitial pulmonary fibrosis, heart/lung transplant, 522–532, 523t–532t
- Intertrochanteric femoral fractures, 1134–1137
- Interval, secondary cytoreductive and second-look laparotomy, 849–853, 849t, 851t–853t
- Intestinal fistula, small bowel resection
  - with anastomosis, 585–586, 585f, 586t, 588–591, 588t– 591t
- Intestinal surgery
  - appendectomy, open, 575–577, 576t, 576f, 577t
  - continent ileostomy pouch (Kock), 583–585, 583t, 584f, 584t
  - duodenotomy, 574–575, 574t, 575f
  - enteric fistulae, closure of, 588–591, 588t–591t
  - enterolysis, 587–588, 587t
  - enterostomy, 580–583, 580f, 581t, 581t–582t
  - intestinal perforation, pediatric, 1469–1473
  - Meckel's diverticulum, excision of, 577–579, 577t–579t
  - small bowel resection with anastomosis, 585–586, 585f, 586t, 588–591, 588t–591t
- Intra-abdominal and retroperitoneal tumors, excision of, 716–717, 716t–717t
- Intra-abdominal hemorrhage, 828–829
- Intra-abdominal trauma and hemorrhage, 828
- Intracameral lidocaine, 173–174
- Intracapsular approach, 781–782
- Intracapsular cataract extraction, 158
- Intracorporeal power morcellation, 965
- Intracranial aneurysms, craniotomy for, 4–17, 4f, 5t, 6f, 7b, 8t–13t
  - giant, 13–17, 14t–16t
  - Hess and Hunt clinical grading system, 4, 5t
  - location of aneurysms, 4f
- Intracranial arteriovenous malformation, surgery for, 1317–1322
- Intracranial neuroendoscopy, 1314–1317, 1314f

- Intracranial neurosurgery, 4–76
- Intracranial vascular malformations, craniotomy for, 20–26, 20t–25t, 21b, 21f–22f
- Intractable postpartum hemorrhage (PPH), 934
- Intramedullary nailing
  - of femoral shaft, 1138–1139
  - of long-bone fractures, 1570–1571, 1570f, 1587–1591
  - of tibia, 1167–1168
- Intraop hemorrhage, 1500
- Intraoperative nerve monitoring (IONM), 747, 1311
- Intraoperative radiation therapy (IORT), 716, 730, 869–870
- Intraosseous (IO)
  - access, 1760, 1760f, 1761f
  - infusion, 839, 839f
- Intraspinal opioids, 946t
- Intrathecal pumps, 84–87, 85t–87t
- Intrauterine myelomeningocele repair, 1307
- Intravenous lidocaine infusion, 701t–703t
  - exploratory/staging laparotomy, 711t–713t
- Intravitreal injection, 1333
- Intubation
  - epiglottitis, 214–215, 214t–215t
  - nasotracheal, 809
  - orotracheal, 808
- Invasive breast cancer, 733, 737, 739
- Invasive vulvar cancer, 855
- Invasive vulvar carcinoma, 853
- IONM (intraoperative nerve monitoring), 751, 754, 1311
- IORT (intraoperative radiation therapy), 716, 730, 869–870
- IPAA (ileal pouch anal anastomosis), 596–597
- Iridectomy, 162–163
- Irreversible electroporation (IRE ablation), 1700–1704
- Irving technique, postpartum tubal ligation, 937–940
- Islet cell tumors, 695
  - pancreatectomy, 693–696, 694f, 695f, 699–705
- Isoflurane, 766t–768t
- Isoniazid, drug interactions, F–1t–F–8t
- Isosulfan blue, 732
- Isosulfan dye, 735t
- Isthmus ablation, 1670f
- Ivacaftor, drug interactions, F–1t–F–8t

- Ivor Lewis approach, 547–554, 547f, 548f, 549t, 557

J

- Jackson modification of Orticochea flap, 1615
- Janeway gastrostomy, 570
- Jatene atrial switch, 1402–1403
- Jaw thrust maneuver, 808, 838
- Jejunoileal bypass, 674
- Jejunoileal (JI) bypass, 563, 565f
- Jejunojejunostomy, 674–675
- Jejunum, gastric resection, 556–559, 557f, 558t, 561–563, 561t–562t
- Jersey finger, 1043–1044
- Jet ventilation, 206, 206f
- Johnson method, 950–951
- Joint arthroplasty and arthrodesis, 1031–1032
- Joint replacement (arthroplasty), 1031–1032
- Juvenile rheumatoid arthritis, 1587t

K

- Kasai procedure, 1473
- Kelly urethral plication, 919
- Ketamine, 673t, 818t, 826, 836t–837t, 847t–848t, 857t, 873t–874t, 877t, 882t–883t, 888t, 906t, 929t, 931t–932t, 943t, 949t, 952, 952t, 1001t
  - drug interactions, F–1t–F–8t
  - low-dose
    - exploratory/staging laparotomy, 711t–713t
    - pancreatic surgery, 701t–703t
  - pancreatic surgery, 701t–703t
- Ketorolac, 701t–703t, 1009t, 1012t, 1018t
  - drug interactions, F–1t–F–8t
  - exploratory/staging laparotomy, 711t–713t
  - pediatric use of, E–1t–E–3t
  - postop, C–3t
- Kidney(s)
  - nephrectomy, 989, 990f, 991f, 992t–993t, 992f, 993

