Care has been taken to confirm the accuracy of the information presented and to describe generally accepted practices. However, the authors, editors, and publisher are not responsible for errors or omissions or for any consequences from application of the information in this book and make no warranty, expressed or implied, with respect to the currency, completeness, or accuracy of the contents of the publication. Application of this information in a particular situation remains the professional responsibility of the practitioner; the clinical treatments described and recommended may not be considered absolute and universal recommendations.

The authors, editors, and publisher have exerted every effort to ensure that drug selection and dosage set forth in this text are in accordance with the current recommendations and practice at the time of publication. However, in view of ongoing research, changes in government regulations, and the constant flow of information relating to drug therapy and drug reactions, the reader is urged to check the package insert for each drug for any change in indications and dosage and for added warnings and precautions. This is particularly important when the recommended agent is a new or infrequently employed drug.

Some drugs and medical devices presented in this publication have Food and Drug Administration (FDA) clearance for limited use in restricted research settings. It is the responsibility of the health care provider to ascertain the FDA status of each drug or device planned for use in his or her clinical practice.

LWW.com

This book is dedicated to my loving husband Glenn, who has shown me the joy of learning,—and living—who continues to support me in all of my professional pursuits and whose patience and understanding have meant the world to me. And also to my children, Brian and Jennifer, who have always inspired me throughout their lives.

Susan Scott Ricci

This text is dedicated to my awesome family. My husband John has consistently encouraged and persuaded me to continue moving forward. My wonderful children, Christian and Caitlin, constantly delight and surprise me. I thank them for their support and faith in me.

Terri Kyle

Acknowledgments

We would like to thank so many people who have helped bring the exciting prospect of this textbook into being. Our appreciation goes to Jean Rodenberger for her ongoing leadership and Elizabeth Nieginski for approaching us with this project and believing that we could assist in achieving her vision. We would also like to especially thank Danielle DiPalma for her editorial expertise and for her steadfastness to this project. She has been ever patient through chapter drafts and revisions. In addition, we would like to thank Maryann Foley for her professional collaboration and attention to detail within the chapters. Her nursing background has been invaluable from the start. Special thanks also to Sarah Kyle for her continued dedication to the vision and format of this textbook, as well as for her expert editing, and to Erin Sweeney for gently prodding us to complete revisions.

We would like to thank Tom Gibbons for his skillful production of the text. We would also like to thank Brett MacNaughton for his role in the beautiful illustrations and photographs, as well as photographer Gus Freedman and photo producer Amy Geller for their dedicated work on the photo shoot. We would like to thank the following institutions for their help in obtaining the photos for this book:

Boston Shriners Hospital
UMass Memorial Health Care
The Birthplace at Wellesley
Brigham and Women's Hospital
Newton-Wellesley Hospital

Also thanks to the many nurses, midwives, doctors, and families for their participation in this book, especially Debbie Turner, Paula McGarr, Susan Martinson, Grace Jackson, and Marianne Cummings. As always, special thanks to Terri's close friend and colleague Susan Carman for all of the physical work she performed on this text and, even more importantly, the emotional and moral support she so unfailingly provides.

S.S.R., T. K.

About the Authors

Susan Scott Ricci has a diploma from Washington Hospital Center School of Nursing, with a BSN, MSN, from Catholic University of America in Washington, D.C., and an M.Ed. in Counseling from the University of Southern Mississippi. She has worked in numerous women's health care settings, including labor and delivery, postpartum, prenatal, and family planning ambulatory care clinics. Susan is a women's health care nurse practitioner who has spent 30+ years in nursing education teaching in LPN, ADN, and BSN programs. She is involved in several professional nursing organizations and holds memberships in Sigma Theta Tau International Honor Society of Nursing, National Association of Ob/Gyn Nurses, Who's Who in Professional Nursing, American Nurses Association, and the Florida Council of Maternal-Child Nurses.

With Susan Scott Ricci's wealth of practical and educational experience, the time has come for her to concentrate on the "essential facts" of nursing instruction and reduce the amount of "nice to know" information that is presented to students. As an educator, she recognized the tendency for nursing educators to want to "cover the world" when teaching rather than focusing on the facts that students need to know to practice nursing. With this thought, Susan has directed her energy to the *birth* of this essentials textbook.

She recognizes that instructional time is shrinking as the world of health care is expanding exponentially. Therefore, with the valuable instructional time allotted, she has recognized the urgent need to present pertinent facts as concisely as possible to promote application of knowledge within nursing practice.

Terri Kyle earned a Bachelor of Science in Nursing from the University of North Carolina at Chapel Hill and a Master of Science in Nursing from Emory University in Atlanta, Georgia. She is a certified pediatric nurse practitioner and is currently enrolled in the Doctor of Nursing Practice program at the University of Florida. Practicing pediatric nursing for over 20 years, Terri has had the opportunity to serve children and their families in a variety of diverse settings.

She has experience in inpatient pediatrics in pediatric and neonatal intensive care units, newborn nursery, specialized pediatric units, and community hospitals. She has worked as a pediatric nurse practitioner in pediatric specialty clinics and primary care. She has been involved in teaching nursing for over 15 years with experience in both graduate and undergraduate education. Terri is a fellow in the National Association of Pediatric Nurse Practitioners and a member of the Sigma Theta Tau International Honor Society of Nursing, the National League for Nursing, the Society of Pediatric Nurses, and the Association of Camp Nurses.

With the limited time allotted in schools to the topic of maternity and pediatric nursing, Terri recognized the need for a textbook that "got to the point." She strongly believes in a concepts-based approach for learning nursing—that is, to teach the basics to students in a broad, contextual format so that they can apply that knowledge in a variety of situations. The concepts-based approach to nursing education is time efficient for nursing educators and fosters the development of critical thinking skills in student nurses.

PREFACE

Many nursing curricula combine and teach maternity and pediatrics in tandem. This can be viewed as a *natural fit* of two content areas that belong together. Nursing education in general is founded upon the principle of mastering simpler concepts first and incorporating those concepts into the student's knowledge base. The student is then able to progress to problem solving in more complex situations. In today's education climate with reduced class time devoted to specialty courses, it is particularly important for nursing educators to focus on key concepts, rather than attempting to cover everything within a specific topic.

The intent of *Maternity and Pediatric Nursing* is to provide the nurse the basis needed for sound nursing care of women and children. The content in the book will enable the reader to guide women and children toward higher levels of wellness throughout the life cycle. In addition, the focus of the textbook will allow the reader to anticipate, identify, and address common problems and provide timely, evidence-based interventions to reduce long-term sequelae.

This textbook is designed as a practical approach to understanding the health of women and children. The main objective is to help the student build a strong knowledge base and assist with the development of critical thinking skills. Women in our society are becoming empowered to make informed and responsible choices regarding their health and that of their children, but to do so they need the encouragement and support of nurses who care for them. This textbook focuses on women and children throughout their lifespan, covering a broad scope of topics with emphasis placed upon common issues. Maternity nursing content coverage is comprehensive, yet presented in a concise and straightforward manner. The pediatric nursing content presents the important differences when caring for children compared with caring for adults. A nursing process approach provides relevant information in a concise and non-redundant manner. The content covered in the text arms the student or practicing nurse with essential information to care for women and their families, to assist them to make the right choices safely, intelligently, and with confidence.

Organization

Each chapter of *Maternity and Pediatric Nursing* focuses on a different aspect of maternity and/or pediatric nursing care. The book is divided into eleven units, beginning with general concepts related to maternity and pediatric nursing care, progressing from women's health, pregnancy and birth, through child health promotion and nursing management of alterations in children's health.

Unit 1: Introduction to Maternity and Pediatric Nursing

Unit 1 helps build a foundation for the student beginning the study of the care of women, infants, and children. This unit explores contemporary issues and trends in maternity and pediatric nursing. Perspectives on women's health and pediatric nursing, use of the nursing process, family-centered and atraumatic care, communication, and community-based nursing are addressed.

Unit 2: Women's Health Throughout the Lifespan

Unit 2 introduces the student to selected women's health topics, including structure and function of the reproductive system, common reproductive concerns,

sexually transmitted infections, problems of the breast, and benign disorders and cancers of the female reproductive tract. This unit encourages the student to assist women in maintaining their quality of life, reducing their risk of disease, and becoming active partners with their health care professional.

Unit 3: Pregnancy

Unit 3 addresses topics related to normal pregnancy, including fetal development, genetics, and maternal adaptation to pregnancy. Nursing management during normal pregnancy is addressed, encouraging application of basic knowledge to nursing practice. Nursing management includes maternal and fetal assessment throughout pregnancy, interventions to promote self-care and minimize common discomforts, and patient education.

Unit 4: Labor and Birth

Unit 4 begins with an explanation of the normal labor and birth process, including maternal and fetal adaptations. This is followed by content focusing on the nurse's role during normal labor and birth, which includes maternal and fetal assessment, pharmacologic and non-pharmacologic comfort measures and pain management, and specific nursing interventions during each stage of labor and birth.

Unit 5: Postpartum Period

Unit 5 focuses on maternal adaptation during the normal postpartum period. Both physiologic and psychological aspects are explored. Paternal adaptation is also considered. This unit also presents related nursing management, including assessment of physical and emotional status, promoting comfort, assisting with elimination, counseling about sexuality and contraception, promoting nutrition, promoting family adaptation, and preparing for discharge.

Unit 6: The Newborn

Unit 6 covers physiologic and behavioral adaptations of the normal newborn. It also delves into nursing management of the normal newborn, including immediate assessment and specific interventions as well as ongoing assessment, physical examination, and specific interventions during the early newborn period.

Unit 7: Childbearing at Risk

Unit 7 shifts the focus to at-risk pregnancy, childbirth, and postpartum care. Preexisting conditions of the woman, pregnancy-related complications, at-risk labor, emergencies associated with labor and birth, and medical conditions and complications affecting the postpartum woman are all covered. Treatment and nursing management are presented for each medical condition. This organization allows the student to build on a solid foundation of normal material when studying the at-risk content.

Unit 8: The Newborn at Risk

Unit 8 continues to center on at-risk content. Issues of the newborn with birthweight variations, gestational age variations, congenital conditions, and acquired disorders are explored. Treatment and nursing management are presented for each medical condition. This organization helps cement the student's understanding of the material.

Unit 9: Health Promotion for the Growing Child and Family

Unit 9 provides information related to growth and development expectations of the well child from newborn through adolescence. Although not exhaustive in nature, this unit provides a broad knowledge base related to normal growth and development that the nurse can draw on in any situation. Common concerns related to growth and development and client/family education are included in each age-specific chapter.

Unit 10: Foundations of Pediatric Nursing

Unit 10 covers broad concepts that provide the foundation for providing nursing care for children. Rather than reiterating all aspects of nursing care, the unit focuses on specific details needed to provide nursing care for children in general. The content remains focused upon differences in caring for children compared with adults. Topics covered in this unit include anticipatory guidance and routine well child care (including immunization and safety), health assessment, nursing care of the child in the hospital, concerns common to special needs children, pediatric variations in medication and intravenous fluid delivery and nutritional support, and pain management in children.

Unit 11: Nursing Care of the Child With a Health Disorder

Unit 11 focuses on children's responses to health disorders. This unit provides comprehensive coverage of illnesses affecting children and is presented according to broad topics of disorders organized with a body systems approach. It also includes infectious, genetic, and mental health disorders as well as pediatric emergencies. Each chapter follows a similar format in order to facilitate presentation of the information as well as reduce repetition. The chapters begin with a nursing process overview for the particular broad topic, presenting differences in children and how the nursing process applies. The approach provides a general framework for addressing disorders within the chapter. Individual disorders are then addressed with attention to specifics related to pathophysiology, nursing assessment, nursing management, and special considerations. Common pediatric disorders are covered in greater depth than less common disorders. The format of the chapters allows for the building of a strong knowledge base and encourages critical thinking. Additionally, the format is nursing process driven and consistent from chapter to chapter, providing a practical and sensible presentation of the information.

Recurring Features

In order to provide the instructor and student with an exciting and user-friendly text, a number of recurring features have been developed.

Key Terms

A list of terms that are considered essential to the chapter's understanding is presented at the beginning of each chapter. Each key term appears in boldface, with the definition included in the text. Key terms may also be accessed on thePoint.

Learning Objectives

Learning Objectives included at the beginning of each chapter guide the student in understanding what is important and why, leading the student to prioritize information for learning. These valuable learning tools also provide opportunities for self-testing or instructor evaluation of student knowledge and ability.

WOW

Each chapter opens with inspiring Words of Wisdom, which offer helpful, timely, or interesting thoughts. These WOW statements set the stage for each chapter and give the student valuable insight into nursing care of women, children, and their families.

Case Studies

Real-life scenarios present relevant woman, child, and family information that is intended to perfect the student's caregiving skills. Questions about the scenario provide an opportunity for the student to critically evaluate the appropriate course of action.

Watch and Learn Icon

A special icon WATCH & LEARN throughout the book directs the student to free video clips that highlight maternity nursing care, childhood growth and development, communication with children, and provision of nursing care to children in the hospital. These clips can be viewed on thePoint website and also on the Student Resource CD.

Evidence-Based Practice

The consistent promotion of evidence-based practice is a key feature of the text. Throughout the chapters, pivotal questions addressed by current research have been incorporated into Evidence-Based Practice displays, which cite studies relevant to chapter content.

Healthy People 2010

Throughout the textbook, relevant *Healthy People 2010* objectives are outlined in box format. The nursing implications or guidance provided in the box serve as a roadmap for improving the health of women, mothers, and children.

Teaching Guidelines

An important tool for achieving health promotion and disease prevention is health education. Throughout the textbook, Teaching Guidelines raise awareness, provide timely and accurate information, and are designed to ensure the student's preparation for educating women, children, and their families about various issues.

Drug Guides

Drug guide tables summarize information about commonly used medications. The actions, indications, and significant nursing implications presented assist the student in providing optimum care to women, children, and their families.

Common Laboratory and Diagnostic Tests

The Common Laboratory and Diagnostic Tests tables in many of the chapters provide the student with a general understanding of how a broad range of disorders is diagnosed. Rather than reading the information repeatedly throughout the narrative, the student is then able to refer to the table as needed.

Common Medical Treatments

The Common Medical Treatments tables in many of the nursing management chapters provide the student with a broad awareness of how a common group of disorders is treated either medically or surgically. The tables serve as a reference point for common medical treatments.

Nursing Care Plans

Nursing Care Plans provide concrete examples of each step of the nursing process and are included in numerous chapters. The Nursing Care Plans summarize issue- or system-related content, thereby minimizing repetition.

Comparison Charts

These charts compare two or more disorders or other easily confused concepts. They serve to provide an explanation that clarifies the concepts for the student.

Nursing Procedures

Step-by-step Nursing Procedures are presented in a clear, concise format to facilitate competent performance of relevant procedures as well as to clarify pediatric variations when appropriate.

Consider This!

In every chapter the student is asked to *Consider This!* These first-person narratives engage the student in real-life scenarios experienced by their patients. The personal accounts evoke empathy and help the student to perfect caregiving skills. Each box ends with an opportunity for further contemplation, encouraging the student to think critically about the scenario.

Take Note!

The *Take Note!* feature draws the student's attention to points of critical emphasis throughout the chapter. This feature is often used to stress life-threatening or otherwise vitally important information.

Tables, Boxes, Illustrations, and Photographs

Abundant tables and boxes summarize key content throughout the book. Additionally, beautiful illustrations and photographs help the student to visualize the content. These features allow the student to quickly and easily access information.

Key Concepts

At the end of each chapter, Key Concepts provide a quick review of essential chapter elements. These bulleted lists help the student focus on the important aspects of the chapter.

References and Websites

References and websites that were used in the development of the text are provided at the end of each chapter. These listings enable the student to further explore topics of interest. Many online resources are provided as a means for the student to electronically explore relevant content material. These resources can be shared with women, children, and their families to enhance patient education and support.

Chapter Worksheets

Chapter worksheets at the end of each chapter assist the student in reviewing essential concepts. Chapter worksheets include:

- **Multiple Choice Questions**—These review questions are written to test the student's ability to apply chapter material. Questions cover maternal-newborn and women's health content that the student might encounter on the national licensing exam (NCLEX).

- **Critical Thinking Exercises**—These exercises challenge the student to incorporate new knowledge with previously learned concepts and reach a satisfactory conclusion. They encourage the student to think critically, problem solve, and consider his or her own perspective on given topics.
- **Study Activities**—These interactive activities promote student participation in the learning process. This section encourages increased interaction/learning via clinical, on-line, and community activities.

Teaching-Learning Package

Instructor's Resource DVD

This valuable resource for instructors includes all the materials instructors need to teach the maternity-pediatric course, including:

- PowerPoint presentations that correspond to each chapter and serve as a supplement to the instructor's course development
  - A Test Generator that features hundreds of questions within a powerful tool to help the instructor create quizzes and tests
- An Image Bank that provides access to photographs and illustrations from the text in a convenient, searchable format
- Lecture Outlines for organizing classroom instruction
- Sample syllabi for setting up the maternity-pediatric nursing course
- Assignments and reading comprehension quizzes, designed to test the student's understanding

Student Resource CD-ROM

The student resource CD-ROM, which is included for free in the front of the book, features video clips highlighting the developmental stages of pregnancy, vaginal labor and birth, scheduled cesarean section, breastfeeding assistance, developmental considerations, and nursing care of the child in the hospital. The CD-ROM also includes a Spanish-English audio glossary and an NCLEX alternate-item format tutorial.

ThePoint Solution

ThePoint Solution, http://thepoint.lww.com, a trademark of Wolters Kluwer Health, is a web-based course and content management system providing every resource that the instructor and student need in one easy-to-use site. Advanced technology and superior content combine at ThePoint to allow instructors to design and deliver online and offline courses, maintain grades and class rosters, and communicate with students. Students can visit ThePoint to access supplemental multimedia resources, such as Answers to Worksheets, a Glossary, and NCLEX-style student review questions to enhance their learning experience. ThePoint Solution package also includes an EBook, so students can search their text electronically, and journal articles to help students understand evidence-based practice. Students can also check the course syllabus, download content, upload assignments, and join an online study group. For instructors, a wealth of information can be found at ThePoint, all designed to make teaching easier, for example:

- Pre-lecture quizzes, made of five true/false and five fill-in-the-blank questions, are meant to be given at the beginning of class and help evaluate whether students are keeping up with the reading and the material it covers.
- Assignments, broken into four types—written, group, clinical, and Web—and organized by learning objective, provide opportunities for in- or after-class activities.
- Discussion topics, also organized by learning objective, allow students to critically

think through scenarios and discuss their ideas with other students. Case studies help bring the discussion topics and critical thinking exercises to life by presenting realistic and challenging situations in which to apply new skills.
- Guided lecture notes organize the chapter objective by objective and provide references to appropriate PowerPoint slides and figures from the text.
- Sample syllabi assist instructors with setting their courses and are provided for four different course lengths: 6, 8, 10, and 15 weeks.

Nursing Management 228

Cervical Cancer 229
Pathophysiology 229
Screening and Diagnosis 230
Therapeutic Management 230
Nursing Assessment 231
Nursing Management 233

Vaginal Cancer 235
Pathophysiology 235
Therapeutic Management 235
Nursing Assessment 235
Nursing Management 235

Vulvar Cancer 236
Pathophysiology 236
Screening and Diagnosis 237
Therapeutic Management 237
Nursing Assessment 237
Nursing Management 237

CHAPTER 9
Violence and Abuse 242

Intimate Partner Violence 243
Incidence 243
Background 244
Characteristics of Intimate Partner Violence 244
Types of Abuse 245
Myths and Facts About Intimate Partner Violence 245
Abuse Profiles 245
Violence Against Pregnant Women 246
Violence Against Older Women 247
Nursing Management 248

Sexual Violence 253
Sexual Abuse 253
Incest 254
Rape 255
Female Genital Mutilation 258
Human Trafficking 259

Summary 259

UNIT THREE
PREGNANCY 263

CHAPTER 10
Fetal Development and Genetics 265

Fetal Development 266
Preembryonic Stage 266
Embryonic Stage 269
Fetal Stage 272
Fetal Circulation 272

Genetics 273
Advances in Genetics 273
Inheritance 275
Patterns of Inheritance 277
Chromosomal Abnormalities 279
Genetic Evaluation and Counseling 281
Nursing Roles and Responsibilities 282

CHAPTER 11
Maternal Adaptation During Pregnancy 288

Signs and Symptoms of Pregnancy 289
Subjective (Presumptive) Signs 289
Objective (Probable) Signs 290
Positive Signs 290

Physiologic Adaptations During Pregnancy 291
Reproductive System Adaptations 291
General Body System Adaptations 293

Changing Nutritional Needs of Pregnancy 299
Nutritional Requirements During Pregnancy 302
Maternal Weight Gain 304
Nutrition Promotion 305
Special Nutritional Considerations 305

Psychosocial Adaptations During Pregnancy 307
Maternal Emotional Responses 307
Maternal Role Tasks 308
Pregnancy and Sexuality 308
Pregnancy and the Partner 309
Pregnancy and Siblings 309

CHAPTER 12
Nursing Management During Pregnancy 313

Preconception Care 314
Risk Factors for Adverse Pregnancy Outcomes 314
Nursing Management 315

The First Prenatal Visit 315
Comprehensive Health History 317
Physical Examination 320

Follow-Up Visits 324
Fundal Height Measurement 324
Fetal Movement Determination 324
Fetal Heart Rate Measurement 325
Follow-Up Visit Intervals and Assessments 325
Teaching About the Danger Signs of Pregnancy 326

Assessment of Fetal Well-Being 326
Ultrasonography 326

Doppler Flow Studies 327
Alpha-Fetoprotein Analysis 327
Marker Screening Tests 328
Nuchal Translucency Screening 328
Amniocentesis 328
Chorionic Villus Sampling 330
Percutaneous Umbilical Blood Sampling 331
Nonstress Test 332
Contraction Stress Test 332
Biophysical Profile 332

Nursing Management for the Common Discomforts of Pregnancy 333
First-Trimester Discomforts 333
Second-Trimester Discomforts 337
Third-Trimester Discomforts 339

Nursing Management to Promote Self-Care 341
Personal Hygiene 341
Hot Tubs and Saunas 341
Perineal Care 341
Dental Care 341
Breast Care 342
Clothing 342
Exercise 342
Sleep and Rest 343
Sexual Activity and Sexuality 344
Employment 344
Travel 345
Immunizations and Medications 345

Nursing Management to Prepare the Woman and Her Partner for Labor, Birth, and Parenthood 347
Childbirth Education Classes 348
Options for Birth Settings and Care Providers 349
Preparation for Breast-Feeding or Bottle-Feeding 351
Final Preparation for Labor and Birth 352

UNIT FOUR
LABOR AND BIRTH 357

CHAPTER 13
Labor and Birth Process 359

Initiation of Labor 360

Premonitory Signs of Labor 360
Cervical Changes 360
Lightening 360
Increased Energy Level 360
Bloody Show 360
Braxton Hicks Contractions 361
Spontaneous Rupture of Membranes 361

True Versus False Labor 361

Factors Affecting the Labor Process 362
Passageway 362
Passenger 364
Powers 370
Psychological Response 372
Position (Maternal) 372
Philosophy 372
Partners 373
Patience 374
Patient Preparation 375
Pain Management 375

Physiologic Responses to Labor 375
Maternal Responses 375
Fetal Responses 376

Stages of Labor 376
First Stage 376
Second Stage 378
Third Stage 379
Fourth Stage 379

CHAPTER 14
Nursing Management During Labor and Birth 385

Maternal Assessment During Labor and Birth 386
Vaginal Examination 386
Assessing Uterine Contractions 387
Performing Leopold's Maneuvers 388

Fetal Assessment During Labor and Birth 388
Analysis of Amniotic Fluid 388
Analysis of the FHR 390
Other Fetal Assessment Methods 396

Promoting Comfort and Providing Pain Management During Labor 398
Nonpharmacologic Measures 398
Pharmacologic Measures 403

Nursing Care During Labor and Birth 408
Nursing Care During the First Stage of Labor 409
Nursing Management During the Second Stage of Labor 414
Nursing Management During the Third Stage of Labor 419
Nursing Management During the Fourth Stage of Labor 421

UNIT FIVE
POSTPARTUM PERIOD 427

CHAPTER 15
Postpartum Adaptations 429

Maternal Physiologic Adaptations 430
Reproductive System Adaptations 430
Cardiovascular System Adaptations 432

Urinary System Adaptations 433
Gastrointestinal System Adaptations 434
Musculoskeletal System Adaptations 434
Integumentary System Adaptations 435
Respiratory System Adaptations 435
Endocrine System Adaptations 435
Lactation 435

Psychological Adaptations 437
Maternal Psychological Adaptations 437
Partner Psychological Adaptations 438

CHAPTER 16
Nursing Management During the Postpartum Period 443

Assessment 445
Vital Signs 446
Breasts 446
Uterus 446
Bladder 447
Bowels 447
Lochia 447
Episiotomy and Perineum 448
Extremities 449
Emotional Status 449

Bonding and Attachment 449
Factors Affecting Attachment 451
Critical Attributes of Attachment 451
Positive and Negative Attachment Behaviors 452

Nursing Interventions 452
Providing Optimal Cultural Care 452
Promoting Comfort 452
Assisting With Elimination 456
Promoting Activity, Rest, and Exercise 457
Preventing Stress Incontinence 459
Assisting With Self-Care Measures 459
Ensuring Safety 460
Counseling About Sexuality and Contraception 460
Promoting Nutrition 460
Supporting the Woman's Choice of Feeding Method 461
Teaching About Breast Care 463
Promoting Family Adjustment and Well-Being 464
Teaching About Postpartum Blues 467
Preparing for Discharge 467

UNIT SIX
THE NEWBORN 477

CHAPTER 17
Newborn Adaptation 479

Physiologic Adaptations 480
Cardiovascular System Adaptations 480
Respiratory System Adaptations 482
Body Temperature Regulation 483
Hepatic System Function 487
Gastrointestinal System Adaptations 488
Renal System Changes 489
Immune System Adaptations 490
Integumentary System Adaptations 490
Neurologic System Adaptations 491

Behavioral Adaptations 491
Behavioral Patterns 491
Newborn Behavioral Responses 492

CHAPTER 18
Nursing Management of the Newborn 497

Nursing Management During the Immediate Newborn Period 498
Assessment 498
Nursing Interventions 503

Nursing Management During the Early Newborn Period 505
Assessment 506
Nursing Interventions 519

UNIT SEVEN
CHILDBEARING AT RISK 547

CHAPTER 19
Nursing Management of Pregnancy at Risk: Pregnancy-Related Complications 549

Bleeding During Pregnancy 550
Spontaneous Abortion 551
Ectopic Pregnancy 552
Gestational Trophoblastic Disease (GTD) 557
Cervical Insufficiency 559
Placenta Previa 560
Abruptio Placentae 564

Hyperemesis Gravidarum 567
Pathophysiology 567
Therapeutic Management 567
Nursing Assessment 568
Nursing Management 569

Gestational Hypertension 569
Pathophysiology 570
Therapeutic Management 571
Nursing Assessment 572
Nursing Management 573
Intervening With Preeclampsia 573

HELLP 577
Pathophysiology 577
Therapeutic Management 577

Nursing Assessment 577
Nursing Management 578

Gestational Diabetes 578

Blood Incompatibility 578
Pathophysiology 578
Nursing Assessment 578
Nursing Management 579

Amniotic Fluid Imbalances 579
Polyhydramnios 579
Oligohydramnios 580

Multiple Gestation 580
Therapeutic Management 581
Nursing Assessment 581
Nursing Management 581

Premature Rupture of Membranes 581
Therapeutic Management 582
Nursing Assessment 582
Nursing Management 583

CHAPTER 20

Nursing Management of the Pregnancy at Risk: Selected Health Conditions and Vulnerable Populations 588

Diabetes Mellitus 589
Pathophysiology 590
Therapeutic Management 590
Nursing Assessment 593
Nursing Management 594

Cardiovascular Disorders 597
Congenital and Acquired Heart Disease 598
Chronic Hypertension 603

Respiratory Conditions 604
Asthma 604
Tuberculosis 606

Hematologic Conditions 607
Iron Deficiency Anemia 607
Thalassemia 608
Sickle Cell Anemia 609

Infections 609
Cytomegalovirus 609
Rubella 611
Herpes Simplex Virus 611
Hepatitis B Virus 611
Varicella Zoster Virus 612
Parvovirus B19 613
Group B Streptococcus 613
Toxoplasmosis 614

Vulnerable Populations 614
Pregnant Adolescent 615
The Pregnant Woman Over Age 35 618
Women Who Are HIV Positive 619
The Pregnant Woman With Substance Abuse 622

CHAPTER 21

Nursing Management of Labor and Birth at Risk 634

Dystocia 635
Problems With the Powers 635
Problems With the Passenger 643
Problems With the Passageway 644
Problems With the Psyche 645

Preterm Labor 646
Therapeutic Management 646
Nursing Assessment 647
Nursing Management 650

Postterm Labor 652
Nursing Assessment 652
Nursing Management 652

Women Requiring Labor Induction and Augmentation 653
Therapeutic Management 654
Nursing Assessment 657
Nursing Management 657

Intrauterine Fetal Demise 658
Nursing Assessment 658
Nursing Management 660

Women Experiencing an Obstetric Emergency 660
Umbilical Cord Prolapse 660
Placental Abruption 661
Uterine Rupture 662
Amniotic Fluid Embolism 662
Women Requiring Birth-Related Procedures 663
Amnioinfusion 663
Forceps- or Vacuum-Assisted Birth 664
Cesarean Birth 665
Vaginal Birth After Cesarean 666

CHAPTER 22

Nursing Management of the Postpartum Woman at Risk 671

Postpartum Hemorrhage 672
Pathophysiology 672
Therapeutic Management 674
Nursing Assessment 674
Nursing Management 675

Thromboembolic Conditions 678
Pathophysiology 678
Nursing Assessment 678
Nursing Management 678

Postpartum Infection 679
Metritis 680

Wound Infections 680
Urinary Tract Infections 680
Mastitis 680
Therapeutic Management 681
Nursing Assessment 681
Nursing Management 682

Postpartum Affective Disorders 683
Postpartum or Baby Blues 685
Postpartum Depression 685
Postpartum Psychosis 686
Nursing Assessment 687
Nursing Management 688

UNIT EIGHT
THE NEWBORN AT RISK 693

CHAPTER 23
Nursing Care of the Newborn With Special Needs 695

Birthweight Variations 696
Small-for-Gestational-Age Newborns 697
Large-for-Gestational-Age Newborns 698
Nursing Assessment 702
Nursing Management 702

Gestational Age Variations 703
Postterm Newborn 703
Preterm Newborn 704
Late Preterm Newborn 720

CHAPTER 24
Nursing Management of the Newborn at Risk: Acquired and Congenital Newborn Conditions 724

Acquired Disorders 726
Neonatal Asphyxia 726
Transient Tachypnea of the Newborn 727
Respiratory Distress Syndrome 728
Meconium Aspiration Syndrome 731
Persistent Pulmonary Hypertension of the Newborn 732
Periventricular–Intraventricular Hemorrhage 733
Necrotizing Enterocolitis 734
Infants of Diabetic Mothers 735
Birth Trauma 740
Newborns of Substance-Abusing Mothers 743
Hyperbilirubinemia 750
Newborn Infections 755

Congenital Conditions 758
Esophageal Atresia and Tracheoesophageal Fistula 759
Omphalocele and Gastroschisis 760
Imperforate Anus 762
Bladder Exstrophy 762

UNIT NINE
HEALTH PROMOTION FOR THE GROWING CHILD AND FAMILY 767

CHAPTER 25
Growth and Development of the Newborn and Infant 769

Growth and Development Overview 770
Physical Growth 770
Weight 770
Height 770
Head and Chest Circumference 770
Organ System Maturation 771
Neurologic System 771
Respiratory System 771
Cardiovascular System 775
Gastrointestinal System 775
Genitourinary System 776
Integumentary System 776
Hematopoietic System 776
Immunologic System 777
Psychosocial Development 777
Cognitive Development 777
Motor Skill Development 777
Gross Motor Skills 777
Fine Motor Skills 779
Sensory Development 779
Sight 779
Hearing 780
Smell and Taste 780
Touch 780
Communication and Language Development 780
Social and Emotional Development 782
Stranger Anxiety 783
Separation Anxiety 783
Temperament 783
Cultural Influences on Growth and Development 783

The Nurse's Role in Newborn and Infant Growth and Development 784
Nursing Process Overview 784
Promoting Healthy Growth and Development 784
Promoting Growth and Development Through Play 784
Promoting Early Learning 787
Promoting Safety 787
Promoting Nutrition 789
Promoting Healthy Sleep and Rest 793
Promoting Healthy Teeth and Gums 793

Promoting Appropriate Discipline 794
Addressing Child Care Needs 794
Addressing Common Developmental Concerns 794
Colic 794
Spitting Up 795
Thumb Sucking, Pacifiers, and Security Items 795
Teething 795

CHAPTER 26
Growth and Development of the Toddler 799

Growth and Development Overview 800
Physical Growth 800
Organ System Maturation 800
Neurologic System 800
Respiratory System 800
Cardiovascular System 801
Gastrointestinal System 801
Genitourinary System 801
Musculoskeletal System 801
Psychosocial Development 801
Cognitive Development 801
Motor Skill Development 803
Gross Motor Skills 803
Fine Motor Skills 803
Sensory Development 804
Communication and Language Development 804
Emotional and Social Development 805
Separation Anxiety 806
Temperament 806
Fears 807
Moral and Spiritual Development 807
Cultural Influences on Growth and Development 807

The Nurse's Role in Toddler Growth and Development 807
Nursing Process Overview 808
Promoting Healthy Growth and Development 808
Promoting Growth and Development Through Play 808
Promoting Early Learning 811
Promoting Safety 813
Promoting Nutrition 815
Promoting Healthy Sleep and Rest 819
Promoting Healthy Teeth and Gums 820
Promoting Appropriate Discipline 820
Addressing Common Developmental Concerns 822
Toilet Teaching 822
Negativism 824
Temper Tantrums 824
Thumb Sucking and Pacifiers 824
Sibling Rivalry 825
Regression 825

CHAPTER 27
Growth and Development of the Preschooler 829

Growth and Development Overview 830
Physical Growth 830
Organ System Maturation 830
Psychosocial Development 830
Cognitive Development 831
Moral and Spiritual Development 831
Motor Skill Development 832
Gross Motor Skills 833
Fine Motor Skills 833
Sensory Development 834
Communication and Language Development 834
Emotional and Social Development 834
Cultural Influences on Growth and Development 836

The Nurse's Role in Preschool Growth and Development 837
Nursing Process Overview 837
Promoting Healthy Growth and Development 837
Promoting Growth and Development Through Play 840
Promoting Early Learning 842
Promoting Safety 843
Promoting Nutrition 846
Promoting Healthy Sleep and Rest 847
Promoting Healthy Teeth and Gums 848
Promoting Appropriate Discipline 848
Addressing Common Developmental Concerns 850
Lying 850
Sex Education 850
Masturbation 850

CHAPTER 28
Growth and Development of the School-Age Child 853

Growth and Development Overview 854
Physical Growth 854
Organ System Maturation 854
Neurologic System 855
Respiratory System 855
Cardiovascular System 855
Gastrointestinal System 855
Genitourinary System 855
Prepubescence 855
Musculoskeletal System 855
Immune System 855
Psychosocial Development 855
Cognitive Development 856
Moral and Spiritual Development 856
Motor Skill Development 857
Gross Motor Skills 857
Fine Motor Skills 858
Sensory Development 858
Communication and Language Development 858
Emotional and Social Development 858
Temperament 858
Self-Esteem Development 859
Body Image 859
School-Age Fears 859

Peer Relationships 859
Teacher and School Influences 859
Family Influences 860
Cultural Influences on Growth and Development 860

The Nurse's Role in School-Age Growth and Development 860
Nursing Process Overview 860
Promoting Healthy Growth and Development 861
Promoting Growth and Development Through Play 861
Promoting Learning 861
Promoting Safety 864
Promoting Nutrition 867
Promoting Healthy Sleep and Rest 868
Promoting Healthy Teeth and Gums 868
Promoting Appropriate Discipline 869
Addressing Common Developmental Concerns 869
Television and Video Games 871
Obesity 871
School Phobia 872
Latchkey Children 872
Stealing, Lying, and Cheating 872
Bullying 873
Tobacco and Alcohol Education 873

CHAPTER 29
Growth and Development of the Adolescent 877

Growth and Development Overview 878
Physiologic Changes Associated With Puberty 878
Physical Growth 879
Organ System Maturation 880
Neurologic System 880
Respiratory System 880
Cardiovascular System 880
Gastrointestinal System 880
Musculoskeletal System 880
Integumentary System 880
Psychosocial Development 880
Cognitive Development 882
Moral and Spiritual Development 882
Motor Skill Development 882
Gross Motor Skills 882
Fine Motor Skills 883
Communication and Language Development 883
Emotional and Social Development 883
Relationship With Parents 883
Self-Concept and Body Image 884
Importance of Peers 884
Sexuality and Dating 884
Cultural Influences on Growth and Development 885

The Nurse's Role in Adolescent Growth and Development 885
Nursing Process Overview 886
Promoting Healthy Growth and Development 886
Promoting Growth and Development Through Sports and Physical Fitness 886
Promoting Learning 886
Promoting Safety 888
Promoting Nutrition 892
Promoting Healthy Sleep and Rest 893
Promoting Healthy Teeth and Gums 893
Promoting Personal Care 894
Promoting Appropriate Discipline 895
Addressing Common Developmental Concerns 895
Obesity 895
Violence 896
Substance Use 897

UNIT TEN
FOUNDATIONS OF PEDIATRIC NURSING 903

CHAPTER 30
Health Supervision 905

Principles of Health Supervision 906
Wellness 906
Medical Home 906
Partnerships 906

Special Issues in Health Supervision 907
Cultural Influences on Health Supervision 907
Community Influences on Health Supervision 907
Health Supervision and the Child With Chronic Illness 908
Health Supervision and the Child Adopted Internationally 908

Components of Health Supervision 908
Developmental Surveillance and Screening 908
Injury and Disease Prevention 910
Health Promotion 930

CHAPTER 31
Health Assessment of Children 938

Health History 939
Preparing for the Health History 939
Gathering Materials and Preparing Yourself for the Health History 939
Determining the Type of History Needed 941
Performing a Health History 941
Components of the Health Interview 941
Demographics 942
Chief Complaint and History of Present Illness 942
Past Health History 942
Family Health History 942
Review of Systems 942
Developmental History 943
Functional History 944

Family Composition, Resources, and Home Environment 944

Performing a Physical Examination 944
Preparing for the Physical Examination 944
Gathering Materials and Preparing for the Examination 944
Approaching the Child 945
Steps of the Physical Examination 947
Performing a Physical Examination 948
General Appearance 948
Measurement of Vital Signs 948
Body Measurements 954
Skin 957
Head 959
Neck 960
Eyes 960
Ears 962
Nose and Sinuses 963
Mouth and Throat 963
Thorax and Lungs 965
Breasts 966
Heart and Peripheral Perfusion 968
Abdomen 970
Genitalia and Anus 971
Musculoskeletal 973
Neurologic 974

CHAPTER 32
Nursing Care of Children During Illness and Hospitalization 979

Hospitalization in Childhood 980
Children's Reactions to Hospitalization 980
Factors Affecting Children's Reaction to Hospitalization 983

The Hospitalized Child's Family 984
Reactions of Parents 984
Reactions of Siblings 985
Factors Influencing Family Reactions 985

The Nurse's Role in Caring for the Hospitalized Child 985
Preparing Children and Families for Hospitalization 985
Admitting the Child to the Facility 990
Addressing the Effects of Hospitalization Developmentally 993
Preparing the Child and Family for Surgery 995
Maintaining Safety During Hospitalization 996
Providing Basic Care for the Hospitalized Child 1000
Providing Play, Activities, and Recreation for the Hospitalized Child 1002
Promoting Schoolwork and Education During Hospitalization 1004
Addressing the Needs of Family Members 1004
Providing Client Teaching 1005
Preparing the Child and Family for Discharge 1005

CHAPTER 33
Nursing Care of the Child With Special Needs 1009

The Medically Fragile Child 1010
Effect of Special Needs on the Child and Family 1011
Effects on Siblings 1012
Nursing Management of the Medically Fragile Child 1012

The Dying Child 1022
Grieving 1022
Palliative Care of the Dying Child 1022
Hospice Care 1023
Nursing Management of the Dying Child 1023

CHAPTER 34
Medication Administration, Intravenous Therapy, and Nutritional Support 1029

Children and Procedures 1030
Before the Procedure 1030
During the Procedure 1030
After the Procedure 1030

Medication Administration 1031
Differences in Pharmacodynamics and Pharmacokinetics 1032
Developmental Issues and Concerns 1033
Determination of Correct Dose 1035
Oral Administration 1036
Rectal Administration 1037
Ophthalmic Administration 1037
Otic Administration 1038
Nasal Administration 1039
Intramuscular Administration 1040
Subcutaneous and Intradermal Administration 1040
Intravenous Administration 1040
Providing Atraumatic Care 1040
Educating the Child and Parents 1043

Intravenous Therapy 1043
Sites 1043
Equipment 1044
Fluid Administration 1045

Nutritional Support 1048
Enteral Nutrition 1048
Parenteral Nutrition 1054

CHAPTER 35
Pain Management in Children 1061

Physiology of Pain 1062
Transduction 1062

Transmission 1062
Perception 1062
Modulation 1063

Types of Pain 1063
Classification by Duration 1063
Classification by Etiology 1064
Classification by Source or Location 1064

Factors Influencing Pain 1064
Age and Gender 1065
Cognitive Level 1065
Temperament 1065
Previous Pain Experiences 1065
Family and Culture 1065
Situational Factors 1065

Developmental Considerations 1065
Infants 1065
Toddlers 1067
Preschoolers 1067
School-Age Children 1067
Adolescents 1067

Common Fallacies and Myths About Pain in Children 1067
Nursing Process Overview for the Child in Pain 1067

Management of Pain 1076
Nonpharmacologic Management 1076
Pharmacologic Management 1082
Management of Procedure-Related Pain 1090
Management of Chronic Pain 1091

UNIT ELEVEN
NURSING CARE OF THE CHILD WITH A HEALTH DISORDER 1097

CHAPTER 36
Nursing Care of the Child With an Infectious or Communicable Disorder 1099

Infectious Process 1100
Stages of Infectious Disease 1101
Chain of Infection 1101
Preventing the Spread of Infection 1102

Variations in Pediatric Anatomy and Physiology 1103

Common Medical Treatments 1103
Nursing Process Overview for the Child With a Communicable Disorder 1103

Sepsis 1114
Pathophysiology 1114
Therapeutic Management 1114
Nursing Assessment 1114
Nursing Management 1115

Bacterial Infections 1116
Scarlet Fever 1116

CHAPTER 40

Nursing Care of the Child With a Cardiovascular Disorder 1280

Variations in Pediatric Anatomy and Physiology 1281
Circulatory Changes From Gestation to Birth 1281
Structural and Functional Differences 1281

Common Medical Treatments 1282
Nursing Process Overview for the Child With a Cardiovascular Disorder 1282

Congenital Heart Disease 1291
Pathophysiology 1295
Therapeutic Management 1296
Disorders With Decreased Pulmonary Blood Flow 1296
Tetralogy of Fallot 1296
Tricuspid Atresia 1299
Disorders With Increased Pulmonary Blood Flow 1300
Atrial Septal Defect 1300
Ventricular Septal Defect 1301
Atrioventricular Canal Defect 1302
Patent Ductus Arteriosus 1303
Obstructive Disorders 1304
Coarctation of the Aorta 1304
Aortic Stenosis 1304
Pulmonary Stenosis 1305
Mixed Defects 1306
Transposition of the Great Vessels (Arteries) 1306
Total Anomalous Pulmonary Venous Connection 1307
Truncus Arteriosus 1307
Hypoplastic Left Heart Syndrome 1308
Nursing Management of the Child With Congenital Heart Disease 1309
Improving Oxygenation 1309
Promoting Adequate Nutrition 1309
Assisting the Child and Family to Cope 1310
Preventing Infection 1310
Providing Care for the Child Undergoing Cardiac Surgery 1310
Providing Patient and Family Education 1312

Acquired Cardiovascular Disorders 1312
Heart Failure 1313
Pathophysiology 1313
Therapeutic Management 1313
Nursing Assessment 1313
Nursing Management 1314
Infective Endocarditis 1315
Nursing Assessment 1315
Nursing Management 1316
Acute Rheumatic Fever 1316
Nursing Assessment 1317
Nursing Management 1317
Cardiomyopathy 1317
Nursing Assessment 1318
Nursing Management 1318
Hypertension 1318
Pathophysiology 1318
Nursing Assessment 1318
Nursing Management 1319
Kawasaki Disease 1319
Pathophysiology 1320
Nursing Assessment 1320
Nursing Management 1320
Hyperlipidemia 1321
Pathophysiology 1321
Therapeutic Management 1321
Nursing Assessment 1321

Heart Transplantation 1322
Surgical Procedure and Postoperative Therapeutic Management 1322
Nursing Management 1322

CHAPTER 41

Nursing Care of the Child With a Gastrointestinal Disorder 1327

Variations in Pediatric Anatomy and Physiology 1328
Mouth 1328
Esophagus 1328
Stomach 1328
Intestines 1328
Biliary System 1328
Fluid Balance and Losses 1328

Common Medical Treatments 1329
Nursing Process Overview for the Child With a GI Disorder 1329

Stool Diversions 1335

Structural Anomalies of the GI Tract 1339
Cleft Lip and Palate 1339
Pathophysiology 1339
Therapeutic Management 1340
Nursing Assessment 1340
Nursing Management 1340
Meckel's Diverticulum 1342
Nursing Assessment 1342
Nursing Management 1342
Inguinal and Umbilical Hernias 1342
Inguinal Hernia 1342
Umbilical Hernia 1343
Anorectal Malformations 1344
Nursing Assessment 1344
Nursing Management 1344

Acute GI Disorders 1344
Dehydration 1344
Nursing Assessment 1344
Nursing Management 1345
Vomiting 1346
Nursing Assessment 1346
Nursing Management 1347
Diarrhea 1347
Pathophysiology 1347
Nursing Assessment 1347
Nursing Management 1349
Oral Candidiasis (Thrush) 1350
Nursing Assessment 1350
Nursing Management 1350
Oral Lesions 1351
Nursing Assessment 1351
Nursing Management 1352
Hypertrophic Pyloric Stenosis 1352
Nursing Assessment 1352
Nursing Management 1353
Intussusception 1353
Nursing Assessment 1354
Nursing Management 1354
Malrotation and Volvulus 1354
Nursing Assessment 1354
Nursing Management 1354
Appendicitis 1354
Pathophysiology 1354
Therapeutic Management 1354
Nursing Assessment 1354
Nursing Management 1356

Chronic GI Disorders 1356
Gastroesophageal Reflux 1356
Pathophysiology 1356
Therapeutic Management 1356
Nursing Assessment 1356
Nursing Management 1357
Peptic Ulcer Disease 1358
Therapeutic Management 1359
Nursing Assessment 1359
Nursing Management 1359
Constipation and Encopresis 1359
Pathophysiology 1360
Therapeutic Management 1360
Nursing Assessment 1360
Nursing Management 1361

Hirschsprung's Disease (Congenital Aganglionic Megacolon) 1362
Therapeutic Management 1362
Nursing Assessment 1362
Nursing Management 1363
Short Bowel Syndrome 1363

Nursing Management 1374
Liver Transplantation 1374
Nursing Assessment 1375
Nursing Management 1375

CHAPTER 42
Nursing Care of the Child With a Genitourinary Disorder 1379

Variations in Pediatric Anatomy and Physiology 1380
Urinary Concentration 1380
Structural Differences 1380
Urine Output 1380
Reproductive Organ Maturity 1380

Common Medical Treatments 1380
Nursing Process Overview for the Child With a GU Disorder 1380

Urinary Tract and Renal Disorders 1387
Structural Disorders 1387
Bladder Exstrophy 1388
Hypospadias/Epispadias 1392
Obstructive Uropathy 1394
Hydronephrosis 1394
Vesicoureteral Reflux 1396
Urinary Tract Infection 1397
Pathophysiology 1397
Therapeutic Management 1398
Nursing Assessment 1398
Nursing Management 1398
Enuresis 1399
Nursing Assessment 1400
Nursing Management 1400
Acquired Disorders Resulting in Altered Renal Function 1401
Nephrotic Syndrome 1401
Acute Glomerulonephritis 1403
Hemolytic-Uremic Syndrome 1404
Renal Failure 1405
Acute Renal Failure 1405
End-Stage Renal Disease 1406
Dialysis and Transplantation 1407
Renal Transplantation 1410

Reproductive Organ Disorders 1411
Female Disorders 1411
Labial Adhesions 1411
Vulvovaginitis 1412
Male Disorders 1412
Phimosis and Paraphimosis 1412
Circumcision 1413
Cryptorchidism 1414
Hydrocele and Varicocele 1415
Testicular Torsion 1415
Epididymitis 1415

CHAPTER 43
Nursing Care of the Child With a Neuromuscular Disorder 1419

Variations in Pediatric Anatomy and Physiology 1420
Brain and Spinal Cord Development 1420
Myelinization 1420
Muscular Development 1420

Common Medical Treatments 1420
Nursing Process Overview for the Child With a Neuromuscular Disorder 1420

Congenital Neuromuscular Disorders 1428
Neural Tube Defects 1429
Spina Bifida Occulta 1429
Meningocele 1429
Myelomeningocele 1430
Muscular Dystrophy 1434
Pathophysiology 1435
Therapeutic Management 1435
Nursing Assessment 1436
Nursing Management 1436
Spinal Muscular Atrophy 1438
Nursing Assessment 1438
Nursing Management 1438

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Identify the key milestones in the evolution of maternal and child health nursing.
2. Describe the major components, concepts, and influences associated with the nursing management of women, children, and families.
3. Compare the past definitions of health and illness to the current definitions, as well as the measurements used to assess health and illness in children.
4. Identify the factors that affect maternal and child health.
5. Delineate the structures, roles, and functions of the family and how they affect the health of women and children.
6. Evaluate how society and culture can influence the health of women, children, and families.
7. Appraise the health care barriers affecting women, children, and families.
8. Discuss the ethical and legal issues that may arise when caring for women, children, and families.

Sophia Greenly, a 38-year-old woman pregnant with her third child, comes to the prenatal clinic for a routine follow-up visit. Her mother, Betty, accompanies her because Sophia's husband is out of town. Sophia lives with her husband and two children, ages 4 and 9. She works part-time as a lunch aide in the local elementary school. What factors may play a role in influencing the health of Sophia and her family?

Wow

Being pregnant and giving birth is like crossing a narrow bridge: people can accompany you to the bridge, and they can greet you on the other side, but you walk that bridge alone. And the journey doesn't end there: children are the future of a society and special gifts to the world. Changes in our society and world require us to be attentive to and value them and their health.

A person's ability to lead a fulfilling life and to participate fully in society depends largely on his or her health status. Although the overall health of children has improved and the rates of death and illness in some areas have decreased, the need to focus on the health of women and children remains. Habits and practices established during pregnancy and early during childhood can have profound effects on a person's health and illness throughout life. As a society, creating a population that cares about women, children, and families and promotes solid health care and lifestyle choices is crucial.

Maternal and newborn nursing encompasses a wide scope of practice typically associated with childbearing. It includes care of the woman before pregnancy, care of the woman and her fetus during pregnancy, care of the woman after pregnancy, and care of the newborn, usually during the first 6 weeks after birth. The overall goal of maternal and newborn nursing is to promote and maintain optimal health of the woman and her family. Child health nursing, commonly referred to as pediatric nursing, involves the care of the child from infancy through adolescence. In the United States, the number of children under age 18 years is approximately 73.5 million, accounting for 25% of the population (Child Trends, 2006a, 2006b). The overall goal of pediatric nursing practice is to promote and assist the child in maintaining optimal levels of health, while recognizing the influence of the family on the child's well-being. This goal involves health promotion and disease and injury prevention as well as assisting with care during illness. The common thread in both of these is the care of the family.

Now more than ever, nurses contribute to nearly every health care experience. Events from birth to death, and every health care emergency in between, will likely involve the presence of a nurse. Involvement of a knowledgeable, supportive, comforting nurse often leads to a positive health care experience. Skilled nursing practice depends on a solid base of knowledge and clinical expertise delivered in a caring, holistic manner. Nurses, using their knowledge and passion, help meet the health care needs of their clients throughout the life span, whether the client is a pregnant woman, a fetus, a partner, a child, or the parents or family members of a child. Nurses fill a variety of roles in helping clients to live healthier lives by providing direct care, emotional support, comfort, information, advice, advocacy, support, and counseling. Nurses are often "in the trenches" advocating for issues, drawing attention to the importance of health care for the client, and dealing with the lack of resources, the lack of access to health care, and the focus on acute care rather than education and prevention.

This chapter presents a general overview of the health care of women, children, and families and describes the major factors affecting maternal and child health. Nurses need to be knowledgeable about these concepts and factors to ensure that they provide professional care.

Historical Development

The health care of children has changed over the years due in part to devastating epidemics, social trends in our country, changes in the health care system, and federal and state regulations. By reviewing historical events, nurses can gain a better understanding of the current and future status of maternal and child health nursing.

Evolution of Maternal and Newborn Nursing

Childbirth in colonial America was a difficult and dangerous experience. During the 17th and 18th centuries, women giving birth often died as a result of exhaustion, dehydration, infection, hemorrhage, or seizures (Cassidy, 2006). Approximately 50% of all children died before age 5 (Brodsky, 2006; Jolivet, 2006), compared with the 0.06% infant mortality rate of today (World Factbook, 2006).

Centuries ago, "granny midwives" handled the normal birthing process for most women. They learned their skills through an apprenticeship with a more experienced midwife. Physicians usually were called only in extremely difficult cases, and all births took place at home.

During the early 1900s, physicians attended about half the births in the United States. Midwives often cared for women who could not afford a doctor. Many women were attracted to hospitals because this showed affluence and they provided pain management, which was not available in home births. In the 1950s, "natural childbirth" practices advocating birth without medication and focusing on relaxation techniques were introduced. These techniques opened the door to childbirth education classes and helped bring the father back into the picture. Both partners could participate by taking an active role in pregnancy, childbirth, and parenting (Fig. 1.1).

Box 1.1 shows a timeline of childbirth in America. In many ways, childbirth practices in the United States have come full circle, as we see the return of nurse midwives and doulas. The concept of women helping other women during childbirth is not new: women who labored and gave birth at home were traditionally attended to by relatives and midwives (see Evidence-Based Practice box). A **certified nurse midwife** (**CNM**) has postgraduate training in the care of normal pregnancy and delivery and is certified by the American College of Nurse Midwives (ACNM). A **doula** is a birth assistant who provides emotional, physical, and educational support to the woman and family during childbirth and the postpartum period. Many nurses working in labor and birth areas today are credentialed in their specialty so that they can provide optimal care to the woman and her newborn. Childbirth

FIGURE 1.1 Today fathers and partners are welcome to take an active role in the pregnancy and childbirth experience. (**A**) A couple can participate together in childbirth education classes. (Photo by Gus Freedman.) (**B**) Fathers and partners can assist the woman throughout her labor and delivery. (Photo by Joe Mitchell.)

choices are often based on what works best for the mother, child, and family.

Evolution of Child Health Nursing

In the 17th and 18th centuries in the United States, the overall health of the country was poorer than it is today, as demonstrated by the high mortality rates and shorter life spans. Beginning in the early 19th century, a flood of immigrants left the eastern American cities, which had high rates of infectious diseases as a result of the crowded living conditions, inadequate and unsanitary food such as contaminated milk, and harsh working conditions, including child labor. The devastating epidemics of smallpox, diphtheria, scarlet fever, and measles hit the young the hardest. During this period, society viewed children as a commodity to increase the population and share in the work to be done.

Over time, changes have focused attention on the health of children. During the 19th century, public schools were developed in this country and the court system began viewing children as minors. In 1870, the first pediatric professorship for a physician was awarded in the United States to Abraham Jacobi, who is known as the father of pediatrics. This event was a major change in the United States because it underlined the importance of providing specialized training and education about children to health care providers. In 1889 Jacobi started milk distribution centers, which provided mothers with uncontaminated milk for their sick infants as well as information about the importance of pasteurization. This one intervention decreased the number of infant deaths.

In the early 1900s, Lillian Wald established the Henry Street Settlement House in New York City; this is considered the start of public health nursing. This facility provided medical and other services to the poor families. Services included home nurse visits to mothers to provide instruction and nursing care. As hospitals developed during this time, health care personnel were trained to take care of children in this setting. Parents of hospitalized children were actually discouraged from visiting their children to prevent the spread of infection or transmission of disease. Health care personnel also thought that restricted parental involvement would minimize emotional stress.