- Ventricular shunt, 65–70, 66f, 67f, 68b, 68t–69t
- Ventricular tachycardia, catheter ablation of, 1669–1675, 1670f–1671f
- Ventriculoarterial concordance, 1410–1411
- Verapamil, 755t–756t
  - drug interactions, F–1t–F–8t
- Veress needle, 645, 648, 650, 655, 667, 683, 957
- Verner-Morrison syndrome (VIPoma), 699t–700t
- Vertical banded gastroplasty (VRG), 563, 564f, 674
- Vertical partial laryngectomy (VPL), 223
- Vesical neck suspension, 1019
- Vesicoureteral reflux (VUR), 1520, 1528
- Vesicoureteral reflux (VUR), bladder operations, open, 1002–1005, 1003t–1005t
- Vesicovaginal fistulas, repair of, 1019
- Vesicovaginal or enterovesical fistula, 1002
  - repair of, 1002
- Vestibular schwannomas, 276, 282
- Video-assisted thoracoscopy surgery (VATS), 309–313, 310t, 311f, 311t–313t, 824
  - blebs/bullae excision, 342
  - mediastinal tumor excision, 370
  - procedure, 309–313, 310t–312t, 311f
- Video-assisted thyroidectomy, 747
- Vinblastine, 710t, 851t
- Vincristine, 850, 851t
- Visceral injury, 653t–654t, 666t, 669t–670t
- Vitrectomy, 188–189, 1332–1339
- Vitreoretinal surgery
  - laser photocoagulation, 1332–1333
  - vitrectomy, 1332–1339
- VNS. See Vagus nerve stimulation (VNS)
- Volvulus
  - colectomy, segmental/partial, 599–602, 601t, 604–607, 604t–606t
  - small bowel resection with

- anastomosis, 585–586, 585f, 586t, 588–591, 588t–591t
- Von Langenbeck technique, 1612
- VRG. See Vertical banded gastroplasty (VRG)
- VSD. See Ventricular septal defect (VSD)
- Vulva
  - anesthetic issues for laser therapy to, 862–864
  - interstitial perineal implants, 885–888, 886f, 886t–888t, 887b
- Vulvar reconstruction, 853–854
- Vulvectomy, radical, 853–858, 854f–855f, 855t–856t, 856b
  - anesthetic issues, 857–858, 857t, 858t
  - deep pelvic lymphadenectomy, 853
  - electrocautery, 853–854
  - en bloc radical vulvectomy incisions, 854f
  - hemivulvectomy, 854–855
  - pelvic lymphadenectomy, 853
  - postop radiation therapy, 853
  - three-incision technique, 854–855, 854f–855f
  - unilateral groin node dissection, 854–855
  - unilateral lymphadenectomy, 855f
  - vulvar reconstruction, 853–854

W

- Wagner limb lengthening, 1577–1579, 1578f, 1587–1591
- Waldhausen artery flap, 1386
- Wardill–Kilner technique, 1612
- Warfarin, drug interactions, F–10t–F–14t
- Warren shunt, 497–498
- Waterston shunt, 1411
- Wedge resection, lung lesion, 313
- Wegener's disease, 221
- Whipple procedure, 556–557
- Whipple resection, 696–705, 697f, 698t
- Whitehead hemorrhoidectomy, 614–616, 615t–616t, 618–620, 618t–620t
- Williams airway, 205
- Wilms' tumors, pediatric, 1465–1469
- Wilson's disease, 784–785
- Wong–Baker faces scale, E–2f
- Wound dehiscence, 724
  - repair of abdominal, 724–727

- Wound infection, 1500
- Wrist
  - arthrodesis, 1033–1034
  - arthroscopy, 1047–1048
  - fractures/dislocations, 1051–1054
  - ganglion, excision of, 1040–1041
  - replacement, total, 1034–1035

X

- X-ray
  - fluoroscopy, 1684–1690
  - preoperative chest, A–2t–A–4t

Y

- Yacoub atrial switch, 1402–1403
- Yount–Ober release, 1563–1564, 1587–1591

Z

- Zenker's diverticulum, 204, 206, 215–217
  - surgery for, 537–541, 538f, 539f, 540t
- Zollinger–Ellison syndrome, 699t–700t
  - gastrectomy, 556–559, 557f, 558t, 561–563, 561t–562t
- Zosyn, 668t, 718t
- Z-plasty
  - cleft palate, 1612, 1614f
  - lip repair, 1610, 1611f
  - palatoplasty, 1612–1615, 1613f, 1614f, 1622–1625
  - torticollis, release for, 1545–1547, 1550–1553
- Zygote intrafallopian transfer (ZIFT), 905