Nursing in public schools began in 1902 with the appointment of Lina Rogers as a full-time public school nurse in New York. A professional course in pediatric nursing started in the early 1900s at Teachers' College of Columbia University.

The turn of the 20th century brought new knowledge about nutrition, sanitation, bacteriology, pharmacology, medication, and psychology. Penicillin, corticosteroids, and vaccines, which were developed during this time, assisted with the fight against communicable diseases. By the end of the 20th century, technological advances significantly affected all aspects of health care. These trends have led to increased survival rates in children; however, many of these survivors have chronic disabilities. For example, mechanical ventilation and medications to foster lung development in premature infants have increased their survival rate, but the survivors are often faced with a myriad of chronic illnesses such as bronchopulmonary dysplasia, retinopathy of prematurity, cerebral palsy, or developmental delay.

In the 1960s, changes in the health care delivery system and shifts in the population's health status led to the development of the nurse practitioner role. The 1970s saw the introduction of cost-control systems from the federal government because of rapid escalation of health care expenditures. The significant changes in the U.S. health care system in the 1980s have affected pediatric nursing and child health care, as outcomes and cost containment were emphasized. Some of these changes brought more advanced practice nurses into the field of pediatrics. Modern maternal–child advanced practice nursing includes nurse practitioners, nurse midwives, clinical nurse specialists, and case managers. In the 1980s, the Division of

BOX 1.1 Childbirth in America: A Time Line

1700s
- Men did not attend births because it was considered indecent.
- Women faced birth not with joy and ecstasy but with fear of death.
- Female midwives attended the majority of all births at home.

1800s
- There is a shift from using midwives to doctors among middle-class women.
- The word *obstetrician* was formed from the Latin, meaning "to stand before."
- Puerperal (childbed) fever was occurring in epidemic proportions.
- Louis Pasteur demonstrated that streptococci were the major cause of puerperal fever that was killing mothers after delivery.
- The first cesarean section was performed in Boston in 1894.
- The x-ray was developed in 1895 and was used to assess pelvic size for birthing purposes (Feldhusen, 2003).

1900s
- Twilight sleep (a heavy dose of narcotics and amnesiacs) was used on women during childbirth in the United States.
- The United States was 17th out of 20 nations in infant mortality rates.
- Fifty percent to 75% of all women gave birth in hospitals by 1940.
- Nurseries were started because mothers could not care for their baby for several days after receiving chloroform gas.
- Dr. Grantley Dick–Reed (1933) wrote *Childbirth Without Fear*, which reduced the "fear–tension–pain" cycle women experienced during labor and birth.
- Dr. Fernand Lamaze (1984) wrote *Painless Childbirth: The Lamaze Method*, which advocated distraction and relaxation techniques to minimize the perception of pain.
- Amniocentesis was first performed to assess fetal growth in 1966.
- In the 1970s the cesarean section rate was about 5%. By 1990 it rose to 24%, where it stands currently (Martin, 2002).
- The 1970s and 1980s see a growing trend to return birthing back to the basics—nonmedicated, nonintervening childbirth.
- In the late 1900s, freestanding birthing centers—LDRPs—were designed, and the number of home births began to increase.

2000s
- One in four women undergo a surgical birth (cesarean).
- CNMs once again assist couples at home, in hospitals, or in freestanding facilities with natural childbirths. Research shows that midwives are the safest birth attendants for most women, with lower infant mortality and maternal rates, and fewer invasive interventions such as episiotomies and cesareans (Keefe, 2003).
- Childbirth classes of every flavor abound in most communities.
- According to the latest available data, the United States ranks 21st in the world in maternal deaths. The maternal mortality rate is approximately 7 in 1,000 live births.
- According to the latest available data, the United States ranks 27th in the world in infant mortality rates. The infant mortality rate is approximately 7 in 1,000 live births (United Nations, 2003).

Maternal–Child Health Nursing Practice of the American Nurses Association developed maternal–child health standards to provide important guidelines for delivering nursing care.

Core Concepts of Maternal and Child Health Nursing

Maternal and child health nursing focuses on providing evidence-based care to the client within the context of the family. This care involves the implementation of an interdisciplinary plan in a collaborative manner to ensure continuity of care that is cost-effective, quality-oriented, and outcome-focused. Maternal and child health nursing involves family-centered, evidence-based, case-managed care. Children should receive atraumatic care to minimize the stress associated with health care procedures or situations.

Family-Centered Care

Family-centered care is the delivery of safe, satisfying, high-quality health care that focuses on and adapts to the physical and psychosocial needs of the family. It is a cooperative effort of families and other caregivers that recognizes the strength and integrity of the family. The basic principles of family-centered care are:

- Childbirth is considered a normal, healthy event in the life of a family.
- Childbirth affects the entire family, and relationships will change.
- Families are capable of making decisions about their own care if given adequate information and professional support (Roudebush et al., 2006).

The philosophy of family-centered care recognizes the family as the constant. The health and functioning of the family affect the health of the client and other mem-

EVIDENCE-BASED PRACTICE 1.1
How Do Women in Childbirth Respond to Continuous Labor Support?

● Study
Throughout history, women have been helping other women in labor by providing emotional support, comfort measures, information, and advocacy. However, in recent years this practice has waned, and facilities frequently adhere to strict specific routines that may leave women feeling "dehumanized." A study was done to assess the effects on mothers and their newborns of continuous, one-to-one intrapartum care in comparison to usual care. The study also evaluated routine practices and policies in the birth environment that might affect a woman's autonomy, freedom of movement, and ability to cope with labor; who the caregiver was, whether or not a staff member of the facility; and when the support began, early or late in labor.

All published and unpublished randomized clinical trials comparing continuous support during labor with usual care were examined. One author and one research assistant used standard methods for data collection and analysis and extracted the data independently. Clinical trial authors provided additional information. The researchers used relative risk for categorical data and weighted mean difference for continuous data. Sixteen trials from 11 countries involving 13,391 women were examined to provide the data.

▲ Findings
Women receiving continuous intrapartum support had a greater chance of a spontaneous vaginal delivery (including without forceps or vacuum extraction). They also had a slight decrease in the length of labor and required less analgesia during this time. These women also reported increased satisfaction with their labor and childbirth experience. Overall, the support, when provided by someone other than a facility staff member and initiated early in labor, proved to be more effective.

■ Nursing Implications
Based on this research, it is clear that women in labor benefit from one-to-one support during labor. Nurses can use the information gained from this study to educate women about the importance of support persons during labor and delivery. Nurses can also act as client advocates in facilities where they work to foster an environment that encourages the use of support persons during the intrapartum period. The focus of nursing needs to be individualized, supportive, and collaborative with the family during their childbearing experience. In short, nurses should place the needs of the mother and her family first in providing a continuum of care.

Although the study found that support is more effective when provided by someone other than a staff member, support from an individual is key. Assigning the same nurse to provide care to the couple throughout the birthing experience also fosters a one-to-one relationship that helps meet the couple's needs and promotes feelings of security. By meeting the couple's needs, the nurse is enhancing their birthing experience.

Source: Hodnett, E. D., Gates, S. Hofmeyr, G. J., & Sakata, C. Continuous support for women during childbirth. *Cochrane Database of Systematic Reviews* 2007. Issue 3. Art No.: CD003766.DOI:10.1002/14651858.CD003766.pub2.

bers of the family. Family members support one another well beyond the health care provider's brief time with them, such as during the childbearing process or during a child's illness. Birth is viewed as a normal life event rather than a medical procedure.

With family-centered care, support and respect for the uniqueness and diversity of families are essential, along with encouragement and enhancement of the family's strengths and competencies. It is important to create opportunities for families to demonstrate their abilities and skills. Families also can acquire new abilities and skills to maintain a sense of control and empowerment in meeting the needs of the client. Family-centered care promotes greater family self-determination, decision-making abilities, control, and self-efficacy, thereby enhancing the client's and family's sense of empowerment. When implementing family-centered care, nurses seek caregiver input; these suggestions and advice are incorporated into the client's plan of care as the nurse counsels and teaches the family appropriate health care interventions. Today, as nurses partner with various experts to provide high-quality and cost-effective care, one expert partnership that nurses can make is with the client's family.

The impact of family-centered care can be seen in the models of care delivery for women. From the 1980s to the present, there have been increased access to care for all women (regardless of their ability to pay) and hospital redesigns (labor, delivery, and recovery [LDR] rooms; labor, delivery, recovery, and postpartum [LDRP] spaces) aimed at keeping families together during the childbirth experience. This impact also can be seen in the care of children: rooming-in and liberal visiting policies allow parents and other family members to participate in the child's care (Fig. 1.2).

Evidence-Based, Case-Managed Care

Evidence-based nursing practice involves the use of research or evidence in establishing a plan of care and

FIGURE 1.2 Providing an opportunity for the parent to interact with the child is an important component of family-centered nursing care.

implementing that care. Evidence-based practice is a problem-solving approach to making nursing clinical decisions (Newhouse, 2006). This model of nursing practice includes the use of the best current evidence in making decisions about care. Widespread use of evidence-based practice may lead to a decrease in variation of care while at the same time increasing quality.

Modern health care focuses on an interdisciplinary plan of care designed to meet a client's physical, developmental, educational, spiritual, and psychosocial needs. This interdisciplinary collaborative type of care is termed **case management**, a collaborative process involving assessment, planning, implementation, coordination, monitoring, and evaluation. It involves the following components:

- Advocacy, communication, and resource management
- Client-focused comprehensive care across a continuum
- Coordinated care with an interdisciplinary approach (Commission for Case Management Certification, n.d.)

When the nurse effectively functions in the role as a case manager, client and family satisfaction is increased, fragmentation of care is decreased, and outcome measurement for a homogenous group of clients is possible.

Atraumatic Pediatric Care

Children undergo a wide range of interventions, many of which can be traumatic, stressful, and painful. The various settings where the child receives care can be scary and overwhelming to the child and family. The child and family interact with various health care personnel, which leads to an increased potential for anxiety. A major component of the child health nursing philosophy is the importance of providing **atraumatic care**. This involves the use of interventions that minimize physical and psychological distress for children and families. Nurses must be ever-vigilant for any situation that has the potential for causing distress and should be able to identify potential stressors. Pediatric nurses should minimize separation of the child from the family, should decrease the child's exposure to stressful situations, and should strive to prevent or minimize pain and injury. The importance of providing atraumatic care to children is integrated throughout this text.

Think back to Sophia and her mother, Betty, who were described at the beginning of the chapter. Sophia and her husband are planning to use natural childbirth and to have their children present for the birth. While Sophia is waiting to be called for her appointment, Betty says, "Things have changed so much since I was pregnant. It's amazing what happens nowadays." Explain how things have changed in maternal and child health care, focusing on the concept of family-centered care.

Health Status

At one time, health was defined simply as the absence of disease; health was measured by monitoring the mortality and morbidity of a group. Over the past century, however, the focus on health has shifted to disease prevention, health promotion, and wellness. The World Health Organization defines health as "a state of complete physical, mental, and social well-being, and not merely the absence of disease or infirmity" (WHO, 2008). The definition of health is complex; it is not merely the absence of disease or an analysis of mortality and morbidity statistics.

In 1979, the Surgeon General's Report, *Healthy People*, presented a prevention agenda for the nation that identified the most significant preventable threats to the health of the United States. Through a series of reports (the current report is *Healthy People 2010: National Health Promotion and Disease Prevention Objectives*), the country now has a comprehensive, nationwide health promotion and disease prevention agenda that includes emphasis on children's health (U.S. Department of Health & Human Services [DHHS], 2000). Ten specific health indicators serve as a way to evaluate progress made in the public health arena and to coordinate the national health improvement efforts. The *Healthy People 2010* Box 1.1 highlights the major health indicators of the 21st century that need to be addressed.

HEALTHY PEOPLE 2010

Major Health Concerns of the 21st Century

- Physical activity
- Overweight and obesity
- Tobacco use
- Substance abuse
- Responsible sexual behavior
- Mental health
- Injury and violence
- Environmental quality
- Immunizations
- Access to health care

Healthy People 2010 also outlines major goals intended to increase the quality and years of healthy life and to eliminate health disparities between ethnic groups by targeting the lifestyle choices and environmental conditions that cause 70% of premature deaths in the United States. The *Healthy People 2010* Box 1.2 identifies specific national health goals related to maternal, infant, and child health.

Measuring health status is not a simple or convenient process. For example, some individuals with chronic illnesses do not see themselves as ill if they can control their condition through self-management. A traditional method used in this country to measure health is to examine mortality and morbidity data. Information is collected and analyzed to provide an objective description of the nation's health.

Mortality

Mortality is the incidence or number of individuals who have died over a specific period. This statistic is presented as rates per 100,000 and is calculated from a sample of death certificates. The National Center for Health Statistics, under the DHHS, collects, analyzes, and disseminates the data on America's mortality rates.

HEALTHY PEOPLE 2010

National Health Goals—Maternal, Infant, and Child Health

- Reduce fetal and infant deaths.
- Reduce maternal deaths.
- Reduce maternal illness and complications resulting from pregnancy.
- Increase the proportion of pregnant women who receive early and adequate prenatal care.
- Increase the proportion of pregnant women who attend a series of prepared childbirth classes.
- Increase the proportion of very low-birth weight (VLBW) infants born at level III hospitals or subspecialty perinatal centers.
- Reduce cesarean births among low-risk (full-term, singleton, vertex presentation) women.
- Reduce low birth weight (LBW) and VLBW.
- Reduce preterm births.
- Increase the proportion of mothers who achieve a recommended weight gain during their pregnancies.
- Increase the percentage of healthy, full-term infants who are laid down to sleep on their backs.
- Reduce the occurrence of developmental disabilities.
- Reduce the occurrence of spina bifida and other neural tube defects (NTDs).
- Increase the proportion of pregnancies begun with an optimum folic acid level.
- Increase abstinence from alcohol, cigarettes, and illicit drugs among pregnant women.
- Reduce the occurrence of fetal alcohol syndrome (FAS).
- Increase the proportion of mothers who breast-feed their babies.
- Ensure appropriate newborn bloodspot screening, follow-up testing, and referral to services.

Maternal Mortality

The **maternal mortality rate** is the number of deaths from any cause during the pregnancy cycle per 100,000 live births. In the United States, the maternal mortality rate is 7.5 (McClure, Goldenberg & Bann, 2007). The federal government has pledged to improve maternal–child care outcomes and thus reduce mortality rates for women and children.

During the past several decades, mortality and morbidity have dramatically decreased as a result of an increased emphasis on hygiene, good nutrition, exercise, and prenatal care for all women. However, women are still experiencing complications at significant rates. The United States is one of the most medically and technologically advanced nations and has the highest per capita spending on health care in the world, but our current mortality rates indicate the need for improvement. For example:

- Two to three women die in the United States every day from pregnancy complications, and more than 30% of pregnant women (1.8 million women annually) experience some type of illness or injury during childbirth (Centers for Disease Control and Prevention [CDC], 2006b, 2006e, 2006f).
- The United States ranks 21st (in other words, below 20 other countries) in rates of maternal deaths (deaths per 100,000 live births).
- Most pregnancy-related complications are preventable. The most common are ectopic pregnancy, preterm labor, hemorrhage, emboli, hypertension, infection, stroke, diabetes, and heart disease. The leading causes of pregnancy-related mortality for the year 2003 (the last year for which data are available) are embolism (20%), hemorrhage (17%), pregnancy-related hypertension (16%), and infection (13%; CDC, 2006b, 2006e, 2006f).

The maternal mortality and morbidity rates for African-American women have been three to four times higher than for whites (Matthews & MacDorman, 2006). Researchers do not entirely understand what accounts for this disparity, but some suspected causes of the higher maternal mortality rates for minority women include low socioeconomic status, limited or no insurance coverage, bias among health care providers (which may foster distrust), and quality of care available in the community. Language and legal barriers may also explain why some immigrant women do not receive good prenatal care.

Lack of care during pregnancy is a major factor contributing to a poor outcome. Prenatal care is well known to prevent complications of pregnancy and to support the birth of healthy infants, and not all women receive the same quality and quantity of health care during a pregnancy. More than 40% of African-American, Native American, and Latino women do not obtain prenatal care during their first trimester of pregnancy (Hollander, 2006).

The CDC has noted that the disparity in maternal mortality rates between women of color and white women represent one of the largest racial disparities among public health indicators. Eliminating racial and ethnic disparities in maternal–child health care requires enhanced efforts at preventing disease, promoting health, and delivering appropriate and timely care (CDC, 2006b, 2006e, 2006f). The CDC has called for more research and monitoring to understand and address racial disparities, along with increased funding for prenatal and postpartum care. Research is needed to identify causes and to design initiatives to reduce these disparities, and the CDC is calling on Congress to expand programs to provide preconception and prenatal care to underserved women.

The Health Resources and Services Administration (HRSA)'s Maternal and Child Health Bureau (MCHB) has primary federal responsibility for improving the health of mothers and children in the United States. More than 28 million infants, children, and pregnant women are served by an MCHB program annually (CDC, 2006e).

Fetal Mortality

The **fetal mortality rate** or fetal death rate refers to the intrauterine death of a fetus who is 20 weeks of gestation or more per 1,000 live births. Fetal mortality may be attributable to maternal factors (e.g., malnutrition, disease, or preterm cervical dilation) or fetal factors (e.g., chromosomal abnormalities or poor placental attachment). Fetal mortality provides an overall picture of the quality of maternal health and prenatal care.

Neonatal and Infant Mortality

The **neonatal mortality rate** is the number of infant deaths occurring in the first 28 days of life per 1,000 live births. The **infant mortality rate** is the number of deaths occurring in the first 12 months of life. It also is documented as the number of deaths of infants younger than 1 year of age per 1,000 live births. The infant mortality rate is used as an index of the general health of a country. Generally, this statistic is one of the most significant measures of children's health. In the United States, the infant mortality rate is 6.0 (CDC, 2006e; National Center for Health Statistics [NCHS], 2006) (Fig. 1.3).

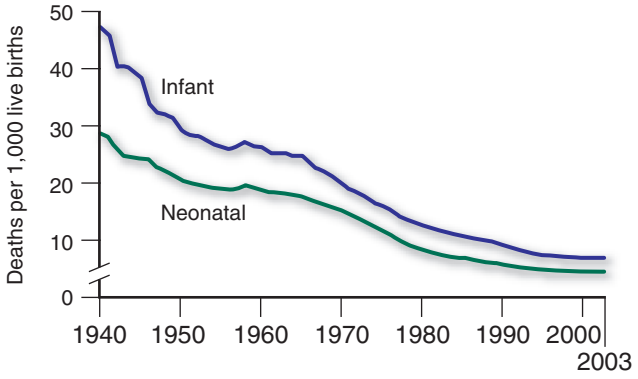

FIGURE 1.3 Infant and neonatal mortality, 1940–2003.

The infant mortality rate varies greatly from state to state as well as between ethnic groups. The United States has one of the highest gross national products in the world and is known for its technological capabilities, but in 2000 it ranked 27th in infant mortality rates among industrialized nations (U.S. Department of Health and Human Services, 2006). The main causes of early infant death in this country include problems occurring at birth or shortly thereafter. These include prematurity, low birthweight, congenital anomalies, sudden infant death syndrome, and respiratory distress syndrome.

▶ *Take* NOTE!

African-American and American Indian/Alaska Native infants have consistently had higher infant mortality rates than other ethnic groups (Federal Interagency Forum on Child and Family Statistics, 2006).

Congenital anomalies remain the leading cause of infant mortality in the United States. Low birthweight and prematurity are major indicators of infant health and significant predictors of infant mortality (Hoyert et al., 2006). The lower the birthweight, the higher the risk of infant mortality; thus, the high incidence of low birthweight (<2,500 g) in the United States is a significant reason why its infant mortality rate is higher than that of other countries (Ogbolu, 2007).

After birth, other health promotion strategies can significantly improve an infant's health and chances of survival. Breastfeeding has been shown to reduce rates of infection in infants and to improve their long-term health. Emphasizing the importance of placing an infant on his or her back to sleep will reduce the incidence of sudden infant death syndrome (SIDS). Encouraging mothers to join support groups to prevent postpartum depression and learn sound child-rearing practices will improve the health of both mothers and their infants.

Childhood Mortality

The **childhood mortality rate** is the number of deaths per 100,000 population in children 1 to 14 years of age. The childhood mortality rate in the United States has decreased by about 50% since 1980: in 2003, the mortality rate for children ages 1 to 4 years was 31 per 100,000, and the rate for children ages 5 to 14 years was 17 per 100,000 (Child Trends, 2006b). The leading cause of death in children is motor vehicle accidents. Many of these deaths could be prevented by educating parents about the value of car seats and seat belt use, the dangers of driving under the influence of alcohol and other substances, and the importance of pedestrian safety. Other causes of childhood mortality are suicide, homicide, and AIDS.

Morbidity

Morbidity is the measure of the prevalence of a specific illness in a population at a particular time. It is presented in rates per 1,000 population. Morbidity is often difficult to define and record because the types of measurement used vary widely—for example, visits to the physician or diagnosis for hospital admission. Information may be difficult to obtain, such as that gathered by household interviews from research studies. Morbidity statistics are revised less frequently because of this difficulty in defining or obtaining the information.

Women's Health Indicators

Women today face not only diseases of genetic origin but also diseases that arise from poor personal habits. Even though women represent 51% of the population, only recently have researchers and the medical community focused on their special health needs. A recent significant study identified an urgent need to improve women's access to health insurance and health care services, place a stronger emphasis on prevention, and invest in more research on women's health (National Women's Law Center [NWLC] et al., 2007). It identified indicators of women's access to health care services, measuring the degree to which women receive preventive health care and engage in health-promoting activities (Box 1.2). The report card gave the nation an overall grade of "unsatisfactory," and not a single state received a grade of "satisfactory." Other substandard findings included the following:

- No state has focused enough attention on preventive measures, such as smoking cessation, exercise, nutrition, and screening for diseases.
- Too many women lack health insurance coverage: nationally, nearly one in seven women (14%) has no health insurance.
- No state has adequately addressed women's health needs in the areas of reproductive health, mental health, and violence against women.
- Limited research has been done on health conditions that primarily affect women and that affect women differently than men (NWLC et al., 2007).

BOX 1.2 The National Indicators of Women's Health

- Lung cancer death rate
- Diabetes
- Heart disease death rate
- Binge drinking
- High school completion
- Poverty
- Wage gap
- Rate of AIDS
- Maternal mortality rate
- Rate of *Chlamydia* infection
- Breast cancer death rate
- Heart disease death rate
- Smoking
- Being overweight
- No physical activity during leisure time
- Eating five fruits and vegetables daily
- Colorectal screening
- Mammograms
- Pap smears
- First-trimester prenatal care
- Access to health insurance

Adapted from National Women's Law Center, FOCUS/University of Pennsylvania, the Lewin Group. (2007). *Making the grade on women's health: a national state-by-state report card.* Washington, DC: National Women's Law Center.

Poor health habits can have a negative impact on all women. Smoking, drug abuse, high cholesterol levels, and obesity lead to high mortality and morbidity rates in our nation. Cardiovascular disease (CVD) is the number-one cause of death of women, regardless of racial or ethnic group. More than 500,000 women die annually in the United States of CVD—about one death per minute (Alexander et al., 2007) Women who have a heart attack are more likely than men to die. Heart attacks in women are often more difficult to diagnose than in men because of their vague and varied symptoms. Heart disease is still thought of as a "man's disease" and thus a heart attack may not be considered in the differential diagnosis when a woman presents to the emergency room. Nurses need to look beyond the obvious "crushing chest pain" textbook symptom that heralds a heart attack in men. Manifestations of heart disease are different between men and women in several other ways—for example, menopause (associated with a significant rise in coronary events); diabetes, high cholesterol levels, and left ventricular hypertrophy; and repeated episodes of weight loss and gain (increased coronary morbidity and mortality) (Framingham Heart Study [FHS], 2007).

Cancer is the second leading cause of death among women (American Cancer Society [ACS], 2007a, 2007b; Wong, Chung, Boscardin, et al., 2006). Women have a one-in-three lifetime risk of developing cancer, and one out of every four deaths is from cancer (Alexander et al., 2007). Although much attention is focused on cancer of the reproductive system, lung cancer is the number-one killer of women. This is largely the result of smoking and second-hand smoke. Lung cancer has no early symptoms, making early detection almost impossible. Thus, lung cancer has the lowest survival rate of any cancer: more than 90% of people who get lung cancer die of it (ACS, 2007).

Breast cancer occurs in one in every seven women in a lifetime, with more than 213,000 women diagnosed annually in the United States. It is the most common malignancy in women and second only to lung cancer as a cause of cancer mortality in women (ACS, 2007). Although a positive family history of breast cancer, aging, and irregularities in the menstrual cycle at an early age are major risk factors, others risk factors include excess weight, not having children, oral contraceptive use, excessive alcohol consumption, a high-fat diet, and long-term use of hormone replacement therapy (ACS, 2007). Breast cancer rates have dropped recently, possibly due to the decreased use

of long-term hormone replacement therapy that occurred after the Women's Health Initiative (WHI) report was released in 2002 (Pace, 2006). However, early detection and treatment continue to offer the best chance for a cure, and reducing the risk of cancer by decreasing avoidable risks continues to be the best preventive plan.

Women's health is a complex issue, and no single policy is going to change the overall dismal state ratings. Although progress in science and technology has helped reduce the incidence of and improve the survival rates for several diseases, women's health issues continue to have an impact on our society. By eliminating or decreasing some of the risk factors and causes for prevalent diseases and illnesses, society and science could minimize certain chronic health problems. Focusing on the causes and effects of particular illnesses could help resolve many women's health issues of today.

Childhood Morbidity

According to a 2002 summary of children's health statistics, 56% of children had excellent health and 28% had very good health (Dey, Schiller & Tai, 2004). Factors that may increase morbidity include homelessness, poverty, low birthweight, chronic health disorders, foreign-born adoption, attending a daycare center, and barriers to health care. For example, 16% of children live in poverty. These children have a higher incidence of disease, limited coordination of health services, and limited access to health care except for visits to the emergency department (Federal Interagency Forum on Child and Family Statistics, 2006). Although the poverty rate has declined from 22% in 1993 to 18% in 2005, 35% of African-American children live in poverty; these children are at an increased risk for illness and disease (Federal Interagency Forum on Child and Family Statistics, 2007).

The most important aspect of morbidity is the degree of disability it produces, which is measured in children as the number of days missed from school or confined to bed. In 2005, only 25% of children did not miss any school due to illness or injury; however, 5% missed more than 11 days of school because of injury or illness (Bloom et al., 2006). In the United States during 2003, there were 3.7 million hospitalizations in children 1 to 21 years of age (U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau, 2005). Figure 1.4 shows the major causes of hospitalization by age in the United States during this period.

Common health problems in children include respiratory disorders, such as asthma and allergies; gastrointestinal disturbances, which lead to malnutrition and dehydration; and injuries. In the United States, 12.7% of children have asthma and 11.7% of children have respiratory allergies. Diseases of the respiratory system were the major cause of hospitalization for children 1 to 9 years of age (Bloom et al., 2006). As more immunizations become available, common childhood communicable diseases affect fewer children. Tracking the leading indicators from *Healthy People 2010* provides information about how children's health is improving.

One trend in the United States is an increase in the number of children with mental health disorders and other emotional, social, or behavioral problems. According to the Methodology for Epidemiology of Mental Disorders in Children and Adolescents (MECA) Study, as many as 20% of children have mental health problems (InCrisis, 2007). These problems may reduce the child's educational success and may also increase his or her risk for significant mental health problems later in life and the chance of firearms use, reckless driving, promiscuous sexual activity,

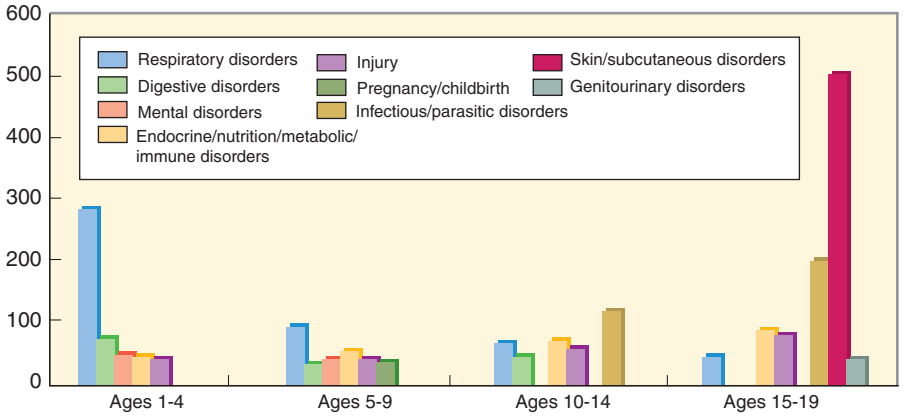

FIGURE 1.4 Major causes of hospitalization (number of hospital discharges, in thousands), by age, for the year 2002. (Adapted from U.S. Department of Health and Human Services, Health Resources and Services Administration, Maternal and Child Health Bureau. *Child health USA 2004.* Rockville, MD: U.S. Department of Health and Human Services, 2004.)

and substance abuse during adolescence. Overall, these behavioral, social, and educational problems can interfere with children's social and academic development.

The incidence of mental health disorders and other emotional, social, or behavioral problems can range from 5% to 30%, depending on how the problems are defined. In addition to HIV/AIDS, experts now identify the "new morbidity" in children as including academic difficulties, mental health disorders, harm to self and others, firearms use, school hostility, substance abuse, and adverse media influence (Reasor & Farrell, 2004). Often insurance does not pay for treatment of these problems, so they may go untreated.

▶ ***Take*** NOTE!

Environmental and psychosocial factors are now an identified area of concern in the morbidity of children. The "new morbidity" in children includes academic difficulties, complex psychiatric disorders, increased incidence of self-harm and harm to others, use of firearms, hostility at school, substance abuse, HIV/AIDS, and adverse media influences.

Factors Affecting Maternal and Child Health

From conception, children are shaped by a myriad of factors such as genetics and the environment. As members of a family, they are also members of a specific population, community, culture, and society. As they learn and grow, they are affected by multiple, complex, and ever-changing influences around them. For example, dramatic demographic changes in the United States have led to shifts in majority and minority population groups. Globalization has led to an international focus on health. Access to and the types of health care available have changed due to modifications in health care delivery and financing. In addition, the United States is still grappling with issues such as immigration, poverty, homelessness, and violence.

These factors may affect the person positively, promoting healthy growth and development, or negatively, increasing the person's health risks. Nurses, especially those working with women and children, need to understand how these influences affect the quality of nursing care and health outcomes. They must examine the impact of these variables to gain the knowledge and skills needed to plan effective care, thereby achieving the best possible outcomes for women, children, and families.

Family

The **family** is considered the basic social unit. The way that families are defined has changed. The U.S. Census Bureau (2007) defines family as a group of two or more persons related by birth, marriage, or adoption and living together. Earlier definitions of family emphasized the legal ties or genetic relationships of people living in the same household with specific roles. The American Academy of Family Physicians recognizes that family may be considered as "a group of intimates with a history and a future" and that it may be seen as more or less inclusive (Ventres & Gobbo, 2005). Today's multiple types of families do not fall under a single definition, and the definition of family is changing to reflect today's structural and functional changes.

The family greatly influences the development and health of its members. For example, children learn health care activities, health beliefs, and health values from their family. The family's structure, the roles assumed by family members, and social changes that affect the family's life can influence the child and his or her health status. Families are unique: each one has different views and requires distinct methods for support.

Various theories and models have been generated to explain the concept of family. They have influenced the definition of family, the understanding of the structure and function of the family, and the way family coping and adaptation are assessed. Table 1.1 summarizes some of the major theories related to family.

▶ ***Take*** NOTE!

The lifestyle of the parents basically is the lifestyle of the children. For instance, parents who are inactive and eat poorly will have children who do the same, and the problems associated with these unhealthy habits, such as diabetes, obesity, and early heart disease, are showing up earlier in children and adolescents. It is important for parents to serve as role models for proper nutrition and physical activity (through sports, hobbies, or other activities).

Family Structure

Family structure is the composition of individuals who interact with one another on a regular, recurring basis in socially sanctioned ways. It involves how the family unit is organized, which often influences the relationship of the members of the family. Family members are gained or lost through events such as divorce, marriage, birth, death, abandonment, and incarceration. All of these events can

TABLE 1.1 Summary of Major Theories Related to Family

Theory	Description	Key Components
Friedman's (2002) structural functional theory	Emphasizes the social system of family such as the organization or structure of the family and how the structure relates to the function	Identified five functions of families: • Affective function: meeting the love and belonging needs of each member • Socialization and social placement function: teaching children how to function and assume the adult roles in society • Reproductive role: continuing the family and society in general • Economic function: ensuring the family has necessary resources with appropriate allocation • Health care function: involving the provision of physical needs to keep the family healthy
Duvall's (1977) developmental theory	Emphasizes the developmental stages that all families evolve through beginning with marriage; the longitudinal career of the family, also known as the family life cycle	Described eight chronological stages with specific predictable tasks that each family completes: • Marriage: beginning of family • Childbearing stage • Family with preschool children • Family with school-aged children • Family with adolescents • Family with young adults • Middle-aged parents • Family in later years
Von Bertalanffy's (1968) general systems theory applied to families	Emphasizes the family as a system with interdependent, interacting parts that endure over time to ensure the survival, continuity, and growth of its components; the family is not the total sum of its parts but is characterized by wholeness and unity	Used to define how families interact with and are influenced by the members of their family and society and how to analyze the interrelationships of the members and the impact that change affecting one member will have on the other members
Family stress theory (Boss, 2002)	Addresses the way families respond to stress and how the family copes with the stress as a group and as individuals	Described elements of stress as occurring within the family (such as values, beliefs, structure), which the family can control or change, or from outside the family (such as the culture of the surrounding community, genetics, the family's current time or place), over which the family has no control. Mobilization of family resources results in either a positive response of constructive coping or a negative response of a crisis. Identified the main determinant of adequate coping based on the meaning of the stressful event to the family and its members
Resiliency model of family stress, adjustment, and adaptation	Addresses the way families adapt to stress and can rebound from adversity	Identified the elements of risks and protective factors that aid a family in achieving positive outcomes

alter the family structure, leading to roles being redefined or redistributed. Table 1.2 provides examples of the types of family structures found in today's society.

The traditional nuclear family is no longer considered the dominant family structure (Fig. 1.5). From 1970 to 1996, the percentage of children under age 18 who were living with two married parents decreased steadily from 85% to 68%; in 2005, this percentage was 67% (Child Trends, 2005). By understanding clients' family structure and any changes that may occur, nurses can provide them with support to alleviate or prevent dysfunctional alterations in family coping and adaptation.

TABLE 1.2 EXAMPLES OF FAMILY STRUCTURES IN TODAY'S SOCIETY

Theory	Description	Key Components
Nuclear family	Husband, wife, and children living in same household	May include natural or adopted children Once considered the traditional family structure; now less common due to increased divorce rates and child-rearing by unmarried persons
Binuclear family	Child who is a member of two families due to joint custody; parenting is considered a "joint venture"	Always works better when the interests of the child are put first and above the parents' needs and desires
Single-parent family	One parent is responsible for care of children	May result from death, divorce, desertion, birth outside marriage, or adoption These families are likely to face challenges because of economic, social, and personal restraints; one person serves as homemaker, caregiver, and financial provider.
Commuter family	Adults in the family live and work apart for professional or financial reasons, often leaving the daily care of children to one parent.	Similar to single-parent family
Step- or blended family	Adults with children from previous marriages or from the new marriage	May lead to family conflict due to different expectations on the part of the child and adults; they may have different views and practices related to childcare and health
Extended family	Nuclear family and grandparents, cousins, aunts, and uncles	Need to identify decision-maker and primary caretaker of the children Popular in some cultures, such as Hispanic and Asian cultures
Same-sex family (also called homosexual or gay/lesbian family)	Adults of the same sex living together with or without children	May face negative attitudes about their "different" lifestyle
Communal family	Group of people living together to raise children and manage household; unrelated by blood or marriage	May face negative attitudes about their "different" lifestyle Need to determine the decision-maker and caretaker of the children
Foster family	A temporary family for children who are placed away from their parents to ensure their emotional and physical well-being	May include the foster family's children and other foster children in the home Foster children are more likely to have unmet health needs and chronic health problems because they may have been in a variety of health systems (AAP, 2000).
Grandparents-as-parent families	Grandparents raising their grandchildren due to the inability or absence of the parents	May increase the risk for physical, financial, and emotional stress on older adults May lead to confusion and emotional stress for child if biological parents are in and out of child's life
Adolescent families	Young parents who are still mastering the developmental tasks of their childhood	Are at greater risk for health problems in pregnancy and delivery; more likely to have premature infants, which then leads to risk of subsequent health and developmental problems Probably still need support from their family related to financial, emotional, and school issues

FIGURE 1.5 Nurses must take into account family dynamics when providing health care. There are many different family structures, and they influence the client's needs. (**A**) The traditional nuclear family is composed of two parents and their biological or adopted children. (**B**) The extended family includes the nuclear family plus other family members, such as grandparents, aunts, uncles, and cousins. (**C**) Gay and lesbian families comprise two people of the same sex sharing a committed relationship with or without children.

Family Roles and Functions

Within a family, each member has a specific position or status and role when interacting with other members of the family. Typical family roles and their functions include:

- Nurturer: the primary caregiver
- Provider: the person who is primarily responsible for generating the family's income
- Decision maker: the person who is responsible for making choices, especially related to lifestyle and leisure time
- Financial manager: the person who works with the money, such as paying bills and saving
- Problem solver: the person to whom other members go for help in solving problems
- Health manager: the person responsible for maintaining the family members' health, such as scheduling visits and ensuring that immunizations or screenings are up to date
- Gatekeeper: the person who manages information inflow and outflow (Pillitteri, 2007)

Roles and functions are further defined by each family using its own traditions and values and the set of standards for interacting within and outside the family. For example, birth order may affect roles and relationships. First-born children are typically different from those born later. The older child may feel that he or she is in a position of greater power and may attempt to control younger siblings. The youngest child, in response, may learn how to bargain and interact effectively to deal with the situation.

Parental Roles

The parents or caregivers are of utmost importance for the survival and healthy development of a young child (WHO, 2004). The parents or caregivers provide the physical and emotional care of the child and also impart the rules and expected behaviors of a society. These expected behaviors depend on the culture of the family, the child's developmental stage and physical and cognitive abilities, and the values and beliefs of the family. The parents should nurture their children and provide them with the environmental influences to become competent, productive, self-directed members of society. Young children are particularly dependent on the care they receive; their growth, health, and personhood depend on the capacity of the adults in their life to understand, perceive, and respond to their bids for assistance and support (WHO, 2004).

Parenting Styles

The three major parenting styles are authoritarian, authoritative, and permissive. These three styles differ in the amount of control exerted over the child during parenting. Whatever the style, however, sensitive and responsive care is needed for appropriate physical, neurophysiologic, and psychological development (WHO, 2004).

Authoritarian parents expect unquestioning obedience from the child. The parents' rules and standards are strictly enforced and firm. Parents also expect the children to accept the family's beliefs and values and demand respect for these beliefs. The parents are the ultimate authority on matters and behaviors and allow little if any participation by the child in making decisions. Behavior that does not adhere to the family rules and standards is forcibly punished.

Authoritative or democratic parents show some respect for the opinions of children. Although parents have the ultimate authority and expect adherence to rules, authoritative parents allow children to be different and believe that each child is an individual. They employ consistent, firm enforcement of the family rules and standards but without the emphasis on punishment of the child.

Permissive or laissez-faire parents exert little control over the behavior of their children. Rules or standards may be inconsistent, unclear, or nonexistent. Permissive parents allow their children to set their own standards and rules for behavior. Discipline can be lax, inconsistent, or absent.

Discipline

Much of parenting involves increasing desirable behaviors and decreasing or eliminating undesirable behaviors, a process known as **discipline**. People in our society have various beliefs about the best or most effective method of discipline. Discipline should be based on expectations that are appropriate for the child's age and should be used to set reasonable, consistent limits while permitting choices among acceptable alternatives (Banks, 2002). Discipline is an ongoing learning process, and if it is to be effective, the child needs to feel secure and loved.

The American Academy of Pediatrics (1998) suggests three strategies for effective discipline:

- Maintaining a positive, supportive, nurturing caregiver–child relationship
- Using positive reinforcement techniques to increase the desirable behaviors
- Removing positive reinforcements or using punishment to reduce or eliminate undesirable behaviors (Fig. 1.6)

Teaching Guidelines 1.1 gives advice about appropriate discipline.

Changes in Parental Roles Over Time

Parental roles have evolved over time due to social and economic changes as well as family changes. Traditionally, the role of provider was assigned to the father. However, with increased numbers of women in the workplace and more households with two parents working, today both parents are often the providers as well as the nurturers for the children. Technological expansion has provided parents with opportunities to work at home, allowing some parents to maintain the provider role while simultaneously fulfilling the nurturer and health manager roles. Fathers also are taking on greater responsibilities related to household management and child care. Additionally, the number of single-father parent families and grandparent families are increasing.

FIGURE 1.6 Although he might not like it, quiet solitude helps the child develop inner control.

Recall Sophia, the pregnant woman described at the beginning of the chapter. Identify the parental roles assumed by Sophia. How might these roles be different from those of her mother when she was Sophia's age?

Changes in Family Structure and Roles

Families today face complex challenges as they try to nurture, develop, and socialize their members. Family structure changes such as divorce, blending families, adoption, or foster care can have wide-ranging and lifelong effects.

Divorce

As many as 50% of marriages end in divorce (Hetherington, 2005). Conflict between the parents and family dysfunction may exert a significant stress on children. Parents need to understand the impact that divorce can have on their children, placing the children's interest first. Parents can use the rules given in Teaching Guidelines 1.2 to help reduce the tension and conflict associated with divorce.

Single Parenting

Single-parent families may result from divorce or separation, death of a spouse, childbearing by an unmarried woman, or adoption by an unmarried man or woman. For

TEACHING GUIDELINES 1.1

Promoting Effective Discipline

- Set clear, consistent, and developmentally appropriate expected behaviors; offer choices whenever possible.
- Maintain consistency in responding to behaviors; provide encouragement and affection.
- Role-model appropriate behaviors.
- Provide an age-appropriate explanation of the consequence if the child demonstrates unacceptable behavior.
- Always administer the consequence soon after the unacceptable behavior.
- Keep the consequence appropriate to the age of the child and the situation.
- Stay calm but firm without showing anger when administering the consequence.
- Always praise the child for displaying appropriate behavior (positive reinforcement).
- Set the environment to assist the child in accomplishing the appropriate behavior; remove temptations that may lead to inappropriate behavior.
- Reinforce that the child's behavior was "bad" but the child was not "bad."
- Use extinction to reduce or eliminate reinforcement for an inappropriate behavior (for example, ignore a temper tantrum).
- When using time-out, use 1 minute per year of the child's age (a 3-year-old would have time-out for 3 minutes). Do not exceed 5 minutes.

TEACHING GUIDELINES 1.2

Guidelines for Divorcing Parents

- Tell your children about the divorce and the reasons for the divorce in terms that they can understand. Be sure that you and your spouse are present together when telling the children; tell all the children at the same time.
- Reassure your children that the divorce is not their fault. Repeat this as often as possible and as necessary.
- Inform the children well in advance before anyone moves out of the house (except when abuse is present or there are concerns for immediate safety).
- Clearly inform the children about the family structure after the divorce, such as who will live with whom and where; also discuss visitation clearly and honestly.
- Do not make your children be or act like adults.
- Do not discuss money or finances with your children.
- Maintain rules and be consistent in this area.
- Never force or allow your children to take sides.
- Avoid belittling your spouse with earshot of the children. However, do not lie to cover up for irresponsible behavior by the other parent.
- Never put your children in the middle between you and your spouse.

Adapted from Bryner, C. L. (2001). Children of divorce. *Journal of the American Board of Family Practice, 14*(3), 176–183.
Accessed 9/21/06 Available at: http://www.medscape.com/viewarticle/405852

several reasons, this family structure can affect the health of family members. Life in a single-parent household can be stressful for the adult and children. The single parent may feel overwhelmed by the responsibility of juggling child care, maintaining a job, and keeping up with the bills and household chores (American Psychological Association, 2008). These issues may be compounded by other pressures, such as custody problems, decreased time available to spend with children, continuing conflicts between separated or divorced parents, or changes in relationships with extended family members. Communication and support are essential to the optimal functioning of the single-parent family. The parent and children need to be able to discuss their feelings and work through the problems together.

Blending Families

The creation of a blended family can be a stressful time for the parents and children involved. Although it creates a structure and stability and reduces some of the financial stresses of single parenthood, making the transition to a blended family takes time. Children may feel jealous of the stepparent or feel disloyal to the biological parent. There may be competition or rivalry among the stepchildren. The child may fear that the stepparent is interfering with the child's relationship with the parent or taking away his or her source of love, affection, and attention. Mutual respect is necessary to ease the transition to a blended family, as is open, honest communication among all individuals involved—and this includes the biological parent when possible.

Adoption

Adopted families are created in a number of different ways. The parents may contact an agency or intermediary such as an attorney in their own area or country to seek a child. Families may adopt a child from another country (intercountry or international adoption). The child may be of a different culture, race, or ethnicity (Fig. 1.7). Some children may have complex medical, developmental, behavioral, educational, and psychological issues. Children may be adopted after spending time in foster care. An increas-

FIGURE 1.7 An adoptive family in which the child is from a different culture.

ing number of single-parent families, blended families, families with gay or lesbian partners, and families with older parents are providing homes to children through adoption (American Psychological Association, 2005).

The amount of contact between the adoptive parents and the birth mother can vary greatly. There may be no contact at all (closed adoption) or there may be as much direct contact as desired (open adoptions). Regardless of the method used to adopt a child, adoptive families may be faced with unique issues that can affect the health of the family members, such as:

- The adopted child may have been exposed to risk factors (e.g., poverty; neglect; infectious diseases; lack of adequate food, clothing, shelter, and consistent caregivers), increasing the child's risk for problems.
- Information about the adopted child's family medical history may be lacking.
- Parents may not know when to tell a child that he or she was adopted.
- The adopted child may be troubled about his or her loss of a "birth family" or the reason for the birth mother's decision for an adoption plan. He or she may have feelings of abandonment, emotional uncertainty, and identity conflict.
- The child and family may face racism or bigotry if the child is from a different culture or race.

Foster Care

Foster care refers to the care given to a child who is placed in an alternative living situation apart from his or her parents of origin or legal guardians. The child typically is placed in this living situation due to some difficulty in the family situation such as abuse, neglect, abandonment, or the parent's inability to meet the child's needs such as from illness, substance abuse, or death. The living situation may be with relatives (termed kinship care) or foster parents, who are strangers providing protection and shelter in a state-approved foster home.

Many children who are placed in foster care have been the victims of abuse or neglect. In addition, 30% of children in foster care have severe emotional, behavioral, or developmental problems (AACAP, 2008). Children who are placed in foster care may have a wide range of problems, including:

- Physical health problems
- Self-blame and feelings of guilt
- Feelings of being unwanted
- Feelings of helplessness
- Insecurity and uncertainty about the future
- Ambivalent feelings related to foster parents; feelings of being disloyal to birth parents (AACAP, 2008)

Genetics

Genetics (the study of heredity and its variations) has implications for all stages of life and all types of diseases. The child's biological traits, including gender, race, some behavioral traits, and the presence of certain diseases or illnesses, are directly linked to genetic inheritance. New technologies in molecular biology and biochemistry have led to a better understanding of the mechanisms involved in hereditary transmission, including those associated with genetic disorders. These advances are leading to better diagnostic tests and better management options.

Gender

Gender is established when the sex chromosomes join. A person's gender can influence many aspects, such as physical characteristics and personal attributes, attitudes, and behaviors (Fig. 1.8). Some diseases or illnesses are more common in one sex; for example, scoliosis is more common in females and color blindness in males.

Race

Race refers to the physical features that distinguish members of a particular group, such as skin color, bone structure, or blood type. Some physical features that are normal in a particular race may be considered a sign of a disorder in other races. For example, epicanthal folds (the vertical folds of skin that partially or completely cover the inner canthi of the eye) are normal in Asian children but may occur with Down syndrome or renal agenesis in other races. In addition, certain malformations and diseases are found more commonly in specific races. For example, sickle cell anemia occurs more often in African and Mediterranean population groups, and cystic fibrosis is

FIGURE 1.8 Interactions with family members and peers as well as activities and societal values affect how children perceive themselves as a certain gender.

seen more often in individuals from the Northwestern European population group.

Society

Society has a major impact on the health of women, children, and families. Major influences include social roles, socioeconomic status, the media, and the expanding global nature of society. Each of these may influence a person's self-concept, where he or she lives, the lifestyle he or she leads—and thus his or her health.

Social Roles

Society often prescribes specific patterns of behaviors: certain behaviors are permitted and others are prohibited. These social roles are often an important factor in the development of self-concept. Social roles influence a person's ideas about himself or herself. Social roles are generally carried out in groups with which the individual has intimate daily contact, such as the family, school, workplace, or peer groups.

Socioeconomic Status

Another dominant influence is a person's socioeconomic status, his or her relative position in society. This includes the family's economic, occupational, and educational levels. Children are raised differently by parents of different educational levels, occupations, and incomes. Low socioeconomic status typically has an adverse influence on an individual's health. Health care costs are continuing to rise, as are health insurance premiums. The family may not be able to afford food, health care, and housing; meals may be unbalanced, erratic, or insufficient. Housing may be overcrowded or have poor sanitation. These families may not understand the importance of preventive care or may simply not be able to afford it. As a result, they may be exposed to health risks such as lead poisoning or may not be immunized against communicable diseases.

Poverty

Poverty is a measurement based on the specific monetary income of a family. The poverty threshold is the dollar amount that the U.S. Census Bureau uses to determine whether a family is living in poverty. If the individual's or family's income is below the threshold, then that person or family is said to be living in poverty. According to the Census Bureau, about 18.5% of children under age 18 years live in poverty. Although the rates have stabilized somewhat after several years of consecutive increases, more children live in poverty than all other Americans, and these rates are highest among minority groups.

Despite the many global economic gains that have been made during the past century, poverty continues to grow and the gap between rich and poor is widening. Major gaps continue between the economic opportunities and status afforded to women and those offered to men. A disproportionate share of the burden of poverty rests on women's shoulders, and this undermines their health. However, poverty, particularly for women, is more than monetary deficiency. Women continue to lag behind men in control of cash, credit, and collateral. Other forms of impoverishment may include deficiencies in literacy, education, skills, employment opportunities, mobility, and political representation, as well as pressures on time and energy linked to their responsibilities. These poverty factors may affect a woman's health (WHO, 2007a, 2007b, 2007c).

The effects of poverty on children's health can be wide-ranging. The child may live in substandard housing or housing that poses a threat to the child (e.g., unsanitary conditions, exposure to toxins, or exposure to violence). Poverty may lead to homelessness for the family. Children living in poverty are more likely than other children to be poorly nourished, to have inadequate health care, to become teen parents, and to have insufficient education. Children living in poverty are also at increased risk for experiencing abuse and violence (Children's Defense Fund, 2005).

Homelessness

Families with children are the fastest-growing segment of the homeless population. Homeless families commonly are victims of violence and may have mental health challenges. According to the National Coalition for the Homeless, approximately 1.35 million children are homeless on any given night (National Center on Family Homelessness, 2008). Children make up 39% of the homeless population; 42% of these children are under age 5 years (National Coalition for the Homeless, 2006). Homelessness occurs in large urban areas and midsize cities as well as suburban and rural areas.

Homelessness can have a negative impact on health and well-being in numerous ways, including:

- Increased mental health issues such as anxiety, depression, or aggressive behavior

- Higher incidence of chronic health problems and trauma-related injuries
- Problems related to nutritional deficiencies, affecting fetal or child growth and development
- Participation in behaviors such as illegal substance use or unprotected sex with multiple partners
- Limited access to health care services such as preventive care, prenatal care, or dental care

Media

Today's children are inundated with various forms of media, such as television, the Internet, videos, movies, magazines, books, and newspapers (Fig. 1.9). Some of these present images and information that may not be in the child's best interest. Children may identify with and mimic characters who engage in risky behaviors or lifestyles. They may believe that those lifestyles or behaviors are the norm and acceptable. Research has demonstrated that exposure to media violence is linked to increased aggression in children (Bushman & Huesmann, 2006) and that television viewing places young adolescents at risk for sexual initiation (Ashby et al., 2006).

The images that children view every day will affect their behaviors and may influence their health. For instance, magazines, movies, and television shows portray thinness as a body type to be emulated, and boys and girls may take up unhealthy dieting or other behaviors to develop that body type. Those whose body type does not fit the ideal may develop depression or self-esteem issues.

The media's influence relates not only to its content but also to the total viewing time. For example, excessive television viewing has been linked to lack of exercise, weight gain, and obesity (Lumeng et al., 2006).

However, the media may also exert positive influences. Public service messages about the negative effects of substance abuse, smoking, or gang involvement or about teenage pregnancy and birth control are two examples of the media's positive influence. In addition, positive television programs can serve as valuable educational resources.

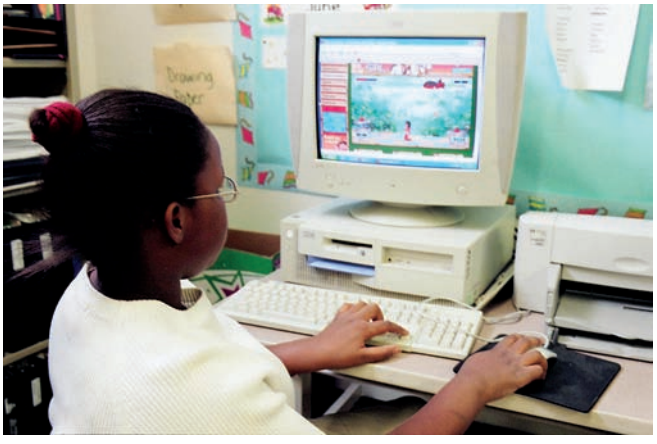

FIGURE 1.9 Computer games can be fun and educational, but the child should be monitored while using the computer and other forms of media to minimize negative effects.

The Internet has fostered closer connections between distant areas of the world. Individuals are no longer limited to their immediate surroundings. The Internet can be a valuable resource for people to access information, learn new things, and communicate, but it also brings threats to health and safety (American Academy of Pediatrics, 2006). Online exposure to sexual predators, illicit sex, pornography, violence, and racism are a few of the potential threats. Parents need to be alert to these hazards and safeguard their children (Teaching Guidelines 1.3).

Violence

Violence can occur in any setting and can involve any individual. Violence against women is a major health

TEACHING GUIDELINES 1.3

Promoting Safe Internet Use

- Determine a specific time limit that your child can spend online each day or week. Be consistent in enforcing this time limit.
- Ensure that Internet use does not replace or interfere with homework, friends, or household or school activities.
- Tell your child NEVER to share personal information with anyone online unless you are sure of the person and the child has your permission to do so.
- Tell your child NEVER to share his or her password with anyone, even friends.
- Review Internet sites with your child, and explain what information and websites are appropriate. Use safety and parental controls offered by your Internet service provider.
- Avoid placing the computer in the child's room. Instead, place the computer in a public area of your home, such as the den or kitchen, so that you can monitor your child's use.
- Discuss with your child the need for maintaining safety while using the Internet. Explain potential hazards in terms the child can understand.
- Advise your child to immediately close any sites or stop any communication that makes him or her confused or uncomfortable. Tell your child NEVER to arrange any face-to-face meeting with persons he or she meets online. Urge your child to seek you out if he or she encounters such a situation.
- Teach the child NEVER to open e-mail from any unknown senders.
- Be aware of computer use policies in your child's school.

concern—it affects thousands of lives and costs the health care system millions of dollars. Violence affects families, women, and children of all ages, ethnic backgrounds, races, educational levels, and socioeconomic levels. Pregnancy is often a time when physical abuse starts or escalates, resulting in poorer outcomes for the mother and the baby. The nurse is responsible for assessing for and following up on any abuse.

Domestic Violence

Violence in the home environment, known as domestic violence, affects many lives in the United States. The U.S. Bureau of Justice estimates that 1 million violent crimes are committed by former spouses, boyfriends, or girlfriends each year; about 85% of the victims are women (Rennison & Welchans, 2000). This violence is known as intimate partner abuse, family violence, wife beating, battering, marital abuse, or partner abuse, but regardless of the term used, its effects are widespread.

Children often witness domestic violence, and they may be physically, sexually, or emotionally abused themselves (Abell & Ey, 2008). The federal Child Abuse Prevention and Treatment Act (CAPTA) defines child abuse and neglect as any recent act or failure to act on the part of a parent or caretaker that results in death, serious physical or emotional harm, sexual abuse or exploitation, or an act or failure to act that presents an imminent risk of serious harm to a child (Child Welfare Information Gateway, 2007). Of the children identified as being maltreated, 61% were victims of neglect, 19% were victims of physical abuse, 10% were victims of sexual abuse, and 5% were victims of emotional or psychological abuse (CDC, 2006a, 2006c, 2006d, 2006g). According to Prevent Child Abuse America (2008), four children die in America every day as a result of child abuse or neglect. About 78% of these deaths occur in infants and children younger than 3 years of age.

Domestic violence is often accompanied by other major risk factors for children, such as poverty, female-headed households, and low education level of the primary caregiver. Children may feel the need to call for help or to blame themselves for the dispute that led to the abuse (Hornor, 2005). Children who experience domestic violence or child abuse are at risk for problems such as sleep disturbances, headaches, stomach aches, depression, enuresis, aggressive behaviors, decreased social competencies, withdrawal, developmental regression, fears, anxiety, and learning problems (Children's Defense Fund; 2005, CDC, 2006a, 2006c, 2006d, 2006g). Additional risks include poor academic outcomes, teenage prostitution, substance abuse, and conducting abuse or sexual assault as an adult (National Coalition Against Domestic Violence, 2005).

Nurses serve their clients best not by trying to rescue them, but by helping them build on their strengths and providing support, thereby empowering them to help themselves. All nurses need to include "RADAR" in every client visit (Box 1.3).

Youth Violence

Although the new century has shown an overall decline in violence by and against children, youth violence is still an important public health problem. Violent crimes include those such as murder, rape, robbery, and aggravated assault. CDC (2006d) statistics revealed that for young people between 10 and 24 years of age:

- Approximately 5,570 individuals were murdered; of those murders, firearms accounted for 82% of the deaths in 2003.
- More than 750,000 individuals were treated in emergency departments for injuries due to violence in 2004.
- Homicide was the leading cause of death for African Americans, the second leading cause of death for Hispanics, and the third leading cause of death for American Indians, Alaska Natives, and Asian/Pacific Islanders.

Youth violence affects not only the child and family in terms of injury and death, but also the entire community. Studies have shown that youth violence is associated with a disruption in social services, an increase in health care costs, and a decline in property values.

In recent years, school violence has received much attention, resulting in an increased concern for student safety, which in turn has led to a decline in school violence (Children's Defense Fund, 2005). Students are more likely to be victims of violent crimes away from school, but physical fights, thefts, weapon carrying, teacher victimization, and fear of school environments have increased (National Youth Violence Prevention Resource Center, 2005). For example, in a nationwide CDC survey of high school students about risk behavior, approximately 36% of the students reported that they had been involved in a physical altercation at least once in the previous year, and just under one fifth of the surveyed students reported carrying a weapon for at least one of the days in the month prior to the survey. Of the students who admitted to carrying a weapon, approximately 5% had carried a gun (CDC, 2006g). The continued coordination among

BOX 1.3 RADAR

A–Assess your client's safety.
R–Review options and provide referrals.

schools, law enforcement, social services, and mental health systems and the development of effective programs will help to reduce these risk behaviors.

Due to the potential impact of violence on children and families, it is essential to identify any violent situation via a thorough assessment. Providing referrals to shelters and child advocacy centers and intervening to assist children in dealing with this issue are key.

▶ *Take* NOTE!

Not all children exposed to violence suffer negative consequences. Children have resiliency, and preliminary studies indicate that protective factors, such as involvement in social activities, a strong commitment to school and academic performance, and ability to discuss problems with a supportive adult, can buffer children from the effects of violence, thereby helping to reduce the risk of developing violent behaviors.

Community

Community encompasses a broad range of concepts, from the nation where a person lives down to a particular neighborhood or group. The surrounding community affects many aspects of a person's health and general welfare. The quality of life within the community has a great influence on an individual's ability to develop and become a functional member of society. Community influences include the school, which is a community in itself, and peer groups. The support and assistance offered to women, children, and families from other areas of the community, such as school programs and community centers, can improve the individual's overall health and well-being.

Schools

Over the past century, major societal changes have led to children starting school earlier, spending more time in child care settings, and being involved in various community centers and activities. By age 4, many children spend several hours a day in a preschool setting; some children spend more time in school and child care settings than they do at home. As many as 63% of children under age 5 years attend child care regularly (Child Trends, 2005). As a result, schools serve as major influences on children.

Although the primary role of schools has always been academic education, today they are performing more health-related functions. School also serves as a means of socialization. School rules about attendance and authority relationships and the system of sanctions and rewards based on achievement transmit to children behavioral expectations that will help them succeed in employment and relationships in the adult world. Schools can also play a major role in improving health and encouraging healthy behaviors. Academic success is linked to healthy behaviors, good mental health, and avoidance of pregnancy and juvenile justice problems, as well as health, jobs, and self-sufficiency in adult life.

Because of social changes in America, more children are in child care and after-school programs than ever before. Thus, the socialization process begins earlier and involves a larger percentage of the child's waking hours (Fig. 1.10). Community centers and after-school programs can provide support, empowerment, boundaries and expectations, and constructive use of time (Search Institute, 2007).

Peer Groups

Peer groups can have a great impact on children. Relationships with peers often begin early, and they continue to be a large part of the child's world, particularly in school-age children and adolescents. This influence starts in the play groups in early preschool or elementary school. The child comes into contact with a variety of values and belief systems from interactions with peer groups. When these values and beliefs differ from those of the child's family, conflicts can occur, possibly separating children from parents and strengthening the bond with the peer group. When the peer group is involved with school activities, athletics, or other healthy behaviors, the influence is very positive, but the opposite is also true: peer groups can exert negative influences on the child. Thus, it is vital to identify the important peer groups in a child's life and the positive or negative behaviors associated with these groups.

Community and Neighborhood Connectedness

Social capital refers to the bonds between individuals that assist social networks in communities to achieve a variety of goals. Basically, it is a mechanism by which resources in a community can be mobilized by and from the

FIGURE 1.10 Daycare centers provide socialization and support for young children.

people, not for them (Looman & Lindeke, 2005). Such connectedness, relationships, and common interests propel neighborhoods and communities toward engagement. Connected communities support an environment that makes it easy for people to engage in health-promoting behaviors. Looman and Lindeke (2005) believe that asking a simple question such as, "How is your relationship with your neighbors?" can help give an understanding of a client's social milieu. They suggest three areas to include in nursing interventions and strategies:

- Bringing families together in communities to set the stage for networking
- Disseminating knowledge about what helps create healthy, supported communities
- Thinking of relationships as investments, with social interactions as the processes by which resources for health are exchanged (Looman & Lindeke, 2005)

Culture

Culture is a view of the world and a set of traditions that are used by a specific social group and are transmitted to the next generation. It plays a critical role with women, children, and families. A person's culture influences not only socialization but also his or her experiences related to health and specific health practices (Pillitteri, 2007). Culture is a complex phenomenon involving many components, such as beliefs, values, language, time, personal space, and view of the world, all of which shape a person's actions and behavior. Individuals learn these patterns of cultural behaviors from their family and community through a process called enculturation, which involves acquiring knowledge and internalizing values. Culture influences every aspect of development and is reflected in child-bearing and child-rearing beliefs and practices designed to promote healthy adaptation.

With today's changing demographic patterns, nurses must be able to assimilate cultural knowledge into their interventions so they can care for culturally diverse women, children, and families. Nurses must be aware of the wide range of cultural traditions, values, and ethics. **Cultural competence** is the ability to apply knowledge about a client's culture so that the health care provided can be adapted to meet his or her needs. Nurses need to learn about general cultural groups, ethnicity, health practices and how they affect women and children and their health, and the changing demographics of the population. This will help them view culture as a point of congruence rather than as a potential source of conflict with clients.

Cultural Groups

A society typically includes dominant and minority groups. The dominant group, often the largest group, is the group that has the greatest authority to control values and sanctions of the society (Taylor et al., 2005). As a result, the dominant or majority culture may have the largest impact on health. The minority cultural groups may remain in their own communities and maintain some of their traditions and values while mainstreaming into American society. A culture may contain many subcultures, and geographic differences also can occur: for example, Latin Americans living in New York may be quite different from Latin Americans living in Florida. Being aware of these differences is essential in providing culturally competent care.

Ethnicity is sometimes used synonymously with culture; the definition basically involves group membership by virtue of common ancestry. The basic groups or divisions are differentiated by customs, characteristics, language, or similar distinguishing factors. Ethnic groups can be identified by their specific family structures, languages, food preferences, moral codes, and health care practices. Children learn the group's mode of behavior by observing and imitating those around them. Many Americans in the dominant culture do not view themselves as belonging to any specific ethnic group, though some persons may closely identify with their ethnicity. The influences of culture and ethnicity on women and children and families are highly variable, and traditional behaviors can change based on new circumstances and a dynamic environment.

Ethnocentrism is a belief that one's own ethnic group is superior to other groups, and thus one's one way of living, ideas, and practices are the best. This attitude can lead to a slanted view of the world and may hinder a nurse's ability to give culturally competent care.

Nurses need to be aware of the health care values and practices that are passed along from one generation to the next. For example, the belief in folk healers relates to how the culture interprets illness and health. Some of these parts of the culture may have major influences on an individual's health. Table 1.3 highlights some major cultural groups and their common health beliefs and practices.

▶ ***Take*** *NOTE!*

Nurses can have a lifelong influence on an individual's perceptions of health and use of health services. By understanding how the child's and family's culture influences their health practices, nurses can enhance the family's traditional practices, and different cultural practices can become sources of strength rather than areas of conflict.

Spirituality and Religion

Spirituality is a basic human quality involving the belief in something greater than oneself and a faith that affirms life. It is a major influence for many people, providing a meaning or purpose to life and a foundation for and source of love, relationships, and service. Spirituality is considered a universal human phenomenon. During life-changing events and crises, such as a serious illness or the birth of a

TABLE 1.3 **Beliefs and Practices of Selected Cultural Groups**

Cultural Group	Beliefs and Practices Affecting Maternal and Children's Health
African Americans	Strong extended family relationships; mother as head of household; older family members valued and respected Food as a symbol of health and wealth View of health as harmony with nature; illness as disruption in harmony Use of folk healing and home remedies common View of pregnancy as a state of wellness Emotional support during labor commonly from other women, primarily the woman's own mother Liberal use of oil on newborn's and infant's scalp and skin Belief in illnesses as natural (due to natural forces person hasn't protected self against) and unnatural (due to person or spirit) Illness commonly associated with pain Pain and suffering inevitable; relief achieved through prayers and laying on of hands Individuals vulnerable to external forces
Asian Americans	Strong loyalty to the family Family as the center, with members expected to care for one another Use of complementary modalities with Western health care practices View of life as a cycle with everything connected to health Pain described by diverse body symptoms Health viewed as a balance between the forces of yang and yin Respect for authority emphasized View of pregnancy as a natural process and happy time for woman Little involvement of the father during labor; quiet, stoic appearance of woman during labor Protection of woman from cold forces for 30 days after birth of newborn
Arab Americans	Women subordinate to men; young individuals subordinate to older persons Family loyalty is primary Good health associated with eating properly, consuming nutritious foods, and fasting to cure disease Illness is due to inadequate diet, shifts in hot and cold, exposure of stomach while sleeping, emotional or spiritual distress, and 'evil eye' Little emphasis on preventive care View of pain as unpleasant, requiring immediate control or relief Birthmarks on newborn due to unsatisfied maternal cravings Pain of labor demonstrated via facial expressions, verbalizations, and body movements; reluctant to use breathing and relaxation techniques during labor Wrapping of newborn's stomach at birth to prevent cold or wind from entering baby's body Breastfeeding often delayed for 2 to 3 days after birth Cleanliness important for prayer
Native Americans	High value on family and tribe; respect for elders Family as an extended network providing care for newborns and children Women as the verbal decision-makers View of pregnancy as normal and natural process; entire family may be present at birth Newborn not given colostrum Celebrations to mark the stages of growth and development Use of food to celebrate life events and in healing and religious ceremonies Health as harmony with nature; illness due to disharmony, evil spirits Restoration of physical, mental, and spiritual balance through healing ceremonies View of pain as something to be tolerated
Hispanic	Family important; father as the source of strength, wisdom, and self-confidence Mother as the caretaker and decision-maker for health View of children as persons to continue the family and culture Birthmark on baby due to unsatisfied food cravings during pregnancy Mother's legs brought together after birth of newborn to prevent air from entering uterus Possibly boisterous and loud during labor Bedrest for first 3 days postpartum; no bathing for 14 days Newborn protection from the evil eye Use of food for celebrations and socialization Health as God's will, maintainable with a balance of hot and cold food intake Freedom from pain indicative of good health; pain tolerated stoically due to belief that it is God's will Folk medicine practices and prayers, herbal teas and poultices for illness treatment

child with a congenital defect, families often turn to spirituality for hope, comfort, and relief.

Though the word "religion" is often used interchangeably with spirituality in our society, they are distinctly different. Spirituality is considered private and individual. **Religion,** in contrast, is an organized way of sharing beliefs and practicing worship. Over 95% of parents in America believe in God. Their spiritual or religious beliefs and views can provide strength and support during times of stress and illness. In some religions, illness is seen as a punishment for sin or wrongdoing. Others religions view illness as a test of strength that allows them to strive for faithfulness.

Identifying a client's religious beliefs and customs is important. Families appreciate recognition of and respect for their beliefs. Dietary restrictions, rituals such as baptism or communion, use of amulets or icons, or practices related to birth or newborn care can be incorporated into the plan of care.

▶ ***Take*** *NOTE!*

Never make assumptions about a family's religious or spiritual affiliation. Although they may belong to a particular religion, they may not adhere to all of its beliefs or participate in all aspects of the religion. Be alert for clues that would provide insight into their specific beliefs.

Diversity of Client Populations

The United States is no longer a melting pot of various cultures and ethnicities but a society with each individual bringing a diversity and richness that enriches the country as a whole. According to the U.S. Census Bureau reports, the Hispanic population is now the fastest-growing population group, increasing by 3.3% from July 1, 2004, to July 1, 2005, and accounting for almost half of the total population growth during that time frame. At the same time, non-Hispanic whites accounted for less than one fifth of the total population growth (U.S. Census Bureau, 2006). In addition, the increasing number of intermarriages between individuals from different ethnic origins is producing an increasing number of children who have a heritage that represents more than one cultural group.

The United States is also viewed as a place of employment and economic opportunities, expanded human rights, educational opportunities, and other types of freedoms and opportunities, thus inspiring many individuals to move to the United States from other countries. Immigration significantly affects the health, educational, and social services offered in this country. It also presents issues related to access to care and the types of care that need to be offered. The United States is currently evaluating, enforcing, and changing many of its immigration laws.

Immigration imposes unique stresses on women, children and families, including:

- Depression, grief, or anxiety associated with migration and acculturation
- Separation from support systems
- Inadequate language skills in a society that is not tolerant of linguistic differences
- Disparities in social, professional, and economic status between the country of origin and the United States
- Traumatic events such as war or persecution that may have occurred in their native country (American Academy of Pediatrics Committee on Community Health Services, 2005)

Immigrant families may face financial, language, cultural, and other type of barriers that reduce their ability to receive preventive care, and care for minor conditions may be delayed until they become more serious. Stresses experienced by immigrant children and their families, such as those associated with relocation, separation, and traumatic events, also can affect their psychological health.

Health Status and Lifestyle

An individual's chronic health conditions and his or her lifestyle can increase or decrease the risk of health problems. Chronic health conditions can begin soon after birth. For example, the incidence of multiple births has been increasing in this country due to the increased use of in vitro fertilization and other assisted technologies (Reynolds et al., 2003). The complications associated with multiple births include intrauterine growth retardation and prematurity (Reynolds et al., 2003). These complications may lead to chronic health problems that can hinder the child's growth and development. Children with chronic health conditions may experience developmental delays, especially in acquiring skills related to cognition, communication, adaptation, social functioning, and motor functioning. Thus, the beginning health status of a child may affect his or her long-term health and development.

Developmental Level and Disease Distribution

Developmental level has a major impact on an individual's health status. In general, the distribution of diseases or illnesses varies with age. For example, adolescents who become pregnant are at a higher risk for certain complications, such as anemia, hypertension, preterm labor, cephalopelvic disproportion, and postpartum hemorrhage. Pregnant adolescents also experience higher rates of intimate partner violence and substance abuse. Moreover, substance abuse can contribute to low birthweight, intrauterine growth restriction, preterm births, newborn addiction, and sepsis (Mittendorfer-Rutz & Wasserman, 2008). Women who become pregnant after age 35 are at risk for hypertension, dystocia, and postpartum hemorrhage. Older pregnant women are also more likely to have

a pre-existing condition that could complicate the pregnancy. Moreover, fetuses of older pregnant women are at risk for chromosomal abnormalities.

Certain communicable diseases are more commonly associated with certain age groups. Before the use of routine immunizations, conditions such as measles and mumps were more commonly seen in younger school-age children. The physiologic immaturity of an infant's body systems increases the risk for infection. Ingestion of toxic substances and poisoning are major health concerns for toddlers as they become more mobile and inquisitive. Adolescents are establishing their identity, which may lead them to distance themselves from their family values and traditions for a period of time and conform more with their peers. This journey may lead to risky behaviors, resulting in injuries or other health problems.

Nutrition

Nutrition provides the body with the calories and nutrients to sustain life and promote growth, as well as the essentials required to maintain health and prevent illness. Nutritional deficiencies or excesses are common problems in the United States, as evidenced by the persistent problem of iron-deficiency anemia and the increasing incidence of childhood obesity. Inadequate food intake, social and cultural food practices or habits that may be nutritionally unsound, the availability of processed and nutritionally inadequate foods, lack of nutrition education in homes and schools, and the presence of illness that interferes with the ingestion, digestion, and absorption of food are factors that can affect an individual's nutrition.

During pregnancy, a woman needs additional calories to support fetal growth and development as well as to support her own needs, and an adequate intake of folic acid is important to prevent neural tube defects (Fig. 1.11). For the child, inadequate nutrition is associated with lowered cognitive ability, poor or altered emotional and mental health, increased susceptibility to childhood illnesses, and stunted physical growth. The "fast food" or "junk food" that is prevalent in today's society is a key factor in the epidemic of childhood obesity and increases in the prevalence of childhood type 2 diabetes. Nutrition and its effects on health status are integrated throughout this text.

Lifestyle Choices

Lifestyle choices that affect an individual's health include patterns of eating, exercise, use of tobacco, drugs, or alcohol, and methods of coping with stress. Most health problems that arise today are due to an individual's lifestyle. For children, the lifestyle of the parents basically is the lifestyle of the child, so parents need to set a good example in terms of nutrition and physical activity.

Environmental Exposure

Some environmental exposures can jeopardize health. In utero, the child can be affected by lack of maternal nutrition, maternal infections, or maternal use of alcohol, tobacco, and drugs. Nurses caring for pregnant women should be aware of the risks to the fetus posed by certain drugs, chemicals, and dietary agents, as well as maternal illnesses. These agents, known as teratogens, may be linked to birth defects in children. Not all drugs or agents have fetal effects, however, and research is necessary to

FIGURE 1.11 (**A**) The dietary habits established early in life can have a long-lasting impact on the child's health and quality of life. (**B**) This pregnant client is eating a healthy meal to ensure adequate nutrition.

identify the correlations between teratogens and other variables.

The environment continues to affect a child's health after birth. Exposure to lead, air pollution, tobacco, and water or food contaminants can impair a child's health. Exposure to safety hazards in the home or community can lead to falls, burns, drowning, or other accidents. Statistically, more drownings occur in children in warmer states because more homes have pools. Exposure to secondhand smoke, radiation, or chemicals is another health hazard for children. Because children are smaller and still developing, environmental exposures can cause more health problems, both in the short and long term, for them than for adults.

Stress and Coping

Disasters such as the terrorist attacks of Sept. 11, 2001, the killings at Columbine High School, or Hurricane Katrina can have a significant impact on the well-being of women, children, and families. Stressors such as war, terrorism, school violence, and natural disasters may decrease a person's coping ability (Ryan-Wenger, Sharrer, & Campbell, 2005) and lead to alterations in growth and development (Crane & Clements, 2005). Exposure to traumatic events and violence may have long-term effects on an individual's psychosocial development and status. Children who have experienced these events are at risk for the development of post-traumatic stress disorder, behavioral issues, and depression (Wexler, Branski, & Kerem, 2006).

Exposure to stress is not limited to disasters or traumatic events, however. Stress can also include areas such as inadequate finances, family crises, inadequate support systems, or domestic violence. Like disasters and traumatic events, the effects of these stressors can dramatically affect the health status of a woman, child, or family.

Recall Sophia, the 38-year-old pregnant woman who has come to the prenatal clinic for a visit. While talking with the nurse, Sophia mentions that her children are very involved in activities. She says, "My husband is busy at work, so I do most of the running around. Sometimes I feel like the people at the drive-through know me by name! My husband helps out on the weekends, but during the week, it's all me." What factors may be influencing Sophia's health? How might these factors be influencing the health of the children and the family?

Health Care Cost Containment

The health care system functions within a market setting, offering goods and services that carry a cost to health care consumers and clients. The advent of managed care has led to a trend of attempting to reduce health care costs. These efforts have led to shorter hospital stays and increased awareness on the part of nurses of the costs of supplies and services. The overall challenge is to maintain the quality of care while reducing its cost. For example, if a pregnant diabetic woman needs to go to an endocrinologist, she has very little choice except to purchase the services needed or go without care. In today's managed care environment, the woman will need to go through her "primary health care professional" or "gatekeeper" to receive a referral to a specialist. Often she must trust her primary provider to make that choice for her instead of making that decision on her own.

Although cost containment is important to restrain health care spending, such efforts should not reduce the quality or safety of care delivered. Preventive care (remember the old saying "an ounce of prevention is worth a pound of cure") has been shown to lower costs significantly. Mammograms, cervical cancer screenings, prenatal care, smoking cessation programs, and immunizations are a few examples of preventive care that yield positive outcomes and reduce overall health care costs. Using technological advances to diagnose and treat diseases early saves lives as well as money.

Nurses can be leaders in providing quality care within a limited-resource environment by emphasizing to their clients the importance of making healthy lifestyle and food choices, seeking early interventions for minor problems before they become major ones, and learning about health-related issues that affect them so they can select the best option for themselves and their families. Prevention services and health education are the cornerstones of delivering quality maternal and child health care.

Access to Health Care

The health care system continues to change. In the United States, changes in the health care system result from pressures coming from many directions. These changes reflect shifts in social and economic realities and the results of the biomedical and technological progress that has been made over the past several decades. The effects are felt by every individual who seeks health care in any form. The system of providing medical care in a hi-tech environment has changed to providing health care in an environment with limited resources and access to services. Ways to allocate our limited health care resources continue to be the focus.

A major factor involved access to care is health insurance. People without health insurance typically cannot afford to seek health care for maintenance and prevention interventions, and 11.7% of children lack health insurance; many of them are minority children, children in immigrant families, and adolescents (Future of Children, 2004). The "working poor" may not earn enough money to afford health insurance or medical care, and part-time workers do not always receive benefits such as health insurance.

Preventive Care Focus

The emphasis on cost reduction also led to an emphasis on preventive care and services. Anticipatory guidance is

vital during each health contact with women, children, and families. Education of the family includes everything from keeping the home safe to ways to prevent illness.

The Continuum of Care Emphasis

A "continuum of care" strategy is cost-effective and provides more efficient and effective services. This continuum extends from acute care settings such as hospitals to outpatient settings such as ambulatory care clinics, primary care offices, rehabilitative units, community care settings, long-term facilities, homes, and even schools. For example, the hospital stay is now integrated into a continuum that allows the client to complete therapy at home, school, or other community settings, while re-entering the hospital for short periods for specific treatments or illnesses.

Improvements in Diagnosis and Treatments

Because of the tremendous improvements that have been made in technology and biomedicine, disorders and diseases are being diagnosed and treated earlier. The 1990s witnessed a remarkable and productive connection between genetics and various pathophysiologic processes. For example, female fetuses with congenital adrenal hyperplasia, a genetic disorder resulting in a steroid enzyme deficiency that can lead to disfiguring anatomic abnormalities, are beginning to receive treatment before birth. In addition, many genetic defects are being identified so counseling and treatment may occur early. With these improved diagnoses and treatments, nurses may now be caring for individuals who have survived situations that once would have been fatal, who are living well beyond their life expectancy for a specific illness, or who are functioning with chronic disabilities. For example, at one time women with congenital heart disease did not live long enough to become pregnant. However, with new surgical techniques to correct the defects, many of these women survive and become pregnant, progressing through their pregnancy without significant problems.

While positive and exciting, these advances and trends also pose new challenges for the health care community. For example, as health care for premature newborns improves and survival rates increase, the incidence of long-term chronic conditions such as respiratory airway dysfunction or developmental delays has also increased. As a result, nurses are faced with caring for clients at all stages along the health–illness continuum, such as well children, those who are occasionally ill, and women, children, and families with chronic and sometimes disabling conditions.

Empowerment of Health Care Consumers

Due to the influence of managed care, the focus on prevention, a more educated population, and technological advances, individuals and families have taken an increased responsibility for their own health. Health consumers are now better informed, and they want to play a greater role in managing health and illness. Families want information about illnesses and they want to participate in making decisions about treatment options. As client advocates valuing family-centered care, nurses are instrumental in promoting this empowerment. To do this, the nurse should respect the family's views and concerns, address all issues and concerns, consider the family members as important participants, and always include the woman, child, and family in the decision-making process.

Barriers to Health Care

Women are major consumers of health care services, in many cases arranging not only their own care but also that of family members. Compared with men, women have more health problems, longer life spans, and more significant reproductive health needs. Access to care can be jeopardized by lower incomes and greater responsibilities (juggling work and family). Lack of finances or transportation, language or cultural barriers, inconvenient clinic hours, and poor attitudes by health care workers often discourage clients from seeking health care.

Finances

Financial barriers are one of the most important factors that limit care. Many women have limited or no health insurance and cannot afford to pay for care. Although Medicaid covers prenatal care in most states, the paperwork and enrollment process can be so overwhelming that many women do not register.

Although the poverty rate is declining in this country, 36% of America's households with children had inadequate or crowded housing, or the housing cost more than 30% of the household income in 2001 (Federal Interagency Forum on Child and Family Statistics, 2006). The percentage of children covered by health insurance was 88% (leaving 12% of children without insurance). The majority of coverage since 1999 has not been from private health insurance but from government-supported plans (Federal Interagency Forum on Child and Family Statistics, 2006). Many children and families do not have health insurance, do not have enough insurance to cover services obtained, or cannot pay for services.

Transportation

Getting to and from appointments can be challenging for clients who do not drive or own a car or cannot use public transportation (if there is public transportation in the area). It can be difficult for these clients to attend all recommended prenatal health care visits or well-child visits, especially if the woman has other small children who must be taken along on the visit. These challenges can reduce the adherence to scheduled appointments and follow-up.

Language and Culture

Language is how people communicate with each other to increase their understanding or knowledge. If a health care worker cannot speak the same language as the client or does not have a trained interpreter available, a barrier is created. The client's complaints can be misinterpreted or ignored or their significance can be misconstrued. The language barrier might prevent the client from accessing the necessary care, such as prenatal care or preventative care.

Sociocultural and ethnic factors also pose barriers to health care. These factors may involve the lack of transportation, financial situations that require both parents to work, or genetic factors. Knowledge barriers (e.g., lack of understanding or awareness of the importance of prenatal care or child health promotion) and spiritual barriers (e.g., some forms of treatment are proscribed by religions) also cross all ethnic groups.

Health Care Delivery System

The health care delivery system itself can create barriers. Eighty-five percent of employed families with insurance are covered by some type of managed health care plan or health maintenance organization (HMO). This prospective payment system based on diagnosis-related groups (DRGs) limits the amounts of health care the family may receive. This also includes Medicaid reimbursement. Due to cost-containment efforts, the trend is to discharge clients as soon as possible from the hospital and to deliver care in the home or through community-based services. Although overall insurance plans may improve access to preventive services, they may limit access to specialty care—which greatly impacts clients with chronic or long-term illnesses.

Clinic hours must meet the needs of the clients, not the health care providers who work there. Evening or weekend hours might be needed to meet the schedules of working clients. Clinic personnel should evaluate the availability and accessibility of the services they offer.

Unfortunately, some health care workers exhibit negative attitudes toward poor or culturally diverse families, and this could deter these clients from seeking health care. Long delays, hurried examinations, and rude comments by staff discourage clients from returning.

▶ *Consider* THIS!

I was a 17-year-old pregnant migrant worker needing prenatal care. Although my English wasn't good, I was able to show the receptionist my "big belly" and ask for services. All the receptionist seemed interested in was a social security number and health insurance—neither of which I had. She proceeded to ask me personal questions concerning who the father was and commented on how young I looked. The receptionist then "ordered" me in a loud voice to sit down and wait for an answer by someone in the back, but never contacted anyone that I could see. It seemed to me like all eyes were on me while I found an empty seat in the waiting room. After sitting there quietly for over an hour without any attention or answer, I left.

Thoughts: Why did she leave before receiving any health care service? What must she have been feeling during her wait? Would you come back to this clinic again? Why or why not?

Legal and Ethical Issues in Maternal and Child Health Care

Law and ethics are interrelated and affect all of nursing. Professional nurses must understand their scope of practice, standards of care, institutional or agency policies, and state laws. Every nurse is responsible for knowing current information regarding ethics and laws related to their practice.

Numerous federal programs have had a major impact on women's and children's health (Table 1.4).

Several areas are of particular importance to the health care of women and children. These include abortion, substance abuse, fetal therapy, informed consent, client rights, and confidentiality.

Abortion

Abortion was a volatile legal, social, and political issue even before *Roe v. Wade,* the 1973 Supreme Court decision that legalized abortion. Forty-nine percent of pregnancies in American women are unintended, and 40% of them are terminated by abortion (Alan Guttmacher Institute, 2007).

Abortion is one of the most common procedures performed in the United States. It has become a hotly debated political issue that separates people into two camps: pro-choice and pro-life. The pro-choice group supports the right of any woman to make decisions about her reproductive functions based on her own moral and ethical beliefs. The pro-life group feels strongly that abortion is murder and deprives the fetus of the basic right to life. Both sides will continue to debate this very emotional issue for years to come.

Medical and surgical modalities are available to terminate a pregnancy, depending on how far the pregnancy has developed. A surgical intervention can be performed up to 14 weeks' gestation; a medical intervention can be performed up to 9 weeks' gestation (Gan et al., 2008). All women undergoing abortion need emotional support,

TABLE 1.4 MILESTONES IN FEDERAL PROGRAMS IN SUPPORT OF THE HEALTH OF WOMEN AND CHILDREN

Date	Action	Impact
1909	First White House Conference on Care of Dependent Children (convened by President Theodore Roosevelt)	Addressed the poor working and living conditions of many children in the United States
1912	U.S. Children's Bureau	First governmental agency to oversee children's health and environmental conditions
1921	Maternity & Infancy (Sheppard-Towner) Act	Provided grants to states to establish maternal and child health divisions in state health departments
1930	White House Conference on Child Welfare Standards and American Academy of Pediatrics	Produced the Children's Charter, documenting the child's need for health, education, welfare, and protection
1935	Title V of the Social Security Act	Established federal–state partnership and provided Aid to Families with Dependent Children (AFDC), maternal–child health services, and child welfare services
1959	14th General Assembly of United Nations	Approved the Declaration of the Rights of the Child
1965	Medicaid Program under Title XIX of Social Security Act; special programs such as Child Health Assessment Program	Provided state block grants to reduce financial barriers to health care for the poor and special services to pregnant women and young children
1966/1974	Women, Infants, Children (WIC) Program	Provided nutritional supplements and education to low-income families, pregnant, postpartum, and lactating women, and infants and children up to age 5
1969	U.S. Children's Bureau moved to Office of Health, Education, & Welfare (HEW)	Established greater presence for the programs
1975	Education for All Handicapped Children Act (Public Law 94-142) Title XX Social Services	Established federally mandated special education in public schools; provided block grants to day care, emergency shelters, counseling, family planning, and other services for children
1981	Alcohol, Drug Abuse & Mental Health block grants	Began funding services for children and adolescents with mental health issues
1986	Education of Handicapped Act Amendments (Public Law 99-457)	Established federal funding for states to create statewide, comprehensive, coordinated, and multidisciplinary early intervention services for handicapped infants and toddlers
1990	Omnibus Budget Reconciliation Act	Extended Medicaid coverage to all children (6–18 years) with family income below 133% of poverty level
1993	Family & Medical Leave Act (FMLA)	Allowed eligible employees to take up to 12 weeks of unpaid leave from their jobs every year to care for newborns or newly adopted children or children, parents, or spouses with serious health condition; employee can return to previous job or an comparable job with the same conditions

a stable environment in which to recover, and nonjudgmental care throughout.

Abortion is a complex issue, and the controversy is not only in the public arena: many nurses struggle with the conflict between their personal convictions and their professional duty. Nurses are taught to be supportive client advocates and to interact with a nonjudgmental attitude under all circumstances. However, nurses have their own personal and political views, which may be very different from those of their clients. Nurses need to clarify their personal values and beliefs on this issue and must be able to provide nonbiased care before assuming responsibility for clients who might be in a position to consider abortion. Their decision to care for or refuse to care for such clients affects staff unity, influences staffing decisions, and challenges the ethical concept of duty (Trybulski, 2006).

The ANA's Code of Ethics for Nurses upholds the nurse's right to refuse to care for a client undergoing an abortion if the nurse ethically opposes the procedure (ANA, 2001). Nurses need to make their values and beliefs known to their managers before the situation occurs so that alternative staffing arrangements can be made. Open communication and acceptance of the personal beliefs of others can promote a comfortable working environment.

Substance Abuse

Substance abuse for any person is a problem, but when it involves a pregnant woman, substance abuse can cause fetal injury and thus has legal and ethical implications. In some instances, courts have issued jail sentences to pregnant women who caused harm to their fetuses. Many state laws require reporting evidence of prenatal drug exposure, which may lead to charges of negligence and child endangerment against the pregnant woman. This punitive approach to fetal injury raises ethical and legal questions about the degree of governmental control that is appropriate in the interests of child safety.

Fetal Therapy

Intrauterine fetal surgery is a procedure that involves opening the uterus during pregnancy, performing a surgery, and replacing the fetus in the uterus. Although the risks to the fetus and the mother are both great, fetal therapy may be used to correct anatomic lesions (Noble & Rodeck, 2008). Some argue that medical technology should not interfere with nature, and thus this intervention should not take place. Others would argue that the surgical intervention improves the child's quality of life. For many people, these are the subjects of debates and intellectual discussions, but for nurses, these procedures may be part of their daily routine.

Nurses play an important supportive role in caring and advocating for clients and their families. As the use of technology grows, situations will surface more frequently that test a nurse's belief system. Encouraging open discussions to address emotional issues and differences of opinion among staff members is healthy and increases tolerance for differing points of view.

Informed Consent

Informed consent has four key components: disclosure, comprehension, competency, and voluntariness (Taylor et al., 2005). It occurs prior to initiation of the procedure or specific care and addresses the legal and ethical requirement of informing the client about the procedure. The physician or advanced practice nurse is responsible for informing the client about the procedure and obtaining consent by providing a detailed description of the procedure or treatment, its potential risks and benefits, and alternative methods available. If the client is a child, typically this information is provided to the parents or legal guardian. The nurse's responsibility related to informed consent includes:

- Ensuring that the consent form is completed with signatures from the client (or parents or legal guardians if the client is a child)
- Serving as a witness to the signature process
- Determining whether the client or parents or legal guardians understand what they are signing by asking them pertinent questions

Although laws vary from state to state, certain key elements are associated with informed consent (Box 1.4). Nurses need to be familiar with their specific state laws as well as the policies and procedures of the health care agency. Treating clients without obtaining proper consent may result in charges of assault, and the health care provider and/or facility may be held liable for any damages.

Generally, only people over the age of majority (18 years of age) can legally provide consent for health care. Since children are minors, when care is rendered to them, the process involves obtaining written permission from a parent or legal guardian. In cases requiring a signature for consent, usually the parent provides consent for care for children less than 18 years of age, except in certain situations (see further discussion below).

▶ *Take* NOTE!

Allow older children and adolescents to be involved in the decision-making process to the extent possible. However, keep in mind that the parent is still ultimately responsible for giving consent to treatment.

BOX 1.4 Key Elements of Informed Consent

- The decision-maker must be of legal age in that state, with full civil rights, and must be competent (have the ability to make the decision).
- Information is presented in a manner that is simple, concise, and appropriate to the level of education and language of the individual responsible for making the decision.
- The decision must be voluntary, without coercion or force or under duress.
- There must be a witness to the process of informed consent.
- The witness must sign the consent form.

Most care rendered in a health care setting is covered by the initial consent for treatment signed when the individual becomes a client at that office or clinic or by the consent to treatment signed upon admission to the hospital or other inpatient facility. Certain procedures, however, require a specific process of informed consent: major and minor surgery; invasive procedures such as amniocentesis, internal fetal monitoring, lumbar puncture (LP), or bone marrow aspiration; treatments placing the client at higher risk, such as chemotherapy or radiation therapy; procedures or treatments involving research; and photography involving the client. Applying restraints to children now requires consent.

If the client cannot provide consent or, in the case of a child, the parent is not available, then the person closest to the client or in charge of the child (relative, babysitter, or teacher) may give consent for emergency treatment if he or she has a signed form from the parent or legal guardian allowing him or her to do so. During an emergency situation, a verbal consent, via the telephone, may be obtained. Two witnesses must also be listening simultaneously and must sign the consent form, indicating that consent was received via telephone. Health care providers can provide emergency treatment to a child without consent if they have made reasonable attempts to contact the child's parent or legal guardian (AAP, 2005). Table 1.5 provides additional information about the informed consent process with children.

▶ ***Take*** *NOTE!*

Never assume that the adult accompanying the child is the parent or legal guardian. Always clarify the relationship of the accompanying adult.

Refusal of Medical Treatment

All clients have the right to refuse medical treatment, based on the American Hospital Association's Bill of Rights. In the case of a child, parental autonomy (the right to decide for or against medical treatment) is a constitutionally protected right (Linnard-Palmer & Kools, 2004). Ideally, medical care without informed consent should be used only when the life of a client is in danger. Refusal of treatment may occur when the treatment conflicts with religious or cultural beliefs. In these cases, it is important to educate the client and family about the importance of the recommended treatment without coercing or forcing the client to agree. Sometimes common ground may be reached between the family's religious or cultural beliefs and the health care team's recommendations. Communication and education are the keys in this situation.

If providing medical treatment may save a child's life, health care providers and the judicial system strive to advocate for the child. The state has an overriding interest

TABLE 1.5 SPECIAL CONSIDERATIONS RELATED TO INFORMED CONSENT WITH CHILDREN

Issue	Definition	Nursing Considerations
Child not living with biological or adoptive parents	Child is living: • In foster care • With potential adoptive parent • With a relative	– Legally appointed guardian is responsible for providing consent – Verification of authority of legally appointed guardian – Documentation of the legal guardian in the child's medical record (AAP, 2003)
Parental consent after divorce	Ability to give consent for health care rests with parent who has legal custody by divorce degree	– Determination of joint custody or sole custody by one parent – Parent with only physical custody may give consent for emergency care. Court involvement may be needed if there is joint legal custody but parents disagree on care.
Consent for organ donation	For a minor to donate, the parents must be aware of the risks and benefits and must provide emotional support to child; there should be a close relationship between the donor and recipient.	– Referral of potential donors to local organ procurement organization – Family education about policies related to organ donation – Legal guardian or parental consent to organ donation (AAP, 2002)
Consent for medical experimentation	Requirements include consent of parents, assent of child, and a perceived benefit to the child	Need to comply with all federal regulations if federal funds received (see discussion of assent in text)

in the health and welfare of the child and can order that medical treatment proceed without a signed informed consent. This is referred to as *parens patriae* (the state has a right and a duty to protect children).

Parents may refuse treatment if they perceive that their child's quality of life will be significantly impaired by the medical care that is offered. If the parents refuse treatment but the health care team feels the treatment is reasonable and warranted, the case should be referred to the institution's ethics committee. If the issue remains unresolved, then the judicial system becomes involved (Kon, 2006a, 2006b).

Exceptions to Required Parental Consent for Children

The **emancipated minor** is considered to have the legal capacity of an adult and may make health care decisions (AAP, 2003). State laws vary in relation to the definition of an emancipated minor and the types of treatment that may be obtained as an emancipated minor (without parental consent). Emancipation may be considered in any of the following situations, depending upon the state's laws:

- Membership in a branch of the armed services
- Marriage
- Court-determined emancipation
- Financial independence and separate living arrangement from parents
- College attendance
- Pregnancy
- Mother less than 18 years of age
- Runaway

Nurses must be familiar with laws of the state where they work so they can be in compliance when rendering health care and treatment.

In some states, a minor may give consent to certain medical treatments. A mature minor is usually an adolescent over 14 years of age and is considered sufficiently mature and intelligent to make the decision for treatment. The provider considers the complexity of the treatment and the risks and benefits, as well as whether the treatment is necessary or elective, prior to obtaining consent from a mature minor (AAP, 2003).

In addition, many states do not require consent or notification of parents or legal guardians when providing specific types of care to minors. According to the state law, health care may be provided to minors for certain conditions, in a confidential manner, without notifying the parents. These types of care may include pregnancy counseling, prenatal care, contraception, testing and treatment for sexually transmitted infections and communicable diseases (including HIV), substance abuse and mental illness counseling and treatment, or health care required as a result of a crime-related injury (AAP, 2003). These exceptions provide a confidential environment for children who would avoid care if they were required to inform their parents or legal guardian. Again, the laws vary by state, so nurses must be knowledgeable about the laws in the state where they practice.

Assent

Assent may be defined as agreeing to something. In the care of children, the term refers to the child's participation in the decision-making process about his or her health care (McCullough & Stein, 2007). The age of assent depends on the child's developmental level and maturity. The American Academy of Pediatrics recommends the age of 7 years (Bray, 2007; Broome & Richards, 2003). Certainly, the older the child is, the stronger the ethical obligation is to include the child in the decision-making process (Olechnowicz et al., 2002). The Society of Pediatric Nurses (2006) makes the following recommendations related to assent:

- Child 4 to 6 years of age: Use developmentally appropriate materials to inform the child about the participation in research or treatment.
- Child 7 to 12 years of age: Obtain assent for non-therapeutic research.
- Adolescent 13 to 17 years of age: Obtain assent for therapeutic and non-therapeutic research.

The AAP recommends that if a health care provider solicits the child's opinion about the direction of treatment or participation in research, then the child's views and desires should be seriously considered.

The converse of assent is dissent (disagreeing with the treatment plan), and dissent by an adolescent 13 to 17 years of age is considered binding in some states. The Society of Pediatric Nurses (2006) believes that dissent in the 7- to 12-year-old should also be considered binding. If the decision is made to move forward with treatment despite the child's dissent, this decision must be explained to the child in developmentally appropriate terms. In the case of research studies, the study itself must specifically ascertain if child assent is necessary, and at what age (Kimberly et al., 2006). Prior to recruitment for a research study, the researchers must also decide if the child's objection to participation will be honored (Kon, 2006a).

Clients' Rights

The American Hospital Association first established a Patient's Bill of Rights in 1972 as a way to promote the value and dignity of the client. This information is updated periodically. Most health care agencies and professional organizations have developed some type of document that addresses clients' rights.

Ensuring that clients' rights are upheld is a key aspect in the care of any client. For the pregnant woman, two clients must be considered—the pregnant woman and her fetus. The American Foundation for Maternal and Child Health developed the Pregnant Patient's Bill of Rights to address specific concerns and situations involving the health and well-being of the mother and her fetus. A child, due to his or her age and developmental level, may lack mature decision-making abilities. Many pedi-

atric institutions have adopted a bill of rights for children's health care specific to that institution (Box 1.5).

The U.S. Department of Health and Human Services has issued laws related to protecting the welfare of newborns ("Baby Doe" law). Parents ultimately are the decision-makers for their children. In ethical dilemmas such as babies born with brain damage or extremely preterm birth, parents must be accurately informed about the risks and benefits of treatment before giving consent to treatment or deciding to withdraw or forego treatment (Hurst, 2006). Some professionals are advocating for prenatal advance directives that would guide care from the time of birth of an extremely premature or otherwise impaired term infant (Catlin, 2005).

A number of national and international organizations have been formed in recent years to protect the rights of women and children in the United States and worldwide. These organizations focus on issues such as violence and abuse, child labor and soldiering, juvenile justice, child immigrants and orphans, abandoned children, and homeless women, children, and families. All of these issues can have negative impacts on the health of women, children, and families. As client advocates, nurses need to support policies that protect their clients' rights and improve health care.

Confidentiality

With the establishment of the Health Insurance Portability and Accountability Act (HIPAA) of 1996, the confidentiality of health care information is now mandated by law. The primary intent of the law is to protect health insurance coverage for workers and their families when they change or lose jobs. Another aspect of the law requires the Department of Health and Human Services to establish national standards for electronic transmission of health information. The plan also addresses the security and privacy of health information. For example, no information that clearly identifies a client can be in public display, including information on a client's chart. In maternal and child health care, information is shared only with the client, legal partner, parents, legal guardians, or individuals as established in writing by the client or the child's parents. This law promotes the security and privacy of health care and health information for all clients. Client information should always be kept confidential in the context of the state law, as well as the institution's policies.

Exceptions to confidentiality exist. For example, suspicion of physical or sexual abuse and injuries caused by a weapon or criminal act must be reported to the proper authorities. Abuse cases are reported to the appropriate welfare authorities, whereas criminal acts are reported to the police. The health care provider must also follow public health laws related to reporting certain infectious diseases to the local health department (e.g., tuberculosis, hepatitis, HIV, and other sexually transmitted diseases). Finally, there is a duty to warn third parties when there is a specific threat to an identifiable person. There must be a balance between confidentiality and required disclosure. If health care information must be disclosed by law, the client must be informed that this will occur (Feldman-Winter & McAbee, 2002).

BOX 1.5 A Child's Bill of Rights

- To be called by name
- To receive compassionate health care in a careful, prompt, and courteous manner
- To know the names of all providers caring for the child
- To have basic needs met and usual schedules or routines honored
- To be kept without food or drink when necessary for the shortest time possible
- To be unrestrained if able
- To have parents or other important persons with the child
- To have an interpreter for the child and family when needed
- To object noisily if desired
- To be educated honestly about the child's health care
- To be respected as a person—not having people talk about the child within earshot unless the child knows what is happening
- For all health care providers to respect the child's confidentiality about his/her illness at all times

Adapted from UCI University Children's Hospital, 2006.

Implications for Nurses

The health care system is intricately woven into the political and social structure of our society, and nurses should understand social, legal, and ethical health care issues so that they can play an active role in meeting the health care needs of women, children, and families. Nurses need to take a proactive role in advocating for and empowering their clients. For example, nurses can help women to increase control over the factors that affect health, thereby improving their health status. A woman may become empowered by developing skills not only to cope with her environment, but also to change it. Nurses also can assume this mentoring role with children and families, thus helping them to improve their overall health status and health outcomes.

Nurses must have a solid knowledge base about the factors affecting maternal and child health and barriers to health care. They can use this information to provide anticipatory guidance, health counseling, and teaching for women, children, and families. It also is useful in identifying high-risk groups so that interventions can be initiated early on, before problems occur.

When caring for women, children, and families, the nurse operates within the framework of the nursing process, which is applicable to all health care settings. Maternal and child health nursing is ever-changing as globalization and the exchange of information expands. Nurses must remain up to date about new technologies and treatments

and integrate high-quality, evidence-based interventions into the care they provide.

Key Concepts

- Maternal and child health nurses provide care using a philosophy that focuses on the family as the emphasis of care, providing atraumatic care and using evidence-based practice in a case management environment to provide quality, cost-effective care.
- Healthy People 2010 presents a national set of health goals and objectives for adults and children that focuses on health promotion and disease prevention.
- One method to establish the aggregate health status of women, infants, and children is with statistical data, such as mortality and morbidity rates.
- The infant mortality rate is the lowest in the history of the United States, but it is still higher when compared with other industrialized countries. This high rate may be the result of the increase in low-birth-weight infants born in this country.
- The family is considered the basic social unit. The family greatly influences the development and health of its members. Members learn health care activities, health beliefs, and health values from their family.
- Social roles are often an important factor in the development of one's self-concept, which can have a very positive influence on health or present various limitations and problems, possibly resulting in a negative influence on health.
- Culture influences every aspect of development and is reflected in childbearing and childrearing beliefs and practices designed to promote healthy adaptation.
- Spirituality, a major influence for many individuals, provides a meaning and purpose to life and is a foundation for and a source of love, relationships, and service. Spiritual and religious beliefs and views can provide strength and support to women, children, and their families during times of stress and illness.
- Other factors impacting the health of women and children include health status and lifestyles, health care cost containment, improved diagnosis and treatment, and health care consumer empowerment. Finances, transportation, language, culture, and the health care delivery system can provide barriers to health care.
- Advances in science and technology have led to increased ethical dilemmas in health care.
- All clients have the right to refuse medical treatment based on the American Hospital Association's Bill of Rights. For a child, the parents have the legal right to decide for or against medical treatment. Minor children (under the age of 18 years) must have their parents or legal guardians provide consent for health care in most cases.
- In certain states, mature minors and emancipated minors may consent to their own health care and certain health care may be provided to adolescents without parental notification, including contraception, pregnancy counseling, prenatal care, testing and treatment of sexually transmitted infections and communicable diseases (including HIV), substance abuse and mental illness counseling and treatment, and health care required as a result of a crime-related injury.
- The nurse must be knowledgeable about the laws related to health care of women and children in the specific state of nursing practice as well as the specific policies of the health care institution.

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. When preparing a presentation for a local woman's group on women's health problems, what would the nurse include as the number-one cause of mortality for women in the United States?

   a. Breast cancer

   b. Childbirth complications

   c. Injury resulting from violence

   d. Heart disease

2. Which factor would most likely be responsible for a pregnant women's failure to receive adequate prenatal care in the United States?

   a. Belief that it is not necessary in a normal pregnancy

   b. Use of denial to cope with pregnancy

   c. Lack of health insurance to cover expenses

   d. Inability to trust traditional medical practices

3. When caring for children, how should the nurse best incorporate the concept of family-centered care?

   a. Encouraging the family to allow the physician to make health care decisions for the child

   b. Using the concepts of respect, family strengths, diversity, and collaboration with family

   c. Advising the family to choose a pediatric provider who is on the covered child's health care plan

   d. Recognizing that families undergoing stress related to the child's illness cannot make good decisions

4. When caring for an adolescent, in which instance must the nurse share information with the parents, no matter which state care is provided in?

   a. Pregnancy counseling

   b. Depression

   c. Contraception

   d. Tuberculosis

5. The following events were milestones in the support of women's and children's health. Place the events in the correct sequence, from oldest to most recent.

   ___a. Declaration of the Rights of the Child approved

   ___b. WIC program established

   ___c. U.S. Children's Bureau established

   ___d. Sheppard-Towner Act passed

   ___e. Family and Medical Leave Act passed

   ___f. Education for all Handicapped Children Act passed

6. The nurse is preparing a class for a group of students about homelessness. Which factors contribute to homelessness? Select all that apply.

   ___a. Decrease in the number of people living in poverty

   ___b. Rises in unemployment

   ___c. Exposure to abuse or neglect

   ___d. Cutbacks in public welfare programs

   ___e. Development of community crisis centers

CRITICAL THINKING EXERCISES

1. As a nurse working in a federally funded low-income clinic offering women's health services, you are becoming increasingly frustrated with the number of "no-shows" or appointments missed in your maternity clinic. Some clients come for their initial prenatal intake appointment and never come back. You realize that some just forget their appointments, but most don't even call to notify you. Many of the clients are high risk and thus are jeopardizing their health and the health of their future child.

   a. What changes might be helpful to address this situation?

   b. Outline what you might say at your next staff meeting to address the issue of clients making one clinic visit and then never returning.

   c. What strategies might you use to improve attendance and notification?

   d. Describe what cultural and customer service techniques might be needed.

2. A couple has adopted an 11-month-old infant girl from China and have brought her to the health care facility for a checkup. The couple had no contact with the infant's birth parents. The infant spent 7 months in an orphanage before being adopted. Describe the family structure and the issues that may affect this family.

3. You have been asked by the local school district to speak to a group of middle-school children and their parents about Internet safety. Describe the topics that you should address.

4. A 12-year-old is to undergo research treatment for a serious illness. Explain the concept of assent as it relates to this situation.

Study Activities

1. Research a current policy, bill, or issue being debated on the community, state, or national level that pertains to the health and welfare of women or children. Summarize the major facts and supporting and opposing arguments and prepare an oral report on your findings.
2. Interview a child life specialist about the effects of using the atraumatic approach or the traditional approach for restraining children during procedures. Compare and contrast the effects on children at various developmental stages.
3. Within your clinical group, debate the following statement: Should access to health care be a right or a privilege?
4. Visit a local community health center that offers services to women and children from various cultures. Interview the staff about any barriers to health care that they have identified. Investigate what the staff has done to minimize these barriers.

CHAPTER 2

Family-Centered Community-Based Care

KEY TERMS

community
cultural competence
epidemiology
Individualized Health Plan (IHP)
health literacy
medically fragile children
respite care

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Examine the major components and key elements of family-centered home health care.
2. Explain the reasons for the increased emphasis on community-based care.
3. Differentiate community-based nursing from nursing in acute care settings.
4. Explain the different levels of prevention in community-based nursing, providing examples of each.
5. Give examples of cultural issues that may be faced when providing community-based nursing.
6. Provide culturally competent care to women, children, and families.
7. Identify the variety of settings where community-based care can be provided to women, children, and families.
8. Outline the various roles and functions assumed by the community health nurse.
9. Demonstrate the ability to use excellent therapeutic communication skills when interacting with women, children, and families.
10. Explain the process of health teaching as it relates to women, children, and families.
11. Examine the importance of discharge planning and case management in providing community-based care.

Maria was home a few days after giving birth to her first child. She had just changed her newborn son and placed him on his stomach for a nap when the community health nurse arrived for a postpartum visit. Because the nurse didn't speak Spanish and Maria didn't speak English, a great deal of gesturing followed. After examining Maria, the nurse then picked up her son and placed him on his back in the crib. How might the nurse have prepared for this home visit? What message did the nurse convey in changing the newborn's position?

Wow

To recognize diversity in others and respect it, we must first have some awareness of who we are.

Women, children, and families receive most of their health care, both well and ill care, in the community setting. During the past several years, the health care delivery system has changed dramatically. With a focus on cost containment, people are spending less time in the hospital. Clients are being discharged "sicker and quicker" from their hospital beds. The health care system has moved from reactive treatment strategies in hospitals to a proactive approach in the community. This has resulted in an increasing emphasis on health promotion and illness prevention within the community.

Nurses play an important role in the health and wellness of a community. They not only meet the health care needs of the individual but also go beyond that to implement interventions that affect the community as a whole. Nurses practice in a variety of settings within a community, such as clinics and physician offices, schools, shelters, churches, health departments, community health centers, and homes. They promote the health of individuals, families, groups, communities, and populations and promote an environment that supports health.

This chapter describes the concepts of community and community-based nursing, addressing the varied settings where such care is provided to women, children, and families. The chapter also highlights the major roles and functions of community-based nurses, emphasizing their role as educators in health promotion and maintenance.

Family-Centered Care

Family-centered cares refers to the collaborative partnership among the individual, family, and caregivers to determine goals, share information, offer support, and formulate plans for health care (Chia-Chen & Thompson, 2007). Key elements in the provision of family-centered care include demonstrating interpersonal sensitivity, providing general health information and being a valuable resource, communicating specific health information, and treating people respectfully (Grindel, 2006). The philosophy of family-centered care recognizes the family as the constant: the health of all the family members and their functional abilities influence the health of the client and other members of the family. Family-centered care works well in all arenas of health care, from preventive care to long-term care. Family-centered care enhances the confidence of all those involved about their skills and helps to prepare children and young adults for assuming responsibility for their own health care needs. It is vital for the nurse to assess how much knowledge the family has about the client's health or illness.

Using a family-centered approach is associated with positive outcomes such as decreased anxiety, improved pain management, shortened recovery times, and enhanced confidence and problem-solving skills. Communication between the health care team and the family is also improved, leading to greater satisfaction for both health care providers and health care consumers (families). Practicing true family-centered care may empower the family, strengthen family resources, and help the woman or child feel more secure throughout the process.

Community-Based Care

Community may be defined as a "specific group of people, often living in a defined geographical area, who share a common culture, values, and norms and who are arranged in a social structure according to relationships the community has developed over a period of time" (Canadian Community Health Nursing Standards of Practice, 2003, p. 18). The common features of a community may be common rights and privileges as members of a certain city or common ties of identity, values, norms, culture, language, or social support. Women are caregivers to children, parents, spouses, and neighbors and provide important social support in these roles. The child's community consists of the family, school, neighborhood, youth organizations, and other peer groups.

A person can be a part of many communities during the course of daily life. Examples might include area of residence (home, apartment, shelter), gender, place of employment (organization or home), language spoken (Spanish, Chinese, English), educational background or student status, culture (Italian, African-American, Indian), career (nurse, businesswoman, housewife), place of worship (church or synagogue), and community memberships (garden club, YMCA, support group, school PTA, youth organizations, athletic teams).

In community-based care, the community is the unit of service. The providers of care are concerned not only with the clients who present for service but also with the larger population of potential or at-risk clients.

Community Health Nursing

Community health nursing focuses on preventing illness and improving the health of populations and communities. Population is defined as "a collection of individuals who have one or more personal or environmental characteristics in common" (Canadian Community Health Nursing Standards of Practice, 2003, p. 20). Community health nurses work in geographically and culturally diverse settings. They address current and potential health needs of the population or community. They promote and preserve the health of a population and are not limited to particular age groups or diagnoses. Public health nursing is a specialized area of community health nursing.

Epidemiology (the study of the causes, distribution, and control of disease in populations) can help determine the health and health needs of a population and assist in planning health services. Community health nurses per-

form epidemiologic investigations to help analyze and develop health policy and community health initiatives. Community health initiatives can be focused on the community as a whole or a specific target population with specific needs. *Healthy People 2010* (HP 2010) is an example of national health initiatives developed using the epidemiological process. HP 2010 ensures that health care professionals evaluate the individual as well as the community. It emphasizes the ever-present link between the individual's health and the health of the community (Clark, 2007; Zahner & Block, 2006). HP 2010 identifies two major goals: to increase the quality of life and the life expectancy of individuals of all ages and to decrease health disparities among different populations. The focus of health care initiatives today is on people and their needs, strengthening their abilities to shape their own lives. The emphasis has shifted away from dependence on health professionals toward personal involvement and personal responsibility, and this gives nurses the opportunity to interact with individuals in a variety of self-help roles. Nurses in the community can be the primary force in identifying the challenges and implementing changes in women's and children's health for the future. (Relevant HP 2010 objectives are highlighted throughout this text, and HP 2010 is available online at www.healthypeople.gov.)

Community-Based Nursing

In the past, the only community-based roles for nurses were community health nurses or public health nurses. This is now a subset of what is considered community-based nursing. The health needs of the society and consumer demand brought about community-based and community-focused services. The movement from an illness-oriented "cure" perspective in hospitals to a focus on health promotion and primary health care in community-based settings has dramatically changed employment opportunities for today's nurses. This shift in emphasis to primary care and outpatient treatment and management will likely continue. As a result, employment growth in a variety of community-based settings can be expected for properly educated nurses.

The 2004 National Sample Survey of Registered Nurses (U.S. Department of Health and Human Services [USDHHS], Bureau of Health Professions, 2004) found the following trends in registered nurse (RN) employment settings:

- 44% of RNs work outside the hospital setting.
- The number of RNs employed in community-based settings showed a 35% increase between 2000 and 2004; this was largely the result of an increase in nurses working in home health care and managed care organizations.

Community-based nursing settings include ambulatory care, home health care, occupational health, school health, and hospice settings (Table 2.1). Clinical practice within the community may also include case management, research, quality improvement, and discharge planning. Nurses with advanced practice and experience may be employed in areas of staff development, program development, and community education.

Community-Based Nursing Interventions

Nursing interventions involve any treatment that the nurse performs to enhance the client's outcome. Nursing practice in the community uses the nursing process and is similar to that in the acute care setting, because assessing, performing procedures, administering medications, coordinating services and equipment, counseling clients and their families, and teaching about care are all part of the care administered by nurses in the community. Box 2.1 highlights the most common nursing interventions used in community-based nursing practice.

Community-Based Nursing Challenges

Despite the benefits achieved by caring for families in their own homes and communities, challenges also exist. Clients are being discharged from acute care facilities very early in their recovery course and present with more

TABLE 2.1 COMMUNITY-BASED PRACTICE SETTINGS

Setting	Description
Ambulatory care settings	Doctor's offices Health maintenance organizations (HMOs) Day surgery centers Freestanding urgent care centers Family planning clinics Mobile mammography centers
Home health care services	High-risk pregnancy/neonate care Maternal/child newborn care Skilled nursing care Hospice care
Health Department services	Maternal/child health clinics Family planning clinics Sexually transmitted infection programs Immunization clinics Substance abuse programs Jails and prisons
Long-term care	Skilled nursing facilities Nursing homes Hospices Assisted living
Other community-based settings	Parish nursing programs Summer camps Childbirth education programs School health programs Occupational health programs

BOX 2.1 Community-Based Nursing Interventions

- Health screening—detecting unrecognized or preclinical illness among individuals so they can be referred for definitive diagnosis and treatment (e.g., mammogram or Pap smear, well-child vision and hearing checks)
- Health education programs—assisting clients in making health-related decisions about self-care, use of health resources, and social health issues such as smoking bans and motorcycle helmet laws (e.g., childbirth education or breast self-examination, child safety programs, poisoning prevention, youth drug awareness programs)
- Medication administration—preparing, giving, and evaluating the effectiveness of prescription and over-the-counter drugs (e.g., hormone replacement therapy in menopausal women, childhood immunizations)
- Telephone consultation—identifying the problem to be addressed; listening and providing support, information, or instruction; documenting advice/instructions given to concerns raised by caller (e.g., consultation for a mother with a newborn with colic, interaction with a parent whose child has a fever or is vomiting)
- Health system referral—passing along information about the location, services offered, and ways to contact agencies (e.g., referring a woman for a breast prosthesis after a mastectomy, arranging for home tutoring for a child with a long-term illness)
- Instructional—teaching an individual or a group about a medication, disease process, lifestyle changes, community resources, or research findings concerning their environment (e.g., childbirth education class, basic life support classes for parents, child safety education classes)
- Nutritional counseling—demonstrating the direct relationship between nutrition and illness while focusing on the need for diet modification to promote wellness (e.g., Women, Infants, and Children [WIC] program; counselor interviewing a pregnant woman or a child and parents who have anemia; eating disorders program)
- Risk identification—recognizing personal or group characteristics that predispose people to develop a specific health problem, and modifying or eliminating them (e.g., genetic counseling of an older pregnant woman at risk for a Down syndrome infant; genetic screening of family members for cystic fibrosis or Huntington's disease.

Source: Dochterman, J. M., & Bulechek, G. M. (2004). *Nursing interventions classification* (NIC) (4th ed.). St. Louis: Mosby.

health care needs than in the past. As a result, nursing care and procedures in the home and community are becoming more complex and time-consuming. Consider the example of a woman who developed a systemic infection, a pelvic abscess, and deep vein thrombosis in her leg after a cesarean birth who is being discharged from the hospital. The nurse's primary focus of care in this situation would be to administer heparin and antibiotics intravenously rather than educating her about childcare and follow-up appointments. In the past, this woman would have remained hospitalized for treatment, but home infusion therapy is now less costly and allows the client to be discharged sooner.

This demand on the nurse's time may limit the amount of time spent on prevention measures, education, and the family's psychosocial issues. More time may be needed to help families deal with these issues and concerns. With large client caseloads, nurses may find it difficult to spend the time needed while meeting the time restrictions dictated by their health care agencies.

Nurses working in the community have fewer resources available to them compared with the acute care setting. Decisions often have to be made in isolation. The nurse must possess excellent assessment skills and the ability to communicate effectively with the family to be successful in carrying out the appropriate plan of care.

Nurses interested in working in community-based settings must be able to apply the nursing process in an environment that is less structured or controlled than that associated with acute care facilities. Nurses must be able to assimilate information well beyond the immediate physical and psychosocial needs of the client in a controlled acute care setting and deal with environmental threats, lifestyle choices, family issues, different cultural patterns, financial burdens, transportation problems, employment hazards, communication barriers, limited resources, and client acceptance and compliance.

Although opportunities for employment in community-based settings are plentiful, many positions require a baccalaureate degree. Previous medical-surgical experience in an acute care setting is typically required by home health agencies because these nurses must function fairly independently within the home environment.

The nurse must also be familiar with and respectful of many different cultures and socioeconomic levels, remaining objective in dealing with such diversity and demonstrating an understanding of and appreciation for cultural differences. Interventions must be individualized to address the cultural, social, and economic diversity among clients in their own environment (Papadopoulos, 2006).

Shift in Responsibilities from Hospital-Based to Community-Based Nursing

Community care, especially home care, is a rapidly growing service in the United States. Community-based care has been shown to be a cost-effective method for providing care. An increase in disposable income and the increased longevity of children with chronic and debilitating health conditions have also contributed to the continued shift of health care to the community and home setting. Technology has advanced, allowing for improved monitoring of clients in community settings and at home

as well as allowing complicated procedures to be done at home, such as intravenous administration of antibiotics. A major cause for the increase in community care, especially home care in the pediatric population, is the understanding that an acute care setting is not an appropriate environment for children to grow (Hewitt-Taylor, 2005). Caring for children at home not only improves their physical health but also allows for adequate growth and development within their family. They are in a familiar environment with the comfort and support of family, which leads to improved care and quality of life.

Levels of Prevention in Community-Based Nursing

The concept of prevention is a key part of community-based nursing practice. The emphasis on health care delivery in community-based settings has moved beyond primary preventive health care (e.g., well-child checkups, routine physical examinations, prenatal care, and treatment of common acute illnesses) and now encompasses secondary and tertiary care.

Primary Prevention

The concept of primary prevention involves preventing the disease or condition before it occurs through health promotion activities, environmental protection, and specific protection against disease or injury. It encompasses a vast array of areas, including nutrition, good hygiene, sanitation, immunization, adequate shelter, smoking cessation, family planning, and the use of seat belts (Fig. 2.1; Stanhope & Lancaster, 2008).

Prevention of neural tube defects (NTDs), such as anencephaly and spina bifida, in children is an example of primary prevention. The use of folic acid supplementation daily for 3 months before and 3 months after conception reduces the risk of first occurrence of NTD (American College of Obstetricians and Gynecologists [ACOG], 2007). All women of childbearing age should take 0.4 mg folic acid daily as soon as they plan to become pregnant and should

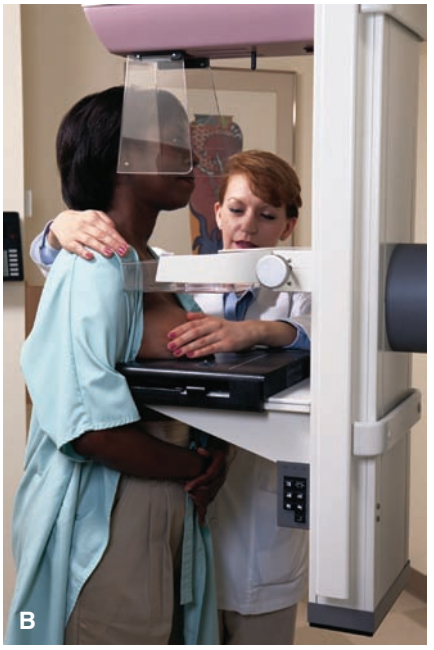

FIGURE 2.1 Levels of prevention in community-based nursing. (**A**) At the primary prevention level, the nurse provides anticipatory guidance and family teaching. (**B**) At the secondary level of prevention, a woman undergoes a mammography screening for early detection of breast problems. (**C**) At the tertiary level of prevention, a child with a developmental disability participates in a rehabilitation program.

continue taking it throughout the pregnancy to prevent this devastating condition. Giving anticipatory guidance to parents about poison prevention and safety during play is another example of primary prevention.

Secondary Prevention

Secondary prevention is the early detection and treatment of adverse health conditions. Health screenings are the mainstay of secondary prevention. Pregnancy testing, blood pressure evaluations, cholesterol monitoring, fecal occult blood testing, breast examinations, mammography screening, hearing and vision examinations, and Papanicolaou (Pap) smears are examples of this level of prevention. Such interventions do not prevent the health problem but are intended for early detection and prompt treatment to prevent complications (Anderson & McFarlane, 2007).

Tertiary Prevention

Tertiary prevention is designed to reduce or limit the progression of a disease or disability. The purpose of tertiary prevention is to restore individuals to their maximum potential (Anderson & McFarlane, 2007). Tertiary prevention measures are supportive and restorative. For example, tertiary prevention efforts would focus on minimizing and managing the effects of a chronic illness, such as a spinal cord injury or cerebral palsy, or the chronic effects of sexually transmitted infections such as herpes, human immunodeficiency virus (HIV), and untreated syphilis. Another example would involve working with women who have suffered long-term consequences of violence. The focus of the nurse would be to maximize the woman's strengths, to help them recover from the trauma and loss, and to build support systems.

The Nurse's Role in Community-Based Preventive Care

All health professionals have a special role in health promotion, health protection, and disease prevention. Much of community nursing involves prevention, early identification, and prompt treatment of health problems and monitoring for emerging threats that might lead to health problems. Community-based nurses provide health care for women and children at all three levels of prevention. This care often involves advocacy for services to meet their needs.

Cultural Issues in Community-Based Nursing

The United States contains an ever-changing mix of cultural groups. The Yearbook of Immigration Statistics (United States Department of Homeland Security [USDHS], 2006) reports that the U.S. immigrant population has reached 38 million, with people arriving from every corner of the world. One million immigrants come to the United States each year, and more than half are of childbearing age. Latin America accounts for more than 50% of immigrants to the United States. By the year 2050, people of African, Asian, and Latino backgrounds will make up one half of our population (U.S. Census Bureau, 2007).

This growing diversity has strong implications for the health care system. For years nurses have struggled with the issues of providing optimal health care that meets the needs of women, children, and families from varied cultures and ethnic groups. In addition to displaying competence in technical skills, nurses must also become competent in caring for clients from varied ethnic and racial backgrounds. Adapting to different cultural beliefs and practices requires flexibility and acceptance of others' viewpoints. Nurses must listen to clients and learn about their beliefs about health and wellness. To provide culturally appropriate care to diverse populations, nurses need to know, understand, and respect culturally influenced health behaviors. Chapter 1 provides a more detailed discussion of culture and its impact on the health of women, children, and families.

Nurses must research and understand the cultural characteristics, values, and beliefs of the various people to whom they deliver care so that false assumptions and stereotyping do not lead to insensitive care. Time orientation, personal space, family orientation (patriarchal, matriarchal, or egalitarian), and language are important cultural concepts.

Culturally Competent Nursing Care

Cultural competence is defined as the knowledge, willingness, and ability to adapt health care to enhance its acceptability to and effectiveness with clients from diverse cultures (Clark, 2007). Cultural competence is a dynamic process during which nurses obtain and then apply cultural information. Nurses must look at clients through their own eyes and the eyes of clients and family members. Nurses must develop nonjudgmental acceptance of cultural differences in clients, using diversity as a strength that empowers them to achieve mutually acceptable health care goals (Kersey–Matusiak, 2006). This cultural awareness allows nurses to see the entire picture and improves the quality of care and health outcomes.

Cultural competence does not appear suddenly; it must be developed through a series of steps (Box 2.2).

Barriers to Cultural Competence

Barriers to cultural competence can be grouped into two categories: those related to providers and those related to systems (Godfrey, 2006). When a health care provider lacks knowledge of a client's cultural practices and beliefs or when the provider's beliefs differ from those of the client, the provider may be unprepared to respond when the client makes unexpected health care decisions. System-related barriers can occur if agencies that have not been designed for cultural diversity want all clients to conform to the established rules and regulations and attempt to fit everyone into the same mold.

BOX 2.2 Steps to Developing Cultural Competence

1. Cultural Self-Awareness
   - Become aware of, appreciate, and become sensitive to the values, beliefs, customs, and behaviors that have shaped one's own culture.
   - Engage in self-exploration beyond one's own culture and "see" clients from different cultures.
   - Examine personal biases and prejudices toward other cultures.
   - Become aware of differences in personal and clients' backgrounds.
2. Cultural Knowledge
   - Obtain knowledge about various worldviews of different cultures, such as through reading about different cultures, attending continuing education courses on different cultures, accessing websites, and attending cultural diversity conferences.
   - Become familiar with culturally/ethnically diverse groups, worldviews, beliefs, practices, lifestyles, and problem-solving strategies.
3. Cultural Skills
   - Learn how to perform a competent cultural assessment.
   - Assess each client's unique cultural values, beliefs, and practices without depending solely on written facts about specific cultural groups.
4. Cultural Encounter
   - Engage in cross-cultural interactions with people from culturally diverse backgrounds, such as attending religious services or ceremonies and participating in important family events.
   - Participate in as many cultural encounters as possible to avoid cultural stereotyping.

Cultural competence does not mean replacing one's own cultural identity with another, ignoring the variability within cultural groups, or even appreciating the cultures being served. Instead, nurses skilled at cultural competence show a respect for difference, an eagerness to learn, and a willingness to accept multiple views of the world (Godfrey, 2006; Laveist, 2005).

Community-Based Nursing Care Settings for Women and Children

Community-based nursing takes place in a variety of settings, including physician's offices, clinics, health departments, urgent care centers, hospital outpatient centers, schools, camps, churches, shelters, and clients' homes. Nurses provide well care, episodic ill care, and chronic care. They work to promote, preserve, and improve the health of the women, children, and families in these settings.

Due to technological advances, cost containment, and shortened hospital stays, the home is a common care setting for women, children, and families today. Home care is geared toward the needs of the client and family. Private-duty nursing care is used when more extensive care is needed; it may be delivered hourly (several hours per day) or on a full-time, live-in basis. Periodic nursing visits may be used for intermittent interventions, such as IV antibiotic administration, follow-up with client teaching, and monitoring. The goals of nursing care in the home setting include promoting, restoring, and maintaining the health of the client.

Home care focuses on minimizing the effects of the illness or disability along with providing the client with the means to care for the illness or disability at home. Nurses in the home care setting are direct care providers, educators, advocates, and case managers.

Prenatal Care

Early, adequate prenatal care has long been associated with improved pregnancy outcomes (March of Dimes, 2007). Adequate prenatal care is a comprehensive process in which any problems associated with pregnancy are identified and treated. Basic components of prenatal care are early and continuing risk assessment, health promotion, medical and psychosocial interventions, and follow-up. Within the community setting, several services are available to provide health care for pregnant women (Box 2.3).

Not all women are aware of the community resources available to them. Most public health services are available for consultation, local hospitals have "hotlines" for questions, and public libraries have pregnancy-related resources as well as Internet access. Nurses can be a very helpful link to resources for all women regardless of their economic status.

Technologically advanced care has been shown to improve maternal and child outcomes. Regionalized high-risk care, recommended by the American Academy of Pediatrics in the late 1970s, aimed to promote uniformity nationwide, covering the prenatal care of high-risk pregnancies and high-risk newborns. The advanced technology found in level III perinatal regional centers and community-based prenatal surveillance programs have resulted in better risk-adjusted mortality rates (Britt, Edean & Evans, 2006; Martin & Foley, 2006). For example, fetal monitoring and ultrasound technology have traditionally been used in acute care settings to monitor the progress of many high-risk pregnancies. However, with the increased cost of hospital stays, many services were moved to outpatient facilities and into the home. The intent was to reduce health care costs and to monitor women with complications of pregnancy in the home rather than in the hospital. Examples of services offered in the home setting might include:

- Infusion therapy to treat infections or combat dehydration
- Hypertension monitoring for women with gestational hypertension

BOX 2.3 Maternal/Child Community Health Care Services

- State public health prenatal clinics provide access to care based on a sliding scale payment schedule or have services paid for by Medicaid.
- Federally funded community clinics typically offer a variety of services, which may include prenatal, pediatric, adult health, and dental services. A sliding scale payment schedule or Medicaid may cover costs.
- Hospital outpatient health care services offer maternal–child health services. Frequently they are associated with a teaching hospital in which medical school students, interns, and OB/GYN residents rotate through the clinic services to care for patients during their education process.
- Private OB/GYN offices are available for women with health insurance seeking care during their pregnancies. Some physicians in private practice will accept Medicaid patients as well as private patients.
- Community free clinics offer maternal–child services in some communities for women with limited economic resources (homeless, unemployed).
- Freestanding birth centers offer prenatal care for low-risk mothers as well as childbirth classes to educate couples regarding the birthing process. Most centers accept private insurance and Medicaid for reimbursement services.
- Midwifery services are available in many communities where midwives provide women's health services. They usually accept a multitude of payment plans from private pay to health insurance to Medicaid for reimbursement purposes.
- WIC provides food, nutrition counseling, and access to health services for low-income women, infants, and children. WIC is a federally funded program and is administered by each state. All persons receiving Aid to Families with Dependent Children (AFDC), food stamps, or Medicaid are automatically eligible for WIC. An estimated 45% of the infants born in the United States are served by WIC (USDA Food and Nutrition Service, 2004; Fig. 2-1).
- Childbirth classes offer pregnant women and their partners a series of educational classes on childbirth preparation. Women attend them during their last trimester of pregnancy. Some classes are free and some have a fee.
- Local La Leche League groups provide mother-to-mother support for breast-feeding, nutrition, and infant care problem-solving strategies. All women who have an interest in breast-feeding are welcome to participate in the meetings, which are typically held in the home of a La Leche member.

- Uterine monitoring for mothers who are at high risk for preterm labor
- Fetal monitoring to evaluate fetal well-being
- Portable ultrasound to perform a biophysical profile to assess fetal well-being

As a result, home care has the potential to produce cost savings compared to inpatient care.

Labor and Birth Care

Pregnancy involves numerous choices: cloth or disposable diapers, breastfeeding or bottle feeding, doctor or midwife, and where to give birth—at a birthing center, at home, or at a hospital. Deciding where to give birth depends on the woman's pregnancy risk status. For the pregnant woman who is at high risk as a result of medical or social factors, the hospital is considered the safest place for birth. Potential complications can be addressed because medical technology, skilled professionals, and neonatal services are available. For low-risk women, a freestanding birthing center or a home birth is an option.

The choice between a birthing center, home birth, or hospital depends on the woman's preferences, her risk status, and her distance from a hospital. Some women choose an all-natural birth with no medications and no medical intervention, whereas others would feel more comfortable in a setting in which medications and trained staff are available if needed. Presenting the facts to women and allowing them to choose in collaboration with their health care provider is the nurse's role. Safety is paramount, but at the same time nurses must protect the woman's right to select birth options and should promote family-centered care in all maternity settings (see Evidence-Based Practice box).

Birthing Center

A birthing center is a cross between a home birth and a hospital. Birthing centers offer a homelike setting but with close proximity to a hospital in case of complications. Midwives often are the sole care providers in freestanding birthing centers, with obstetricians as backups in case of emergencies. Birthing centers usually have fewer restrictions and guidelines for families to follow and allow for more freedom in making decisions about labor. The rates of cesarean birth and the costs are much lower than those of a hospital (Steppe, 2006). The normal discharge time after birth is usually measured in hours (4 to 24 hours), not days.

Birthing centers aim to provide a relaxing home environment and promote a culture of normalcy. Birth is considered a normal physiologic process, and most centers use a non-interventional view of labor and birth. The range of services for the expectant family often includes prenatal care, childbirth education, intrapartum care, and postpartum care, including home follow-up and family plan-

EVIDENCE-BASED PRACTICE 2.1
Is a Home-Like Institutional Birth Setting Better for Women Than a Conventional Institutional Birth Setting?

● Study
Women have been giving birth to newborns in the home setting since the beginning of time. Births occurring in a facility or institution became the norm during the early 20th century. These institutions continue to be the primary setting for birth. However, with the growing emphasis of the client as a consumer of health care and the desire for family-centered care, greater numbers of facilities and institutions are attempting to incorporate some of the home birth components into their delivery of care. A study was done to compare the effect of care in a home-like institutional birth setting and a conventional institutional birth setting.

Two researchers using standard methods for data collection and analysis compiled information from all randomized and quasi-randomized controlled trials involving a comparison of home-like institutional and conventional institutional birth settings. In addition, the researchers evaluated eight journals and two published conference proceedings. Six trials that involved 8,677 women were included. The researchers were unable to include information related to freestanding birthing centers because they found no trials on this topic. The researchers reported the results using relative risk and 95% confidence intervals.

▲ Findings
The results showed that women giving birth in home-like institutional birth settings were less likely to receive or require intrapartum analgesia or anesthesia, less likely to have an episiotomy, and more likely to experience a spontaneous vaginal birth. Other benefits identified included a greater chance for choosing the same setting for future births, greater satisfaction with intrapartum care, and a greater likelihood for initiating breastfeeding with continuation for the next 6 to 8 weeks. Unfortunately, women giving birth in a home-like institutional birth setting had an increased risk for vaginal or perineal tears. Additionally, the risks for perinatal mortality were increased.

■ Nursing Implications
The study did identify several important benefits that nurses can integrate into their practice when counseling and teaching pregnant women about available birthing options. However, nurses need to underscore the increased risk for perinatal mortality when providing this education so that women can make informed decisions about their choice of birth setting.

Nurses also can provide input about incorporating a more "home-like" atmosphere when their facilities are constructing and designing birthing areas. In addition, nurses can advocate for the pregnant woman in labor to ensure that she has freedom to move about the birthing area, allowing her to feel more "at home."

Source: Hodnett, D. D., Downe, S., Edwards, N., & Walsh, D. Home-like versus conventional institutional settings for birth. *Cochrane Database of Systematic Reviews* 2005. Issue 1. Art. No.: CD000012. DOI:10.1002/14651858.CD000012.pub2.

ning (Fig. 2.2). One of the hallmarks of the freestanding birthing center is that it can provide truly family-centered care by approaching pregnancy and birth as a normal family event and encouraging all family members to participate. Education is often provided by such centers, encouraging families to become informed and self-reliant in the care of themselves and their families (Bainbridge, 2006).

Birthing centers provide an alternative for women who are uncomfortable with a home birth but who do not want to give birth in a hospital. Advantages of birthing centers include a non-interventional approach to obstetric care, freedom to eat and move around during labor, ability to give birth in any position, and the right to have any number of family and friends attend the birth. Disadvantages are that some centers have rigid screening criteria, which may eliminate healthy mothers from using birth centers; many have rigid rules concerning transporting the mother to the hospital (e.g., prolonged labor, ruptured membranes); and many have no pediatrician on staff if the newborn has special needs after birth (Clarke, Bowcock & Gales, 2007; Downe, 2006).

Home Birth
For centuries women have been giving birth to babies in their home. Many feel more comfortable and relaxed when giving birth in their own environment. Women who want no medical interventions and a very family-centered birth often choose to have a home birth. Home births are recommended for pregnant women who are considered to be at low risk for complications during labor and birth. Home birth is advantageous because it:

- Is the least expensive
- Allows the woman to experience labor and birth in the privacy, comfort, and familiarity of home while surrounded by loved ones
- Permits the woman to maintain control over every aspect affecting her labor (e.g., positions, attire, support people)

Figure 2.2 Birthing centers aim to provide a relaxing home environment and promote a culture of normality while offering a full range of health care services to the expectant family. (Photos by Gus Freedman.)

- Minimizes interference and unnecessary interventions, allowing labor to progress normally
- Provides continuous one-on-one care by the midwife throughout the childbirth process
- Promotes the development of a trusting relationship with the nurse midwife (American Pregnancy Association [APA], 2007)

A home birth does have some disadvantages, including the limited availability of pain medication and danger to the mother and baby if an emergency arises (e.g., placenta abruptio, uterine rupture, cord prolapse, or a distressed fetus). Delay in getting to the hospital could jeopardize the life of the child or the mother. A backup plan for a health care provider and nearby hospital on standby must be established should an emergency occur (Ramsey, 2007).

Postpartum and Newborn Care

Recent reforms in health care financing have reduced hospital stays significantly for women after giving birth. As a result, community-based nurses play a major role in extending care beyond the hospital setting. When new mothers are discharged from the hospital, most are still experiencing perineal discomfort and uterine cramping. They may still have pain from an episiotomy. They are fatigued and may be constipated. They may feel uncertain about feeding and caring for their newborn. These new mothers need to be made aware of community resources such as telephone consultation by nurses, outpatient clinics, and home visits.

Telephone Consultation

Many hospitals offer telephone consultation services by their maternity nurses. The discharged mother is given the phone number of the nursing unit on the day of discharge and is instructed to call if she has any questions or concerns. Because the nurses on the unit are familiar with her birth history and the newborn, they are in a good position to assist her in adjusting to her new role. Although this service is usually free, not all families recognize a problem early or use this valuable informational resource.

Outpatient Clinics

Outpatient clinics offer another community-based site where the childbearing family can obtain services. Usually the mother has received prenatal care before giving birth and thus has established some rapport with the nursing staff there. The clinic staff is usually willing to answer any questions she may have about her health or that of her newborn. Appointments usually include an examination of the mother and newborn and instructions about umbilical cord care, postpartum and infant care, and nutrition for both mother and infant.

Postpartum Home Visits

Home visits offer services similar to those offered at a scheduled clinic visit, but they also give the nurse an opportunity to assess the family's adaptation and dynamics and the home environment. During the past decade, hospital stays have averaged 24 to 48 hours or less for vaginal births and 72 to 96 hours for cesarean births (Centers for Disease Control [CDC], 2007a). Federal legislation went into effect in 1998 that prohibited insurers from restricting hospital stays for mothers and newborns to less than 2 days for vaginal births or 4 days for cesarean births (CDC, 2007a). These shortened stays have reduced the time available for educating mothers about caring for themselves and their newborns.

Postpartum care in the home environment usually includes:

- Monitoring the physical and emotional well-being of the family members (Fig. 2.3)
- Identifying potential or developing complications for the mother and newborn
- Bridging the gap between discharge and ambulatory follow-up for mothers and their newborns (Rice, 2005)

High-Risk Newborn Home Care

With the reduced lengths of stay, high-risk newborns are also being cared for in community settings. Hi-tech care once was provided only in the hospital. Now, however, the increasing cost of complex care and the influences of managed care have led to the provision of hi-tech care at home. Families have become "health care systems" by providing physical, emotional, social, and developmental home care for their technology-dependent infants. Suitable candidates for home care may include preterm infants who continue to need oxygen, low-birthweight infants needing nutritional or hypercaloric formulas or adjunct feeding methods (e.g., tube feedings), or infants with hydrocephalus or cerebral palsy. A wide range of equipment may be used, including mechanical ventilation, electronic apnea monitors, home oxygen equipment, intravenous infusions, respiratory nebulizers, phototherapy, and suction equipment.

FIGURE 2.3 The nurse makes a postpartum home visit to assess the woman and her newborn. During the visit, the nurse assists the mother with breastfeeding.

All family members must work together to provide 24-hour care. The parents must negotiate with insurers for reimbursement for durable medical equipment, must be able to troubleshoot equipment problems, and must be able to manage inventories of supplies and equipment. In addition, they must be able to assess the infant for problems, determine the problem, decide when to call the nurse, pharmacist, or physical therapist, and interpret and implement prescriptions. Technology in the home requires nurses to focus on the family "home care system" to provide total care to the infant.

Nurses can play a key role in assisting families by preparing them for and increasing their confidence in caring for their infants at home. This adaptation begins before discharge from the hospital. Family members are active participants in the transition-to-home plan. Recognition of parental needs and addressing each area in the discharge plan will ease the transition home.

Assessment of the family's preparedness is essential. The following questions can provide valuable information about this area:

- How well prepared are you to take care of your infant's physical, emotional, and equipment needs?
- How well prepared are you to obtain the home services you need for your infant?
- How well prepared are you to manage the stress of home care?

These simple questions convey the nurse's concern for the infant and family while obtaining a thorough assessment of the family's learning needs.

Once preparedness has been assessed, the nurse can intervene as necessary. For example, if the caretakers do not think they are prepared to maintain machinery, technology, medication, or developmental therapy, then the nurse can demonstrate the care to the family. The nurse provides instructions and hands-on experience within a supportive environment until the family's confidence increases. The nurse can also assist the family to anticipate the common problems that might occur (e.g., advising them to avoid running out of supplies, to have enough

medication or special formula mixture to last throughout the weekend, and to keep backup batteries for powering machines or portable oxygen). The outcome of the preparedness assessment and intervention is that the safety of the infant is established and maintained.

Nursing for families who are using complex home care equipment requires caring for the infant and family members' physical and emotional well-being as well as providing effective solutions to problems they may encounter. Home health nurses need to identify, mobilize, and adapt a myriad of community resources to support the family in giving the best possible care in the home setting. Preparing families for hi-tech care before hospital discharge, with home health nurses continuing and reinforcing that focus, will help ease the burden of managing hi-tech equipment in the home.

Women's Health Care

A woman's reproductive years span half her lifetime, on average. This is not a static period, but rather one that encompasses several significant stages. As her reproductive goals change, so do a woman's health care needs. Because of these changing needs, comprehensive community-centered care is critical.

Community-based women's health services have received increased emphasis during the past few decades simply because of economics. Women use more health care services than men, they make as many as 90% of health care decisions, and they represent the majority of the population (CDC, 2007b). Women spend 66 cents of every health care dollar, and 7 of the 10 most frequently performed surgeries in the United States are specific to women (Alexander et al., 2007). Examples of community-based women's health care services that can be freestanding or hospital-based include:

- Screening centers that offer mammograms, Pap smears, bone density assessments, genetic counseling, ultrasound, breast examinations, complete health risk appraisals, laboratory studies (complete blood count, cholesterol testing, thyroid testing, glucose testing for diabetes, follicle-stimulating hormone [FSH] levels), and electrocardiograms
- Educational centers that provide women's health lectures, instruction on breast self-examinations and Pap smears, and computers for research
- Counseling centers that offer various support groups: genetics, psychotherapy, substance abuse, sexual assault, and domestic violence
- Wellness centers that offer stress reduction techniques, massage therapy, guided imagery, hypnosis, smoking cessation, weight reduction, tai chi, yoga, and women's fitness/exercise classes
- Alternative/wholeness healing centers that provide acupuncture, aromatherapy, biofeedback, therapeutic touch, facials, reflexology, and herbal remedies
- Retail centers that offer specialty equipment for rental and purchase, such as breast prostheses

Women have multiple choices regarding services, settings, and health care providers. In the past most women received health care services from physicians such as obstetricians, gynecologists, and family physicians, but today nurse midwives and nurse practitioners are becoming more prevalent in providing well-women care.

Nurses who work in community-based settings need to be familiar with the many health issues commonly encountered by women within their communities. All nurses who work with women of any age in community-based settings, including the workplace, schools, practitioner offices, and clinics, should possess a thorough understanding of the scope of women's health care and should be prepared to intervene appropriately to prevent problems and to promote health.

Child Health Care

The majority of care for a child occurs in the community setting. The numerous settings may be broad or highly specialized. For example, one setting may provide well-child care as well as illness-related care. Another setting may be limited to providing well-child care; a third setting may be limited to diagnostic evaluation, emergency care, or surgical intervention. Other settings may focus on caring for children with specific conditions or diagnosis, such as diabetes or cancer.

Outpatient and Ambulatory Care

Outpatient and ambulatory care is health care provided to individuals who do not require care in an acute setting. Due to advances in medical technology, more medical procedures, such as diagnostic tests and treatments and surgeries, can be performed on an outpatient basis, thereby minimizing the need for the child to be hospitalized. Outpatient and ambulatory care offers convenient and cost-effective access to health care for children and their families, many times right within their own community. These settings allow for increased independence and permit children to return to their normal routine as quickly as possible. More and more outpatient and ambulatory care centers are developing; they are associated with health maintenance organizations (HMOs), physician offices, community agencies and public health departments, and hospitals (Hunt, 2005).

Physician Offices, Clinics, and Urgent Care Centers

Physician offices, clinics, and urgent care centers are used by children and their families for well care, episodic ill care, acute care, and care of chronic conditions. For well care and illness or injury, children are often seen by their primary care physician. They may use a physician office or clinic. In more acute situations or for after-hours issues

that cannot wait until clinic operating hours, a child may be seen in an urgent care center or may be referred to the emergency department. The American Academy of Pediatrics does not encourage the use of urgent care centers or the emergency department for routine care since it is difficult to provide coordinated, comprehensive family-centered care consistent with a "medical home" concept (refer to Chapter 30 for more information on medical homes)(Krug et al., 2005).

The nurse's role in these settings includes preparing clients, collecting pertinent health information, performing assessments, assisting the physician with diagnostic testing and procedures, administering injections and medications, changing dressings, assisting with minor surgery, helping to maintain records, and educating the child and family about follow-up care, including when to call the physician or return to be seen.

Outpatient Units

Outpatient units are used to keep hospital stays short and decrease the cost of hospitalization. Outpatient units may be a part of the hospital or a freestanding facility. The child and family arrive in the morning; the child has the procedure, test, or surgery and then goes home later in the day. Examples of surgeries and procedures performed in outpatient units include tympanostomy tube placement, hernia repair, tonsillectomy, cystoscopy, bronchoscopy, blood transfusions, dialysis, and chemotherapy. This setting is advantageous because there is minimal separation of the child from the family, minimal disruption of the family pattern, a decreased risk of infection, and decreased cost. However, the unit does not have the equipment for overnight stays. Thus, if the child develops a complication, he or she will need to be transported to the acute care facility.

Many centers offer presurgery health assessment and teaching sessions, which allows the parent and child opportunities to voice questions and concerns so that they can be resolved before the procedure or surgery. On the day of the procedure or surgery, parents usually are allowed to remain with their child until the procedure or surgery begins. Parents should also be allowed to be with their child in the post-anesthesia care unit (PACU) as soon as possible. Minimizing separation between the parents and the child provides reassurance, promotes comfort, and meets the physical and emotional needs of the child and family.

Nurses working in the outpatient unit setting are involved with admission and assessment, preoperative teaching and preparation, client assessment and support, postoperative monitoring, case management, discharge planning, and teaching. Before the procedure or surgery, the nurse commonly reviews the routine to be followed and any special instructions such as nothing by mouth (NPO) orders and familiarizes the child and family with the setting.

▶ *Take* NOTE!

Encourage the parent to bring a favorite toy, blanket, or game to make the child feel more comfortable.

The nurse performs any surgical preparation and discusses intraoperative procedures as necessary. The nurse also provides provide postprocedural or postoperative care and assessment of the child. Once the child is stable and meets the discharge criteria of the facility, the nurse reviews instructions, including pain management, care of the incision if appropriate, diet, and activity, including the time frame for returning to school, necessary follow-up, and when to call the physician.

Medically Fragile Day Care Centers

The number of **medically fragile children**, children who have complex medical needs that require skilled nursing interventions, is growing. Reasons include the increased sophistication of medical technology, the increase in preterm births, and the increase in childhood trauma (Mentro, 2003). It is estimated that 1 million children in the United States have complex, disabling, and costly health conditions (Anonymous, 2000). For many years these children lived in hospital settings their entire lives. Due to concerns about the high cost of long-term hospitalization and the quality of life for these children, alternative care settings in the community, such as medically fragile day care centers, are being developed.

Medically fragile day care centers are designed to meet the needs of these children. Most centers accept children who have complicated medical needs or are technology-dependent. Examples include children with multiple congenital anomalies, children who are ventilator-dependent, children with respiratory conditions, children with cardiac conditions, and children with cancer. Some centers will accept children with less complicated needs, such as cardiorespiratory monitoring or asthma. Some centers include children without health care needs to promote peer relationships and acceptance.

Medically fragile day care centers are similar to typical day care centers. Parents or caregivers can drop off the child in the morning and pick up the child in the afternoon. Some centers offer after-school, weekend, or respite services. The centers usually have indoor and outdoor play areas, educational activities, arts and crafts, and needed therapies.

Health care professionals are present to provide for the child's medical, emotional, and developmental needs. Nurses trained in pediatric and neonatal care, physical therapists, occupational therapists, speech therapists, child life specialists, and social workers staff the centers; some centers also have respiratory therapists on

site. Children can receive all of their prescribed therapies while at the center.

Nurse provide direct care such as medication administration and dressing changes, assess and evaluate the child's overall condition, identify potential medical emergencies, determine the need for changes in care or treatment and monitoring, and provide the necessary treatments or interventions to maintain life and health. Most centers are located in the community to help ease transportation issues. Some centers will provide transportation to and from home or school. Centers are licensed by the state day care licensing authorities or, in some states, Physician Prescribed Extended Care (PPEC) agencies. Families may be eligible for financial assistance from their private insurance or Medicaid. The cost of this type of community-based service, on average, is one third that of inpatient hospitalization (Anonymous, 2000). Additionally, there appear to be decreases in the number of rehospitalizations and in family stress (Anonymous, 2000).

Telephone Triage

Telephone triage constitutes a large percentage (more than 25%) of child health treatment (Simonsen-Anderson, 2002). Up to 380 calls per week are received in the average pediatric office (Corjulo, 2005). When parents feel comfortable with the providers in their child's medical home office, they often call for advice to treat their child at home. This practice saves health care dollars by keeping stable or less ill children at home rather than seeking care in an emergency department or urgent care center. If the call is received during office hours and the child's condition warrants evaluation, then the child can be seen in the pediatric primary care office. Telephone triage also is used extensively by pediatric specialty practices.

While telephone triage can be a money-saving and even life-saving intervention, it cannot be used without caution. Triage nurses must be able to determine from the call whether the child needs to be evaluated and if that evaluation should be made emergently. The nurse must carefully question the parent or caregiver about the specifics of the child's condition to determine whether it fits into a low or high risk category. When counseling a parent over the phone, obtain the following information:

- Signs and symptoms; their onset and progression; and characteristics such as location, severity, and aggravating or relieving factors
- History of the child's present illness, including onset and duration, progression of symptoms, any care given at home, and whether this condition is related to a recent diagnostic procedure, surgery, or hospitalization
- The child's health history, including chronic illnesses and routine medications or alternative treatments
- The child's current status in relation to eating, drinking, elimination, and energy and activity level
- Degree and effectiveness of coping by the child and family to this health alteration (adapted from Simonsen-Anderson, 2002)

After obtaining this thorough assessment, the nurse must use critical thinking skills, experience, and established telephone triage protocols to determine the severity and risk of the child's situation. Pediatric telephone protocols are available for purchase through the American Academy of Pediatrics (http://www.aap.org). If the child's situation is determined to be low risk, then home care instruction and advice is appropriate. Children with moderate risk should be seen in the office that day or within 24 hours; advise the family on appropriate care while awaiting the office visit. High-risk children should be evaluated immediately, either in the office or emergency department. Certain high-risk situations warrant activation of the emergency medical system and immediate paramedic evaluation.

▶ *Take* NOTE!

Parents or caregivers often can pick up on subtle problems or cues. Although they may not be able to describe the signs and symptoms accurately, they do know that their child is not acting right. Nurses must listen carefully and act on the parents' or caregivers' concerns.

Schools

School nursing is a specialized practice of professional nursing and focuses on improving student health to enhance the achievement and success of students. School nurses work to remove or minimize health barriers to learning, thereby providing students with the best opportunity at academic success. The National Association of School Nurses defines school nursing as "a specialized practice of professional nursing that advances the well-being, academic success, and life-long achievement of students. To that end, school nurses facilitate positive student responses to normal development; promote health and safety; intervene with actual and potential health problems; provide case management services; and actively collaborate with others to build student and family capacity for adaptation, self management, self-advocacy, and learning" (*Pediatrics*, 2008). A goal of HP 2010 speaks directly to students and school nurses (Healthy People 2010 2.1).

At the heart of school nursing is the belief that all children have the ability to learn and a right to an education, and that society is best served if children are educated (*Pediatrics*, 2008). School nurses coordinate school health programs and link health service programs within the school and community. School nurses carry out a variety of roles in providing healthcare to children (Fig. 2.4). Box 2.4 provides examples of activities performed by the school nurse.

HEALTHY PEOPLE 2010

Objective	Significance
Increase the proportion of middle, junior high, and senior high schools that provide school health education to prevent health problems in the following areas: unintentional injury; violence; suicide; tobacco use and addiction; alcohol and other drug use; unintended pregnancy, HIV/AIDS, and STD infection; unhealthy dietary patterns; inadequate physical activity; and environmental health.	• Provide education and training to school staff in health problem areas. • Work with schools to develop appropriate health education with focus on health problem areas.

FIGURE 2.4 The school nurse provides nursing assessment as well as health education to students in the school setting.

BOX 2.4 Examples of Activities of the School Nurse

- Conducting health screenings (e.g., vision, hearing, and scoliosis)
- Assessing growth and development
- Providing emergency first aid
- Training and educating staff on CPR and first aid and health issues
- Assessing, monitoring, and referring students with communicable diseases
- Educating on health promotion and disease prevention (e.g., immunizations, bike and car safety, and decreasing high-risk behaviors, such as smoking, drinking, drug use, and sexual activity)
- Acting as a resource for health issues and education
- Acting as a liaison between home, school, and community and between health care provider and school
- Reinforcing client and family health education (e.g., discharge instructions, self-care measures such as catheterization)
- Monitoring long-term illness in students
- Networking with community agencies and making necessary referrals

The population of students has changed over the years. Access to public schools for children with disabilities is mandated. Because of advances in technology, children with chronic conditions or special needs live longer and enter school. Schools are seeing an increased number of children with psychiatric conditions such as depression, attention-deficit/hyperactivity disorder, and bipolar disorder. All of these factors have contributed to an increase of children with diverse and sometimes complex health needs in the school system.

Although the essential role of the school nurse has not changed, the responsibilities and expectations have. School nurses are challenged to meet the growing needs of this changing school population.

Just as nurses in the acute care setting develop nursing care plans, nurses in the school setting develop **Individualized Health Plans (IHPs)**. An individual health plan formalizes the plan of support for a student with complex health care needs. It is a written agreement developed by an interdisciplinary collaboration of school staff along with the student, the student's family, and the student's health care provider. The plan will describe the student's needs and how the school plans to meet them. The nurse plays a critical role in developing these plans, using the nursing process to develop goals and interventions based on the nursing assessment and diagnosis to ensure that the needs of the child are being met. Examples of students who may need an IHP include students with asthma, serious allergies, chronic conditions such as type I diabetes, physical

disabilities, attention-deficit/hyperactivity disorder, and medication needs. Figure 2.5 gives an example of an IHP for a child with asthma.

▶ *Take* NOTE!

The IHP needs to include directions for care while the child is at school and also must take into account variations in school routine, absence of staff, field trips and extracurricular activities, and emergency plans.

Childcare Centers, Camps, Health Department Clinics, and Shelters

Other settings in the community, such as childcare centers, camps, health department clinics, and shelters, also focus on promoting health, preventing disease and injury, and ensuring a safe environment. Nurses play important roles in these settings. In childcare centers nurses address infection control issues and assess for a safe environment. They provide education and training to staff members. Camp nurses ensure a safe environment for all campers and provide first aid and acute illness care as needed. Camps for children with special health care needs employ specially trained nurses (Fig. 2.6). These camps cater to children with complex health care needs, such as diabetes, head injuries, and physical disabilities, and allow the children the opportunity to experience camp while providing a safe environment and necessary medical care while there. Nurses working in health department clinics and shelters focus on health supervision services and connecting clients to needed community resources.

▶ *Take* NOTE!

Nurses have a unique opportunity to give back to their community by volunteering their services in various settings, such as shelters and clinics in medically underserved areas.

Pediatric Home Care

Pediatric home care provides short- or long-term services for children and their families in their home. It also is used for medically needy and technology-dependent children, such as children requiring mechanical ventilation. Children with acute illnesses, such as a child with osteomyelitis requiring intravenous antibiotics, or chronic health care issues, such as a child with bronchopulmonary dysplasia, that traditionally would have required inpatient care can often benefit from home care.

Pediatric home care can be advantageous for the child and family, minimizing the separation of the child from the family and allowing the child to remain in an environment that is familiar and comfortable. However, pediatric home health care does have some disadvantages. The presence of health care professionals in the home can be an intrusion on family privacy. Also, caring for children with complex medical needs can be overwhelming for some families. Financial issues can become a burden, as families may have higher out-of-pocket costs due to lack of reimbursement from a third party for home care. Having one parent or caregiver at home full time and not earning an income can contribute to increased financial strain, not to mention the social isolation of that person. All of these situations can lead to increased stress on family members. Nurses need to be aware of these potential disadvantages, work in partnership with the family, and provide support and resources as necessary.

Responsibilities of the Pediatric Home Care Nurse

As the provider of care, the home health care nurse uses the nursing process. Assessment in the home is similar to that in the acute care setting, but it will involve obtaining first-hand data about the family and family functioning. The nurse needs to assess growth and development and thoroughly assess the home environment (refer to Chapter 33 for additional information). The nurse should ensure that the home provides a safe and nurturing environment for the child by assessing the following:

- Availability of resources, such as necessary equipment (e.g., hospital bed, oxygen)
- Suitable physical and emotional surroundings (can the family members deal with the stress of the situation?)
- Ability to contact emergency services
- Power backup if needed
- Ease of evacuation of the child in case of a fire

The nurse also needs to ensure that adequate electricity, sanitary conditions, heat, possibly air conditioning, and telephone access exist in the home. If there is no phone in the home, the family needs to have plans for how to access a phone in case of emergency. This may include use of a neighbor's phone or relying on a pay phone near the home. The nurse should identify areas of priority and provide appropriate referrals to resources.

During the assessment phase, the nurse identifies the primary caregiver, who must be included in the plan of care. This person may be the mother, father, grandparent, or older sibling. The primary caregiver should be considered the expert about the child and family, providing valuable insights into direct care and the strategies that will be most effective with this child. The primary caregiver can also give key information about the physical layout of the home, the financial ability of the family, and the family's functioning.

The environment differs greatly between the acute setting and the home setting. In the acute setting the nurse

FIGURE 2.6 The camp nurse may care for typical healthy children or may work at a camp for children with special needs or chronic illness.

is in control of the environment, while in the home setting the nurse is a guest in the home. It is important for the nurse to establish a trusting relationship with both the child and family (Fig. 2.7), because a trusting therapeutic relationship will enhance all aspects of care.

The pediatric home care nurse assesses the family's teaching and learning needs. In many situations, care such as frequent dressing changes must be learned immediately so that the child can be cared for at home. This teaching should begin prior to hospital discharge. However, teaching is ongoing, with teaching and learning needs shifting as the child grows and his or her condition changes. The nurse empowers the child and family through education.

After the assessment is complete, the nurse develops and implements a plan of care. This will include the frequency and duration of the home visits. The nurse adheres to agency policies, certification standards, and private insurance and/or Medicaid regulations to assist in the development of the plan (Thompson, 2000). The nurse may provide direct care to the child or may plan and supervise the care given by others, such as unlicensed personnel and family caregivers.

Nursing care in the home requires excellent assessment and critical thinking skills. The nurse has a great deal of independence since there are no other nurses, supervisors, or physicians on site. Also, due to the potential complexity of care being provided, the nurse needs to adjust procedures to fit the setting. For example, feeding schedules may be adjusted to fit a child's school schedule, or equipment may be adjusted to allow a child to receive feedings continuously while at school (Fig. 2.8).

Home Care of the Technology-Dependent Child

Due to advances in medicine and technology, a new population of children with chronic disease and disability has emerged. Some of these children are considered technology-dependent, meaning they need medical or technical assistance to remain alive or avoid further disability. To improve the quality of life for these children and to reduce health care costs, more and more families are providing care for these children at home.

Meeting the needs of these children usually requires an interdisciplinary team approach. The team may consist of a specialty physician, occupational therapist, speech therapist, physical therapist, nutritionist, special educators, psychologist, social worker, and nurse. Studies have shown that families of technology-dependent children experience increased emotional, physical, psychological, and financial stress (Fleming, 2004). Nurses need to assess the family for these stressors and assist them in finding appropriate resources for assistance.

Due to the intensive, around-the-clock care that many of these children require, physical and emotional exhaustion can occur. Therefore, **respite care**, the provision of

FIGURE 2.7 Listening to the child helps to develop a trusting relationship between the home care nurse and the child and her family.

FIGURE 2.8 The home care nurse may have to adjust procedures and equipment to fit the home setting. Placing a feeding pump in a backpack allows this child to receive feedings continuously while at school.

support services to temporarily relieve the caregiver from responsibility of providing care, is crucial. Nurses must assess the need for respite care and assist families in finding appropriate resources. (Refer to Chapter 33 for additional information about respite care.)

Roles and Functions of the Community-Based Nurse

Many nurses find the shift from acute care to community settings a challenge. With the shift in responsibilities from hospital care to community care, changes in nursing care have resulted. Nurses working in community-based settings share many of the same roles and responsibilities as their colleagues in acute care settings, but there are some differences. For example, in the community or home care setting the nurse will provide direct client care but will spend more time in the role of educator, communicator, and manager than the nurse in the acute care setting. In home care the nurse will spend a significant amount of time in the supervision or management role.

Communicator

Effective therapeutic communication with women, children, and families is critical to the provision of quality nursing care. Client- and family-centered communication increases satisfaction with nursing care and aids in improving knowledge and health care skills (Sobo, 2004).

Communicating with children can be more difficult than communicating with adults. However, children are able to inform nurses of their experiences reliably and accurately, and nurses need to be able to discern this information from communication with the child. Children may be more apt to communicate if they are engaged in another activity, may use fewer words than adults, and tend to rely more upon nonverbal communication and silence (Curtin, 2001). Parents and adults more often require neutral communication—that is, verbal communication that is related to assessing and solving problems. On the other hand, children usually desire affective communication (establishment of rapport and trust, giving comfort). Therefore, nurses need to find a balance between neutral and affective communication, communicating on multiple levels with children of different ages and on a supportive level with adolescents and adults (Shin & White-Traut, 2005).

Verbal and Nonverbal Communication

Nurses use verbal communication continuously throughout the day when interacting with their clients. Good verbal communication skills are necessary for excellent nursing assessment and teaching. Nonverbal communication, also referred to as body language, includes attending to others and active listening. When clients and families feel they are being heard, trust and rapport are established.

Recall Maria, who recently was discharged from the hospital with her newborn son. How did the nurse communicate with Maria? Did the nurse's actions during the visit promote the development of trust between Maria and the nurse? What might have been done differently to foster trust?

▶ *Take* NOTE!

People of all ages desire to be listened to without interruption (Deering & Cody, 2002).

Active listening is critical to the communication process. Listening may uncover fears or concerns that the nurse may not have discovered through questioning. By not listening, critical information may be missed. The client or family may sense that the nurse is not listening and thus may be reluctant to share further information. During the interaction, determine whether the client's verbal communication is congruent with his or her nonverbal communication.

Communication With Children

To communicate effectively with children, it is necessary to use a variety of age-appropriate methods. Encourage children to actively participate to promote feelings of control over the interaction (Shin & White-Traut, 2005). Talk to the parents first if the child is shy to allow the child time to become comfortable. Spending time with younger children (even just a few moments) may help them adapt and feel more at ease with the nurse (Donate-Bartfield & Passman, 2000). Use specific and clear phrases in an unhurried, quiet yet confident manner. Communicate at the child's eye level. Instead of direct questioning, use dolls, puppets, or stuffed animals to question younger children (Fig. 2.9). Using metaphors (such as referring to white blood cells as "bad guy fighters") helps to illustrate concepts to young and school-age children (Fleitas, 2003).

Older children need privacy. Provide the child or adolescent with honest answers at a developmentally appropriate level. Allow children to express their thoughts and feelings. Offer the child choices only when they truly exist (Mandleco, 2005). Box 2.5 highlights some guidelines for effective communication with children.

Children will be empowered when they are communicated with directly. Children may also desire advice about their health care and reassurance about their health status. To be effective when communicating with children of different developmental stages, the nurse must become familiar with how children of different ages communicate and then use age-appropriate techniques for effective communication. Table 2.2 provides some

FIGURE 2.9 Sitting at the child's level and allowing the child time for self-expression provide for improved therapeutic communication.

suggestions for developmentally appropriate communication techniques.

Communication With Families

When communicating with families, always be honest. Families desire to be valued and should be equal partners

BOX 2.5 Guidelines for Effective Communication with Children

- Introduce yourself and explain your role.
- Position yourself at the child's level.
- Allow the child to remain near the parent if needed, so the child can remain comfortable and relaxed.
- Smile and make eye contact with the child if culturally appropriate.
- Direct your questions and explanations to the child.
- Listen attentively and pause to allow time for the child to formulate his or her thoughts.
- Use the child's or family's terms for body parts and medical care when possible.
- Speak in a calm, quiet, confident, and unhurried voice.
- Use positive rather than negative statements and directions.
- Encourage the child to express his or her feelings and ask questions.
- Observe for nonverbal cues.
- Ask for permission if you need to approach the child to avoid appearing threatening.

TABLE 2.2 Developmentally Appropriate Communication Techniques for Children

Age	Techniques
Infants	• Respond to crying in a timely fashion. • Allow the infant time to warm up to you. • Use play and playful persuasion. • Use a soothing and calming tone when speaking to the infant. • Talk to the baby directly.
Toddlers	• Approach toddlers carefully, as they often are fearful and quite resistant. • Use the toddler's particular words for objects or actions so that he or she is better able to understand. • Use storytelling, dolls, and books. • Prepare toddlers for procedures just before they are about to occur.
Preschoolers	• Use play, puppetry, or storytelling for a "third-party" approach. • Speak honestly. • Use simple, concrete terms. • Allow the child to have choices as appropriate. • Prepare preschoolers about 1 hour prior to a procedure.
School-age children	• Use diagrams, illustrations, books, and videos. • Allow the child to express feelings honestly. • Use third-party stories to elicit desired information. • Allow the child to ask questions related to care and treatment, and allow adequate time for all of the questions to be answered. • Prepare the child a few days in advance for a procedure.
Adolescents	• Always respect the teenager's need for privacy. • Ensure confidentiality. • Use appropriate medical terminology, defining words as necessary. • Use creativity. • Prepare the teen up to 1 week before a procedure.

in the health care team. Allow family members to verbalize concerns and questions. Explain the use of equipment and the correct sequence of procedures thoroughly. Help the members understand the long-term as well as short-term effects of the health treatment. Teach them what the client will feel like and how he or she will look during a procedure or treatment. When interacting with families, remember to ask the members how they are doing and to provide positive reinforcement as well as reassurance (Mandleco, 2005).

When the client is a child, encourage parents to perform as much of the child's care as is reasonable, teaching them how to perform treatments as permitted. Inquire about the parents' perception of the child's progress. Allowing the parents to be involved in the care of their child gives them a sense of control and lets them know that they are valued by the health care team.

Working With an Interpreter

Attempting to communicate with a family who does not speak English can be a highly frustrating situation for health care providers. Interpreters are an invaluable aid and an essential component of client and family education. Working with an interpreter, whether in person or over the phone, requires coordination of efforts so that both the family and the interpreter understand the information to be communicated. Working as a team, the nurse questions or informs and the interpreter conveys the information completely and accurately. Box 2.6 presents tips for working with an interpreter to maximize teaching efforts.

Healthy People 2010 also addresses the topic of language differences (Healthy People 2010 2.2). In addition, many health care facilities subscribe to Language Line (http://www.languageline.com/), which offers telephone access to interpretation of 150 languages. Numerous other interpreters, translators, and language resources are available online.

Recall Maria, the woman with the newborn who is receiving home care. One the second visit to Maria's home, the nurse brought a Spanish-speaking interpreter who explained the reason for the "back to sleep" position and demonstrated to Maria several other useful positions for feeding and holding. Maria was smiling when the nurse left and asking when she would be back. What made the difference in their relationship the second visit? What interventions demonstrate culturally competent care?

Communicating With Deaf or Hearing-Impaired Clients and Families

For the hearing-impaired, determine the method of communication used: lip reading, American Sign Language (ASL), another method, or some combination. If the nurse is not proficient in ASL and the client or family uses it, then an ASL interpreter must be available if another adult family member is not present for translation. According to federal law, deaf clients and deaf family members must be given the ability to communicate effectively with health-care providers (Sheehan, 2000).

BOX 2.6 Tips for Working With Interpreters

- **Help the interpreter prepare and understand what needs to be done ahead of time.** A few minutes of preparation may save a lot of time and help communication flow more smoothly in the long run.
- **Remember, the interpreter is the "communication bridge" and not the "content expert."** The nurse's presence at teaching sessions is vital.
- **Be patient. The interpreter's timing may not match that of others involved.** It often takes longer to say in some languages what has already been said in English; therefore, plan for more time than you normally would.
- **Speak slowly and clearly.** Avoid jargon. Use short sentences and be concise. Avoid interrupting the interpreter.
- **Pause every few sentences so the interpreter can translate your information.** After 30 seconds of speaking, stop and let the interpreter express the information. Talk directly to the family, not the interpreter.
- **Give the family and the interpreter a break.** Sessions that last longer than 20 or 30 minutes are too much for anyone's attention span and concentration.
- **Express the information in two or three different ways if needed.** There may be cultural barriers as well as language and dialect differences that interfere with understanding. Interpreters may often know the correct communication protocols for the family.
- **Use an interpreter to help ensure the family can read and understand translated written materials.** The interpreter can also help answer questions and evaluate learning.
- **Avoid side conversations during sessions.** These can be uncomfortable for the family and jeopardize client–provider relationships and trust.
- **Remember, just because someone speaks another language doesn't mean that he or she will make a good interpreter.** An interpreter who has no medical background may not understand or interpret correctly, no matter how good his or her language skills are.
- **Do not use children as interpreters.** Doing so can affect family relationships, proper understanding, and compliance with health care issues.

Maintenance of Confidentiality and Privacy

Electronic medical records (EMR) improve efficiency and accuracy in a variety of clinical settings and may also improve the quality of client care by simplifying the function

HEALTHY PEOPLE 2010

Objective	Significance
Increase the proportion of local health departments that have established culturally appropriate and linguistically competent community health promotion and disease prevention programs.	• Work with professionals and individuals from various cultures to develop materials and programs for health promotion that are culturally competent. • Ensure teaching materials are provided in the appropriate language.

of recording complete data (Roukema et al., 2006). The EMR also simplifies sharing of client information across health care disciplines (Adams, Mann & Bauchner, 2003). Client confidentiality and privacy must be maintained in the EMR in a similar fashion as is required with paper documentation. At each point of electronic transmission, client data must remain secure and Health Insurance Portability and Accountability Act (HIPAA) guidelines must be followed (Flores & Dodier, 2005). When using computerized documentation and an EMR, continuously ensure that the client's and family's privacy and confidentiality are maintained.

Direct Care Provider

The community-based nurse typically performs less direct physical care than the nurse in the acute care setting. Many times the nurse may observe the client or caregiver performing physical care tasks. Excellent assessment skills are especially important in the community care setting. The nurse often is functioning in a more autonomous role, and after data collection, the community-based nurse will often decide whether to initiate, continue, alter, or end physical nursing care. Assessment extends beyond physical assessment of the client to include the environment and the community.

Management of the Perinatal Client

The nurse provides direct care to the perinatal client, beginning with the woman's first visit to the health care provider and extending through the pregnancy and birth. In addition, the nurse provides direct care involving the following areas:

- Contraception
- Abortion
- Infertility
- Screening for sexually transmitted infections
- Preconceptual risk assessment and care

Provision of Atraumatic Care for Children

To minimize the stress experienced by children and their families in relation to health care, nurses, child life specialists, and other health care professionals advocate for the provision of atraumatic care. Atraumatic care refers to the delivery of health care in a manner that eliminates or minimizes psychological and physical distress to children and families (Wong, 2002). The key principles of atraumatic care include:

- Preventing or minimizing physical stressors
- Preventing or minimizing separation of the child from the family
- Promoting a sense of control

Table 2.3 provides suggestions for incorporating the principles of atraumatic care into nursing care for the child and family.

Educator

Due to shortened hospital stays and decreased admissions, providing client and family education is a key role for nurses in the community. Many times teaching begins in the community setting, especially the home. In the community-based setting, client teaching is often focused on assisting the client and family to achieve independence.

Regardless of the type of setting, nurses are in a unique position to help clients and families manage their own health care needs. Clients and families need to be knowledgeable about areas such as their condition, the health care management plan, and when and how to contact health care providers. With the limited time available in all health care arenas, nurses must focus on teaching goals and begin teaching at the earliest opportunity (London, 2004).

▶ *Take* NOTE!

There is no prescription more valuable than knowledge. (C. Everett Koop, MD, Former Surgeon General of the United States)

Client education occurs when nurses share information, knowledge, and skills with clients and families, thus empowering them to take responsibility for their health care. Through client education, clients and families can overcome feelings of powerlessness and helplessness and gain the confidence and capability to be active members in their plan of care. According to the Joint Commission on the Accreditation of Healthcare Organizations (JCAHO) standards, the goals of client and family education are to:

- Promote interactive communication with providers
- Improve understanding of health status and health care options
- Encourage decision making about care
- Improve compliance with the plan of care
- Reduce anxiety

TABLE 2.3 SUGGESTIONS FOR PROVIDING ATRAUMATIC CARE

Principle	Suggestions for Nursing Care
Preventing or minimizing physical stressors	• For painful injections, use numbing techniques. • During painful or invasive procedures, avoid traditional restraint or "holding down" of the child. Use alternative positioning such as "therapeutic hugging." • If these positions are not an option, have the parent stand near the child's head to provide comfort. • Insert a saline lock if the child will require multiple doses of parenteral medications. • Advocate for minimal laboratory blood specimen collections. • Avoid use of or minimize intramuscular or subcutaneous injections. • Provide appropriate pain management.
Preventing or minimizing child and family separation	• Promote family-centered care. • Allow the family the choice about whether to stay for invasive procedures, and support them in their decision.
Promoting a sense of control	• Maintain the child's home routine related to ADLs. • Encourage the child to have a security item with him or her if desired. • Involve the child and family in planning of care from the first moment of the first encounter. • Empower the family and child by providing knowledge. • Allow the child and family choices when they are available. • Make the environment more inviting, less intimidating.

• Return a sense of autonomy and control
• Promote healthy lifestyles (JCAHO, 2004)

Overall, client and family education allows clients and families to make informed decisions, ensures the presence of basic health care skills, promotes recognition of problem situations, promotes appropriate responses to problems, and allows for questions to be answered (London, 2004). Client and family education is a priority and is addressed in Healthy People 2010 2.3.

HEALTHY PEOPLE 2010

Objective	Significance
Increase the proportion of persons appropriately counseled about health behaviors. (Developmental) Increase the proportion of health care organizations that provide client and family education; increase the proportion of clients who report that they are satisfied with the client education they receive from their health care organization.	• Assess health learning needs of women, children, and their families. • Plan health care education in collaboration with clients and their families. • Provide health education at each client encounter.

▶ *Take* NOTE!

To cope effectively with illness, understand and participate in decisions about treatment plans, and maintain and improve health after treatment, clients and their families must have access to the specific knowledge and skills relevant to their conditions (JCAHO, 2004).

Steps of Client and Family Education

The steps of client and family education are similar to the steps of the nursing process. The nurse must assess, plan, implement, evaluate, and finally document education. Once a level of comfort and experience are obtained with each of these steps, they all blend together into one harmonious whole that becomes an everyday part of nursing practice. Client education begins with the first client encounter and proceeds through discharge and beyond. Reassessment after each step or change in the process is critical to ensuring success.

Assessing Teaching and Learning Needs

Client education begins with a learning needs assessment that includes the client's and family's learning needs,

learning styles, and potential barriers to learning. A learning needs assessment also is a good time to establish rapport with the family to demonstrate interest in them and confidence in their ability to learn.

Based on the results of the assessment, an individualized plan can be developed to reduce the time and effort required for nurses to teach while maximizing learning for the client and family. When caring for children, the educational process is targeted at both the child, when developmentally appropriate, and the adult members of the family. Therefore, it is advisable to conduct a learning needs assessment on both the adult caregivers and the child when appropriate.

The assessment, when completed, should be shared with all members of the interdisciplinary team so that the entire team can facilitate the learning. Although assessment generally takes place during the first or second meeting with the client and family, it should also occur with each encounter to check for any changes to ensure the success of the education across the continuum of care.

Cultural Impact on Assessment of Learning Needs

Culture can have a significant impact on learning. During the learning needs assessment, determine the language spoken in the home and the use of eye and physical contact. Also investigate the following:

- Person responsible for caring for the client and person considered the authority figure in the family
- The social support structure
- Special dietary needs and concerns during illness
- Traditional health practices, such as the use of healers, shamans, talismans, folk remedies, and herbs
- Special clothes or other items that help to maintain health
- Religious beliefs, ceremonies, and spiritual practices

Culture also influences the interpretation and meaning of illness to a client and family. Question them about their thoughts or ideas, such as the cause, effects, severity, and hopes for treatment. Then an individualized teaching plan can be negotiated with the client and family.

▶ *Consider* THIS!

Our medical mission took a team of nurse practitioners into the rural mountains of Guatemala to offer medical services to people who had never had any. One day, a distraught mother brought her 10-year-old daughter to the mission clinic, asking me if there was anything I could do about her daughter's right wrist. She had sustained a fracture a year ago and it had not healed properly. As I looked at the girl's malformed wrist, I asked if it had been splinted to help with alignment, knowing what the answer was going to be. The

(continued)

▶ *Consider* THIS! *(continued)*

interpreter enlightened me by saying that this young girl would never marry and have children because of this injury. I appeared puzzled at the interpreter's prediction of this girl's future. It was later explained to me that if the girl couldn't make tortes from corn meal for her husband because of her wrist disability, she would not be worthy of becoming someone's wife and thus would probably live with her parents the rest of her life.

I reminded myself during the week of the medical mission not to impose my cultural values on the women for whom I was caring and to accept their cultural mores without judgment. These silent self-reminders served me well throughout the week, for I was open to learning about their lifestyles and customs.

Thoughts: What must the young girl be feeling at the age of 10, being rejected for a disability that wasn't her fault? What might have happened if I had imposed my value system on this patient? How effective would I have been in helping her if she didn't feel accepted? This incident ripped my heart out, for this young girl will be deprived of a fulfilling family life based on a wrist disability. This is just another example of female suppression that happens all over the world—such a tragedy—and yet a part of their culture, on which nurses should not pass judgment.

Nurses involved in teaching immigrant or refugee families may encounter specific issues, such as:

- Use of the English versus the metric system for measurement
- Use of measurements such as a "a handful" or "a pinch" rather than specific measurements such as a measuring device
- Lack of access to refrigeration for liquid medications
- Breastfeeding practices

Literacy Issues

Health literacy is the ability to read, understand, and use health care information. The inability to read and comprehend health care information or materials is an enormous problem in America today. Low health literacy affects people of all ages, races, and educational and income levels. Even persons with adequate literacy skills may have difficulty reading and understanding health care information.

Adequate literacy skills are essential for client and family education, yet many people in America today have marginal reading abilities. The average adult in America reads at an eighth-grade level, and approximately 20% read and understand only information written below a fifth-grade level. For the English-speaking Medicaid population, the average reading level is fifth grade; for native Spanish-speaking persons, the average reading level is third

grade (Schillinger, 2002). Studies have reported that literacy skills are a stronger predictor of health status than age, income, employment, education, or racial or ethnic group (Weiss, 2003).

When new and unfamiliar information is disseminated or when emotional distress is present, reading ability and understanding are further reduced. In addition, the last grade completed in school does not equate with reading ability: poor readers often read three to five grade levels below their grade completion. Most health care materials are written at a tenth-grade level. Moreover, medical information is becoming increasingly complex, while the amount of time clients have to spend with nurses and other health care providers is decreasing. As a result, many studies have shown that persons with limited literacy skills cannot understand basic medical words and health concepts, whether verbal or written.

Unfortunately, recognizing poor health literacy skills is difficult: appearance, verbal ability, employment status, and educational level cannot be used to identify persons who do not read well. People who do not read well often go to great lengths to hide their disability: 68% of persons with limited literacy skills have never told their spouse and 75% have never told their health care provider (Weiss, 2003).

▶ *Take* NOTE!

Watch for these red flags that may indicate poor literacy skills:

- *Difficulty filling out registration forms, questionnaires, and consents*
- *Frequently missed appointments*
- *Noncompliance and lack of follow-up with treatment regimens*
- *Responses such as, "I forgot my glasses" or "I'll read this when I get home"*
- *Inability to answer common questions about their treatment or medicines*
- *Avoidance of asking questions for fear of looking "stupid"*

Planning Education

Once the assessment is completed, plan mutually agreed-upon achievable learning goals and objectives. It is important that achievement of goals is possible from both the caregiver's and the learner's perspective. Finding common ground and building a bridge between the client's and family's concerns and what the health care team believes they need to know is a critical part of an education plan. This also is an excellent time to consider client education materials and resources that can be used to maximize learning and retention.

Planning client education should involve input from the entire interdisciplinary team when appropriate. Through good communication and collaboration, team members can work together to empower the client and family to become knowledgeable and skilled. Overriding the traditional path of teacher-centered education by providing family-centered education requires thought and skill.

To achieve maximum success with education, it is beneficial to know how people learn. Edgar Dale (1969) suggested that people learn best when actively involved in the learning process. Figure 2.10 provides a summary of his principles, known as the "cone of learning." The implications for client education are clear: the more senses employed and the more actively involved the learner is, the better he or she will remember what was taught.

Intervening to Enhance Learning

Nurses are in an excellent position to foster an environment that is conducive to learning. For example, it is entirely appropriate to say to the client, "Many people have a problem reading and remembering the information on this paper (booklet, manual). Is this ever a problem for you?" Once a problem is acknowledged, the nurse is free to adjust verbal communication techniques and written materials to assist with learning and to communicate this need to the entire interdisciplinary healthcare team.

Nurses implement individualized teaching techniques based on the assessment information and identified goals. In general, the following techniques can facilitate learning:

- Slow down and repeat information often.
- Speak in conversational style using plain, nonmedical language.
- "Chunk" information and teach it in small bites using logical steps.
- Prioritize information and teach "survival skills" first.
- Use visuals, such as pictures, videos, and models.
- Teach using an interactive, "hands-on" approach.

If the client or family has poor health literacy skills, learning can be fostered by the use of pictures or illustrations, videos or audio tapes, or color coding (such as medication bottles or steps of a procedure). In addition, teaching can include a "back-up" family member.

Children and adolescents have a great need for information about their illness as they attempt to master feelings of anxiety and restore feelings of competency, self-confidence, and hope for the future. As with adults, they learn best when their input is valued and they are actively included and involved in the learning process. The age and developmental level of the child will determine the amount, format, and timing of the information given. Table 2.4 provides some guidelines to keep in mind when teaching children. Before beginning to teach a child, it is important to establish rapport and lay the foundation for good communication.

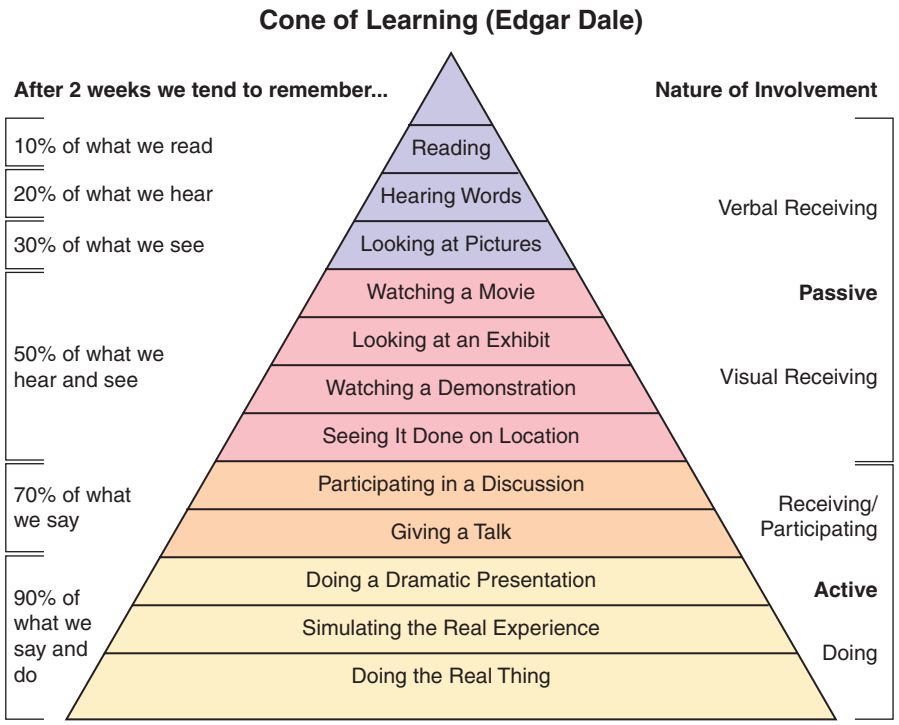

FIGURE 2.10 Cone of Learning (adapted from Dale).

When teaching preschoolers, the nurse or family assumes part or all of the responsibility for what is learned, how it is learned, and when it is learned. Employing their vivid imaginations, young children often attempt to invent pieces of information, or pick up bits and pieces of misinformation that can lead to false assumptions. Skillfully delivered and timed information as well as proper preparation can help encourage trust, calm, and control for an otherwise apprehensive and uncooperative preschooler.

Unless they are quite ill, school-age children need to cooperate and achieve and usually want to participate in their care. When teaching, speak directly to them and include them in the education plan. Parents can often learn by listening to and observing the care being given to their child (Fig. 2.11).

Adolescents are particularly sensitive about maintaining body image and feelings of control and autonomy. This is especially important with health care processes and decisions that affect them. Education is an essential aspect of care for the adolescent who is pregnant.

Evaluating Learning

Teaching, even when done well, does not necessarily mean that learning has occurred. Evaluation of learning is critical to ensure that the client and family have actually learned what the nurse tried to teach. Evaluation should occur with each educational encounter and goals and interventions should be adjusted accordingly. The nurse, along with the rest of the interdisciplinary team, is responsible for client and family learning. If they have not learned, the health care team must adjust teaching strategies so that the client and family do learn.

▶ *Take* NOTE!

The ultimate goal of education is a change in behavior on the part of the client and family; this change can occur in their level of knowledge, skills, or both.

Evaluation of learning can occur in several different ways, depending on the topic and the method of teaching. The client or family may:

- Demonstrate a skill. Learning can quickly and easily be identified using this method.
- Repeat back or teach back information using their own words.
- Answer open-ended questions. Open-ended questions provide an opportunity to assess for missing or incorrect information. Open-ended questions are those that cannot be answered with a simple "yes" or "no."

Another option to evaluate learning is to provide a "pretend" scenario for the client or family, having them verbalize all the steps related to care from the routine measures to those for handling an emergency situation. Information must be conveyed accurately as the client or family walks through the necessary steps.

Documenting Teaching and Learning

Documenting client care and education is part of every nurse's professional practice and serves four main purposes. First and foremost, the client's medical record serves

TABLE 2.4 GUIDELINES FOR TEACHING CHILDREN

Teaching Tips	Practical Applications
Preschoolers	
Offer simple, concise, concrete explanations based on the assessed needs, questions, and developmental level of the child.	Use a child's senses and relate what a procedure will look, sound, smell, taste, or feel like ("The MRI machine will sound very loud, like a big train").
Be honest, even when the information you need to convey is not positive. This helps the child to form a bond of trust and confidence with caregivers.	Use the family's words that the child understands; use "soft words" ("This will feel warm" instead of "This will burn").
Time explanations to decrease anxiety and excess worry before the event. Avoid telling unpleasant news close to bedtime.	As a general rule, give toddlers information about procedures, medicines, and other interventions immediately beforehand; give 4- to 7-year-olds information 1 or 2 days in advance.
Enlist the aid of the parents because they know their child best. Eliciting information from them about their child's past behaviors and coping skills can often mean the difference between a positive and negative experience for their child.	Teach parents how to coach their child with pain management, visualization, or other methods of distraction when appropriate ("Remember when we went to the beach. . . .").
Provide an active role for the child. This helps to foster a child's sense of self-confidence and control over the situation.	Allow the child to help with simple self-care activities such as holding a dressing or piece of tape. Provide props and dolls to touch and feel as much as possible ("Your job is to keep your hands still").
Respect the child's wishes when he or she verbalizes or demonstrates that he or she does not want more information.	Keep explanations short and simple; know when to stop teaching.
Praise children and let them know how much you appreciate their help and cooperation.	Use "please" and "thank you" often ("Thank you. I like the way you held still for me.").
School-age children	
Allow the child some control and involvement in the decision-making process.	Offer choices whenever possible (taking the medicine with juice or milk), but don't offer choices when there are no alternatives (taking the medicine vs. not taking the medicine).
Know that children can relate current happenings to past experiences.	Use examples and past experiences that are familiar to the child ("Remember when you were learning to swim?").
Allow children to be actively involved when possible; achievement and accomplishment are very important to children at this age, so anything they can be actively involved in will help them adjust and learn.	Provide an active role and allow the child to do as much care as possible. Use props, dolls, games, and computers to enhance learning.
Remember that at this age, most children are able to sequence, understand cause-and-effect, and make sense of time.	Teach children the steps involved and how long they will take ("Today I'm going to teach you how to change your dressing. This will help keep your cut clean. First, wash your hands. . . .").
Enhance self-confidence by allowing the child to gain control over the situation and prepare for it mentally.	Provide information 3 to 7 days in advance, depending on the child's age and developmental level.
Praise children and let them know how much you appreciate their help and cooperation.	Use "please" and "thank you" often ("Thanks! You did a great job using your inhaler").
Adolescents	
Allow teens to be in control and involved in the decision-making process.	Speak directly to teens; consider their input in all decisions about their care and education.

(continued)

TABLE 2.4 Guidelines for Teaching Children (continued)

Teaching Tips	Practical Applications
Keep in mind that adolescents can process abstract information and understand how their actions affect long-term outcomes.	Provide reasons why something is important and discuss how their lives will be affected by their decision to take care of their health needs ("If you eat a nutritious diet, you'll help your baby grow").
Remember that adolescents are very concerned about how they look and how they fit in with their peers.	Collaborate with the teen to develop acceptable solutions and strategies for dealing with health issues that affect personal appearance and peer acceptance (wig vs. head scarves for hair loss from chemotherapy).
Know that adolescents strive for independence and have personal values and ideologies that may conflict with those of their parents and the medical community.	Expect some noncompliance with care, despite your best educational efforts. Work together to achieve win–win outcomes of educational goals.

as a communication tool that the entire interdisciplinary team can use to keep track of what the client and family has learned already and what learning still needs to occur. Next, it serves to testify to the education the family has received if and when legal matters arise. Thirdly, it verifies standards set by the JCAHO, Centers for Medicare and Medicaid Services (CMS), and other accrediting bodies that hold health care providers accountable for client education activities. And lastly, it informs third-party payers of goods and services provided for reimbursement purposes.

Documentation of client and family education is imperative. It is the only means available to ensure that the family's educational plan and objectives have been completed.

Discharge Planner and Case Manager

Due to the short length of stays in acute settings and the shift to community settings for clients with complex health needs, discharge planning and case management have become an important nursing role in the community. Discharge planning involves the development and implementation of a comprehensive plan for the safe discharge of a client from a health care facility and for continuing safe and effective care in the community and at home. Case management focuses on coordinating health care services while balancing quality and cost outcomes. Often clients requiring community-based care, especially home care, have complex medical needs that require an interdisciplinary team to meet their physical, psychosocial, medical, nursing, developmental, and education needs. The nurse plays an important role in initiating and maintaining the link between team members and the client to ensure that the client and family are receiving comprehensive, coordinated care.

FIGURE 2.11 Nurses need to adapt teaching to the child's developmental level. For the school-age child, teaching the child and parents together fosters the child's need for achievement.

Advocate and Resource Manager

Client advocate is another important role of the community-based nurse to ensure that the client's and family's needs are being met. Advocacy also helps ensure that the client and family have available resources and appropriate health care services. For example, the pregnant woman on bed rest at home may need help in caring for her other children, maintaining the household, or getting to her appointments. Children with complex medical needs may require financial assistance through Medicaid or Medicaid waivers (state-run programs that use federal and state money to pay for the health care of individuals with certain medical conditions). They may also need assistance in obtaining needed equipment, additional services, and transportation. Community-based nurses need a basic understanding of community, state, and federal resources to ensure that clients and their families have access to those necessary for them.

Key Concepts

- Family-centered care recognizes the concept of the family as the constant. The health and functioning ability of the family influences and impacts the health of the patient and other members of the family. Family-

centered care recognizes and respects family strengths and individuality, encourages referrals for family support, and facilitates collaboration. It ensures flexible, accessible, and responsive health care delivery while incorporating developmental needs and implementing policies to provide emotional and financial support to women, children, and their families.

- Health care delivery has moved from acute care settings out into the community, with an emphasis on health promotion and illness prevention. Community health nursing focuses on prevention and improvement of the health of populations and communities, addressing current and potential health needs of the population or community, promoting and preserving the health of a population regardless of a particular age group or diagnosis. Community health nurses perform epidemiologic investigations to help analyze and develop health policy and community health initiatives.
- Community-based nurses focus on providing personal care to individuals and families in the community. They center on promoting and preserving health as well as preventing disease or injury. They help women, children, and their families cope with illness and disease. Community-based nurses are direct care providers as well as advocators and educators. They focus on minimizing and removing barriers to allow the patient to develop to his or her full potential.
- Community-based nursing uses the nursing process in caring for patients within community settings and applies primary, secondary, and tertiary prevention levels. Nursing interventions in community-based settings include health screening, education, medication administration, telephone consultation, health system referral, instruction, nutritional counseling, and risk identification.
- Nurses working in the community need to develop cultural competence. Steps to gaining cultural competence include cultural self-awareness, cultural knowledge, cultural skills, and cultural encounters.
- Settings for community-based nursing including physicians' offices, clinics, health departments, urgent care centers, clients' homes, schools, camps, churches, and shelters such as abuse, homeless, and disaster shelters. Nurses provide both well, episodic ill care, and chronic care to women, children, and their families.
- There has been a rise in home health care due to shorter hospital stays and cost containment along with an increase in income and longevity of children with chronic and debilitating health conditions. Technology also has improved, which allows for better monitoring of patients at home and for performing complicated procedures at home.
- Roles and functions of the community-based nurse include communicator, direct care provider, educator, discharge planner and case manager, and advocate and resource manager.
- Open, honest lines of communication are essential for community-based nurses. The use of an interpreter may be necessary to ensure effective communication with women, children, and their families in the community setting. Maintaining confidentiality and privacy are key.
- A family's knowledge related to the patient's health or illness is vitally important. Nurses working in the community play a major role in educating women, children, and their families. For children, teaching is provided based on the child's developmental level.
- Discharge planning provides a comprehensive plan for the safe discharge of a client from a health care facility and for continuing safe and effective care in the community. Case management focuses on coordinating health care services while balancing quality and cost outcomes. Both contribute to improved transition from the hospital to the community for women, children, their families, and the health care team.
- Community-based nurses act as advocates and resource managers to help ensure that the patient and family have the necessary resources and appropriate health care services available to them.

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. A community-based nurse is involved in secondary prevention activities. Which activities might be included? Select all that apply.
   a. Fecal occult blood testing
   b. Hearing screening
   c. Smoking cessation program
   d. Cholesterol testing
   e. Hygiene program
   f. Pregnancy testing
2. A woman is to undergo a colonoscopy at a freestanding outpatient surgery center. Which would the nurse identify as a major disadvantage associated with this community-based setting?
   a. Increased risk for infection
   b. Increased health care costs
   c. Need to be transferred if overnight stay is required
   d. Increased disruption of family functioning
3. A 2-year-old boy is scheduled to undergo an endoscopic procedure. His parents are asking when they should tell him about it. Based on the nurse's understanding of the child's developmental stage, when would be the most appropriate time to prepare the child for the procedure?
   a. About 1 week before the scheduled date
   b. A few days in advance of the scheduled date
   c. About an hour before the procedure is to occur
   d. Just before the procedure is to be performed
4. When developing a teaching plan for a child and his parents, which action would the nurse do first?
   a. Decide which procedures and medications the child will be discharged on.
   b. Determine the child's and family's learning needs and styles.
   c. Ask the family if they have ever performed this type of procedure.
   d. Tell the child and family what the goals of the teaching session are.

CRITICAL THINKING EXERCISES

1. A 3-year-old girl from Saudi Arabia has become seriously ill while on a visit to the United States. It is projected that she will require a lengthy hospitalization. Describe the steps the nurse should take to communicate with and provide extensive health care teaching to this child's family.
2. A pregnant woman is discharged home from the hospital after admission due to preterm labor. The woman is to be on complete bed rest and will receive home health care through a local agency to assist her and her family and to monitor her health status. As the home health nurse assigned to this woman, what should your nursing assessment include?

STUDY ACTIVITIES

1. Describe health education topics that would be appropriate in a school setting for elementary students.
2. Shadow a nurse working in a community setting, such as a women's health clinic, birthing center, camp, home care, or health department. Identify the role the nurse plays in the health of women, children, and families in the setting and the community.
3. Arrange for a visit to a community health center that offers services to various cultural groups. Interview the staff about the strategies used to overcome communication barriers and different health care practices for the women and children in these groups.
4. Select one of the websites listed on page 70 and explore the information provided. How could a community-based nurse use this information?

UNIT TWO

Women's Health Throughout the Lifespan

This page intentionally left blank.

CHAPTER 3

Anatomy and Physiology of the Reproductive System

KEY TERMS

breasts
cervix
endometrium
estrogen
fallopian tubes
follicle-stimulating hormone (FSH)
luteinizing hormone (LH)
menarche
menstruation
ovaries
ovulation
penis
progesterone
testes
uterus
vagina
vulva

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms used in this chapter.
2. Explain the structure and function of the major external and internal female genital organs.
3. Outline the phases of the menstrual cycle, the dominant hormones involved, and the changes taking place in each phase.
4. Classify external and internal male reproductive structures and the function of each in hormonal regulation.

Linda, 49, started menstruating when she was 12 years old. Her menstrual periods have always been regular, but now she is experiencing irregular, heavier, and longer ones. She wonders if there is something wrong, or if this is normal.

Wow

All nurses should take care of and respect the human body, for it is a wondrous, precision machine.

The reproductive system consists of organs that function in the production of offspring. The female reproductive system produces the female reproductive cells (the eggs, or ova) and contains an organ (uterus) in which development of the fetus takes place; the male reproductive system produces the male reproductive cells (the sperm) and contains an organ (penis) that deposits the sperm within the female. Nurses need to have a thorough understanding of the anatomy and physiology of the male and female reproductive systems to be able to assess the health of these systems, to promote reproductive system health, to care for conditions that might affect the reproductive organs, and to provide client teaching concerning the reproductive system. This chapter will review the female and male reproductive systems and the menstrual cycle as it relates to reproduction.

Female Reproductive Anatomy and Physiology

The female reproductive system is composed of both external and internal reproductive organs.

External Female Reproductive Organs

The external female reproductive organs collectively are called the **vulva** (which means "covering" in Latin). The vulva serves to protect the urethral and vaginal openings and is highly sensitive to touch to increase the female's pleasure during sexual arousal (Coad & Dunstall, 2005). The structures that make up the vulva include the mons pubis, the labia majora and minora, the clitoris, the structures within the vestibule, and the perineum (Fig. 3.1).

Mons Pubis

The mons pubis is the elevated, rounded fleshy prominence over the symphysis pubis. This fatty tissue and skin is covered with pubic hair after puberty. It protects the symphysis pubis during sexual intercourse.

Labia

The labia majora (large lips), which are relatively large and fleshy, are comparable to the scrotum in males. The labia majora contain sweat and sebaceous (oil-secreting) glands; after puberty, they are covered with hair. Their function is to protect the vaginal opening. The labia minora (small lips) are the delicate hairless inner folds of skin; they can be very small or up to 2 inches wide. They lie just inside the labia majora and surround the openings to the vagina and urethra. The labia minora grow down from the anterior inner part of the labia majora on each side. They are highly vascular and abundant in nerve supply. They lubricate the vulva, swell in response to stimulation, and are highly sensitive.

Clitoris and Prepuce

The clitoris is a small, cylindrical mass of erectile tissue and nerves. It is located at the anterior junction of the labia minora. There are folds above and below the clitoris. The joining of the folds above the clitoris forms the prepuce, a hood-like covering over the clitoris; the junction below the clitoris forms the frenulum.

▶ *Take* NOTE!

The hood-like covering over the clitoris is the site for female circumcision, which is still practiced in some countries by some cultures.

A rich supply of blood vessels gives the clitoris a pink color. Like the penis, the clitoris is very sensitive to touch, stimulation, and temperature and can become erect. For its small size, it has a generous blood and nerve supply.

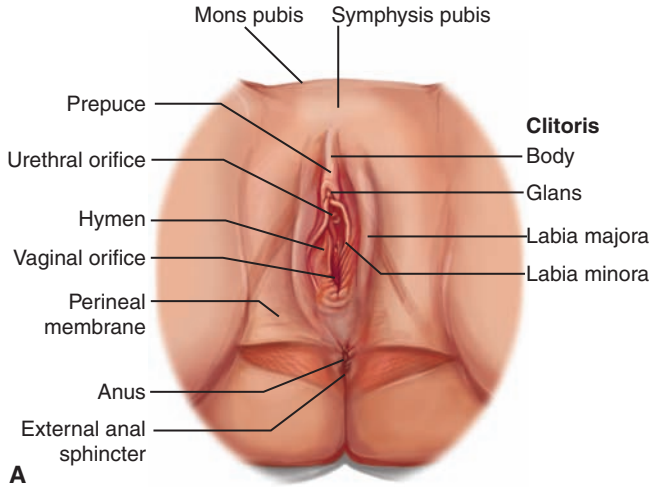

FIGURE 3.1 (**A**) The external female reproductive organs. (**B**) Normal appearance of external structures. (Photo by B. Proud.)

There are more free nerve endings of sensory reception located on the clitoris than on any other part of the body, and it is, unsurprisingly, the most erotically sensitive part of the genitalia for most females. Its function is sexual stimulation (Katz, 2007).

▶ *Take* NOTE!

The word "clitoris" is from the Greek word for key; in ancient times the clitoris was thought to be the key to a woman's sexuality.

Vestibule

The vestibule is an oval area enclosed by the labia minora laterally. It is inside the labia minora and outside of the hymen and is perforated by six openings. Opening into the vestibule are the urethra from the urinary bladder, the vagina, and two sets of glands. The opening to the vagina is called the introitus, and the half-moon–shaped area behind the opening is called the fourchette. Through tiny ducts beside the introitus, Bartholin's glands, when stimulated, secrete mucus that supplies lubrication for intercourse. Skene's glands are located on either side of the opening to the urethra. They secrete a small amount of mucus to keep the opening moist and lubricated for the passage of urine (Schuiling & Likis, 2006).

The vaginal opening is surrounded by the hymen (maidenhead). The hymen is a tough, elastic, perforated, mucosa-covered tissue across the vaginal introitus. In a virgin, the hymen may completely cover the opening, but it usually encircles the opening like a tight ring. Because the degree of tightness varies among women, the hymen may tear at the first attempt at intercourse, or it may be so soft and pliable that no tearing occurs. In a woman who is not a virgin, the hymen usually appears as small tags of tissue surrounding the vaginal opening, but the presence or absence of the hymen can neither confirm nor rule out sexual experience (Mattson & Smith, 2004).

▶ *Take* NOTE!

Heavy physical exertion, use of tampons, or injury to the area can alter the appearance of the hymen in girls and women who have not been sexually active.

Perineum

The perineum is the most posterior part of the external female reproductive organs. This external region is located between the vulva and the anus. It is made up of skin, muscle, and fascia. The perineum can become lacerated or incised during childbirth and may need to be repaired with sutures. Incising the perineum area to provide more space for the presenting part is called an episiotomy. Although still a common obstetric procedure, the use of episiotomy has decreased over the past 25 years. The procedure should be applied selectively rather than routinely. An episiotomy can add to postpartum discomfort and perineal trauma and can lead to fecal incontinence (Cunningham et al., 2005).

Internal Female Reproductive Organs

The internal female reproductive organs consist of the vagina, uterus, fallopian tubes, and ovaries. These structures develop and function according to the specific hormone influences that affect fertility and childbearing (Fig. 3.2).

Vagina

The **vagina** is a highly distensible musculomembranous canal situated in front of the rectum and behind the bladder. It is a tubular, fibromuscular organ lined with mucous membrane that lies in a series of transverse folds called rugae. The rugae allow for extreme dilatation of the canal during labor and birth. The vagina is a canal that connects the external genitals to the uterus. It receives the penis and the sperm ejaculated during sexual intercourse, and it serves as an exit passageway for menstrual blood and for the fetus during childbirth. The front and back walls normally touch each other so that there is no space in the vagina except when it is opened (e.g., during a pelvic examination or intercourse). In the adult, the vaginal cavity is 3 to 4 inches long. Muscles that control its diameter surround the lower third of the vagina. The upper two thirds of the vagina lies above these muscles and can be stretched easily. During a woman's reproductive years, the mucosal lining of the vagina has a corrugated appearance and is resistant to bacterial colonization. Before puberty and after menopause (if the woman is not taking estrogen), the mucosa is smooth due to lower levels of estrogen (Dorland, 2007).

The vagina has an acidic environment, which protects it against ascending infections. Antibiotic therapy, douching, perineal hygiene sprays, and deodorants upset the acid balance within the vaginal environment and can predispose women to infections.

Uterus

The **uterus** is a pear-shaped muscular organ at the top of the vagina. It lies behind the bladder and in front of the rectum and is anchored in position by eight ligaments, although it is not firmly attached or adherent to any part of the skeleton. A full bladder tilts the uterus backward; a distended rectum tilts it forward. The uterus alters its position by gravity or with change of posture, and is the size and shape of an inverted pear. It is the site of menstruation, implantation of a fertilized ovum, development of the fetus during pregnancy, and labor. Before the first pregnancy, it measures approximately 3 inches long, 2 inches wide, and 1 inch thick. After a pregnancy, the uterus remains larger than before the pregnancy. After menopause, it becomes smaller and atrophies.

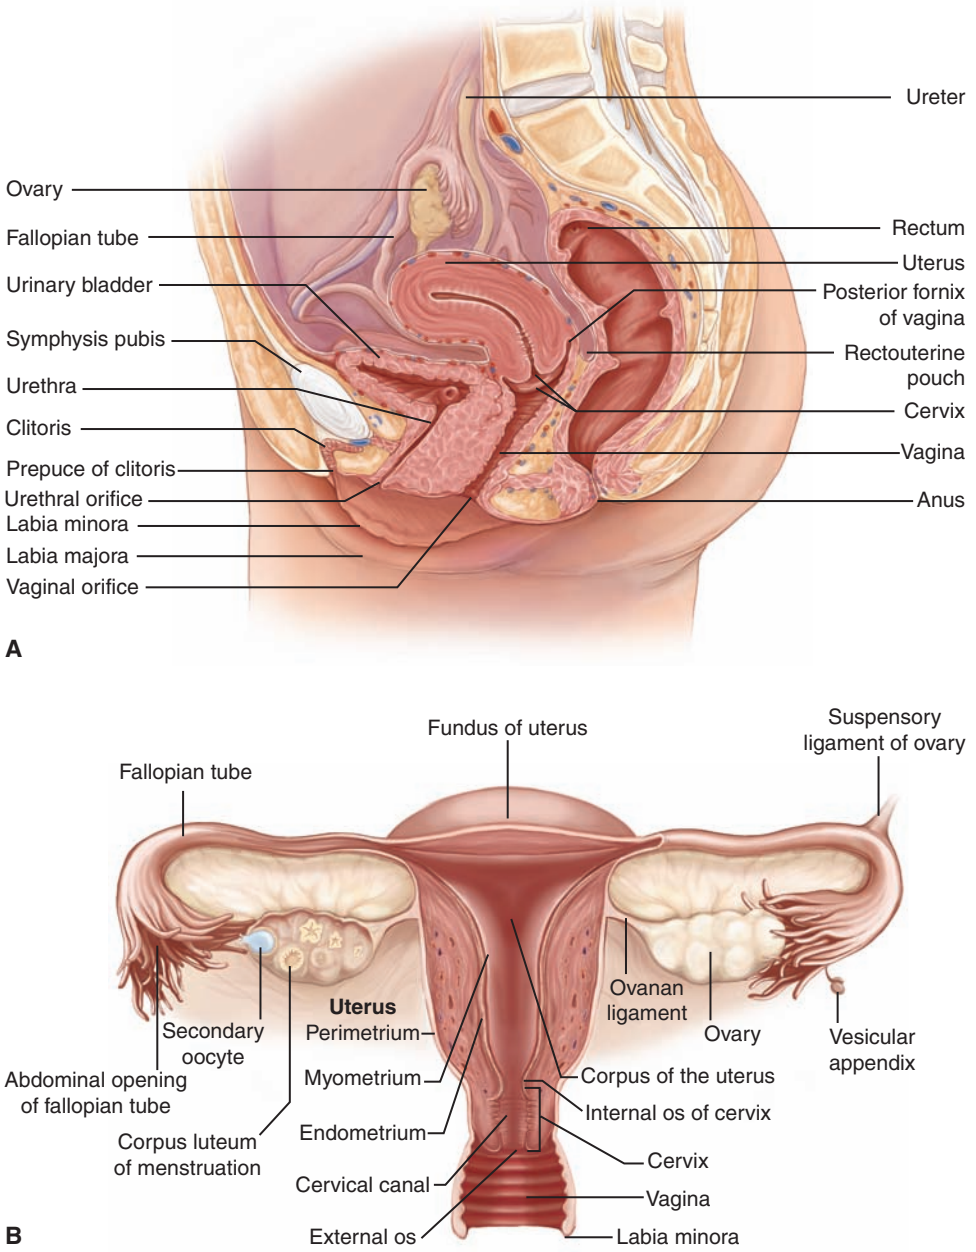

FIGURE 3.2 The internal female reproductive organs. (**A**) Lateral view. (**B**) Anterior view. (Source: Anatomical Chart Company [2001]. *Atlas of human anatomy.* Springhouse, PA: Springhouse.)

The uterine wall is relatively thick and composed of three layers: the endometrium (innermost layer), the myometrium (muscular middle layer), and the perimetrium (outer serosal layer that covers the body of the uterus). The **endometrium** is the mucosal layer that lines the uterine cavity in nonpregnant women. It varies in thickness from 0.5 mm to 5 mm and has an abundant supply of glands and blood vessels (Cunningham et al., 2005). The myometrium makes up the major portion of the uterus and is composed of smooth muscle linked by connective tissue with numerous elastic fibers. During pregnancy, the upper myometrium undergoes marked hypertrophy, but there is limited change in the cervical muscle content.

Anatomic subdivisions of the uterus include the convex portion above the uterine tubes (the fundus); the central portion (the corpus or body) between the fundus and the cervix; and the cervix, or neck, which opens into the vagina.

Cervix

The **cervix**, the lower part of the uterus, opens into the vagina and has a channel that allows sperm to enter the uterus and menstrual discharge to exit. It is composed of fibrous connective tissue. During a pelvic examination, the part of the cervix that protrudes into the upper end of the vagina can be visualized. Like the vagina, this part of the cervix is covered by mucosa, which is smooth, firm, and doughnut-shaped, with a visible central opening called the external os (Fig. 3.3). Before childbirth, the external cervical os is a small, regular, oval opening.

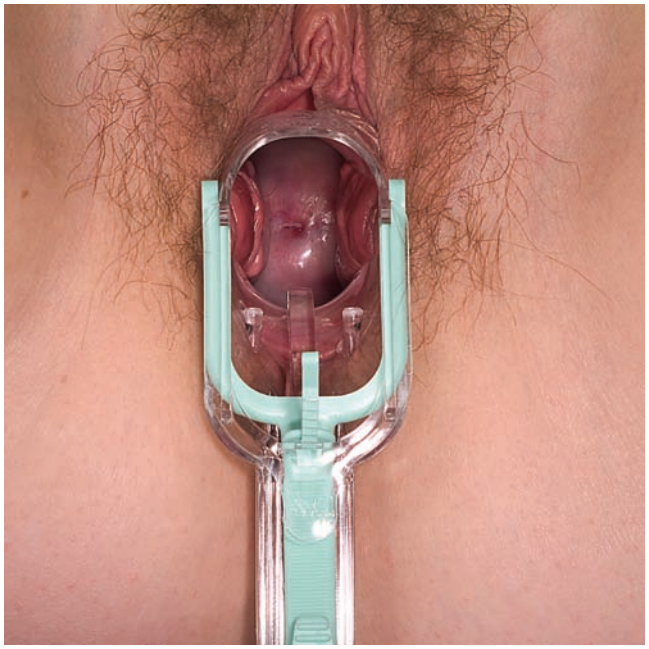

FIGURE 3.3 Appearance of normal cervix. Note: This is the cervix of a multipara female. (Photo by B. Proud.)

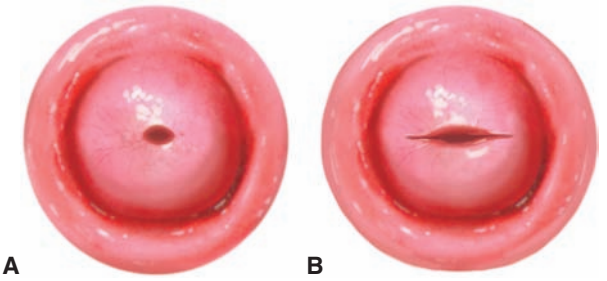

FIGURE 3.4 (**A**) Nulliparous cervical os. (**B**) Parous cervical os.

After childbirth, the opening is converted into a transverse slit that resembles lips (Fig. 3.4). Except during menstruation or ovulation, the cervix is usually a good barrier against bacteria. The cervix has an alkaline environment, which protects the sperm from the acidic environment in the vagina.

The canal or channel of the cervix is lined with mucus-secreting glands. This mucus is thick and impenetrable to sperm until just before the ovaries release an egg (**ovulation**). At ovulation, the consistency of the mucus changes so that sperm can swim through it, allowing fertilization. At the same time, the mucus-secreting glands of the cervix actually become able to store live sperm for 2 or 3 days. These sperm can later move up through the corpus and into the fallopian tubes to fertilize the egg; thus, intercourse 1 or 2 days before ovulation can lead to pregnancy. Because some women do not ovulate consistently, pregnancy can occur at varying times after the last menstrual period. The channel in the cervix is too narrow for the fetus to pass through during pregnancy, but during labor it stretches to let the newborn through.

Corpus

The corpus, or the main body of the uterus, is a highly muscular organ that enlarges to hold the fetus during pregnancy. The inner lining of the corpus (endometrium) undergoes cyclic changes as a result of the changing levels of hormones secreted by the ovaries: it is thickest during the part of the menstrual cycle in which a fertilized egg would be expected to enter the uterus and is thinnest just after menstruation. If fertilization does not take place during this cycle, most of the endometrium is shed and bleeding occurs, resulting in the monthly period. If fertilization does take place, the embryo attaches to the wall of the uterus, where it becomes embedded in the endometrium (about 1 week after fertilization); this process is called implantation (Heffner & Schust, 2006). Menstruation then ceases during the 40 weeks (280 days) of pregnancy. During labor, the muscular walls of the corpus contract to push the baby through the cervix and into the vagina.

Fallopian Tubes

The **fallopian tubes** are hollow, cylindrical structures that extend 2 to 3 inches from the upper edges of the uterus toward the ovaries. Each tube is about 7 to 10 cm long (4 inches) and approximately 0.7 cm in diameter. The end of each tube flares into a funnel shape, providing a large opening for the egg to fall into when it is released from the ovary. Cilia (beating, hair-like extensions on cells) line the fallopian tube and the muscles in the tube's wall. The fallopian tubes convey the ovum from the ovary to the uterus and sperm from the uterus toward the ovary. This movement is accomplished via ciliary action and peristalsis. If sperm is present in the fallopian tube as a result of sexual intercourse or artificial insemination, fertilization of the ovum can occur in the distal portion of the tube. If the egg is fertilized, it will divide over a period of 4 days while it moves slowly down the fallopian tube and into the uterus.

Ovaries

The **ovaries** are a set of paired glands resembling unshelled almonds set in the pelvic cavity below and to either side of the umbilicus. They are usually pearl-colored and oblong. They are homologous to the testes. Each ovary weighs from 2 to 5 grams and is about 4 cm long, 2 cm wide, and 1 cm thick (Speroff & Fritz, 2005). The ovaries are not attached to the fallopian tubes but are suspended nearby from several ligaments, which help hold them in position. The development and the release of the ovum and the secretion of the hormones estrogen and progesterone are the two primary functions of the ovary. The ovaries link

the reproductive system to the body's system of endocrine glands, as they produce the ova (eggs) and secrete, in cyclic fashion, the female sex hormones estrogen and progesterone. After an ovum matures, it passes into the fallopian tubes.

Breasts

The two mammary glands, or **breasts**, are accessory organs of the female reproductive system that are specialized to secrete milk following pregnancy. They overlie the pectoralis major muscles and extend from the second to the sixth ribs and from the sternum to the axilla. Each breast has a nipple located near the tip, which is surrounded by a circular area of pigmented skin called the areola. Each breast is composed of approximately 9 lobes (the number can range between 4 and 18), which contain glands (alveolar) and a duct (lactiferous) that leads to the nipple and opens to the outside (Fig. 3.5). The lobes are separated by dense connective and adipose tissues, which also help support the weight of the breasts (Ramsay, Kent, Hartmann & Hartmann, 2005).

During pregnancy, placental estrogen and progesterone stimulate the development of the mammary glands. Because of this hormonal activity, the breasts may double in size during pregnancy. At the same time, glandular tissue replaces the adipose tissue of the breasts.

Following childbirth and the expulsion of the placenta, levels of placental hormones (progesterone and lactogen) fall rapidly, and the action of prolactin (milk-producing hormone) is no longer inhibited. Prolactin stimulates the production of milk within a few days after childbirth, but in the interim, a dark yellow fluid called colostrum is secreted. Colostrum contains more minerals and protein, but less sugar and fat, than mature breast milk. Colostrum secretion may continue for approximately a week after childbirth, with gradual conversion to mature milk. Colostrum is rich in maternal antibodies, especially immunoglobulin A (IgA), which offers protection for the newborn against enteric pathogens.

Female Sexual Response

With sexual stimulation, tissues in the clitoris and breasts and around the vaginal orifice fill with blood and the erectile tissues swell. At the same time, the vagina begins to expand and elongate to accommodate the penis. As part of the whole vasocongestive reaction, the labia majora and minor swell and darken. As sexual stimulation intensifies, the vestibular glands secrete mucus to moisten and lubricate the tissues to facilitate insertion of the penis.

Hormones play an integral role in the female sexual response as well. Adequate estrogen and testosterone must be available for the brain to sense incoming arousal stimuli. Research indicates that estrogen preserves the vascular function of female sex organs and affects genital sensation. It also is believed to promote blood flow to these areas during stimulation. Testosterone is thought to be the hormone of sexual desire in women (McKinney, 2007).

The zenith of intense stimulation is orgasm, the spasmodic and involuntary contractions of the muscles in the region of the vulva, the uterus, and the vagina that produce a pleasurable sensation to the woman. Typically the woman feels warm and relaxed after an orgasm. Within a short time after orgasm, the two physiologic mechanisms that created the sexual response, vasocongestion and muscle contraction, rapidly dissipate.

The Female Reproductive Cycle

The female reproductive cycle is a complex process that encompasses an intricate series of chemical secretions and reactions to produce the ultimate potential for fertility and birth. The female reproductive cycle is a general term encompassing the ovarian cycle, the endometrial cycle, the hormonal changes that regulate them, and the cyclical changes in the breasts. The endometrium, ovaries, pituitary gland, and hypothalamus are all involved in the cyclic changes that help to prepare the body for fertilization. Absence of fertilization results in menstruation, the monthly shedding of the uterine lining. Menstruation

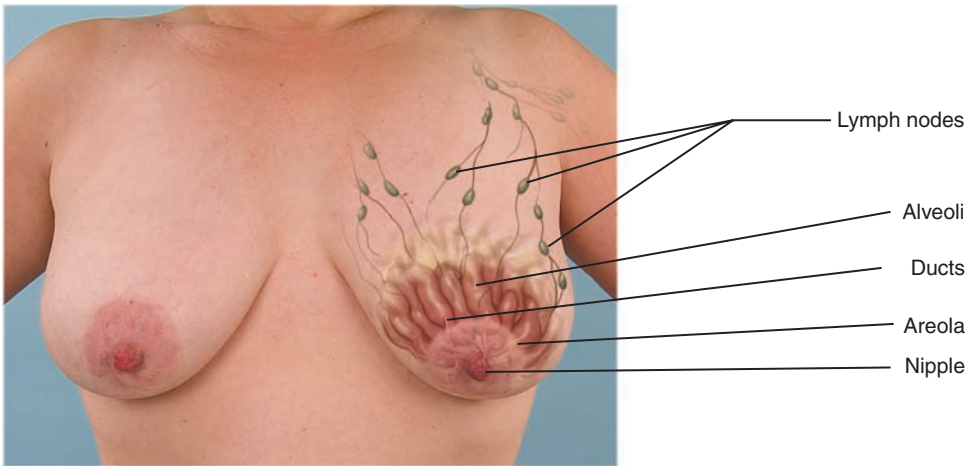

FIGURE 3.5 Anatomy of the breasts. (Photo by B. Proud.)

marks the beginning and end of each menstrual cycle. Menopause is the naturally occurring cessation of regular menstrual cycles.

Menstruation

Menstruation is the normal, predictable physiologic process whereby the inner lining of the uterus (endometrium) is expelled by the body. Typically, this occurs monthly. Menstruation has many effects on girls and women, including emotional and self-image issues. In the United States, the average age at **menarche** (the start of menstruation in females) is 12.8 years, with a range between 8 and 18. Genetics is the most important factor in determining the age at which menarche starts, but geographic location, nutrition, weight, general health, nutrition, and psychological factors are also important (Shelby & Ruocco, 2007). Pubertal events preceding the first menses have an orderly progression: thelarche, the development of breast buds; adrenarche, the appearance of pubic and then axillary hair, followed by a growth spurt; and menarche (occurring about 2 years after the start of breast development). In healthy pubertal girls, the menstrual period varies in flow heaviness and may remain irregular in occurrence for up to 2 years following menarche. After that time, the regular menstrual cycle should be established. Most women will experience 300 to 400 menstrual cycles within their lifetime (Diaz, Laufer & Breech, 2006). Normal, regular menstrual cycles vary in frequency from 21 to 36 days (with the average cycle lasting 28 days), bleeding lasts 3 to 7 days, and blood loss averages 20 to 80 mL (Schuiling & Likis, 2006). Irregular menses can be associated with irregular ovulation, stress, disease, and hormonal imbalances (Cunningham et al., 2005).

Think back to Linda, who was introduced at the beginning of the chapter. What questions might need to be asked to assess her condition? What laboratory work might be anticipated to validate her heavier flow?

Although menstruation is a normal process, various world cultures have taken a wide variety of attitudes toward it, seeing it as everything from a sacred time to an unclean time. In a society where menstruation is viewed negatively, nurses can help women develop a more positive image of this natural physiologic process.

▶ *Take* NOTE!

Knowledge about menstruation has increased significantly and attitudes have changed since early times, when many cultures saw it as "unclean." What was once discussed only behind closed doors is discussed openly today.

Reproductive Cycle

The reproductive cycle, also referred to as the menstrual cycle, results from a functional hypothalamic–pituitary–ovarian axis and a precise sequencing of hormones that lead to ovulation. If conception doesn't occur, menses ensues. The ranges of normal menstrual cycles are as follows:

- Cycle length: 21 to 36 days
- Duration of flow: 3 to 7 days
- Amount of flow: 20 to 80 mL

The female reproductive cycle involves two cycles that occur simultaneously: the ovarian cycle, during which ovulation occurs, and the endometrial cycle, during which menstruation occurs. Ovulation divides these two cycles at midcycle. Ovulation occurs when the ovum is released from its follicle; after leaving the ovary, the ovum enters the fallopian tube and journeys toward the uterus. If sperm fertilizes the ovum during its journey, pregnancy occurs. Figure 3.6 summarizes the menstrual cycle.

Ovarian Cycle

The ovarian cycle is the series of events associated with a developing oocyte (ovum or egg) within the ovaries. While men manufacture sperm daily, often into advanced age, women are born with a single lifetime supply of ova that are released from the ovaries gradually throughout the childbearing years. In the female ovary, 2 million oocytes are present at birth, and about 400,000 follicles are still present at puberty. The excess follicles are depleted during the childbearing years, with only 400 follicles ovulated during the reproductive period (Speroff & Fritz, 2005). The ovarian cycle begins when the follicular cells (ovum and surrounding cells) swell and the maturation process starts. The maturing follicle at this stage is called a graafian follicle. The ovary raises many follicles monthly, but usually only one follicle matures to reach ovulation. The ovarian cycle consists of three phases: the follicular phase, ovulation, and the luteal phase.

Follicular Phase

This phase is so named because it is when the follicles in the ovary grow and form a mature egg. This phase starts on day 1 of the menstrual cycle and continues until ovulation, approximately 10 to 14 days later. The follicular phase is not consistent in duration because of the time variations in follicular development. These variations account for the differences in menstrual cycle lengths (Hackley, Kriebs & Rousseau, 2007). The hypothalamus is the initiator of this phase. Increasing levels of estrogen secreted from the maturing follicular cells and the continued growth of the dominant follicle cell induce proliferation of the endometrium and myometrium. This thickening of the uterine lining supports an implanted ovum if pregnancy occurs.

Prompted by the hypothalamus, the pituitary gland releases follicle-stimulating hormone (FSH), which stimulates the ovary to produce 5 to 20 immature follicles. Each follicle houses an immature oocyte or egg. The follicle that

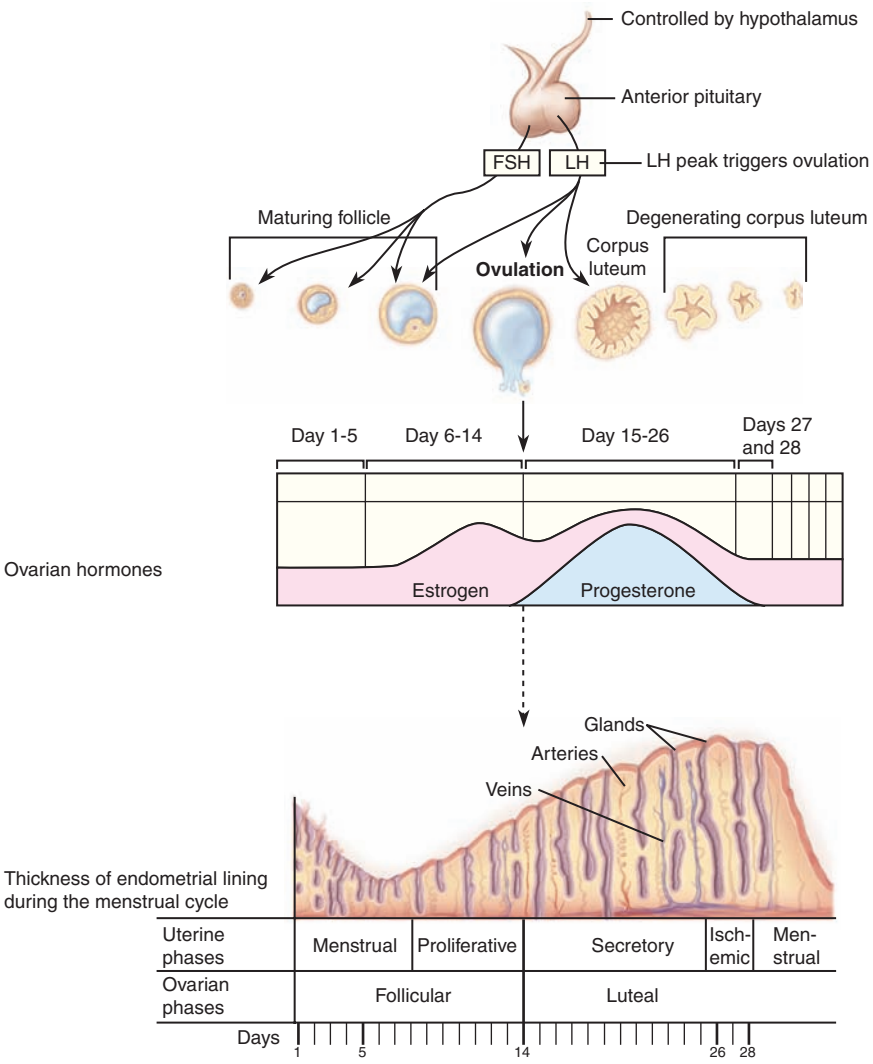

FIGURE 3.6 Menstrual cycle summary based on a 28-day (average) menstrual cycle.

is targeted to mature fully will soon rupture and expel a mature oocyte in the process of ovulation. A surge in luteinizing hormone (LH) from the anterior pituitary gland is actually responsible for affecting the final development and subsequent rupture of the mature follicle.

Ovulation

At ovulation, a mature follicle ruptures in response to a surge of LH, releasing a mature oocyte (ovum). This usually occurs on day 14 in a 28-day cycle. When ovulation occurs, there is a drop in estrogen. Typically ovulation takes place approximately 10 to 12 hours after the LH peak and 24 to 36 hours after estrogen levels peak (Speroff & Fritz, 2005). The distal ends of the fallopian tubes become active near the time of ovulation and create currents that help carry the ovum into the uterus. The lifespan of the ovum is only about 24 hours; unless it meets a sperm on its journey within that time, it will die.

During ovulation, the cervix produces thin, clear, stretchy, slippery mucus that is designed to help the sperm travel up through the cervix to meet the ovum for fertilization. The one constant, whether a women's cycle is 28 days or 120 days, is that ovulation takes place 14 days before menstruation (Shelby & Ruocco, 2007).

▶ **Take** NOTE!

Some women can feel a pain on one side of the abdomen around the time the egg is released. This midcycle pain is called mittelschmerz.

Luteal Phase

The luteal phase begins at ovulation and lasts until the menstrual phase of the next cycle. It typically occurs day 15 through day 28 of a 28-day cycle. After the follicle ruptures as it releases the egg, it closes and forms a corpus luteum. The corpus luteum secretes increasing amounts of the hormone progesterone, which interacts with the endometrium to prepare it for implantation. At the beginning of the luteal phase, progesterone induces

the endometrial glands to secrete glycogen, mucus, and other substances. These glands become tortuous and have large lumens due to increased secretory activity. The progesterone secreted by the corpus luteum causes the temperature of the body to rise slightly until the start of the next period. A significant increase in temperature, usually 0.5 to 1 degrees Fahrenheit, is generally seen within a day or two after ovulation has occurred; the temperature remains elevated for 12 to 16 days, until menstruation begins (Chandran, 2007). This rise in temperature can be plotted on a graph and gives an indication of when ovulation has occurred. In the absence of fertilization, the corpus luteum begins to degenerate and consequently ovarian hormone levels decrease. As estrogen and progesterone levels decrease, the endometrium undergoes involution. In a 28-day cycle, menstruation then begins approximately 14 days after ovulation in the absence of pregnancy. FSH and LH are generally at their lowest levels during the luteal phase and highest during the follicular phase.

▸ *Consider* THIS!

We had been married 2 years when my husband and I decided to start a family. I began thinking back to my high-school biology class and tried to remember about ovulation and what to look for. I also used the Internet to find the answers I was seeking. As I was reading, it all started to come into place. During ovulation, a woman's cervical mucus increases and she experiences a wet sensation for several days midcycle. The mucus also becomes stretchable during this time. In addition, body temperature rises slightly and then falls if no conception takes place. Armed with this knowledge, I began to check my temperature daily before arising and began to monitor the consistency of my cervical mucus. I figured that monitoring these two signs of ovulation could help me discover the best time to conceive. After 6 months of trying without results, I wondered what I was doing wrong. Did I really understand my body's reproductive activity?

What additional suggestions might the nurse offer this woman in her journey to conception? What community resources might be available to assist this couple? How does knowledge of the reproductive system help nurses take care of couples who are trying to become pregnant?

Endometrial Cycle

The endometrial cycle occurs in response to cyclic hormonal changes. The four phases of the endometrial cycle are the proliferative phase, secretory phase, ischemic phase, and menstrual phase.

Proliferative Phase

The proliferative phase starts with enlargement of the endometrial glands in response to increasing amounts of estrogen. The blood vessels become dilated and the endometrium increases in thickness dramatically from 0.5 to 5 mm in height and increases eight-fold in thickness in preparation for implantation of the fertilized ovum (Heffner & Schust, 2006). Cervical mucus becomes thin, clear, stretchy, and more alkaline, making it more favorable to sperm to enhance the opportunity for fertilization. The proliferative phase starts on about day 5 of the menstrual cycle and lasts to the time of ovulation. This phase depends on estrogen stimulation resulting from ovarian follicles, and this phase coincides with the follicular phase of the ovarian cycle.

Secretory Phase

The secretory phase begins at ovulation to about 3 days before the next menstrual period. Under the influence of progesterone released by the corpus luteum after ovulation, the endometrium becomes thickened and more vascular (growth of the spiral arteries) and glandular (secreting more glycogen and lipids). These dramatic changes are all in preparation for implantation, if it were to occur. This phase typically lasts from day 15 (after ovulation) to day 28 and coincides with the luteal phase of the ovarian cycle. The secretory phase doesn't take place if ovulation has not occurred.

Ischemic Phase

If fertilization does not occur, the ischemic phase begins. Estrogen and progesterone levels drop sharply during this phase as the corpus luteum starts to degenerate. Changes in the endometrium occur with spasm of the arterioles, resulting in ischemia of the basal layer. The ischemia leads to shedding of the endometrium down to the basal layer, and menstrual flow begins.

Menstrual Phase

The menstrual phase begins as the spiral arteries rupture secondary to ischemia, releasing blood into the uterus, and the sloughing of the endometrial lining begins. If fertilization does not take place, the corpus luteum degenerates. As a result, both estrogen and progesterone levels fall and the thickened endometrial lining sloughs away from the uterine wall and passes out via the vagina. The beginning of the menstrual flow marks the end of one menstrual cycle and the start of a new one. Most women report bleeding for an average of 3 to 7 days. The amount of menstrual flow varies, but approximately 6 to 8 ounces in volume per cycle is average (Alexander et al., 2007).

Menstrual Cycle Hormones

The menstrual cycle involves a complex interaction of hormones. The predominant hormones include gonadotropin-releasing hormone, FSH, LH, estrogen, progesterone, and prostaglandins. Box 3.1 summarizes menstrual cycle hormones.

BOX 3.1 Summary of Menstrual Cycle Hormones

- Luteinizing hormone (LH) rises and stimulates the follicle to produce estrogen.
- As estrogen is produced by the follicle, estrogen levels rise, inhibiting the output of LH.
- Ovulation occurs after an LH surge damages the estrogen-producing cells, resulting in a decline in estrogen.
- The LH surge results in establishment of the corpus luteum, which produces estrogen and progesterone.
- Estrogen and progesterone levels rise, suppressing LH output.
- Lack of LH promotes degeneration of the corpus luteum.
- Cessation of the corpus luteum means a decline in estrogen and progesterone output.
- The decline of the ovarian hormones ends their negative effect on the secretion of LH.
- LH is secreted, and the menstrual cycle begins again.

Gonadotropin-Releasing Hormone

Gonadotropin-releasing hormone (GnRH) is secreted from the hypothalamus in a pulsatile manner throughout the reproductive cycle. It pulsates slowly during the follicular phase and increases during the luteal phase. GnRH induces the release of FSH and LH to assist with ovulation.

Follicle-Stimulating Hormone

Follicle-stimulating hormone (FSH) is secreted by the anterior pituitary gland and is primarily responsible for the maturation of the ovarian follicle. FSH secretion is highest and most important during the first week of the follicular phase of the reproductive cycle.

Luteinizing Hormone

Luteinizing hormone (LH) is secreted by the anterior pituitary gland and is required for both the final maturation of preovulatory follicles and luteinization of the ruptured follicle. As a result, estrogen production declines and progesterone secretion continues. Thus, estrogen levels fall a day before ovulation, and progesterone levels begin to rise.

Estrogen

Estrogen is secreted by the ovaries and is crucial for the development and maturation of the follicle. Estrogen is predominant at the end of the proliferative phase, directly preceding ovulation. After ovulation, estrogen levels drop sharply as progesterone dominates. In the endometrial cycle, estrogen induces proliferation of the endometrial glands. Estrogen also causes the uterus to increase in size and weight because of increased glycogen, amino acids, electrolytes, and water. Blood supply is expanded as well.

Progesterone

Progesterone is secreted by the corpus luteum. Progesterone levels increase just before ovulation and peak 5 to 7 days after ovulation. During the luteal phase, progesterone induces swelling and increased secretion of the endometrium. This hormone is often called the hormone of pregnancy because of its calming effect (reduces uterine contractions) on the uterus, allowing pregnancy to be maintained.

Prostaglandins

Prostaglandins are a closely related group of oxygenated fatty acids that are produced by the endometrium, with a variety of effects throughout the body. Although they have regulatory effects and are sometimes called hormones, prostaglandins are not technically hormones because they are produced by all tissues rather than by special glands (Speroff & Fritz, 2005). Prostaglandins increase during follicular maturation and play a key role in ovulation by freeing the ovum inside the graafian follicle. Large amounts of prostaglandins are found in menstrual blood. Research is ongoing as to the various roles prostaglandins have on the menstrual cycle (Cunningham et al., 2005).

Menopause

Perimenopause and menopause are biologic markers of the transition from young adulthood to middle age. Neither of these is a symptom or disease, but rather a natural maturing of the reproductive system.

During the perimenopausal years (2 to 8 years prior to menopause) women may experience physical changes associated with decreasing estrogen levels, which may include vasomotor symptoms of hot flashes, irregular menstrual cycles, sleep disruptions, forgetfulness, irritability, mood disturbances, decreased vaginal lubrication, fatigue, vaginal atrophy, and depression (Shifren & Schiff, 2007).

Menopause refers to the cessation of regular menstrual cycles. This naturally occurring phase of every woman's life marks the end of menstruation and childbearing capacity. The average age of natural menopause—defined as 1 year without a menstrual period—is 51 (Alexander et al., 2007). As the average life expectancy for women increases, the number of women reaching and living in menopause has escalated. Most women can expect to spend more than one third of their lives beyond menopause. It is usually marked by atrophy of the breasts, uterus, fallopian tubes, and ovaries (Curran & Bachmann, 2006).

Many women pass through menopause without untoward symptoms. These women remain active and in good health with little interruption of their daily routines. Other women experience vasomotor symptoms, which give rise to sensations of heat, cold, sweating, headache, insomnia,

and irritability (Kessenich, 2007). Until recently, hormone therapy was the mainstay of menopause pharmacotherapy, but with the recent results of the Women's Health Initiative trial, the use of hormone therapy has become controversial. Many women have turned to nontraditional remedies to manage their menopausal symptoms. Common herbal remedies used include Dong Quai, black cohosh, melatonin, ginseng, and St. John's wort. Research to validate their efficacy, safety, and potential harmful effects is lacking at this time, and much of the efficacy is largely anecdotal (Kessenich, 2007). Nurses can play a major role in assisting menopausal women by educating and counseling them about the multitude of options available for disease prevention, treatment for menopausal symptoms, and health promotion during this time of change in their lives. Menopause should be an opportunity for women to strive for a healthy, long life, and nurses can help to make this opportunity a reality. (See Chapter 4 for more information about menopause.)

Recall Linda, who was experiencing changes in her menstrual patterns. Which hormones might be changing, and which systems might they affect? What approach should the nurse take to enlighten Linda about what is happening to her?

Male Reproductive Anatomy and Physiology

The male reproductive system, like that of the female, consists of those organs that facilitate reproduction. The male organs are specialized to produce and maintain the male sex cells, or sperm; to transport them, along with supporting fluids, to the female reproductive system; and to secrete the male hormone testosterone. The organs of the male reproductive system include the two testes (where sperm cells and testosterone are made), the penis, the scrotum, and the accessory organs (epididymis, vas deferens, seminal vesicles, ejaculatory duct, urethra, bulbourethral glands, and prostate gland).

External Male Reproductive Organs

The penis and the scrotum form the external genitalia in the male (Fig. 3.7).

Penis

The **penis** is the organ for copulation and serves as the outlet for both sperm and urine. The skin of the penis is thin, with no hairs. The prepuce (foreskin) is a circular fold of skin that extends over the glans unless it is removed by circumcision shortly after birth. The urinary meatus, located at the tip of the penis, serves as the external opening to the urethra (Fig. 3.8). The penis is composed mostly of erectile tissue. Most of the body of the penis consists of three cylindrical spaces (sinuses) of erectile tissue. The two larger

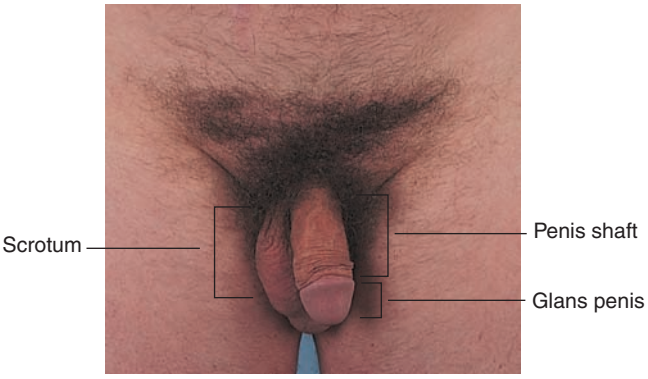

FIGURE 3.7 The external male reproductive organs. (Photo by B. Proud.)

ones, the corpora cavernosa, are side by side. The third sinus, the corpus spongiosum, surrounds the urethra. Erection results when nerve impulses from the autonomic nervous system dilate the arteries of the penis, allowing arterial blood to flow into the erectile tissues of the organ.

Scrotum

The scrotum is the thin-skinned sac that surrounds and protects the testes. The scrotum also acts as a climate-control system for the testes, because they need to be slightly cooler than body temperature to allow normal sperm development. The cremaster muscles in the scrotal wall relax or contract to allow the testes to hang farther from the body to cool or to be pulled closer to the body for warmth or protection (Ceo, 2006). A medial septum divides the scrotum into two chambers, each of which encloses a testis.

Internal Male Reproductive Organs

The internal structures include the testes, the ductal system, and accessory glands (Fig. 3.9).

FIGURE 3.8 The urinary meatus. (Photo by B. Proud.)

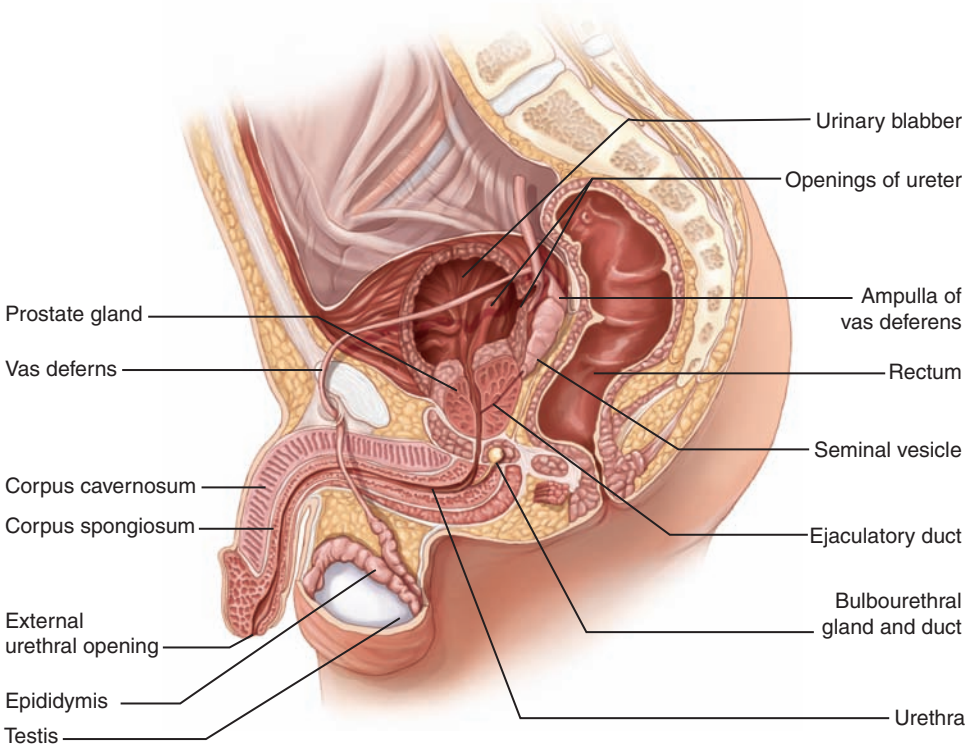

FIGURE 3.9 Lateral view of the internal male reproductive organs. (Source: Anatomical Chart Company. [2001]. *Atlas of human anatomy.* Springhouse, PA: Springhouse.)

Testes

The **testes** are oval bodies the size of large olives that lie in the scrotum; usually the left testis hangs a little lower than the right one. The testes have two functions: producing sperm and synthesizing testosterone (the primary male sex hormone). Sperm is produced in the seminiferous tubules of the testes. Similar to the female reproductive system, the anterior pituitary releases the gonadotropins, FSH and LH. These hormones stimulate the testes to produce testosterone, which assists in maintaining spermatogenesis, increases sperm production by the seminiferous tubules, and stimulates production of seminal fluid (London, Ladewig, Ball & Bindler 2007). The epididymis, which lies against the testes, is a coiled tube almost 20 feet long. It collects sperm from the testes and provides the space and environment for sperm to mature (Fig. 3.10).

The Ductal System

The vas deferens is a cordlike duct that transports sperm from the epididymis. One such duct travels from each testis up to the back of the prostate and enters the urethra to form the ejaculatory ducts. Other structures, such as blood vessels and nerves, also travel along with each vas deferens and together form the spermatic cord. The urethra is the terminal duct of the reproductive and urinary systems, serving as a passageway for semen (fluid containing sperm) and urine. It passes through the prostate gland and the penis and opens to the outside.

Accessory Glands

The seminal vesicles, which produce nutrient seminal fluid, and the prostate gland, which produces alkaline prostatic fluid, are both connected to the ejaculatory duct leading into the urethra. The paired seminal vesicles are

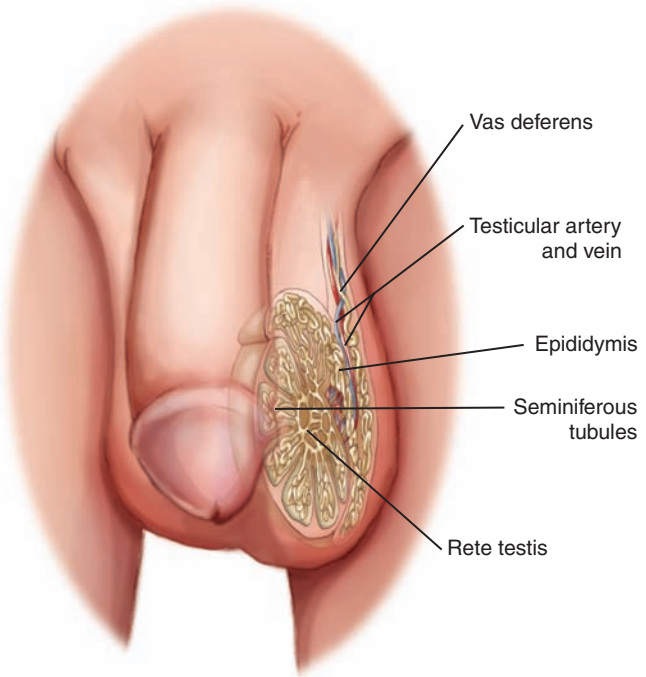

FIGURE 3.10 Internal structures of a testis.

convoluted pouch-like structures lying posterior to, and at the base of, the urinary bladder in front of the rectum. They secrete an alkaline fluid that contains fructose and prostaglandins. The fructose supplies energy to the sperm on its journey to meet the ovum, and the prostaglandins assist in sperm mobility.

The prostate gland lies just under the bladder in the pelvis and surrounds the middle portion of the urethra. Usually the size of a walnut, this gland enlarges with age. The prostate and the seminal vesicles above it produce fluid that nourishes the sperm. This fluid provides most of the volume of semen, the secretion in which the sperm is expelled during ejaculation. Other fluid that makes up the semen comes from the vas deferens and from mucous glands in the head of the penis.

The bulbourethral glands (Cowper's glands) are two small structures about the size of peas, located inferior to the prostate gland. They are composed of several tubes whose epithelial linings secrete a mucus-like fluid. It is released in response to sexual stimulation and lubricates the head of the penis in preparation for sexual intercourse. Their existence is said to be constant, but they gradually diminish in size with advancing age.

Male Sexual Response

With sexual stimulation, the arteries leading to the penis dilate and increase blood flow into erectile tissues. At the same time, the erectile tissue compresses the veins of the penis, reducing blood flow away from the penis. Blood accumulates, causing the penis to swell and elongate and producing an erection. As in women, the culmination of sexual stimulation is an orgasm, a pleasurable feeling of physiologic and psychological release.

Orgasm is accompanied by emission (movement of sperm from the testes and fluids from the accessory glands) into the urethra, where it is mixed to form semen. As the urethra fills with semen, the base of the erect penis contracts, which increases pressure and forces the semen through the urethra to the outside (ejaculation). During ejaculation, the ducts of the testes, epididymis, and vas deferens contract, causing expulsion of sperm into the urethra, where the sperm mixes with the seminal and prostatic fluids. These substances, together with mucus secreted by accessory glands, form the semen, which is discharged from the urethra.

Key Concepts

- The female reproductive system produces the female reproductive cells (the eggs, or ova) and contains an organ (uterus) where the fetus develops. The male reproductive system produces the male reproductive cells (the sperm) and contains an organ (penis) that deposits the sperm within the female.
- The internal female reproductive organs consist of the vagina, the uterus, the fallopian tubes, and the ovaries. The external female reproductive organs make up the vulva. These include the mons pubis, the labia majora and minora, the clitoris, structures within the vestibule, and the perineum.
- The breasts are accessory organs of the female reproductive system that are specialized to secrete milk following pregnancy.
- The main function of the reproductive cycle is to stimulate growth of a follicle to release an egg and prepare a site for implantation if fertilization occurs.
- Menstruation, the monthly shedding of the uterine lining, marks the beginning and end of the cycle if fertilization does not occur.
- The ovarian cycle is the series of events associated with a developing oocyte (ovum or egg) within the ovaries.
- At ovulation, a mature follicle ruptures in response to a surge of LH, releasing a mature oocyte (ovum).
- The endometrial cycle is divided into four phases: the follicular or proliferative phase, the luteal or secretory phase, the ischemic phase, and the menstrual phase.
- The menstrual cycle involves a complex interaction of hormones. The predominant hormones are gonadotropin-releasing hormone (GnRH), follicle-stimulating hormone (FSH), luteinizing hormone (LH), estrogen, progesterone, and prostaglandins.
- The organs of the male reproductive system include the two testes (where sperm cells and testosterone are made), penis, scrotum, and accessory organs (epididymis, vas deferens, seminal vesicles, ejaculatory ducts, urethra, bulbourethral glands, and prostate gland).

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. The predominant anterior pituitary hormones that orchestrate the menstrual cycle include:
   a. Thyroid-stimulating hormone (TSH)
   b. Follicle-stimulating hormone (FSH)
   c. Corticotropin-releasing hormone (CRH)
   d. Gonadotropin-releasing hormone (GnRH)
2. Which glands are located on either side of the female urethra and secrete mucus to keep the opening moist and lubricated for urination?
   a. Cowper's
   b. Bartholin's
   c. Skene's
   d. Seminal
3. What event occurs during the proliferative phase of the menstrual cycle?
   a. Menstrual flow starts
   b. Growth hormone is secreted
   c. Ovulation occurs
   d. Progesterone secretion peaks
4. Which hormone is produced in high levels to prepare the endometrium for implantation just after ovulation by the corpus luteum?
   a. Estrogen
   b. Prostaglandins
   c. Prolactin
   d. Progesterone
5. Sperm maturation and storage in the male reproductive system occurs in the:
   a. Testes
   b. Vas deferens
   c. Epididymis
   d. Seminal vesicles

CRITICAL THINKING EXERCISE

1. The school nurse was asked to speak to a 10th-grade biology class about menstruation. The teacher felt that the students don't understand this monthly event and wanted to dispel some myths about it. After the nurse explains the factors influencing the menses, one girl asks, "Could someone get pregnant if she had sex during her period?"
   a. How should the nurse respond to this question?
   b. What factor regarding the menstrual cycle was not clarified?
   c. What additional topics might this question lead to that might be discussed?

STUDY ACTIVITIES

1. Select a website from the list above and visit it to find information concerning a topic of interest regarding women's health. Be prepared to discuss it in class.
2. List the predominant hormones and their function in the menstrual cycle.
3. The ovarian cycle describes the series of events associated with the development of the _____ within the ovaries.
4. Sperm cells and the male hormone testosterone are made in which of the following structures? Select all that apply.
   a. Vas deferens
   b. Penis
   c. Scrotum
   d. Ejaculatory ducts
   e. Prostate gland
   f. Testes
   g. Seminiferous tubules
   h. Bulbourethral glands

CHAPTER 4

Common Reproductive Issues

Izzy, a 27-year-old, presents to her health care provider complaining of progressive severe pelvic pain associated with her monthly periods. She has to take off work and "dope up" with pills to endure the pain. In addition, she has been trying to conceive for over a year without any luck.

KEY TERMS

abortion
abstinence
amenorrhea
basal body temperature (BBT)
cervical cap
cervical mucus ovulation method
coitus interruptus
condoms
contraception
contraceptive sponge
Depo-Provera
diaphragm
dysfunctional uterine bleeding (DUB)
dysmenorrhea
emergency contraception (EC)
endometriosis
fertility awareness
implant
infertility
lactational amenorrhea method (LAM)
Lunelle injection
menopause
oral contraceptives
premenstrual syndrome (PMS)
Standard Days Method (SDM)
sterilization
symptothermal method
transdermal patch
tubal ligation
vaginal ring
vasectomy

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms used in this chapter.
2. Examine common reproductive concerns in terms of symptoms, diagnostic tests, and appropriate interventions.
3. Identify risk factors and outline appropriate client education needed in common reproductive disorders.
4. Compare and contrast the various contraceptive methods available and their overall effectiveness.
5. Explain the physiologic and psychological aspects of menopause.
6. Delineate the nursing management needed for women experiencing common reproductive disorders.

Wow

When women bare their souls to us, we must respond without judgment.

Good health throughout the life cycle begins with the individual. Women today can expect to live well into their 80s and need to be proactive in maintaining their own quality of life. Women need to take steps to reduce their risk of disease and need to become active partners with their health care professional to identify problems early, when treatment may be most successful (Teaching Guidelines 4.1). Nurses can assist women in maintaining their quality of life by helping them to become more attuned to their body and its clues and can use the assessment period as an opportunity for teaching and counseling.

Common reproductive issues addressed in this chapter that nurses might encounter in caring for women include menstrual disorders, infertility, contraception, abortion, and menopause.

Menstrual Disorders

Many women sail through their monthly menstrual cycles with little or no concern. With few symptoms to worry about, their menses are like clockwork, starting and stopping at nearly the same time every month. For others, the menstrual cycle causes physical and emotional symptoms that initiate visits to their health care provider for consultation. The following menstruation-related conditions will be discussed in this chapter: amenorrhea, dysmenorrhea, dysfunctional uterine bleeding (DUB), premenstrual syndrome (PMS), premenstrual dysphoric disorder (PMDD), and endometriosis. To gain an understanding of menstrual disorders, it is important to know the terms used in describing them (Box 4.1).

TEACHING GUIDELINES 4.1

Tips for Being an Active Partner in Managing Your Health

- Become an informed consumer. Read, ask, and search.
- Know your family history and know factors that put you at high risk.
- Maintain a healthy lifestyle and let moderation be your guide.
- Schedule regular medical checkups and screenings for early detection.
- Ask your health care professional for a full explanation of any treatment.
- Seek a second medical opinion if you feel you need more information.
- Know when to seek medical care by being aware of disease symptoms.

BOX 4.1 Menstrual Disorder Vocabulary

- Meno = menstrual-related
- Metro = time
- Oligo = few
- A = without, none or lack of
- Rhagia = excess or abnormal
- Dys = not or pain
- Rhea = flow

AMENORRHEA

Amenorrhea is the absence of menses during the reproductive years. Amenorrhea is normal in prepubertal, pregnant, and postmenopausal females. The two categories of amenorrhea are primary and secondary amenorrhea. Primary amenorrhea is defined as either:

1. Absence of menses by age 14, with absence of growth and development of secondary sexual characteristics, or
2. Absence of menses by age 16, with normal development of secondary sexual characteristics (Bielak & Harris, 2006)

Ninety-eight percent of American girls menstruate by age 16 (Krantz, 2007a, 2007b). Secondary amenorrhea is the absence of menses for three cycles or 6 months in women who have previously menstruated regularly.

Etiology

There are multiple causes of primary amenorrhea:

- Extreme weight gain or loss
- Congenital abnormalities of the reproductive system
- Stress from a major life event
- Excessive exercise
- Eating disorders (anorexia nervosa or bulimia)
- Cushing's disease
- Polycystic ovary syndrome
- Hypothyroidism
- Turner syndrome
- Imperforate hymen
- Chronic illness
- Pregnancy
- Cystic fibrosis
- Congenital heart disease (cyanotic)
- Ovarian or adrenal tumors (Master-Hunter & Heiman, 2006)

Causes of secondary amenorrhea might include:

- Pregnancy
- Breastfeeding

- Emotional stress
- Pituitary, ovarian, or adrenal tumors
- Depression
- Hyperthyroid or hypothyroid conditions
- Malnutrition
- Hyperprolactinemia
- Rapid weight gain or loss
- Chemotherapy or radiation therapy to the pelvic area
- Vigorous exercise, such as long-distance running
- Kidney failure
- Colitis
- Use of tranquilizers or antidepressants
- Postpartum pituitary necrosis (Sheehan syndrome)
- Early menopause (Bielak & Harris, 2006)

Therapeutic Management

Therapeutic intervention depends on the cause of the amenorrhea. The treatment of primary amenorrhea involves the correction of any underlying disorders and estrogen replacement therapy to stimulate the development of secondary sexual characteristics. If a pituitary tumor is the cause, it might be treated with drug therapy, surgical resection, or radiation therapy. Surgery might be needed to correct any structural abnormalities of the genital tract. Therapeutic interventions for secondary amenorrhea may include:

- Cyclic progesterone, when the cause is anovulation, or oral contraceptives
- Bromocriptine to treat hyperprolactinemia
- Nutritional counseling to address anorexia, bulimia, or obesity
- Gonadotropin-releasing hormone (GnRH), when the cause is hypothalamic failure
- Thyroid hormone replacement, when the cause is hypothyroidism (Schuiling & Likis, 2006)

Nursing Assessment

Nursing assessment for the young girl or woman experiencing amenorrhea includes a thorough health history and physical examination and several laboratory and diagnostic tests.

Health History and Physical Examination

A thorough history and physical examination is needed to determine the etiology. The history should include questions about the women's menstrual history; past illnesses; hospitalizations and surgeries; obstetric history; use of prescription and over-the-counter drugs; recent or past lifestyle changes; and history of present illness, with an assessment of any bodily changes.

The physical examination should begin with an overall assessment of the woman's nutritional status and general health. A sensitive and gentle approach to the pelvic examination is critical in young women. Height and weight should be taken, along with vital signs. Hypothermia, bradycardia, hypotension, and reduced subcutaneous fat may be observed in women with anorexia nervosa. Facial hair and acne might be evidence of androgen excess secondary to a tumor. The presence or absence of axillary and pubic hair may indicate adrenal and ovarian hyposecretion or delayed puberty. A general physical examination may uncover unexpected findings that are indirectly related to amenorrhea. For example, hepatosplenomegaly, which may suggest a chronic systemic disease or an enlarged thyroid gland, might point to a thyroid disorder as well as a reason for amenorrhea (Nelson & Bakalov, 2006).

Laboratory and Diagnostic Tests

Common laboratory tests that might be ordered to determine the cause of amenorrhea include:

- Karyotype (might be positive for Turner syndrome)
- Ultrasound to detect ovarian cysts
- Pregnancy test to rule out pregnancy
- Thyroid function studies to determine thyroid disorder
- Prolactin level (an elevated level might indicate a pituitary tumor)
- Follicle-stimulating hormone (FSH) level (an elevated level might indicate ovarian failure)
- Luteinizing hormone (LH) level (an elevated level might indicate gonadal dysfunction)
- 17-ketosteroids (an elevated level might indicate an adrenal tumor)
- Laparoscopy to detect polycystic ovary syndrome
- CT scan of head if a pituitary tumor is suspected (Pagana & Pagana, 2007)

Nursing Management

Counseling and education are primary interventions and appropriate nursing roles. Address the diverse causes of amenorrhea, the relationship to sexual identity, possible infertility, and the possibility of a tumor or a life-threatening disease. In addition, inform the woman about the purpose of each diagnostic test, how it is performed, and when the results will be available to discuss with her. Sensitive listening, interviewing, and presenting treatment options are paramount to gain the woman's cooperation and understanding.

Nutritional counseling is also vital in managing this disorder, especially if the woman has findings suggestive of an eating disorder. Although not all causes can be addressed by making lifestyle changes, emphasize maintaining a healthy lifestyle (Teaching Guidelines 4.2).

DYSMENORRHEA

Dysmenorrhea refers to painful menstruation. This condition has also been termed cyclic perimenstrual pain (CPPD) (Taylor, 2005). The term **dysmenorrhea** is derived from

TEACHING GUIDELINES 4.2

Tips for Maintaining a Healthy Lifestyle

- Balance energy expenditure with energy intake.
- Modify your diet to maintain ideal weight.
- Avoid excessive use of alcohol and mood-altering or sedative drugs.
- Avoid cigarette smoking.
- Identify areas of emotional stress and seek assistance to resolve them.
- Balance work, recreation, and rest.
- Maintain a positive outlook regarding the diagnosis and prognosis.
- Participate in ongoing care to monitor any medical conditions.
- Maintain bone density through:
  - Calcium intake (1,200 to 1,500 mg daily)
  - Weight-bearing exercise (30 minutes or more daily)
  - Hormone therapy

Source: Nelson & Bakalov, 2006.

the Greek words "dys," meaning difficult, painful, or abnormal, and "rrhea," meaning flow. It may affect more than half of menstruating women (Smith, 2006). Uterine contractions occur during all periods, but in some women these cramps can be frequent and very intense. Dysmenorrhea is categorized as primary or secondary.

Etiology

Primary dysmenorrhea is caused by increased prostaglandin production by the endometrium in an ovulatory cycle. This hormone causes contraction of the uterus, and levels tend to be higher in women with severe menstrual pain than women who experience mild or no menstrual pain. These levels are highest during the first 2 days of menses, when symptoms peak (Doty & Attaran, 2006). This results in increased rhythmic uterine contractions from vasoconstriction of the small vessels of the uterine wall. This condition usually begins within a few years of the onset of ovulatory cycles at menarche.

Secondary dysmenorrhea is painful menstruation due to pelvic or uterine pathology. It may be caused by endometriosis, adenomyosis, fibroids, pelvic infection, an intrauterine device, cervical stenosis, or congenital uterine or vaginal abnormalities. Adenomyosis involves the ingrowth of the endometrium into the uterine musculature. Endometriosis involves ectopic implantation of endometrial tissue in other parts of the pelvis. It occurs most commonly in the third or fourth decades of life and affects 10% of women of reproductive age (Hompes & Mijatovic, 2007). Endometriosis is the most common cause of secondary dysmenorrhea and is associated with pain beyond menstruation, dyspareunia, and infertility (Speroff & Fritz, 2005). Treatment is directed toward removing the underlying pathology.

Think back to Izzy from the chapter opener. Is her pelvic pain complaint a common one with women?

Therapeutic Management

Therapeutic intervention is directed toward pain relief and building coping strategies that will promote a productive lifestyle. Treatment measures usually include treating infections if present; suppressing the endometrium if endometriosis is suspected by administering low-dose oral contraceptives; administering prostaglandin inhibitors to reduce the pain; administering Depo-Provera; and initiating lifestyle changes. Table 4.1 lists selected treatment options for dysmenorrhea.

Nursing Assessment

As with any gynecologic complaint, a thorough focused history and physical examination is needed to make the diagnosis of primary or secondary dysmenorrhea. In primary dysmenorrhea, the history usually reveals the typical cramping pain with menstruation, and the physical examination is completely normal. In secondary dysmenorrhea, the history discloses cramping pain starting after 25 years old with a pelvic abnormality, a history of infertility, heavy menstrual flow, irregular cycles, and little response to nonsteroidal anti-inflammatory drugs (NSAIDs), oral contraceptives, or both (Harel, 2006).

Health History and Clinical Manifestations

Note past medical history, including any chronic illnesses and family history of gynecologic concerns. Determine medication and substance use, such as prescription medications, contraceptives, anabolic steroids, tobacco, and marijuana, cocaine, or other illegal drugs. A detailed sexual history is essential to assess for inflammation and scarring (adhesions) secondary to pelvic inflammatory disease (PID). Women with a previous history of PID, sexually transmitted infections (STIs), multiple sexual partners, or unprotected sex are at increased risk.

During the initial interview, the nurse might ask some of the following questions to assess the woman's history of dysmenorrhea:

- "At what age did you start your menstrual cycles?"
- "Have your cycles always been painful, or did the pain start recently?"
- "When in your cycle do you experience the pain?"
- "How would you describe the pain you feel?"

TABLE 4.1 TREATMENT OPTIONS FOR DYSMENORRHEA

Therapy Options	Dosage	Comments
Nonsteroidal anti-inflammatory agents (NSAIDs)		
Ibuprofen (Ibuprin, Advil, Motrin)	400–800 mg TID	Take with meals. Don't take with aspirin. Avoid alcohol. Watch for signs of GI bleeding.
Naproxen (Anaprox, Naprelan, Naprosyn, Aleve)	250–500 mg TID	Same as above
Hormonal contraceptives		
Low-dose oral contraceptives	Taken daily (42/7 days; 63/7 or 84/7)	Take active pills for an extended time to reduce number of monthly cycles (Archer, 2006).
Depo-medroxyprogesterone (DMPA), Depo-Provera	150 mg IM every 12 wks	Within 9–12 months of DMPA therapy, 75% of women will be amenorrheic (Schuiling & Likis, 2006).
Lifestyle changes		Gives sense of control over life
Daily exercise Limit salty foods Weight loss Smoking cessation Relaxation techniques		

- "Are you sexually active?"
- "What impact does your cycle have on your physical and social activity?"
- "When was the first day of your last menstrual cycle?"
- "Was the flow of your last menstrual cycle a normal amount for you?"
- "Do your cycles tend to be heavy or last longer than 5 days?"
- "Are your cycles generally regular and predictable?"
- "What have you done to relieve your discomfort? Is it effective?"
- "Has there been a progression of symptom severity?"
- "Do you have any other symptoms?"

Assess for clinical manifestations of dysmenorrhea. Affected women experience sharp, intermittent spasms of pain, usually in the suprapubic area. Pain may radiate to the back of the legs or the lower back. Pain usually develops within hours of the start of menstruation and peaks as the flow becomes heaviest during the first day or two of the cycle (Edmundson & Erogul, 2006). Systemic symptoms of nausea, vomiting, diarrhea, fatigue, fever, headache, or dizziness are fairly common. Explore the history for physical symptoms of bloating, water retention, weight gain, headache, muscle aches, abdominal pain, food cravings, or breast tenderness.

Physical Examination

The physical examination performed by the health care provider centers on the bimanual pelvic examination. This examination is done during the nonmenstrual phase of the cycle. Explain to the woman how it is to be performed, especially if is her first pelvic examination. Prepare the woman in the examining room by offering her a cover gown to put on and covering her lap with a privacy sheet on the examination table. Remain in the examining room throughout the examination to assist the health care provider with any procedures or specimens and to offer the woman reassurance.

Laboratory and Diagnostic Tests

Common laboratory tests that may be ordered to determine the cause of dysmenorrhea might include:

- Complete blood count to rule out anemia
- Urinalysis to rule out a bladder infection

- Pregnancy test (human chorionic gonadotropin level) to rule out pregnancy
- Cervical culture to exclude STI
- Erythrocyte sedimentation rate to detect an inflammatory process
- Stool guaiac to exclude gastrointestinal bleeding or disorders
- Pelvic and/or vaginal ultrasound to detect pelvic masses or cysts
- Diagnostic laparoscopy and/or laparotomy to visualize pathology that may account for the symptoms

What diagnostic tests might be ordered to diagnose Izzy's pelvic pain?

Nursing Management

Educating the client about the normal events of the menstrual cycle and the etiology of her pain is paramount in achieving a successful outcome. Explaining the normal menstrual cycle will teach the woman the correct terms so she can communicate her symptoms more accurately and will help dispel myths. Provide the woman with monthly graphs or charts to record menses, the onset of pain, the timing of medication, relief afforded, and coping strategies used. This involves the woman in her care and provides objective information so that therapy can be modified if necessary.

The nurse should explain in detail the dosing regimen and the side effects of the medication therapy selected. Commonly prescribed drugs include NSAIDs such as ibuprofen (Motrin), naproxen (Naprosyn), and Advil. They alleviate dysmenorrhea symptoms by decreasing intrauterine pressure and inhibiting prostaglandin synthesis, thus reducing pain (Skidmore-Roth, 2007). If pain relief is not achieved in two to four cycles, a low-dose combination oral contraceptive may be initiated. Client teaching and counseling should include information about how to take pills, side effects, and danger signs to watch for.

Encourage the woman to apply a heating pad or warm compress to alleviate menstrual cramps. Additional lifestyle changes that the woman can make to restore some sense of control and active participation in her care are listed in Teaching Guidelines 4.3.

TEACHING GUIDELINES 4.3

Tips to Manage Dysmenorrhea

- Exercise to increase endorphins and suppress prostaglandin release.
- Limit salty foods to prevent fluid retention.
- Increase water consumption to serve as a natural diuretic.
- Increase fiber intake with fruits and vegetables to prevent constipation.
- Use heating pads or warm baths to increase comfort.
- Take warm showers to promote relaxation.
- Sip on warm beverages, such as decaffeinated green tea.
- Keep legs elevated while lying down or lie on side with knees bent.
- Use stress management techniques to reduce emotional stress.
- Practice relaxation techniques to enhance ability to cope with pain.
- Stop smoking and decrease alcohol use.

Source: Nasir, 2007.

DYSFUNCTIONAL UTERINE BLEEDING

Dysfunctional uterine bleeding (DUB) is a disorder that occurs most frequently in women at the beginning and end of their reproductive years. Defined as irregular, abnormal bleeding that occurs with no identifiable anatomic pathology, it affects 33% to 50% of women (Rackow & Arici, 2007). It is frequently associated with anovulatory cycles, which are common for the first year after menarche and later in life as women approach menopause.

The pathophysiology of DUB is related to a hormone disturbance. With anovulation, estrogen levels rise as usual in the early phase of the menstrual cycle. In the absence of ovulation, a corpus luteum never forms and progesterone is not produced. The endometrium moves into a hyperproliferative state, ultimately outgrowing its estrogen supply. This leads to irregular sloughing of the endometrium and excessive bleeding (Aeby & Frattarelli, 2006). If the bleeding is heavy enough and frequent enough, anemia can result.

DUB is similar to several other types of uterine bleeding disorders and sometimes overlaps these conditions. They include:

- Menorrhagia (abnormally long, heavy periods)
- Oligomenorrhea (bleeding occurs at intervals of more than 35 days)
- Metrorrhagia (bleeding between periods)
- Menometrorrhagia (bleeding occurs at irregular intervals with heavy flow lasting more than 7 days)
- Polymenorrhea (too frequent periods)

Etiology

The possible causes of DUB may include:

- Adenomyosis
- Pregnancy

- Hormonal imbalance
- Fibroid tumors (see Chapter 7)
- Endometrial polyps or cancer
- Endometriosis
- Intrauterine device (IUD)
- Polycystic ovary syndrome
- Morbid obesity
- Steroid therapy
- Hypothyroidism
- Blood dyscrasias/clotting disorder

Therapeutic Management

Treatment of DUB depends on the cause of the bleeding and the age of the client. When known, the underlying cause of the disorder is treated. Otherwise, the goal of treatment is to relieve the symptoms so that uterine bleeding does not interfere with a woman's normal activities or cause anemia (Dodds & Sinert, 2006).

Management of DUB might include medical care with pharmacotherapy or insertion of an IUD. Oral contraceptives are used for cycle regulation as well as contraception. They help prevent the risks associated with prolonged unopposed estrogen stimulation of the endometrium. NSAIDs and the levonorgestrel-releasing IUD (Mirena) decrease menstrual blood loss significantly (Lethaby, Cooke & Rees, 2006). The drug categories used in the treatment of DUB are:

- Estrogens: cause vasospasm of the uterine arteries to decrease bleeding
- Progestins: used to stabilize an estrogen-primed endometrium
- Oral contraceptives: regulate the cycle and suppress the endometrium
- NSAIDs: inhibit prostaglandins
- Levonorgestrel-20 Intrauterine System: suppresses endometrial growth
- Iron salts: replenish iron stores lost during heavy bleeding

If the client does not respond to medical therapy, surgical intervention might include dilation and curettage (D&C), endometrial ablation, or hysterectomy. Endometrial ablation is an alternative to hysterectomy. A thermal balloon or a laser is used to ablate the tissue, producing improvement in 90% of women (Speroff & Fritz, 2005).

Nursing Assessment

A thorough history should be taken to differentiate between DUB and other conditions that might cause vaginal bleeding, such as pregnancy and pregnancy-related conditions (abruptio placentae, ectopic pregnancy, abortion, or placenta previa); systemic conditions such as Cushing disease, blood dyscrasias, liver disease, renal disease, or thyroid disease; and genital tract pathology such as infections, tumors, or trauma (Hackley, Kriebs & Rousseau, 2007).

Assess for clinical manifestations of DUB, which commonly include vaginal bleeding between periods, irregular menstrual cycles (usually less than 28 days between cycles), infertility, mood swings, hot flashes, vaginal tenderness, variable menstrual flow ranging from scanty to profuse, obesity, acne, and diabetes. Signs of polycystic ovary syndrome might be present, since it is associated with unopposed estrogen stimulation, elevated androgen levels, and insulin resistance and is a common cause of anovulation (Torpy, 2007).

Measure orthostatic blood pressure and orthostatic pulse; a drop in pressure or pulse rate may occur with anemia. The health care provider, with the nurse assisting, performs a pelvic examination to identify any structural abnormalities.

Common laboratory tests that may be ordered to determine the cause of DUB include:

- Complete blood count to detect anemia
- Prothrombin time (PT) to detect blood dyscrasias
- Pregnancy test to rule out a spontaneous abortion or ectopic pregnancy
- Thyroid-stimulating hormone (TSH) level to screen for hypothyroidism
- Transvaginal ultrasound to measure endometrium
- Pelvic ultrasound to view any structural abnormalities
- Endometrial biopsy to check for intrauterine pathology
- D&C for diagnostic evaluation

Nursing Management

Educate the client about normal menstrual cycles and the possible reasons for her abnormal pattern. Inform the woman about treatment options. Do not simply encourage the woman to "live with it": complications such as infertility can result from lack of ovulation; severe anemia can occur secondary to prolonged or heavy menses; and endometrial cancer can occur associated with prolonged buildup of the endometrial lining without menstrual bleeding (Rackow & Arici, 2007). Instruct her about any prescribed medications and potential side effects. For example, if high-dose estrogens are prescribed, the woman may experience nausea. Teach her to take antiemetics as prescribed and encourage her to eat small, frequent meals to alleviate nausea. Adequate follow-up and evaluation for women who do not respond to medical management is essential. See Nursing Care Plan 4.1: Overview of a Woman With Dysfunctional Uterine Bleeding (DUB).

PREMENSTRUAL SYNDROME

Premenstrual syndrome (PMS) describes a wide range of recurrent symptoms that occur during the luteal phase or last half of the menstrual cycle and resolve with the onset of menstruation (Braverman & Neinstein,

Nursing Care Plan 4.1

OVERVIEW OF A WOMAN WITH DYSFUNCTIONAL UTERINE BLEEDING (DUB)

Stacy, a 52-year-old obese woman, comes to her gynecologist with the complaint of heavy erratic bleeding. Her periods were fairly regular until about 4 months ago, and since that time they have been unpredictable, excessive, and prolonged. Stacy reports she is tired all the time, can't sleep, and feels "out of sorts" and anxious. She is fearful she has cancer.

NURSING DIAGNOSIS: Fear related to current signs and symptoms possibly indicating a life-threatening condition

Outcome Identification and Evaluation

The client will acknowledge her fears as evidenced by statements made that fear and anxiety have been lessened after explanation of diagnosis.

Interventions: Reducing Fear and Anxiety

- Distinguish between anxiety and fear to determine appropriate interventions.
- Check complete blood count and assess for possible anemia secondary to excessive bleeding to determine if fatigue is contributing to anxiety and fear. Fatigue occurs because the oxygen-carrying capacity of the blood is reduced.
- Reassure client that symptoms can be managed to help address her current concerns.
- Provide client with factual information and explain what to expect to assist client with identifying fears and help in her coping with her condition.
- Provide symptom management to reduce concerns associated with the cause of bleeding.
- Teach client about early manifestations of fear and anxiety to aid in prompt recognition and to minimize escalation of anxiety.
- Assess client's use of coping strategies in the past and reinforce use of effective ones to help control anxiety and fear.
- Instruct client in relaxation methods, such as deep breathing exercises and imagery, to provide her with additional methods for controlling anxiety and fear.

NURSING DIAGNOSIS: Deficient knowledge related to perimenopause and its management

Outcome Identification and Evaluation

The client will demonstrate understanding of her symptoms as evidenced by making health-promoting lifestyle choices, verbalizing appropriate health care practices, and adhering to measures to comply with therapy.

Interventions: Providing Patient Education

- Assess client's understanding of perimenopause and its treatment to provide a baseline for teaching and developing a plan of care.
- Review instructions about prescribed procedures and recommendations for self-care, frequently obtaining feedback from the client to validate adequate understanding of information.
- Outline link between anovulatory cycles and excessive buildup of uterine lining in perimenopausal women to assist client in understanding the etiology of her bleeding.
- Provide written material with pictures to promote learning and help client visualize what is occurring to her body during perimenopause.
- Inform client about the availability of community resources and make appropriate referrals as needed to provide additional education and support.
- Document details of teaching and learning to allow for continuity of care and further education, if needed.

2007). The American College of Obstetricians and Gynecologists (ACOG) defines premenstrual syndrome as "the cyclic occurrence of symptoms that are sufficiently severe to interfere with some aspects of life, and that appear with consistent and predictable relationship to menses" (ACOG, 2000). A woman experiencing PMS may have a wide variety of seemingly unrelated symptoms; for that reason, it is difficult to define and more challenging to diagnose. PMS affects millions of women during their reproductive years: up to 85% of menstruating women report having one or more premenstrual symptoms, and up to 10% report disabling, incapacitating symptoms

(Campagne & Campagne, 2007). The exact cause of PMS is not known. It is thought to be related to the interaction between hormonal events and neurotransmitter function, specifically serotonin. Not all women respond to serotonin reuptake inhibitors (SSRIs), however, which implies that other mechanisms may be involved (Braverman & Neinstein, 2007).

As defined by the American Psychological Association, premenstrual dysphoric disorder (PMDD) is a more severe variant of PMS. Experts compare the difference between PMS and PMDD to the difference between a mild tension headache and a migraine (Giulio & Reissing, 2006). PMDD markedly interferes with work and school, or with social activities and relationships with others.

Therapeutic Management

Treatment of PMS is often frustrating for both patients and health care providers. Clinical outcomes can be expected to improve as a result of recent consensus on the diagnostic criteria for PMS and PMDD, data from clinical trials, and the availability of evidence-based clinical guidelines.

The management of PMS or PMDD requires a multidimensional approach because these conditions are not likely to have a single cause, and they appear to affect multiple systems within a woman's body; therefore, they are not likely to be amenable to treatment with a single therapy. To reduce the negative impact of premenstrual disorders on a woman's life, education, along with reassurance and anticipatory guidance, are needed for women to feel they have some control over their condition.

▶ *Take* NOTE!

Because there are no diagnostic tests that can reliably determine the existence of PMS or PMDD, it is the woman herself who must decide that she needs help during this time of the month. The woman must embrace multiple therapies and become an active participant in her treatment plan to find the best level of symptom relief.

Therapeutic interventions for PMS and PMDD address the symptoms because the exact cause of this condition is still unknown. Treatments may include vitamin supplements, diet changes, exercise, lifestyle changes, and medications (Box 4.2). Medications used in treating PMDD may include antidepressant and antianxiety drugs, diuretics, anti-inflammatory medications, analgesics, synthetic androgen agents, oral contraceptives, or GNrH agonists to regulate menses (Pavlovich-Danis, 2007).

BOX 4.2 Treatment Options for PMS and PMDD

- Lifestyle changes:
  - Reduce stress.
  - Exercise three to five times each week.
  - Eat a balanced diet and increase water intake.
  - Decrease caffeine intake.
  - Stop smoking.
  - Limit intake of alcohol.
  - Attend a PMS/women's support group.
- Vitamin and mineral supplements
  - Multivitamin daily
  - Vitamin E, 400 units daily
  - Calcium, 1,200 mg daily
  - Magnesium, 200 to 400 mg daily
- Medications
  - NSAIDs taken a week prior to menses
  - Oral contraceptives (low dose)
  - Antidepressants (SSRIs)
  - Anxiolytics (taken during luteal phase)
  - Diuretics to remove excess fluid
  - Progestins
  - Gonadotropin-releasing hormone (GnRH agonists)
  - Danazol (androgen hormone inhibits estrogen production)

Many women use dietary supplements and herbal remedies for their menstrual health and treating their bleeding disorders, although there has been little research to demonstrate their efficacy. Some alternative therapies used might include calcium, magnesium, vitamin B6, evening primrose oil, vitex agnus castus, ginkgo biloba, viburnum, dandelion, stinging nettle, burdock, raspberry leaf, skullcap, and St. John's wort (Canning, Waterman & Dye, 2006). Although research hasn't validated alternative therapy's efficacy, it is important for the nurse to be aware of the alternative products that many women choose to use.

Nursing Assessment

Although little consensus exists in the medical literature and among researchers about what constitutes PMS and PMDD, the physical and psychological symptoms are very real. The extent to which the symptoms debilitate or incapacitate a woman is highly variable.

There are more than 200 symptoms assigned to PMS, but irritability, tension, and dysphoria are the most prominent and consistently described (Moreno & Giesel, 2006). To establish the diagnosis of PMS, elicit a description of cyclic symptoms occurring before the woman's menstrual period. The woman should chart her symptoms daily for two cycles. These data will help demonstrate symptoms

clustering around the luteal phase of ovulation, with resolution after bleeding starts. Ask the woman to bring her list of symptoms to the next appointment. Symptoms can be categorized using the following:

- A: anxiety: difficulty sleeping, tenseness, mood swings, clumsiness
- C: craving: headache, cravings for sweets, salty foods, chocolate
- D: depression: feelings of low self-esteem, anger, easily upset
- H: hydration: weight gain, abdominal bloating, breast tenderness
- O: other: hot flashes or cold sweats, nausea, change in bowel habits, aches or pains, dysmenorrhea, acne breakout (Pavlovich-Danis, 2007)

The ACOG diagnostic criteria for PMS consist of having at least one of the following affective and somatic symptoms during the 5 days before menses in each of the three previous cycles:

- Affective symptoms: depression, angry outbursts, irritability, anxiety
- Somatic symptoms: breast tenderness, abdominal bloating, edema, headache
- Symptoms relieved from days 4 to 13 of the menstrual cycle (ACOG, 2000)

In PMDD, the main symptoms are mood disorders such as depression, anxiety, tension, and persistent anger or irritability. Physical symptoms such as headache, joint and muscle pain, lack of energy, bloating, and breast tenderness are also present (Hsiao & Liu, 2007). It is estimated that 20% to 40% of reproductive-age women experience premenstrual symptoms that meet the ACOG criteria for PMS and up to 10% meet the diagnostic criteria for PMDD (Futterman & Rapkin, 2006).

According to the American Psychiatric Association, a woman must have at least five of the typical symptoms to be diagnosed with PMDD (Andoisek & Rapkin, 2007). These must occur during the week before and a few days after the onset of menstruation and must include one or more of the first four symptoms:

1. Affective lability: sadness, tearfulness, irritability
2. Anxiety and tension
3. Persistent or marked anger or irritability
4. Depressed mood, feelings of hopelessness
5. Difficulty concentrating
6. Sleep difficulties
7. Increased or decreased appetite
8. Increased or decreased sexual desire
9. Chronic fatigue
10. Headache
11. Constipation or diarrhea
12. Breast swelling and tenderness (Htay & Aung, 2006)

Nursing Management

Educate the client about the management of PMS or PMDD. Advise her that lifestyle changes often result in significant symptom improvement without pharmacotherapy. Encourage women to eat a balanced diet that includes nutrient-rich foods to avoid hypoglycemia and associated mood swings. Encourage adolescent girls to participate in aerobic exercise three times a week to promote a sense of well-being, decrease fatigue, and reduce stress. Administer calcium (1,200 to 1,600 mg/day), magnesium (400 to 800 mg/day), and vitamin B6 (50 to 100 mg/day) as prescribed. In some studies, these nutrients have been shown to decrease the intensity of PMS symptoms. NSAIDs may be useful for painful physical symptoms and spironolactone (Aldactone) may help with bloating and water retention. Herbs such as Vitex (chaste tree berry), evening primrose, and SAM-e may be recommended; although not harmful, not all herbs have enough clinical or research evidence to document their safety or efficacy (Schuiling & Likis, 2006).

A recent research study proposes calcium (1,600 mg/day) and vitamin D (400 IU/day) supplementation in adolescents and women in an effort to prevent PMS (Clayton, 2008).

Explain the relationship between cyclic estrogen fluctuation and changes in serotonin levels and how the different management strategies help maintain serotonin levels, thus improving symptoms. It is important to rule out other conditions that might cause erratic or dysphoric behavior. If the initial treatment regimen does not work, explain to the woman that she should return for further testing. Behavioral counseling and stress management might help women regain control during these stressful periods. Reassuring the woman that support and help are available through many community resources/support groups can be instrumental in her acceptance of this monthly disorder. Nurses can be a very calming force for many women experiencing PMS or PMDD.

▶ *Take* NOTE!

Adolescents and women who experience more extensive emotional symptoms with PMS should be evaluated for PMDD, as they may require antidepressant therapy.

ENDOMETRIOSIS

Endometriosis is one of the most common gynecologic diseases, affecting more than 5.5 million women in the United States. In this condition, bits of functioning endometrial tissue are located outside of their normal site, the uterine cavity. This endometrial tissue is commonly found

attached to the ovaries, fallopian tubes, the outer surface of the uterus, the bowels, the area between the vagina and the rectum (rectovaginal septum), and the pelvic side wall (Fig. 4.1). The places where the tissue attaches are called implants, or lesions. Endometrial tissue found outside the uterus responds to hormones released during the menstrual cycle in the same way as endometrial lining within the uterus.

At the beginning of the menstrual cycle, when the lining of the uterus is shed and menstrual bleeding begins, these abnormally located implants swell and bleed also. In short, the woman with endometriosis experiences several "mini-periods" throughout her abdomen, wherever this endometrial tissue exists.

Think back to Izzy, with her progressive pelvic pain and infertility concerns. After a pelvic examination, her health care provider suspects she has endometriosis.

Etiology and Risk Factors

It is not currently known why endometrial tissue becomes transplanted and grows in other parts of the body. Several theories exist, but to date none has been scientifically proven. However, several factors that increase a woman's risk of developing endometriosis have been identified:

- Increasing age
- Family history of endometriosis in a first-degree relative
- Short menstrual cycle (less than 28 days)
- Long menstrual flow (more than 1 week)
- Young age of menarche (younger than 12)
- Few (one or two) or no pregnancies (Speroff & Fritz, 2005)

Therapeutic Management

Therapeutic management of the client with endometriosis needs to take into consideration the following factors: severity of symptoms, desire for fertility, degree of disease, and the client's therapy goals. The aim of therapy is to suppress levels of estrogen and progesterone, which cause the endometrium to grow. Treatment can include surgery or medication (Table 4.2).

Nursing Assessment

Nurses encounter women with endometriosis in a variety of settings: community health settings, schools, clinics, day surgical centers, and hospitals. Health care professionals must not trivialize or dismiss the concerns of these women, because early recognition is essential to preserve fertility.

Health History

Obtain a health history and elicit a description of signs and symptoms to determine risk factors. Endometriosis is often asymptomatic, but it can be a severe and debilitating condition. It typically is chronic and progressive. Assess the client for clinical manifestations, which include:

- Infertility
- Pain before and during menstrual periods
- Pain during or after sexual intercourse
- Painful urination
- Depression
- Fatigue
- Painful bowel movements
- Chronic pelvic pain
- Hypermenorrhea (heavy menses)
- Pelvic adhesions

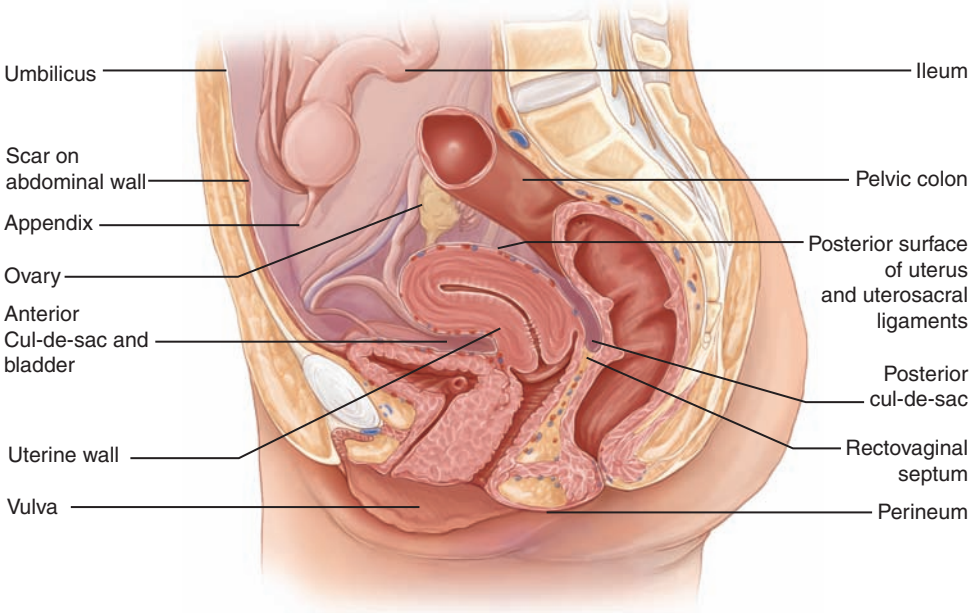

FIGURE 4.1 Common sites of endometriosis formation.

TABLE 4.2 TREATMENT OPTIONS FOR ENDOMETRIOSIS

Therapy Options	Comment
Surgical intervention	
Conservative surgery	Removal of implants/lesions using laser, cautery, or small surgical instruments. This intervention will reduce pain and allows pregnancy to occur in the future.
Definitive surgery	Abdominal hysterectomy, with or without bilateral salpingo-oophorectomy. Will eliminate pain but will leave a woman unable to become pregnant in the future.
Medication therapy	
NSAIDs	First-line treatment to reduce pain; taken early when premenstrual symptoms are first felt
Oral contraceptives	Suppresses cyclic hormonal response of the endometrial tissue
Progestogens	Used to cast off the endometrial cells and thus destroy them
Antiestrogens	Suppresses a woman's production of estrogen, thus stopping the menstrual cycle and preventing further growth of endometrium
Gonadotropin-releasing hormone analogues (GnRH-a)	Suppresses endometriosis by creating a temporary pseudomenopause
Danazol (Danacrine)	A synthetic androgen (male sex hormone) used typically as a second-line treatment of endometriosis. Disrupts the action of the pituitary gland by suppressing the output of some hormones, thus reducing estrogen, halting menstruation, and resulting in the growth of facial hair and acne.

- Irregular and more frequent menses
- Premenstrual vaginal spotting (Schuiling & Likis, 2006)

The two most common symptoms are infertility and pain. Endometriosis occurs in 38% of infertile women and in 71% to 87% of women with chronic pelvic pain (Aeby & Hraoka, 2006). About 30% to 40% of women with this condition are infertile, making it one of the top three causes of female infertility (NICHD, 2006).

What are the two most common symptoms experienced by women with endometriosis? Is Izzy's profile typical? As a nurse, what would be your role in Izzy's continued workup?

Physical Examination and Laboratory and Diagnostic Tests

The pelvic examination typically correlates with the extent of the endometriosis. The usual finding is nonspecific pelvic tenderness. The hallmark finding is the presence of tender nodular masses on the uterosacral ligaments, the posterior uterus, or the posterior cul-de-sac (Saul & Dave, 2006).

After a thorough history and a pelvic examination, the health care practitioner may suspect endometriosis, but the only certain method of diagnosing it is by seeing it. Pelvic or transvaginal ultrasound is used to assess pelvic organ structures. However, a laparoscopy is needed to diagnose endometriosis. Laparoscopy is the direct visualization of the internal organs with a lighted instrument inserted through an abdominal incision. A tissue biopsy of the suspected implant taken at the same time and examined microscopically confirms the diagnosis.

Nurses can play a role by offering a thorough explanation of the condition and explaining why tests are needed to diagnose endometriosis. The nurse can set up appointments for imaging studies and laparoscopy.

Nursing Management

In addition to the interventions outlined above, the nurse should encourage the client to adopt healthy lifestyle habits with respect to diet, exercise, sleep, and stress management. Referrals to support groups and Internet resources

can help the woman to understand this condition and to cope with chronic pain. A number of organizations provide information about the diagnosis and treatment of endometriosis and offer support to women and their families (Box 4.3). See Evidence-Based Practice 4.1.

After completing several diagnostic tests, Izzy is diagnosed with endometriosis. She asks you about her chances of becoming pregnant and becoming pain-free. What treatment options would you explain to Izzy? What information can you give about her future childbearing ability?

Infertility

Infertility is defined as the inability to conceive a child after 1 year of regular sexual intercourse unprotected by contraception, or the inability to carry a pregnancy to term (Covington & Burns, 2006). Secondary infertility is the inability to conceive after a previous pregnancy. Many people take the ability to conceive and produce a

EVIDENCE-BASED PRACTICE 4.1
The Effectiveness of Danazol Compared to Placebo or No Treatment in the Treatment of the Symptoms and Signs (Other than Infertility) of Endometriosis in Women of Reproductive Age

● Study
Endometriosis is defined as the presence of endometrial tissue (stromal and glandular) outside the normal uterine cavity. Conventional medical and surgical treatments for endometriosis aim to remove or decrease deposits of ectopic endometrium. The observation that hyperandrogenic states (an excess of male hormone) induce atrophy of the endometrium has led to the use of androgens in the treatment of endometriosis. Danazol is one of these treatments. The efficacy of danazol is based on its ability to produce a high-androgen/low-estrogen environment (a pseudomenopause), which results in the atrophy of endometriotic implants and thus an improvement in painful symptoms.

Only four trials met the inclusion criteria, and two authors independently extracted data from these trials. All four trials compared danazol to placebo. Two trials used danazol as sole therapy and two trials used danazol as an adjunct to surgery. Although the main outcome was pain improvement, other data relating to laparoscopic scores and hormonal parameters were also collected.

▲ Findings
Treatment with danazol was effective in relieving painful symptoms related to endometriosis when compared to placebo. Laparoscopic scores were improved with danazol treatment when compared with either placebo or no treatment. Side effects were more commonly reported in the patients receiving danazol than those receiving placebo. Thus, danazol is effective in treating the symptoms and signs of endometriosis. However, its use is limited by the occurrence of androgenic side effects.

■ Nursing Implications
According to the results of the study, danazol is an effective treatment for relieving painful symptoms of endometriosis, but it has side effects. As a nurse, it is important to educate the patient about these; they may include clitoral enlargement and masculinization. In addition, the response to the drug may take several weeks or months. Women should be cautioned to report yellowing of the skin (jaundice), fluid retention, shortness of breath, and changes in vaginal bleeding. It is important to stress that there are several effective therapies to treat endometriosis if the side effects are problematic with danazol.

child for granted, but infertility affects over 6 million Americans, or 15% of the reproductive-age population, according to the American Society for Reproductive Medicine (ASRM, 2007). Infertility is a widespread problem that has an emotional, social, and economic impact on couples. Nurses must recognize infertility and understand its causes and treatment options so that they can help couples understand the possibilities as well as the limitations of current therapies. Recent studies found that women wished to be treated with respect and dignity and given appropriate information and support. They wanted their distress recognized and they wanted to feel cared for and to have confidence in health care professionals in situations where outcomes were uncertain. The caring aspect of professional nursing is an essential component of meeting the special needs of these couples (Redshaw, Hockley & Davidson, 2007). Prevention of infertility through education should also be incorporated into any client–nurse interaction.

Cultural Considerations

Cross-culturally, the expectation for couples to reproduce is an accepted norm and the inability to conceive may be considered a violation of this cultural norm. In this context, infertility represents a crisis for the couple. The manner in which different cultures, ethnic groups, and religious groups perceive and manage infertility may be very different. For example, many African-Americans believe that assisted reproductive techniques are unnatural and that they remove the spiritual or divine nature of creation from conception. For this reason, they may seek spiritual rather than medical assistance when trying to conceive. The Hispanic culture believes that children validate the marriage, so families are typically large. Like the African-American culture, Hispanics are very spiritual and may consider infertility a test of faith and seek spiritual counseling.

Religion often influences cultural factors and for this reason may also be considered when pursuing treatment for infertility. In the Jewish religion procreation is felt to be an obligation and a responsibility. Roman Catholics have a very restrictive view on the use of assisted reproductive technologies since in their view procreation cannot be separated from the relationship between parents. Thus, children must be created by the physical union between husband and wife and conceived through sexual intercourse (Schenker, 2005). Nurses must be cognizant of the client's cultural and religious background and how it may dictate which, if any, reproductive treatment options are chosen. Nurses need to include this awareness in their counseling of infertile couples.

Etiology and Risk Factors

Multiple known and unknown factors affect fertility. Female-factor infertility is detected in about 40% of cases, male-factor infertility in about 40% of cases. The remaining 20% fall into a category of combined (both male and female factors) or unexplained infertility. In women, ovarian dysfunction (40%) and tubal/pelvic pathology (40%) are the primary contributing factors to infertility (ASRM, 2007).

Risk factors for infertility include:

- For women:
  - Overweight or underweight (can disrupt hormone function)
  - Hormonal imbalances leading to irregular ovulation
  - Fibroids
  - Tubal blockages
  - Reduced oocyte quality
  - Chromosomal abnormalities
  - Congenital anomalies of the cervix and uterus
  - Immune system disorders
  - Chronic illnesses such as diabetes, thyroid disease, asthma
  - STIs
  - Age older than 27
  - Endometriosis
  - History of PID
  - Smoking and alcohol consumption
  - Multiple miscarriages
  - Psychological stress (Kelly-Weeder & O'Conner, 2006)
- For men:
  - Exposure to toxic substances (lead, mercury, x-rays)
  - Cigarette or marijuana smoke
  - Heavy alcohol consumption
  - Use of prescription drugs for ulcers or psoriasis
  - Exposure of the genitals to high temperatures (hot tubs or saunas)
  - Hernia repair
  - Frequent long-distance cycling
  - STI
  - Undescended testicles (cryptorchidism)
  - Mumps after puberty (Ficorelli & Weeks, 2007)

Therapeutic Management

The test results are presented to the couple and different treatment options are suggested. The majority of infertility cases are treated with drugs or surgery. Various ovulation-enhancement drugs and timed intercourse might be used for the woman with ovulation problems. The woman should understand the drug's benefits and side effects before consenting to take them. Depending on the type of drug used and the dosage, some women may experience multiple births. If the woman's reproductive organs are damaged, surgery can be done to repair them. Still other couples might opt for the hi-tech approaches of artificial insemination (Fig. 4.2), in vitro fertilization (IVF; Fig. 4.3), and egg donation or contract for a gestational

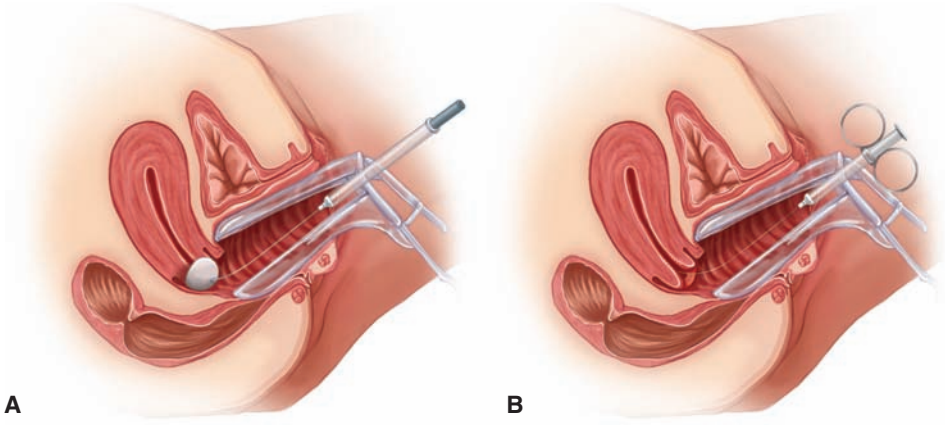

FIGURE 4.2 Artificial insemination. Sperm are deposited next to the cervix (**A**) or injected directly into the uterine cavity (**B**).

carrier or surrogate (Grainger, Frazier & Rowland, 2006). Table 4.3 lists selected infertility options.

Nursing Assessment

Infertile couples are under tremendous pressure and often keep the problem a secret, considering it to be very personal. The couple is often beset by feelings of inadequacy and guilt, and many are subject to pressures from both family and friends. As their problem becomes more chronic, they may begin to blame one another, with consequent marital discord. Seeking help is often a very difficult step for them, and it may take a lot of courage to discuss something about which they feel deeply embarrassed or upset. The nurse working in this specialty setting must be aware of the conflict and problems couples present with and must be very sensitive to their needs.

A full medical history should be taken from both partners, along with a physical examination. The data needed for the infertility evaluation are very sensitive and of a personal nature, so the nurse must use very professional interviewing skills.

There are numerous causes of and contributing factors to infertility, so it is important to use the process of elimination, determining what problems don't exist to better comprehend the problems that do exist. At the first visit, a plan of investigation is outlined and a complete health history is taken. This first visit forces many couples to confront the reality that their desired pregnancy may not occur naturally. Alleviate some of the anxiety associated with diagnostic testing by explaining the timing and reasons for each test.

Assessing Male Factors

The initial screening evaluation for the male partner should include a reproductive history and a semen analysis. From the male perspective, three things must happen for conception to take place: there must be an adequate number of sperm; those sperm must be healthy and mature; and the sperm must be able to penetrate and fertilize the egg. Normal males need to have more than 20 million sperm per milliliter with greater than 50% motility (WHO, 2007). Semen analysis is the most important indicator of male fertility. The man should abstain from

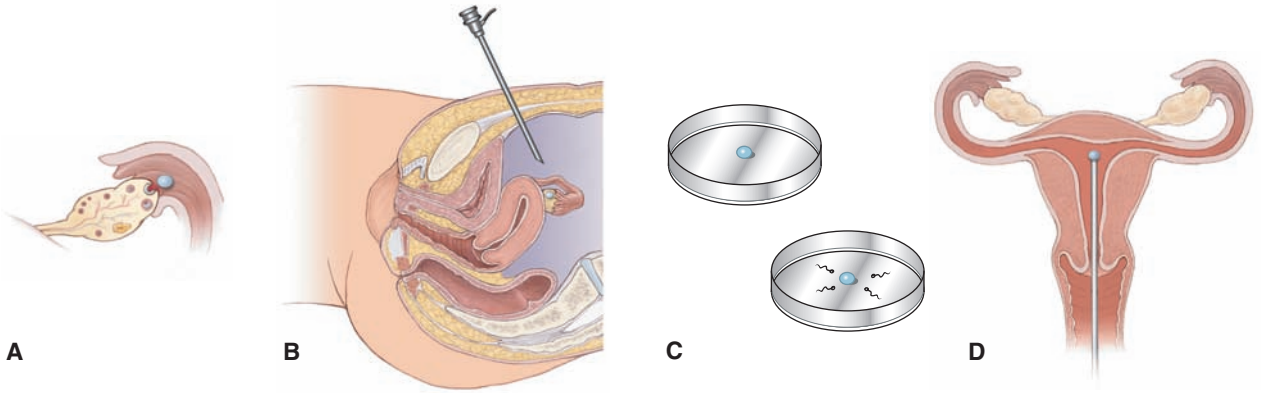

FIGURE 4.3 Steps involved in in vitro fertilization. (**A**) Ovulation. (**B**) Capture of the ova (done here intra-abdominally). (**C**) Fertilization of ova and growth in culture medium. (**D**) Insertion of fertilized ova into uterus.

TABLE 4.3 SELECTED TREATMENT OPTIONS FOR INFERTILITY

Procedure	Comments	Nursing Considerations
Fertility drugs		
Clomiphene citrate (Clomid)	A nonsteroidal synthetic antiestrogen used to induce ovulation	Nurse can advise the couple to have intercourse every other day for 1 week starting after day 5 of medication.
Human menopausal gonadotropin (HMG); Pergonal	Induces ovulation by direct stimulation of ovarian follicle	Same as above
Artificial insemination	The insertion of a prepared semen sample into the cervical os or intrauterine cavity Enables sperm to be deposited closer to improve chances of conception Husband or donor sperm can be used	Nurse needs to advise couple that the procedure might need to be repeated if not successful the first time.
Assisted reproductive technologies*		
In vitro fertilization (IVF)	Oocytes are fertilized in the lab and transferred to the uterus. Usually indicated for tubal obstruction, endometriosis, pelvic adhesions, and low sperm counts	Nurse advises woman to take medication to stimulate ovulation so the mature ovum can be retrieved by needle aspiration.
Gamete intrafallopian transfer (GIFT)	Oocytes and sperm are combined and immediately placed in the fallopian tube so fertilization can occur naturally. Requires laparoscopy and general anesthesia, which increases risk	Nurse needs to inform couple of risks and have consent signed.
Intracytoplasmic sperm injection (ICSI)	One sperm is injected into the cytoplasm of the oocyte to fertilize it. Indicated for male factor infertility.	Nurse needs to inform the male that sperm will be aspirated by a needle through the skin into the epididymis.
Donor oocytes or sperm	Eggs or sperm are retrieved from a donor and the eggs are inseminated; resulting embryos are transferred via IVF. Recommended for women older than 40 and those with poor-quality eggs.	Nurse needs to support couple in their ethical/religious discussions prior to deciding.
Gestational carrier (surrogacy)	Laboratory fertilization takes place and embryos are transferred to the uterus of another woman, who will carry the pregnancy. Medical-legal issues have resulted over the "true ownership" of the resulting infant.	Nurse should encourage an open discussion regarding implications of this method with the couple.

*When other options have been exhausted, these are considered.

sexual activity for 24 to 48 hours before giving the sample. For a semen examination, the man is asked to produce a specimen by ejaculating into a specimen container and delivering it to the laboratory for analysis within 1 to 2 hours. When the specimen is brought to the laboratory, it is analyzed for volume, viscosity, number of sperm, sperm viability, motility, and sperm shape. If semen parameters are normal, no further male evaluation is necessary (Quallich, 2006).

The physical examination routinely includes:

- Assessment for appropriate male sexual characteristics, such as body hair distribution, development of the Adam's apple, and muscle development

- Examination of the penis, scrotum, testicles, epididymis, and vas deferens for abnormalities (e.g., nodules, irregularities, varicocele)
- Assessment for normal development of external genitalia (small testicles)
- Performance of a digital internal examination of the prostate to check for tenderness or swelling (DeMasters, 2004)

Assessing Female Factors

The initial assessment of the woman should include a thorough history of factors associated with ovulation and the pelvic organs. Diagnostic tests to determine female infertility may include:

- Assessment of ovarian function
  - Menstrual history: regularity of cycles
  - Ovulation predictor kits used midcycle
  - Urinary LH level
  - Clomiphene citrate challenge test
  - Endometrial biopsy to document luteal phase
  - Assessment of pelvic organs
  - Papanicolaou (Pap) smear to rule out cervical cancer or inflammation
  - Cervical culture to rule out Chlamydia infection
  - Postcoital testing to evaluate sperm–cervical mucus interaction
  - Ultrasound to assess pelvic structures
  - Hysterosalpingography to visualize structural defects
  - Laparoscopy to visualize pelvic structures and diagnose endometriosis

Laboratory and Diagnostic Testing

The diagnostic procedures that should be done during an infertility workup should be guided by the couple's history. They generally proceed from less to more invasive tests.

Home Ovulation Predictor Kits

Home ovulation predictor kits contain monoclonal antibodies specific for LH and use the ELISA test to determine the amount of LH present in the urine. A significant color change from baseline indicates the LH surge and presumably the most fertile day of the month for the woman.

Clomiphene Citrate Challenge Test

The clomiphene citrate challenge test is used to assess a woman's ovarian reserve (ability of her eggs to become fertilized). FSH levels are drawn on cycle day 3 and on cycle day 10 after the woman has taken 100 mg clomiphene citrate on cycle days 5 through 9. If the FSH level is greater than 15, the result is considered abnormal and the likelihood of conception with her own eggs is very low (Schuiling & Likis, 2006).

Endometrial Biopsy

Another assessment of ovulation that indicates whether the secretion of progesterone is adequate is an endometrial biopsy. A strip of endometrial tissue is removed just before menstruation. Histologic documentation of secretory endometrial development implies that ovulation has taken place. An endometrium that does not conform to the normal histologic pattern indicates a defect in the luteal phase.

Postcoital Testing

Postcoital testing is done to assess the receptivity of the cervical mucus to sperm. Cervical mucus from the woman is examined 2 to 8 hours after intercourse during the expected time of ovulation, and the number of live, motile sperm present is assessed. Cervical mucus is also evaluated for stretchability (spinnbarkeit) and consistency (Alexander et al., 2007). The results are described in Comparison Chart 4.1.

Hysterosalpingogram

In a hysterosalpingogram, 3 to 10 mL of an opaque contrast medium is slowly injected through a catheter into the endocervical canal so that the uterus and tubes can be visualized during fluoroscopy and radiography. If the fallopian tubes are patent, the dye will ascend upward to distend the uterus and the tubes and will spill out into the peritoneal cavity (Fig. 4.4).

Laparoscopy

A laparoscopy is usually performed early in the menstrual cycle. During the procedure, an endoscope is inserted through a small incision in the anterior abdominal wall. Visualization of the peritoneal cavity in an infertile woman may reveal endometriosis, pelvic adhesions, tubal occlusion, fibroids, or polycystic ovaries (DeSutter, 2006).

Nursing Management

Nurses play an important role in the care of infertile couples. They are pivotal educators about preventive health care. There are a number of potentially modifiable risk

COMPARISON CHART 4.1 NORMAL VERSUS ABNORMAL POSTCOITAL TEST RESULTS

Normal	Abnormal
Normal amounts of sperm are seen in the sample.	No sperm or a large percentage of dead sperm are seen in the sample.
Sperm are moving forward through the cervical mucus.	Sperm are clumped.
The mucus stretches at least 2 in (5 cm).	Mucus cannot stretch 2 in (5 cm).
The mucus dries in a fernlike pattern.	Mucus does not dry in a fernlike pattern.

factors associated with the development of impaired fertility in women, and women need to be aware of these risks to institute change. The nurse is most effective when he or she offers care and treatment in a professional manner and regards the couple as valued and respected individuals. The nurse's focus must encompass the whole person, not just the results of the various infertility studies. Throughout the entire process, the nurse's role is to provide information, anticipatory guidance, stress management, and counseling. The couple's emotional distress is usually very high, and the nurse must be able to recognize that anxiety and provide emotional support. The nurse may need to refer couples to a reproductive endocrinologist or surgeon, depending on the problem identified.

There is no absolute way to prevent infertility per se because so many factors are involved in conception. Nurses can be instrumental in educating men and women about the factors that contribute to infertility. The nurse can also outline the risks and benefits of treatments so that the couple can make an informed decision.

With advances in genetics and reproductive medicine also come a myriad of ethical, social, and cultural issues that will affect the couple's decisions. With this in mind, provide an opportunity for the couple to make informed decisions in a nondirective, nonjudgmental environment. It is important to encourage couples to remain optimistic throughout investigation and treatment. Through the use of advocacy and anticipatory guidance, assist and support couples through the diagnosis and treatment of infertility (Jenkins & Jenkins, 2006).

Finances and insurance coverage often dictate the choice of treatment. Help couples decipher their insurance coverage and help them weigh the costs of various procedures by explaining what each will provide in terms of information about their infertility problems. Assisting them to make a priority list of diagnostic tests and potential treatment options will help the couple plan their financial strategy.

Many infertile couples are not prepared for the emotional roller coaster of grief and loss during infertility treatments. Financial concerns and coping as a couple are two major areas of stress when treatment is undertaken. During the course of what may be months or even years of infertility care, it is essential to develop a holistic approach to nursing care. Stress management and anxiety reduction need to be addressed, and referral to a peer support group such as Resolve might be in order (Box 4.4).

BOX 4.4 Organizations and Web Resources to Assist the Client With Infertility

- Resolve: A nationwide network of chapters dedicated to providing education, advocacy, and support for men and women facing infertility. They provide a helpline, medical referral services, and a member-to-member contact system. (http://www.resolve.org)
- American Society of Reproductive Medicine (ASRM): Provides fact sheets and other resources on infertility, treatments, insurance, and other issues (http://www.asrm.org)
- International Counsel on Infertility (INCIID): Provides information about infertility, support forums, and a directory of infertility specialists (http://www.inciid.org)
- American Fertility Association: Offers education, referrals, research, support, and advocacy for couples dealing with infertility (http://www.americaninfertility.org)
- Bertarelli Foundation: The Human Face of Infertility: Aims to promote and improve understanding of infertility by offering resources (http://www.bertarelli.edu)
- International Consumer Support for Infertility: An international network engaged in advocacy on behalf of infertile couples via fact sheets and information (http://www.icsi.ws)

▸ *Consider* THIS!

We had been married for 3 years and wanted to start a family, but much to our dismay nothing happened after a year of trying. I had some irregular periods and was finally diagnosed with endometriosis and put on Clomid. After 3 years of taking Clomid on and off, I went to a fertility expert. The doctor lasered the endometriosis tissue, sent air through my tubes to make sure they were patent, and put me back on Clomid, but still with no luck. Finally, 2 years later, we were put on an IVF waiting list and prayed we would have the money for the procedure when we were chosen. By then I felt a failure as a woman. We then decided that it was more important for us to be parents than it was for me to be pregnant, so we considered adoption. We tried for another year without any results.

We went to the adoption agency to fill out the paperwork for the process to begin. Our blood was

(continued)

Consider THIS! *(continued)*

taken and we waited for an hour, wondering the whole time why it was taking so long for the results. The nurse finally appeared and handed a piece of paper to me with the word "positive" written on it. I started to cry tears of joy, for a pregnancy had started and our long journey of infertility was finally ending.
Thoughts: For many women the dream of having a child is not easily realized. Infertility can affect self-esteem, disrupt relationships, and result in depression. This couple experienced many years of frustration in trying to have a family. What help can be offered to couples during this time? What can be said to comfort the woman who feels she is a failure?

Contraception

In the United States, there are approximately 62 million women in their childbearing years, ages 15 to 44. Overall, 64% of those 60 million women use contraception, but still more than 3 million unintended pregnancies occur every year (CDC, 2006). Although numerous fertility control methods are available, the United States continues to have a higher unintended pregnancy rate than other Western countries. Every minute of every day, 10 people become infected with HIV, most through heterosexual contact; 190 women conceive an unwanted pregnancy; 1 woman dies from a pregnancy-related cause; and 40 women undergo unsafe abortions, as outlined in the UNFPA State of the World Population 2006 Report. Much of this suffering could be prevented by access to safe, efficient, appropriate, modern contraception for everyone who wants it (UNFPA, 2007).

Contraception is any method that prevents conception or childbirth. A woman's reproductive life spans almost 40 years, and throughout those years, a variety of contraceptive methods may be used. Oral contraceptives, sterilization of the female, and the male condom are the most popular methods in the United States (Alan Guttmacher Institute, 2007).

Couples must decide which method is appropriate for them to meet their changing contraceptive needs throughout their life cycles. Nurses can educate and assist couples during this selection process. This part of the chapter will outline the most common birth control methods available.

In an era when many women wish to delay pregnancy and avoid STIs, choices are difficult. There are numerous methods available today, and many more will be offered in the near future. The ideal contraceptive method for many women would have to have the following characteristics: ease of use, safety, effectiveness, minimal side effects, "naturalness," nonhormonal method, and immediate reversibility (Samra & Wood, 2006). Currently, no one contraceptive method offers everything. Box 4.5 outlines the contraceptive methods available today. Table 4.4 provides a detailed summary of each type, including information on failure rates, advantages, disadvantages, STI protection, and danger signs.

BOX 4.5 Outline of Contraceptive Methods

Reversible Methods

Behavioral
- Abstinence
- Fertility awareness
- Withdrawal (coitus interruptus)
- Lactational amenorrhea method (LAM)

Barrier
- Condom (male and female)
- Diaphragm
- Cervical cap
- Sponge

Hormonal
- Oral contraceptives
- Injectable contraceptive
- Transdermal patches
- Vaginal ring
- Implantable contraceptives
- Intrauterine systems
- Emergency contraceptives

Permanent Methods
- Tubal ligation for women
- Vasectomy for men

Types of Contraceptive Methods

Contraceptives methods can be divided into three types: behavioral methods, barrier methods, and hormonal methods.

Behavioral Methods

Behavioral methods refer to any natural contraceptive method that does not require hormones, pharmaceutical compounds, physical barriers, or surgery to prevent pregnancy. These methods require couples to take an active role in preventing pregnancy through their sexual behaviors.

Abstinence

Abstinence (not having vaginal or anal intercourse) is one of the least expensive forms of contraception and has been used for thousands of years. Basically, pregnancy cannot occur if sperm is kept out of the vagina. It also reduces the risk of contracting HIV/AIDS and other STIs, unless body fluids are exchanged through oral sex; however, some infections, like herpes and HPV, can be passed by skin-to-skin contact. There are many pleasurable

(text continues on page 114)

TABLE 4.4 SUMMARY OF CONTRACEPTIVE METHODS

Type	Description	Failure Rate	Pros	Cons	STI Protection	Danger Signs	Comments
Abstinence	Refrain from sexual activity	None	Costs nothing	Difficult to maintain	100%	None	Must be joint couple decision
Fertility awareness	Refrain from sex during fertile period	25%	No side effects; acceptable to most religious groups	High failure rate with incorrect use	None	None	Requires high level of couple commitment
Withdrawal (coitus interruptus)	Man withdraws before ejaculation	27%	Involves no devices and is always available	Requires considerable self-control by the man	None	None	Places woman in trusting and dependent role
Lactational amenorrhea method (LAM)	Uses lactational infertility for protection from pregnancy	1–2% chance of pregnancy in first 6 months	No cost; not coitus-linked	Temporary method; effective for only 6 months after giving birth	None	None	Mother must breastfeed infant on demand without supplementation for 6 months
Male condom	Thin sheath placed over an erect penis, blocking sperm	15%	Widely available; low cost; physiologically safe	Decreased sensation for man; interferes with sexual spontaneity; breakage risk	Provides protection against STIs	Latex allergy	Couple must be instructed on proper use of condom
Female condom	Polyurethane sheath inserted vaginally to block sperm	21%	Use controlled by woman; eliminates postcoital drainage of semen	Expensive for frequent use; cumbersome; noisy during sex act; for single use only	Provides protection against STIs	Allergy to polyurethane	Couple must be instructed on proper use of condom
Diaphragm with spermicide	Shallow latex cup with spring mechanism in its rim to hold it in place in the vagina	16%	Does not use hormone; considered medically safe; provides some protection against cervical cancer	Requires accurate fitting by health care professional; increase in UTIs	None	Allergy to latex, rubber, polyurethane, or spermicide. Report symptoms of toxic shock syndrome. Change size if excessive weight gain or loss.	Woman must be taught to insert and remove diaphragm correctly

(continued)

TABLE 4.4 SUMMARY OF CONTRACEPTIVE METHODS (continued)

Type	Description	Failure Rate	Pros	Cons	STI Protection	Danger Signs	Comments
Cervical cap with spermicide	Soft cup-shaped latex device that fits over base of cervix	24%	No use of hormones; provides continuous protection while in place	Requires accurate fitting by health care professional; odor may occur if left in too long	None	Irritation, allergic reaction; abnormal Pap test; risk of toxic shock syndrome	Instructions on insertion and removal must be understood by client
Sponge with spermicide	Disk-shaped polyurethane device containing a spermicide that is activated by wetting it with water	25%	Offers immediate and continuous protection for 24 hours; OTC	Can fall out of vagina with voiding; is not form-fitting in the vagina	None	Irritation, allergic reactions; toxic shock syndrome can occur if sponge left in too long	Caution woman not to leave sponge in beyond 24 hours
Oral contraceptives (combination)	A pill that suppresses ovulation by combined action of estrogen and progestin	8%	Easy to use; high rate of effectiveness; protection against ovarian and endometrial cancer	User must remember to take pill daily; possible undesirable side effects; high cost for some women; prescription needed	None	Dizziness, nausea, mood changes, high blood pressure, blood clots, heart attacks, strokes	Each woman must be assessed thoroughly to make sure she is not a smoker and does not have a history of thromboembolic disease
Oral contraceptives (progestin-only minipills)	A pill containing only progestin that thickens cervical mucus to prevent sperm from penetrating	8%	No estrogen-related side effects; may be used by lactating women; may be used by women with history of thrombophlebitis	Must be taken with meticulous accuracy; may cause irregular bleeding; less effective than combination pills	None	Irregular bleeding, weight gain, increased incidence of ectopic pregnancy	Women should be screened for history of functional ovarian cysts, previous ectopic pregnancy, hyperlipidemia prior to giving prescription

Lunelle injectable	An injectable form of progestin and estrogen given monthly	3%	Woman will regain fertility 2–3 months after last injection; no need for daily pill taking	Must make arrangements for monthly injection; possible weight gain	None	Irregular spotting; similar to oral combination pills	Screen woman's ability to schedule monthly appointment for injection
Patch (Ortho Evra)	Transdermal patch that releases estrogen and progestin into circulation	8%	Easy system to remember; very effective	May cause skin irritation where it is placed; may fall off and not be noticed and thus provide no protection	None	Less effective in women weighing more than 200 pounds	Instruct woman to apply patch every week for 3 weeks and then not to wear one during week 4
Ring (NuvaRing)	Vaginal contraceptive ring about 2 inches in diameter that is inserted into the vagina; releases estrogen and progestin	8%	Easy system to remember; very effective	May cause a vaginal discharge; can be expelled without noticing and not offer protection	None	Similar to oral contraceptives	Instruct woman to use a backup method if ring is expelled and remains out for more than 3 hours
Depo-Provera injection	An injectable progestin that inhibits ovulation	3%	Long duration of action (3 months); highly effective; estrogen-free; may be used by smokers; can be used by lactating women	Menstrual irregularities; return visit needed every 12 weeks; weight gain, headaches, depression; return to fertility delayed up to 12 months	None	If depression is a problem, this method may increase the depression.	Inform woman that fertility is delayed after stopping the injections

(continued)

TABLE 4.4 SUMMARY OF CONTRACEPTIVE METHODS (continued)

Type	Description	Failure Rate	Pros	Cons	STI Protection	Danger Signs	Comments
Implant (Implanon)	A time-release implant (one rod) of levonorgestrel for 3 years	0.05%	Long duration of action; low dose of hormones; reversible; estrogen-free	Irregular bleeding; weight gain; breast tenderness; headaches; difficulty in removal	None	If bleeding is heavy, anemia may occur.	Before insertion, assess woman to make sure she is aware that this method will produce about 3–5 years of infertility
Intrauterine systems (IUSs)	A T-shaped device inserted into the uterus that releases copper or progesterone or levonorgestrel	1%	It is immediately and highly effective; allows for sexual spontaneity; can be used during lactation; return to fertility not impaired; requires no motivation by the user after insertion	Insertion requires a skilled professional; menstrual irregularities; prolonged amenorrhea; can be unknowingly expelled; may increase the risk of pelvic infection; user must regularly check string for placement; no protection against STIs; delay of fertility after discontinuing for possibly 6 to 12 months	None	Cramps, bleeding, pelvic inflammatory disease; infertility; perforation of the uterus	Instruct woman how to locate string to check monthly for placement

Postcoital emergency contraceptives (ECs)	Combination of progestin-only pills taken within 72 hours after unprotected intercourse	80%	Provides a last chance to prevent a pregnancy	Risk of ectopic pregnancy if EC fails	None	Nausea, vomiting, abdominal pain, fatigue, headache	Inform woman that ECs do not interrupt an established pregnancy, and the sooner they are taken the more effective they are
Permanent sterilization							
Male	Sealing, tying, or cutting the vas deferens	<1%	One-time decision provides permanent sterility; short recovery time; low long-term risks	Procedures are difficult to reverse; initial cost may be high; chance of regret; some pain/ discomfort after procedures	None for both	Postoperative complications: pain, bleeding, infection	Counsel both as to permanence of procedure and urge them to think it through prior to signing consent
Female	Fallopian tubes are blocked to prevent conception	<1%

options for sex play without intercourse ("outercourse"), such as kissing, masturbation, erotic massage, sexual fantasy, sex toys such as vibrators, and oral sex.

Many people have strong feelings about abstinence based on religious and moral beliefs. There are many good and personal reasons to choose abstinence. For some it is a way of life, while for others it is a temporary choice. Some people choose abstinence because they want to:

- Wait until they are older
- Wait for a long-term relationship
- Avoid pregnancy or STIs
- Follow religious or cultural expectations

Fertility Awareness

Fertility awareness is a natural method of contraception in which no contraceptive devices are used; instead, certain observations, techniques, and calculations are used to determine the "fertile" and the "safe" periods in a monthly menstrual cycle. There are normal physiologic changes caused by hormonal fluctuations during the menstrual cycle that can be observed and charted. This information can be used to avoid or promote pregnancy. Fertility awareness methods rely upon the following assumptions:

- A single ovum is released from the ovary 14 days before the next menstrual period. It lives approximately 24 hours.
- Sperm can live up to 5 days after intercourse. The "unsafe period" during the menstrual cycle is thus approximately 6 days: 3 days before and 3 days after ovulation. Since bodily changes start to occur before ovulation, the woman can become aware of them and not have intercourse on these days or use another method to prevent pregnancy.
- The exact time of ovulation cannot be determined, so 2 to 3 days are added to the beginning and end to avoid pregnancy.

Techniques used to determine fertility include the cervical mucus ovulation method, the basal body temperature (BBT) method, and the symptothermal method (Hatcher et al., 2004). Fertility awareness methods are moderately effective but are very unforgiving if not carried out as prescribed: not following the guidelines might cause a 27% failure or pregnancy rate per cycle (Murphy, Morgan & Likis, 2006). Fertility awareness can be used in combination with coital abstinence or barrier methods during fertile days if pregnancy is not desired.

Cervical Mucus Ovulation Method

The **cervical mucus ovulation method** is used to assess the character of the cervical mucus. Cervical mucus changes in consistency during the menstrual cycle and plays a vital role in fertilization of the egg. In the days preceding ovulation, fertile cervical mucus helps draw sperm up and into the fallopian tubes, where fertilization usually takes place. It also helps maintain the survival of sperm. As ovulation approaches, the mucus becomes more abundant, clear, slippery, and smooth; it can be stretched between two fingers without breaking. Under the influence of estrogen, this mucus looks like egg whites. It is called spinnbarkeit mucus (Fig. 4.5). After ovulation, the cervical mucus becomes thick and dry under the influence of progesterone.

The cervical position can also be assessed to confirm changes in the cervical mucus at ovulation. Near ovulation, the cervix feels soft and is high/deep in the vagina, the os is slightly open, and the cervical mucus is copious and slippery (Hatcher et al., 2004).

This method works because the woman becomes aware of her body changes that accompany ovulation. When she notices them, she abstains from sexual intercourse or uses another method to prevent pregnancy. Each woman is an individual, so each woman's unsafe time of the month is unique and thus must be individually assessed and determined.

Basal Body Temperature

The **basal body temperature** (BBT) refers to the lowest temperature reached upon wakening. The woman takes her temperature orally before rising and records it on a chart. Preovulation temperatures are suppressed by estrogen, whereas postovulation temperatures are increased under the influence of heat-inducing progesterone. Temperatures typically rise within a day or two after ovulation and remain elevated for approximately 2 weeks (at which point bleeding usually begins). If using this method by itself, the woman should avoid unprotected intercourse until the BBT has been elevated for 3 days. Other fertility awareness methods should be used along with BBT for better results (Fig. 4.6).

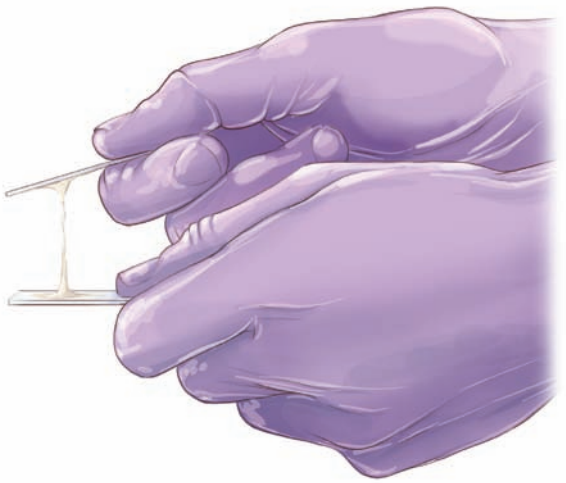

FIGURE 4.5 Spinnbarkeit is the ability of cervical mucus to stretch a distance before breaking.

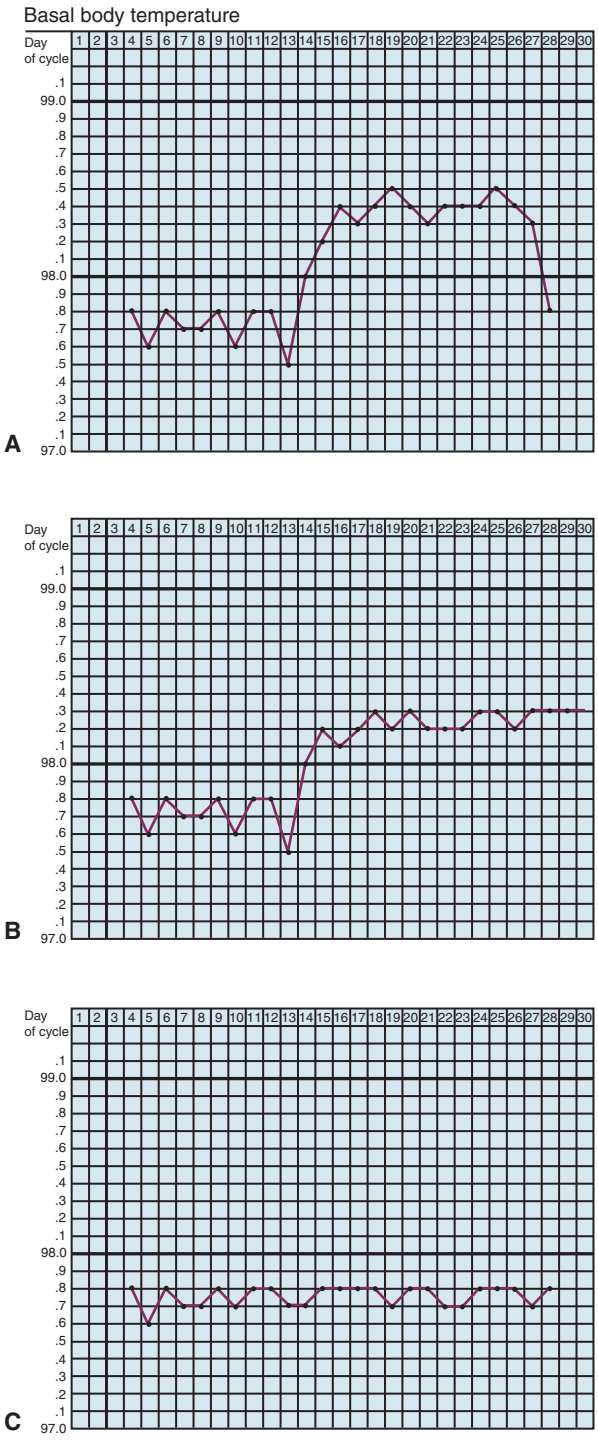

FIGURE 4.6 Basal body temperature graph. (**A**) The woman's temperature dips slightly at midpoint in the menstrual cycle, then rises sharply, an indication of ovulation. Toward the end of the cycle (the 24th day), her temperature begins to decline, indicating that progesterone levels are falling and that she did not conceive. (**B**) The woman's temperature rises at the midpoint in the cycle and remains at that elevated level past the time of her normal menstrual flow, suggesting that pregnancy has occurred. (**C**) There is no preovulatory dip and no rise of temperature anywhere during the cycle. This is the typical pattern of a woman who does not ovulate.

Symptothermal Method

The **symptothermal method** relies on a combination of techniques to recognize ovulation, including BBT, cervical mucus changes, alterations in the position and firmness of the cervix, and other symptoms of ovulation, such as increased libido, mittelschmerz, pelvic fullness or tenderness, and breast tenderness (Dirubbo, 2006). Combining all these predictors increases awareness of when ovulation occurs and increases the effectiveness of this method. A home predictor test for ovulation is also available in most pharmacies. It measures LH levels to pinpoint the day before or the day of ovulation. These tests are widely used for fertility and infertility regimens.

The Standard Days Method and the Two-Day Method

The **Standard Days Method (SDM)** and the Two-Day Method are both natural methods of contraception developed by Georgetown University Medical Center's Institute for Reproductive Health. Both methods provide women with simple, clear instructions for identifying fertile days. Women with menstrual cycles between 26 and 32 days long can use the SDM to prevent pregnancy by avoiding unprotected intercourse on days 8 through 19 of their cycles. An international clinical trial of the SDM showed that the method is more than 95% effective when used correctly (Sinai, Arevalo & Jennings, 2006). SDM identifies the 12-day "fertile window" of a woman's menstrual cycle. These 12 days takes into account the lifespan of the women's egg (about 24 hours) and the viability of the sperm (about 5 days) as well as the variation in the actual timing of ovulation from one cycle to another. For the Two-Day Method, women observe the presence or absence of cervical secretions by examining toilet paper or underwear or by monitoring their physical sensations. Every day, the woman asks two simple questions "Did I note any secretions yesterday?" and "Did I note any secretions today?" If the answer to either question is yes, she considers herself fertile and avoids unprotected intercourse. If the answers are no, she is unlikely to become pregnant from unprotected intercourse on that day (Sinai, Arevalo & Jennings, 2006).

To help women keep track of the days on which they should avoid unprotected intercourse, a string of 32 color-coded beads (CycleBeads) is used, with each bead representing a day of the menstrual cycle. Starting with the red bead, which represents the first day of her menstrual period, the woman moves a small rubber ring one bead each day. The brown beads are the days when pregnancy is unlikely, and the white beads represent her fertile days (Arevalo, 2007). This method has been used in underdeveloped countries for women with limited educational resources (Fig. 4.7).

Withdrawal (Coitus Interruptus)

In **coitus interruptus**, also known as withdrawal, a man controls his ejaculation during sexual intercourse and ejaculates outside the vagina. It is better known colloquially as

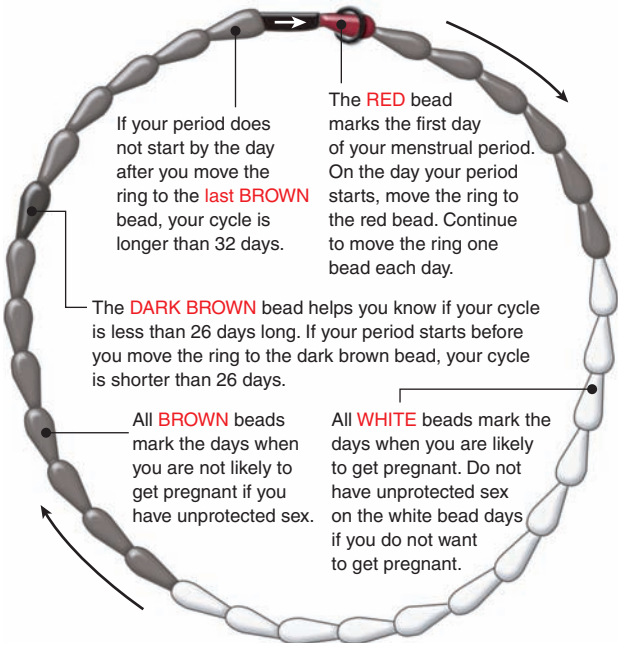

FIGURE 4.7 CycleBeads help women use the Standard Days Method.

"pulling out in time" or "being careful." It is one of the oldest and most widely used means of preventing pregnancy in the world (Murphy, Morgan & Likis, 2006). The problem with this method is that the first few drops of the true ejaculate contain the greatest concentration of sperm, and if some pre-ejaculatory fluid escapes from the urethra before orgasm, conception may result. This method requires that the woman rely solely on the cooperation and judgment of the man.

Lactational Amenorrhea Method

The **lactational amenorrhea method (LAM)** is an effective temporary method of contraception used by breastfeeding mothers. Continuous breastfeeding can postpone ovulation and thus prevent pregnancy. Breastfeeding stimulates the hormone prolactin, which is necessary for milk production, and also inhibits the release of another hormone, gonadotropin, which is necessary for ovulation.

Breastfeeding as a contraceptive method can be effective for 6 months after delivery only if a woman:

- Has not had a period since she gave birth
- Breastfeeds her baby at least six times daily on both breasts
- Breastfeeds her baby "on demand" at least every 4 hours
- Does not substitute other foods for a breast-milk meal
- Provides nighttime feedings at least every 6 hours
- Does not rely on this method after 6 months (Planned Parenthood, 2007)

Barrier Methods

Barrier contraceptives are forms of birth control that prevent pregnancy by preventing the sperm from reaching the ovum. Mechanical barriers include condoms, diaphragms, cervical caps, and sponges. These devices are placed over the penis or cervix to physically obstruct the passage of sperm through the cervix. Chemical barriers called spermicides may be used along with mechanical barrier devices. They come in creams, jellies, foam, suppositories, and vaginal films. They chemically destroy the sperm in the vagina. These contraceptives are called barrier methods because they not only provide a physical barrier for sperm, but also protect against STIs. Since the HIV/AIDS epidemic started in the early 1980s, these methods have become extremely popular.

Many of these barrier methods contain latex. Allergy to latex was first recognized in the late 1970s, and since then it has become a major health concern, with increasing numbers of people affected. According to the American Academy of Allergy, Asthma and Immunology (2007), 6% of the general population, 10% of health care workers, and 50% of spina bifida patients are sensitive to natural rubber latex. Since the late 1980s, with the establishment of policies dictating barrier requirements resulting from the HIV/AIDS epidemic, there has been an exponential increase in the use of latex gloves and condoms (Lenehan, 2004). Teaching Guidelines 4.4 provides tips for individuals with latex allergy.

TEACHING GUIDELINES 4.4

Tips for Individuals Allergic to Latex

- Symptoms of latex allergy include:
  - Skin rash, itching, hives
  - Itching or burning eyes
  - Swollen mucous membranes in the genitals
  - Shortness of breath, difficulty breathing, wheezing
  - Anaphylactic shock (OSHA, 2006)
- Use of or contact with latex condoms, cervical caps, and diaphragms is contraindicated for men and women with a latex allergy.
- If the female partner is allergic to latex, have the male partner apply a natural condom over the latex one.
- If the male partner experiences penile irritation after condom use, try different brands or place the latex condom over a natural condom.
- Use polyurethane condoms rather than latex ones.
- Use female condoms; they are made of polyurethane.
- Switch to another birth control method that isn't made with latex, such as oral contraceptives, intrauterine systems, Depo-Provera, fertility awareness, and other non-barrier methods. However, these methods do not protect against sexually transmitted infections.

Condoms

Condoms are barrier methods of contraceptives made for both males and females. The male condom is made from latex or polyurethane or natural membrane and may be coated with spermicide. Male condoms are available in many colors, textures, sizes, shapes, and thicknesses. When used correctly, the male condom is put on over an erect penis before it enters the vagina and is worn throughout sexual intercourse (Fig. 4.8). It serves as a barrier to pregnancy by trapping seminal fluid and sperm and offers protection against STIs. Condoms are not perfect barriers, though, because breakage and slippage can occur. In addition, the non-latex condoms have a higher risk of pregnancy and STIs than latex condoms (Gallo, Grimes, Lopez & Schultz, 2006).

The female condom is a polyurethane pouch inserted into the vagina. It consists of an outer and inner ring that is inserted vaginally and held in place by the pubic bone. Some women complain that the female condom is cumbersome to use and makes noise during intercourse. Female condoms are readily available, are inexpensive, and can be carried inconspicuously by the woman. The female condom was the first woman-controlled method that offered protection against pregnancy and some STIs.

Diaphragm

The **diaphragm** is a soft latex dome surrounded by a metal spring. Used in conjunction with a spermicidal jelly or cream, it is inserted into the vagina to cover the cervix (Fig. 4.9). The diaphragm may be inserted up to 4 hours before intercourse but must be left in place for at least 6 hours afterwards. Diaphragms are available in a range of sizes and styles. The diaphragm is available only by prescription and must be professionally fitted by

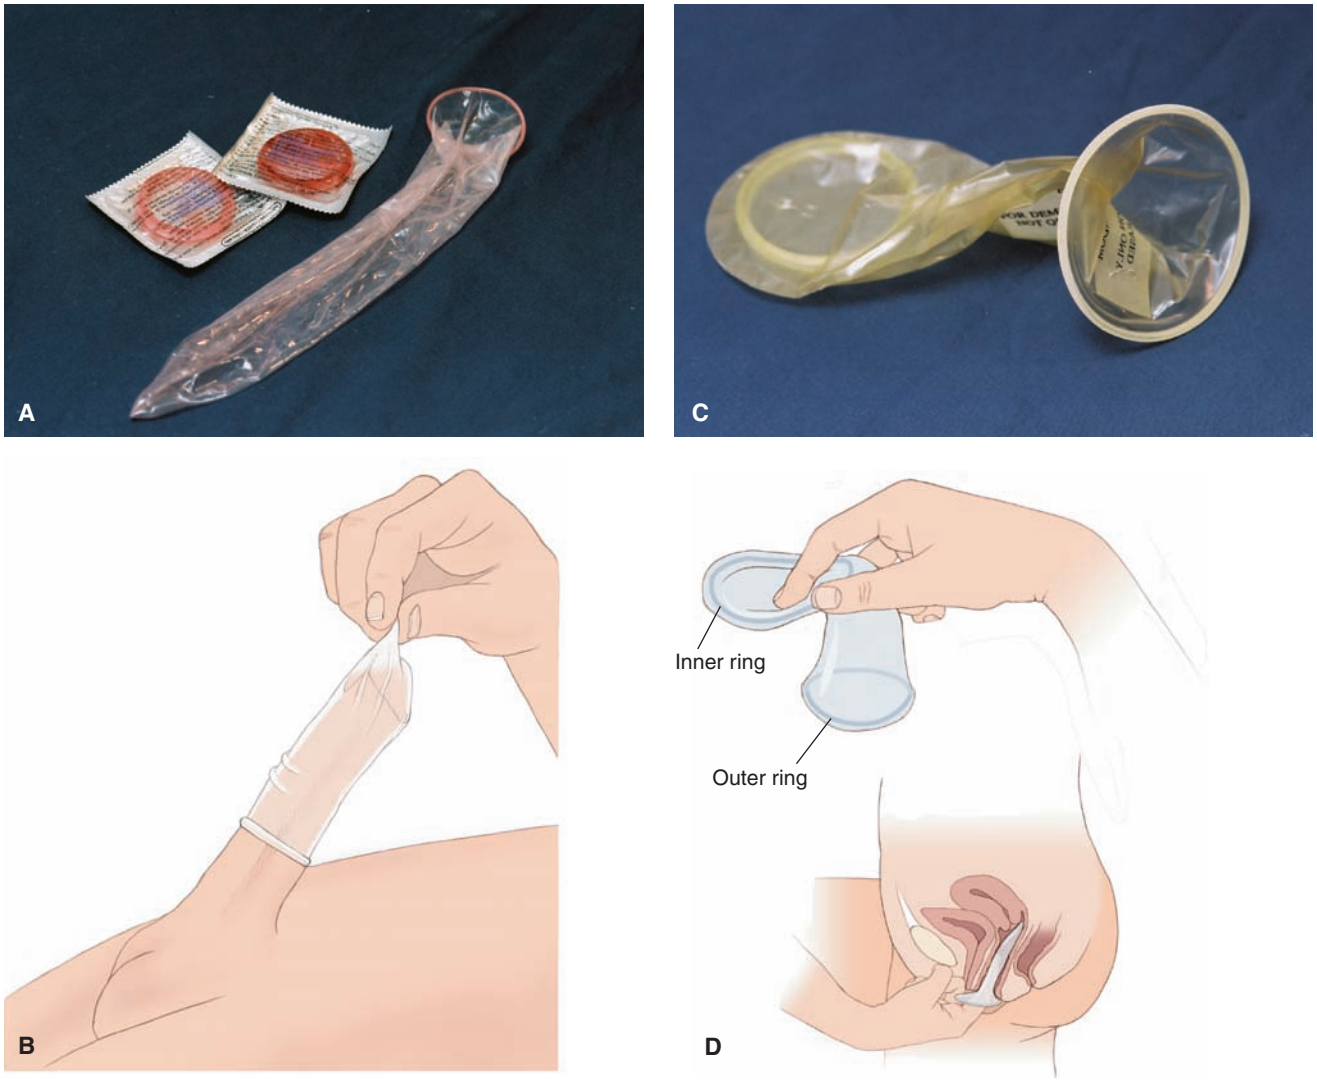

FIGURE 4.8 (**A**) Male condom. (**B**) Applying a male condom. Leaving space at the tip helps to ensure the condom will not break with ejaculation. (**C**) The female condom. (**D**) Insertion technique.

FIGURE 4.9 Sample diaphragm used for measuring.

a health care professional. Women may need to be refitted with a different-sized diaphragm after pregnancy, abdominal or pelvic surgery, or weight loss or gain of 10 pounds or more. As a general rule, diaphragms should be replaced every 1 to 2 years (Female Contraception, 2006). The woman also needs to receive thorough instruction about its use and should practice putting it in and taking it out before she leaves the medical office (Fig. 4.10). Diaphragms are user-controlled, nonhormonal methods that are needed only at the time of intercourse, but they are not effective unless used correctly.

Cervical Cap

The **cervical cap** is smaller than the diaphragm and covers only the cervix; it is held in place by suction. Caps are made from silicone or latex and are used with spermicide (Fig. 4.11). The Prentif cap and the FemCap are the only cervical cap devices approved in the United States currently (Gallo, Grimes & Schultz, 2006). The cap may be inserted up to 12 hours before intercourse and provides protection for 48 hours. The cap must be kept in the vagina for 8 hours after the final act of intercourse and should be replaced every 1 to 2 years. A refitting may also be necessary when a women experiences pregnancy, abortion, or weight changes. The dome of the cap is filled about one-third full with spermicide. Spermicide should

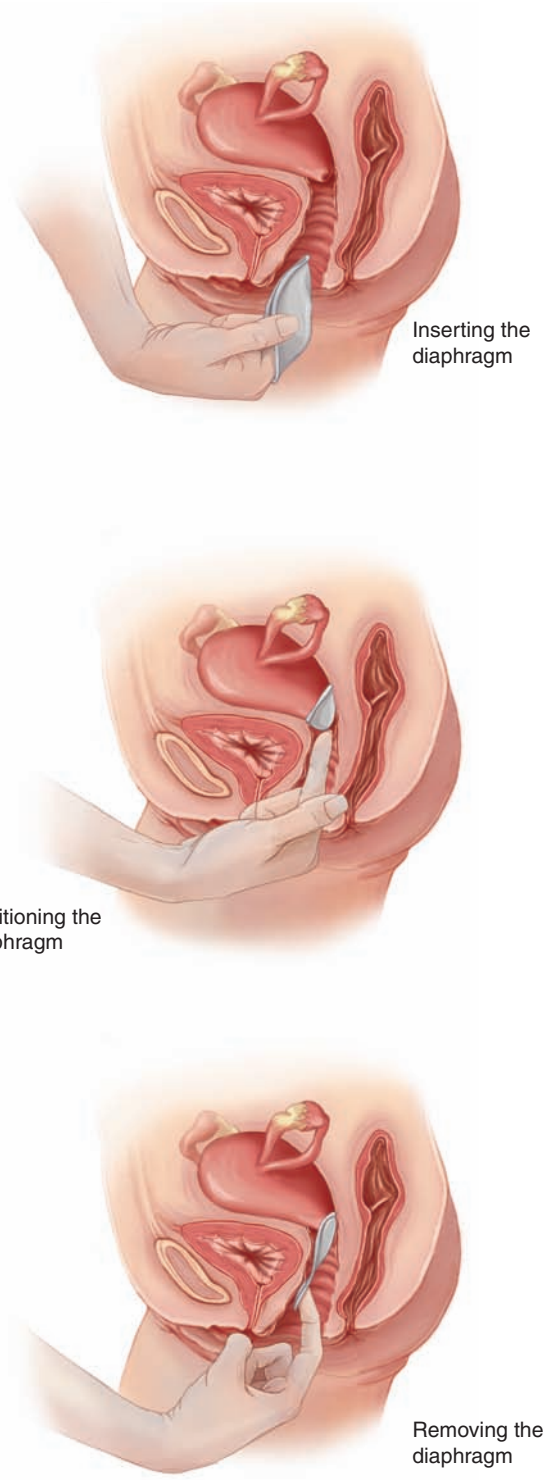

FIGURE 4.10 Application of a diaphragm. (**A**) To insert, fold the diaphragm in half, separate the labia with one hand, then insert upwards and back into the vagina. (**B**) To position, make certain the diaphragm securely covers the cervix. (**C**) To remove, hook a finger over the top of the rim and bring the diaphragm down and out.

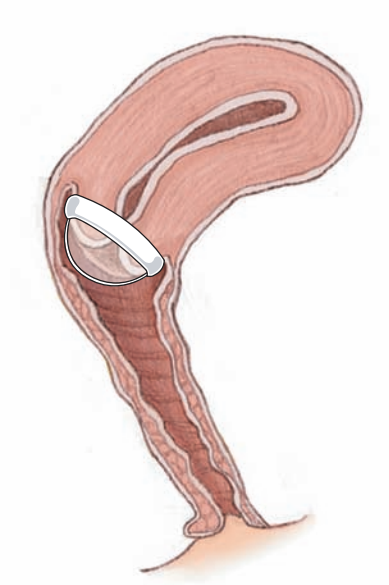

FIGURE 4.11 A cervical cap is placed over the cervix and used with a spermicidal jelly, the same as a diaphragm.

not be applied to the rim because it might interfere with the seal that must form around the cervix. The cap is available only by prescription and must be fitted by a health care professional.

Contraceptive Sponge

The **contraceptive sponge** is a nonhormonal, nonprescription device that includes both a barrier and a spermicide. When it was removed from the market in 1995, it was the most popular over-the-counter female contraceptive in America (Brucker, 2006). The manufacturer, Wyeth, stopped making the sponge rather than upgrade its manufacturing plant after the FDA found deficiencies, but the device's effectiveness and safety were never questioned. After receiving re-approval from the FDA in 2005, the contraceptive sponge is once again being marketed to women.

The contraceptive sponge is a soft polyurethane concave device that prevents pregnancy by covering the cervix and releasing spermicide. While it was less effective than several other methods and does not offer protection against STIs, the sponge achieved a wide following among women who appreciated the spontaneity with which it could be used and its easy availability. To use the sponge, the woman first wets it with water, then inserts it into the vagina with a finger, using a cord loop attachment. It can be inserted up to 24 hours before intercourse and should be left in place for at least 6 hours following intercourse. The sponge provides protection for up to 12 hours, but should not be left in for more than 30 hours after insertion to avoid the risk of toxic shock syndrome (Brucker, 2006). The sponge is a contraceptive method but does not protect against STIs.

Hormonal Methods

Several options are available to women who want long-term but not permanent protection against pregnancy. These methods of contraception work by altering the hormones within a woman's body. They rely on estrogen and progestin or progestin alone to prevent ovulation. When used consistently, these methods are a most reliable way to prevent pregnancy. Hormonal methods include oral contraceptives, injectables, implants, vaginal rings, and transdermal patches.

Oral Contraceptives

As early as 1937, scientists recognized that the injection of progesterone inhibited ovulation in rabbits and provided contraception. Breakthrough bleeding was reported in early clinical trials in women, and the role of estrogen in cycle control was launched. This established the rationale for modern combination **oral contraceptives (OCs)** that contain both estrogen and progesterone (Roederer, Blackwell & Blenning, 2006). In 1960 the FDA approved the first combination OC, Enovid-10 (150 mcg estrogen and 9 mg progesterone), for use in the United States. Today, nearly 50 combination OCs are available in the United States. The most notable change in over 40 years of OC improvement has been the lowering of the estrogen dose to as low as 20 mcg and the introduction of new progestins.

Oral contraceptives are the most popular method of nonsurgical contraception, used by approximately 18 million women in the United States (Dirubbo, 2006) (Fig. 4.12). Unlike the original OCs that women took decades ago, the new low-dose forms carry fewer health risks.

OCs, while most commonly prescribed for contraception, have long been used in the management of a wide range of conditions and have many health benefits, such as:

- Reduced incidence of ovarian and endometrial cancer
- Prevention and treatment of endometriosis
- Decreased incidence of acne and hirsutism

FIGURE 4.12 Oral contraceptive.

- Decreased incidence of ectopic pregnancy
- Decreased incidence of acute PID
- Reduced incidence of fibrocystic breast disease
- Decreased perimenopausal symptoms
- Increased menstrual cycle regularity
- Lower incidence of colorectal cancer
- Reduced iron-deficiency anemia by treating menorrhagia
- Reduced incidence of dysmenorrhea (Roederer, Blackwell & Blenning, 2006)

OCs work primarily by suppressing ovulation by adding estrogen and progesterone to a woman's body, thus mimicking pregnancy. This hormonal level stifles gonadotropin-releasing hormone (GnRH), which in turn suppresses FSH and LH and thus inhibits ovulation. Cervical mucus also thickens, which hinders sperm transport into the uterus. Implantation is inhibited by suppression of the maturation of the endometrium and alterations of uterine secretions (Trussell, 2004).

The combination pills are prescribed as monophasic pills, which deliver fixed dosages of estrogen and progestin, or as multiphasic ones. Multiphasic pills (e.g., biphasic and triphasic OCs) alter the amount of progestin and estrogen within each cycle. To maintain adequate hormonal levels for contraception and enhance compliance, OCs should be taken at the same time daily.

OCs that contain progestin only are called minipills. They are prescribed for women who cannot take estrogen. They work primarily by thickening the cervical mucus to prevent penetration of the sperm and make the endometrium unfavorable for implantation. Progestin-only pills must be taken at a certain time every 24 hours. Breakthrough bleeding and a higher risk of pregnancy have made these OCs less popular than combination OCs (Mishell et al., 2007).

Extended OC regimens have been used for the management of menstrual disorders and endometriosis for years but now are attracting wider attention. Surveys asking women about their willingness to reduce their menstrual cycles from 12 to 4 annually were returned with a resounding "yes!" (Archer, 2006). Recent studies confirm that the extended use of active OC pills carries the same safety profile as the conventional 28-day regimens (Anderson et al., 2006; Edelman et al., 2006; Grimes, 2006). The extended regimen consists of 84 consecutive days of active combination pills, followed by 7 days of placebo. The woman has four withdrawal-bleeding episodes a year. Seasonale, a combination OC, is on the market for women who choose to reduce the number of periods that they have. There is no physiologic requirement for cyclic hormonal withdrawal bleeds while taking OCs (Wysocki, 2007).

The balance between the benefits and the risks of OCs must be determined for each woman when she is being assessed for this type of contraceptive. It is a highly effective contraceptive when taken properly but can aggravate many medical conditions, especially in women who smoke. Comparison Chart 4.2 lists advantages and disadvantages of OCs. A thorough history and pelvic examination, including a Pap smear, must be completed before the medication is prescribed and yearly thereafter. Women should also be counseled that the effectiveness of OCs is decreased when the woman is taking antibiotics; thus, the woman will need to use an alternative or secondary method during this period to prevent pregnancy.

Nurses need to provide OC users with a great deal of education before they leave the health care facility. They need to be able to identify early signs and symptoms that might indicate a problem.

▶ *Take* NOTE!

The mnemonic "ACHES" can help women remember the early warning signs that necessitate a return to the health care provider (Box 4.6).

Injectable Contraceptives

The **Lunelle injection** is a long-term reversible contraceptive for women. It contains the same hormones as the

COMPARISON CHART 4.2 **ADVANTAGES AND DISADVANTAGES OF ORAL CONTRACEPTIVES**

Advantages	Disadvantages
Regulate and shorten menstrual cycle	Offer no protection against STIs
Decrease severe cramping and bleeding	Pose slightly increased risk of breast cancer
Reduce anemia	Modest risk for vein thrombosis and pulmonary emboli
Reduce ovarian and colorectal cancer risk	Increased risk for migraine headaches
Decrease benign breast disease	Increased risk for myocardial infarction, stroke, and hypertension for women who smoke
Reduce risk of endometrial cancer	May increase risk of depression
Improve acne	User must remember to take pill daily
Minimize perimenopausal symptoms	High cost for some women
Decrease incidence of rheumatoid arthritis	
Improve PMS symptoms	
Protect against loss of bone density	

Source: Dirubbo, 2006

BOX 4.6 Early Signs of Complications for OC Users

A: Abdominal pain may indicate liver or gallbladder problems.
C: Chest pain or shortness of breath may indicate a pulmonary embolus.
H: Headaches may indicate hypertension or impending stroke.
E: Eye problems might indicate hypertension or an attack.
S: Severe leg pain may indicate a thromboembolic event

Source: Courtney, 2006.

combination OCs. It is administered once every 28 to 33 days by intramuscular injection. It provides immediate, very effective contraception if given within 5 days after the last normal menses. Its mechanism of action, contraindications, and side effects are similar to those of OCs (Murphy, Morgan & Likis, 2006).

Depo-Provera is the trade name for an injectable form of a progesterone-only contraceptive given every 12 weeks. Depo-Provera works by suppressing ovulation and the production of FSH and LH by the pituitary gland, by increasing the viscosity of cervical mucus and causing endometrial atrophy. A single injection of 150 mg into the buttocks acts like other progestin-only products to prevent pregnancy for 3 months at a time (Fig. 4.13). The primary side effect of Depo Provera is menstrual cycle disturbance.

Recent clinical studies have raised concerns about whether Depo-Provera reduces bone mineral density. This evidence has prompted the manufacturer and the FDA to issue a warning about the long-term use of Depo-Provera and bone loss (Robinson, 2005). It is not entirely clear if this loss in bone mineral density is reversible because there haven't been any long-term prospective studies in current and past users.

Transdermal Patches

A **transdermal patch**, Ortho Evra, is also available. It is a matchbox-sized patch containing hormones that are absorbed through the skin when placed on the lower abdomen, upper outer arm, buttocks, or upper torso (avoiding the breasts). The patch is applied weekly for 3 weeks, followed by a patch-free week during which withdrawal bleeding occurs. The patch delivers continuous levels of progesterone and estrogen. Transdermal absorption allows the drug to enter the bloodstream directly, avoiding rapid inactivation in the liver known as first-pass metabolism. Since estrogen and progesterone are metabolized by liver enzymes, avoiding first-pass metabolism was thought to reduce adverse effects. However, recent evidence suggests that the risk of venous thrombosis and embolism is increased with the patch (Courtney, 2006). Additional studies are underway to understand the clinical significance of these latest findings, but in the interim nurses need to focus on ongoing risk assessment and should be prepared to discuss current research findings with clients.

Compliance with combination contraceptive patch use has been shown to be significantly greater than compliance with OCs (Graziottin, 2006). The patch provides combination hormone therapy with a side effect profile similar to that of OCs. The manufacturer is currently evaluating extended regimens for the patch (Stewart et al., 2006) (Fig. 4.14).

Vaginal Rings

The contraceptive **vaginal ring**, NuvaRing, is a flexible, soft, transparent ring that is inserted by the user for a 3-week period of continuous use followed by a ring-free week to allow withdrawal bleeding (Fig. 4.15). The ring can be inserted by the woman and does not have to be

FIGURE 4.13 Injectable contraceptive.

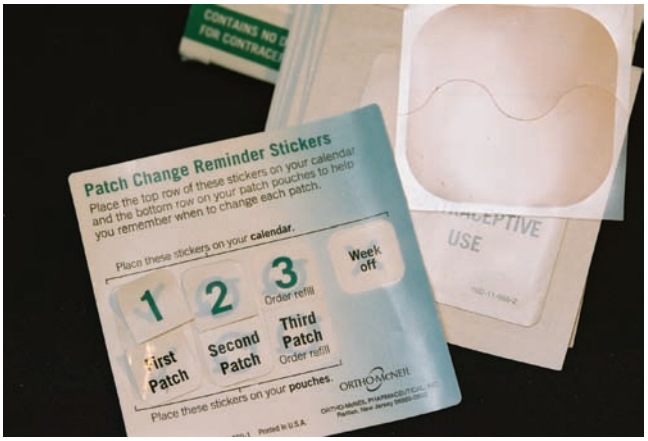

FIGURE 4.14 Transdermal patch.

FIGURE 4.15 Vaginal ring.

fitted. The woman compresses the ring and inserts it into the vagina, behind the pubic bone, as far back as possible, but precise placement is not critical. The hormones are absorbed through the vaginal mucosa. It is left in place for 3 weeks and then removed and discarded. Effectiveness and adverse events are similar to those seen with combination OCs. Clients need to be counseled regarding timely insertion of the ring and what to do in case of accidental expulsion. This device is also being tested for extended regimens to reduce menstrual bleeding.

Implantable Contraceptives

The **implant** is a subdermal time-release method that delivers synthetic progestin. Once in place, it delivers several years of continuous, highly effective contraception. Like progestin-only pills, implants act by inhibiting ovulation and thickening cervical mucus so sperm cannot penetrate. A single-rod progestin implant (Implanon) received FDA approval in 2006 (Tolaymat & Kaunitz, 2007). The side effects are also similar to progestin-only pills: irregular bleeding, headaches, weight gain, breast tenderness, and depression. Fertility is restored quickly after it is removed. Implants require a minor surgical procedure for both insertion and removal. The implants don't offer any protection against STIs.

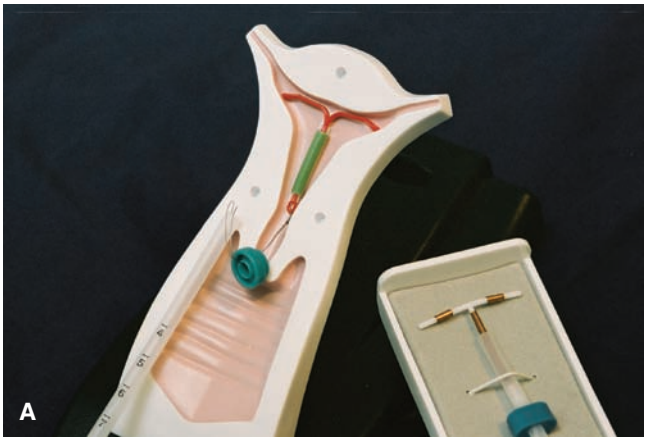
Intrauterine Systems

Intrauterine systems are small plastic T-shaped objects that are placed inside the uterus to provide contraception (Fig. 4.16). They prevent pregnancy by making the endometrium of the uterus hostile to implantation of a fertilized ovum by causing a nonspecific inflammatory reaction (Hearton, 2006). Monthly periods become lighter, shorter, and less painful, making this a useful method for women with heavy, painful periods. Some implants may contain copper or progesterone to enhance their effectiveness. One or two attached strings protrude into the vagina so that the user can check for placement.

Currently there are three intrauterine systems available in the United States: the copper ParaGard-T-380A; Progestasert, a progesterone device; and the levonorgestrel intrauterine system (LNG-IUS) Mirena, a levonorgestrel-releasing device. The ParaGard-T-380A is approved for 10 years of use. The Progestasert may stay in place 1 year, then must be removed and replaced. Mirena provides intrauterine conception for up to 5 years. An advantage of these hormonally impregnated intrauterine systems is that they are relatively maintenance-free: users must consciously discontinue using them to become pregnant rather than making a daily decision to avoid conception (French et al., 2006). Box 4.7 highlights warning signs of complications.

Emergency Contraception

Unplanned pregnancy is a major health, economic, and social issue for women. Approximately half of all unplanned pregnancies end in abortion (CDC, 2006). **Emergency contraception (EC)** reduces the risk of pregnancy after unprotected intercourse or contraceptive failure such as condom breakage (Lever, 2005). It is used within 72 hours of unprotected intercourse to prevent pregnancy. The sooner ECs are taken, the more effective



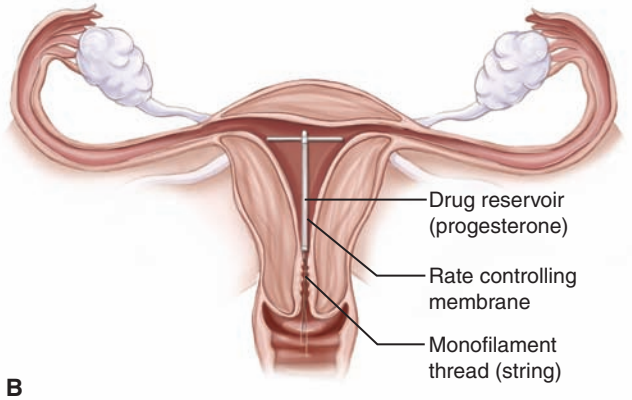


FIGURE 4.16 (**A**) Intrauterine system. (**B**) An IUS in place in the uterus.

BOX 4.7 Warnings for Intrauterine System Users of Potential Complications

P: Period late, pregnancy, abnormal spotting or bleeding
A: Abdominal pain, pain with intercourse
I: Infection exposure, abnormal vaginal discharge
N: Not feeling well, fever, chills
S: String length shorter or longer or missing

Source: Hatcher et al., 2004.

they are. They reduce the risk of pregnancy for a single act of unprotected sex by almost 80% (Cheng et al., 2006). The methods available in the United States are progestin-only OCs, combination OCs, EC kit (Plan B) (Fig. 4.17), or insertion of a copper-releasing intrauterine system up to 7 days after unprotected intercourse (Lever, 2005). The FDA recently approved Plan B (levonorgestrel) to be sold over the counter to women aged 18 and older; it is still available by prescription to women younger than 18 years (U.S. Food & Drug Administration, 2006). Table 4.5 lists recommended oral medication and intrauterine regimens.

Prime points to stress concerning ECs are:

- ECs do not offer any protection against STIs or future pregnancies.
- ECs should not be used in place of regular birth control, as they are less effective.
- ECs are regular birth control pills given at higher doses and more frequently.
- ECs are contraindicated during pregnancy because they are considered to be teratogenic (Ravin, 2006).

FIGURE 4.17 Emergency contraceptive kit.

Contrary to popular belief, ECs do not induce abortion and are not related to mifepristone or RU-486, the so-called abortion pill approved by the FDA in 2000. Mifepristone chemically induces abortion by blocking the body's progesterone receptors, which are necessary for pregnancy maintenance. ECs simply prevent embryo creation and uterine implantation from occurring in the first place. There is no evidence that ECs have any effect on an already-implanted ovum. The side effects are nausea and vomiting.

Sterilization

Sterilization is an attractive method of contraception for those who are certain they do not want any, or any more, children. **Sterilization** refers to surgical procedures intended to render the person infertile. It is one of the most popular methods of contraception in the United States and worldwide (Swica & Westhoff, 2006). More women than men undergo surgical sterilization. According to the

TABLE 4.5 EMERGENCY CONTRACEPTION (EC) OPTIONS

Product	First Dose (Within 72 Hours)	Second Dose (Taken 12 Hours Later)
Combined OCs		
Preven	2 tablets	2 tablets
Ovral		
Lo/Ovral, Nordette Levlen, TriLevlen	4 tablets	4 tablets
Triphasil		
Progestin-Only OCs		
Ovrette	20 tablets	20 tablets
Plan B	1 tablet	1 tablet
Intrauterine Devices		
Copper-containing IUD such as Paragard-T-380A	Inserted within 7 days after unprotected sexual episode	Can be left in for long-term contraception

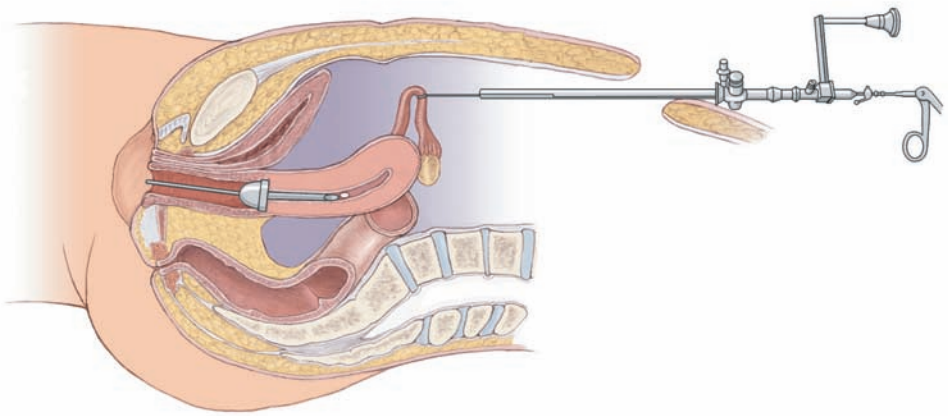

FIGURE 4.18 Laparoscopy for tubal sterilization.

CDC, approximately 18% of women undergo female sterilization in comparison to 7% of men in the United States (CDC, 2006). Sterilization should be considered a permanent end to fertility because reversal surgery is difficult, expensive, and not highly successful.

Tubal Ligation

Tubal ligation, the sterilization procedure for women, can be performed postpartum, after an abortion, or as an interval procedure unrelated to pregnancy. A laparoscope is inserted through a small subumbilical incision to provide a view of the fallopian tubes. They are grasped and sealed with a cauterizing instrument or with rings, bands, or clips or cut and tied (Fig. 4.18).

A new approach used to visualize the fallopian tubes is through the cervix instead of the abdominal incision. This procedure, called transcervical sterilization, offers several advantages over conventional tubal ligation: general anesthesia and incisions are not needed, thereby increasing safety, lowering costs, and improving access to sterilization. A tiny coil (Essure) is introduced and released into the fallopian tubes through the cervix. The coil promotes tissue growth in the fallopian tubes, and over a period of 3 months, this growth blocks the tubes (Valle, 2006). This less-invasive technique has become increasingly popular.

Vasectomy

Male sterilization is accomplished with a surgical procedure known as a **vasectomy**. It is usually performed under local anesthesia in an urologist's office, and most men can return to work and normal activities in a day or two. The procedure involves making a small incision into the scrotum and cutting the vas deferens, which carries sperm from the testes to the penis (Fig. 4.19). After vasectomy, semen no longer contains sperm. This is not immediate, though, and the man must submit semen specimens for analysis until two specimens show that no sperm is present. When the specimen shows azoospermia, the man's sterility is then confirmed (Dassow & Bennett, 2006).

Nursing Management of the Woman Choosing a Contraceptive Method

The choice of a contraceptive method is a very personal one involving many factors. What makes a woman choose one contraceptive method over another? In making contraceptive choices, couples must balance their sexual

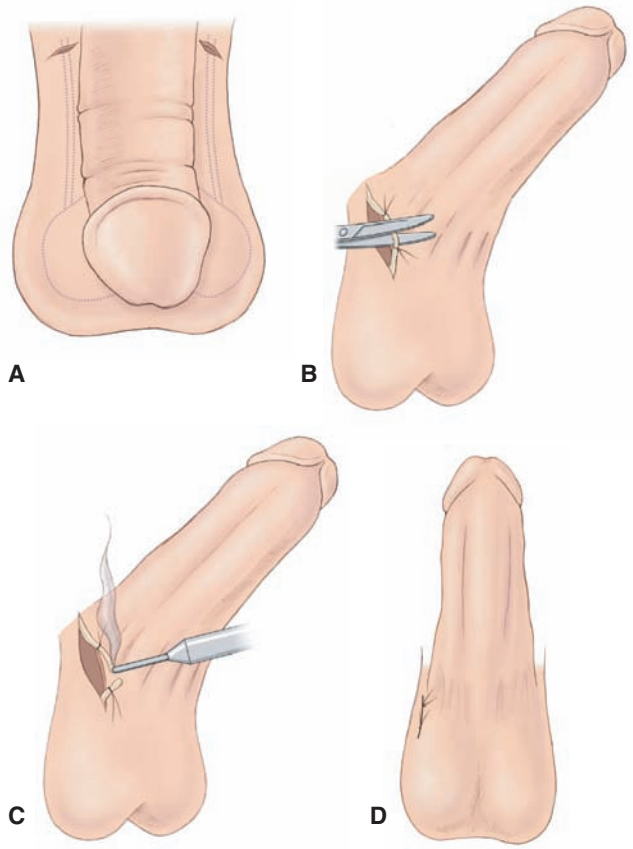

FIGURE 4.19 Vasectomy. (**A**) Site of vasectomy incisions. (**B**) The vas deferens is cut with surgical scissors. (**C**) Cut ends of the vas deferens are cauterized to ensure blockage of the passage of sperm. (**D**) Final skin suture.

lives, their reproductive goals, and each partner's health and safety. The search for a choice that satisfies all three objectives is challenging. A method that works for a sexually active teenage girl may not meet her needs later in life. Several considerations influence a person's choice of contraceptives:

- Motivation
- Cost
- Cultural and religious beliefs (Box 4.8)
- Convenience
- Effectiveness
- Side effects
- Desire for children in the future
- Safety of the method
- Comfort level with sexuality
- Protection from STIs
- Interference with spontaneity

If a contraceptive is to be effective, the woman must understand how it works, must be able to use it correctly and consistently, and must be comfortable and confident with it. If a patient cannot comply with taking a pill daily, consider a method used once a week (transdermal patches), once every 3 weeks (transvaginal ring), or once every 3 months (Depo-Provera injection). Another option may be a progesterone intrauterine device that lasts 3 to 5 years and reduces menstrual flow significantly.

Regardless of which method is chosen, the client's needs should be paramount in the discussion. The nurse can educate clients about which methods are available and their advantages and disadvantages, efficacy, cost, and safety. Counseling can help the woman choose a contraceptive method that is efficacious and fits her preferences and lifestyle.

BOX 4.8 Selected Religious Choices for Family Planning and Abortion

- Roman Catholic—Abstinence and natural family planning; no abortion
- Judaism—Family planning and abortion accepted in first trimester
- Islam—Family planning accepted; abortion only for serious reasons
- Protestant Christianity—Firmly in favor of family planning; mixed on abortion
- Buddhism—Long experience with family planning and abortion
- Hinduism—Accept both family planning and abortion
- Native American religions—Accept both family planning and abortion
- Chinese religions—Taoism and Confucianism accept both

Source: Maguire, 2004.

Nursing Assessment

When assessing which contraceptive method might meet the client's needs, the nurse might ask:

- Do your religious beliefs interfere with any methods?
- Will this method interfere with your sexual pleasure?
- Are you aware of the various methods currently available?
- Is cost a major consideration, or does your insurance cover it?
- Does your partner influence which method you choose?
- Have you heard anything troubling about any of the methods?
- How comfortable are you touching your own body?
- What are your future plans for having children?

Although deciding on a contraceptive is a very personal decision between a woman and her partner, nurses can assist in this process by performing a complete health history and physical examination, and by educating the woman and her partner about necessary laboratory and diagnostic testing. Areas of focus during the nursing assessment are as follows:

- Medical history: smoking status, cancer of reproductive tract, diabetes mellitus, migraines, hypertension, thromboembolic disorder, allergies, risk factors for cardiovascular disease
- Family history: cancer, cardiovascular disease, hypertension, stroke, diabetes
- OB/GYN history: menstrual disorders, current contraceptive, previous STIs, PID, vaginitis, sexual activity
- Personal history: use of tampons and female hygiene products, plans for childbearing, comfort with touching herself, number of sexual partners and their involvement in the decision
- Physical examination: height, weight, blood pressure, breast examination, thyroid palpation, pelvic examination
- Diagnostic testing: urinalysis, complete blood count, Pap smear, wet mount to check for STIs, HIV/AIDS tests, lipid profile, glucose level

Figure 4.20 shows an example of a family planning flow record that can be used during the assessment. After collecting the assessment data above, consider the medical factors to help decide if she is a candidate for all methods or whether some should be eliminated. For example, if she reports she has multiple sex partners and has a lengthy history of various pelvic infections, she would not be a good candidate for an intrauterine system, based on her infection history. Barrier methods (male or female

condoms) of contraception might be recommended to this client to offer protection against STIs.

Nursing Diagnoses

A few nursing diagnoses that might be appropriate based on the nurse's assessment during the decision-making process include:

- Deficient knowledge related to:
  - Methods available
  - Side effects/safety
  - Correct use of method chosen
  - Previous myths believed
- Risk for infection related to:
  - Unprotected sexual intercourse
  - Past history of STIs
  - Methods offering protection

Nursing diagnoses applicable to the contraceptive would be:

- Health-seeking behaviors related to:
  - Perceived need for limiting number of children
  - Overall health relative to contraceptives
- Risk for ineffective health maintenance related to:
  - Not being familiar with the various contraceptive methods
  - Being unaware of high-risk sexual behavior leading to STIs
- Fear related to:
  - Not understanding the correct procedure to use
  - Unintended pregnancy occurring if not used correctly
  - General health concerning the long-term side effects

Nursing Interventions

Contraception is an important issue for all couples, and the method used should be decided by the woman and her partner jointly. Facilitate this process by establishing a trusting relationship with the client and by providing unbiased, accurate information about all methods available. As a nurse, reflect honestly on your feelings towards contraceptives while allowing the client's feelings to be central. Be aware of the practical issues involved in contraceptive use, and avoid making assumptions, making decisions on the woman's behalf, and making judgments about her and her situation. To do so, it is important to keep up to date on the latest methods available and convey this information to clients. Encourage female clients to take control of their lives by sharing information that allows them to plan their futures.

The following guidelines are helpful in counseling and educating the client or couple about contraceptives:

- Encourage the client/couple to participate in choosing a method.
- Provide client education. The client/couple must be informed users before the method is agreed upon. Education should be targeted to the client's level so it is understood. Provide step-by-step teaching and an opportunity for practice for certain methods (cervical caps, diaphragms, vaginal rings, and condoms). See Teaching Guidelines 4.5 and Figure 4.21.
- Obtain written informed consents, which are needed for intrauterine systems, implants, abortion, or sterilization. Informed consent implies that the client is making a knowledgeable, voluntary choice; has received complete information about the method, including the risks; and is free to change her mind before using the method or having the procedure (Youngkin & Davis, 2004).
- Discuss contraindications for all selected contraceptives.
- Consider the client's cultural and religious beliefs when providing care.
- Address myths and misperceptions about the methods under consideration in your initial discussion of contraceptives.

It is also important to clear up common misconceptions about contraception and pregnancy. Clearing up misconceptions will permit new learning to take hold and a better client response to whichever methods are explored and ultimately selected. Some common misconceptions include:

- Breastfeeding protects against pregnancy.
- Pregnancy can be avoided if the male partner "pulls out" before he ejaculates.
- Pregnancy can't occur during menses.
- Douching after sex will prevent pregnancy.
- Pregnancy won't happen during the first sexual experience.
- Taking birth control pills protects against STIs.
- The woman is too old to get pregnant.
- Irregular menstruation prevents pregnancy.

When discussing in detail each method of birth control, focus on specific information for each method outlined. Include information such as how this particular method works to prevent pregnancy under normal circumstances of use; the noncontraceptive benefits to overall health; advantages and disadvantages of all methods; the cost involved for each particular method; danger signs that need to be reported to the health care provider; and the required frequency of office visits needed for the particular method.

In addition, outline factors that place the client at risk for method failure. There are several reasons why there are contraceptive failures. Use Table 4.6 to provide patient education concerning a few of the reasons for contraceptive failure. Help clients who have chosen abstinence or fertility awareness methods to define the sexual activities in which they want and don't want to participate. This helps them set sexual limits or boundaries. Help them to develop communication and negotiation skills that will allow them to be successful. Supporting, encouraging, and respecting a couple's choice of abstinence is vital for nurses.

TEACHING GUIDELINES 4.5

Tips for Cervical Caps, Diaphragms, Vaginal Rings, and Condoms

Cervical Cap Insertion/Removal Technique

- It is important to be involved in the fitting process.
- To insert the cap, pinch the sides together, compress the cap dome, insert into the vagina, and place over the cervix.
- Use one finger to feel around the entire circumference to make sure there are no gaps between the cap rim and the cervix.
- After a minute or two, pinch the dome and tug gently to check for evidence of suction. The cap should resist the tug and not slide off easily.
- To remove the cap, press the index finger against the rim and tip the cap slightly to break the suction, and gently pull out the cap.
- The woman should practice inserting and removing the cervical cap three times to validate her proficiency with this device.

Client teaching and counseling regarding the cervical cap

- Fill the dome of the cap up about one-third full with spermicide cream or jelly. Do not apply spermicide to the rim, since it may interfere with the seal.
- Wait approximately 30 minutes after insertion before engaging in sexual intercourse to be sure that a seal has formed between the rim and the cervix.
- Leave the cervical cap in place for a minimum of 6 hours after sexual intercourse. It can be left in place for up to 48 hours without additional spermicide being added.
- Do not use during menses due to the potential for toxic shock syndrome. Use an alternative method such as condoms during this time.
- Inspect the cervical cap prior to insertion for cracks, holes, or tears.
- After using the cervical cap, wash it with soap and water, dry thoroughly, and store in its container.

Diaphragm Insertion/Removal Technique

- Always empty the bladder prior to inserting the diaphragm.
- Inspect diaphragm for holes or tears by holding it up to a light source, or fill it with water and check for a leak.
- Place approximately a tablespoon of spermicidal jelly or cream in the dome and around the rim of the diaphragm.
- The diaphragm can be inserted up to 6 hours prior to intercourse.
- Select the position that is most comfortable for insertion:
  - Squatting
  - Leg up, raising the nondominant leg up on a low stool
  - Reclining position, lying on her back in bed
  - Sitting forward on the edge of a chair
- Hold the diaphragm between the thumb and fingers and compress it to form a "figure-eight" shape.
- Insert the diaphragm into the vagina, directing it downward as far as it will go.
- Tuck the front rim of the diaphragm behind the pubic bone so that the rubber hugs the front wall of the vagina.
- Feel for the cervix through the diaphragm to make sure it is properly placed.
- To remove the diaphragm, insert the finger up and over the top side and move slightly to the side, breaking the suction.
- Pull the diaphragm down and out of the vagina.

Client Teaching and Counseling Regarding the Diaphragm

- Avoid the use of oil-based products such as baby oil, since this may weaken the rubber.
- Wash the diaphragm with soap and water after use and dry thoroughly.
- Place the diaphragm back into the storage case.
- The diaphragm may need to be refitted after weight loss or gain or childbirth.
- Diaphragms should not be used by women with latex allergies.

Vaginal Ring Insertion/Removal Technique and Counseling

- Each ring is used for one menstrual cycle, which consists of 3 weeks of continuous use followed by a ring-free week to allow for menses.
- No fitting is necessary—one size fits all.
- The ring is compressed and inserted into the vagina, behind the pubic bone, as far back as possible.
- Precision placement is not essential.
- Backup contraception is needed for 7 days if the ring is expelled for more than 3 hours during the 3-week period of continuous use.
- The vaginal ring is left in place for 3 weeks, then removed and discarded.
- The vaginal ring is not recommended for women with uterine prolapse or lack of vaginal muscle tone (Youngkin & Davis, 2004).

(continued)

TEACHING GUIDELINES 4.5

Tips for Cervical Caps, Diaphragms, Vaginal Rings, and Condoms (continued)

Male Condom Insertion/Removal Technique and Counseling

- Always keep the condom in its original package until ready to use.
- Store in a cool, dry place.
- Spermicidal condoms should be used if available.
- Check expiration date before using.
- Use a new condom for each sexual act.
- Condom is placed over the erect penis prior to insertion.
- Place condom on the head of the penis and unroll it down the shaft.
- Leave a half-inch of empty space at the end to collect ejaculate.
- Avoid use of oil-based products, because they may cause breakage.
- After intercourse, remove the condom while the penis is still erect.
- Discard condom after use.

Female Condom Insertion/Removal Technique and Counseling

- Practice wearing and inserting prior to first use with sexual intercourse.
- Condom can be inserted up to 8 hours before intercourse.
- Condom is intended for one-time use.
- It can be purchased over the counter—one size fits all.
- Avoid wearing rings to prevent tears; long fingernails can also cause tears.
- Spermicidal lubricant can be used if desired.
- Insert the inner ring high in the vagina, against the cervix.
- Place the outer ring on the outside of the vagina.
- Make sure the erect penis is placed inside the female condom.
- Remove the condom after intercourse. Avoid spilling the ejaculate.

After clients have chosen a method of contraception, it is important to address the following:

- Emphasize that a second method to use as a backup is always needed.
- Provide both oral and written instructions on the method chosen.
- Discuss the need for STI protection if not using a barrier method.
- Inform the client about the availability of ECs.

FIGURE 4.21 The nurse demonstrates insertion of a vaginal ring during client teaching.

Abortion

Abortion is defined as the expulsion of an embryo or fetus before it is viable (Alexander et al., 2007). Abortion can be a medical or surgical procedure. The purpose of abortion is to terminate a pregnancy. Surgical abortion is the most common procedure performed in the United States (approximately 1.6 million annually) and might be the most common surgical procedure in the world (Speroff & Fritz, 2005). Both medical and surgical abortions are safe and legal in the United States; an abortion is considered a woman's constitutional right based on the fundamental right to privacy (Curlin et al., 2007).

Since the landmark U.S. Supreme Court decision *Roe v. Wade* legalized abortion in 1973, debate has continued over how and when abortions are provided. Every state has laws regulating some aspects of the provision of abortion, and many have passed restrictions such as parental consent or notification requirements, mandated counseling and waiting periods, and limits on funding for abortion. Each state addresses these matters independently, and the laws that are passed or enforced are a legislative decision and a function of the political system. Although opponents of abortion continue to be very much a part of the current debates, recently they have refocused their attention on "regulation legislation" to reduce the number of abortions not medically necessary.

TABLE 4.6 CONTRACEPTIVE PROBLEMS AND EDUCATIONAL NEEDS

Contraceptive Failure Problem	Client Education Needed
Not following instructions for use of contraceptive correctly	Take pill the same time every day. Use condoms properly and check condition before using. Make sure diaphragm or cervical cap covers cervix completely. Check IUD for placement monthly.
Inconsistent use of contraceptive	Contraceptives must be used regularly to achieve maximum effectiveness. All it takes is one unprotected act of sexual intercourse to become pregnant. 2% to 5% of condoms will break or tear during use.
Condom broke during sex	Check expiration date. Store condoms properly. Use only a water-based lubricant. Watch for tears caused by long fingernails. Use spermicides to decrease possibility of pregnancy if failure occurs.
Use of antibiotics or other herbs taken with OCs	Use alternative methods during the antibiotic therapy, plus 7 additional days. Implement on day 1 of taking antibiotics.
Belief that you can't get pregnant during menses or that it is safe "just this one time"	It may be possible to become pregnant on almost any day of the menstrual cycle.

Surgical Abortion

Surgical abortion is usually carried out by vacuum aspiration or suction curettage. It is an ambulatory procedure done under local anesthesia. The cervix is dilated prior to surgery and then the products of conception are removed by suction evacuation. The uterus may gently be scraped by curettage to make sure that it is empty. The entire procedure lasts about 10 minutes.

HEALTHY PEOPLE 2010

Objective	Significance
Reduce pregnancies among adolescent females. Increase the proportion of sexually active, unmarried adolescents age 15–17 years who use contraception that both effectively prevents pregnancy and provides barrier protection against disease.	Would reduce number of unplanned pregnancies and girls not finishing their education. This would in turn reduce the number of single parents on state financial assistance.
Increase the proportion of young adults who have received formal instruction before turning age 18 years on reproductive health issues, including all of the following topics: birth control methods, safer sex to prevent HIB, prevention of sexually transmitted disease, and abstinence.	Awareness of contraceptive methods brings about better compliance and prevention of unintended pregnancies in this age group.
Reduce AIDS and the number of HIV infections among adolescents and adults.	Reduce the number of HIV/AIDS victims by using barrier methods to prevent the transmission of this fatal STI.
Reduce the proportion of adolescents and young adults with *Chlamydia trachomatis* infections.	Reduce the number of women with infertility issues secondary to *Chlamydia* infections.

Medical Abortion

In a medical abortion, the woman takes certain medications to induce a miscarriage to remove the products of conception. There are two methods currently used to terminate a pregnancy during the first trimester. The first method uses methotrexate (an antineoplastic agent) followed by misoprostol (a prostaglandin agent) given as a vaginal suppository or in oral form 3 to 7 days later. Methotrexate induces abortion because of its toxicity to trophoblastic tissue, the growing embryo. Misoprostol works by causing uterine contractions, which helps to expel the products of conception. This method is 90% to 98% successful in completing an abortion (Hatcher et al., 2004).

The second method used to induce first-trimester abortions involves using mifepristone (a progesterone antagonist) followed 48 hours later by misoprostol (a prostaglandin agent), which causes contractions of the uterus and expulsion of the uterine contents. Mifepristone, the generic name for RU-486, is sold under the brand names Mifeprex and Early Option. Mifepristone is

a potent oral anti-progestogen; it blocks the action of progesterone that prepares the endometrium for implantation and then maintains the pregnancy. This method is 95% effective when used within 49 days after the last menstrual cycle (Hatcher et al., 2004).

Abortion is a very emotional, deeply personal issue. Give support and accurate information. If for personal, religious, or ethical reasons you feel unable to actively participate in the care of a woman undergoing an abortion, you still have the professional responsibility to ensure that the woman receives the nursing care and help she requires. This may necessitate a transfer to another area or a staffing reassignment.

Menopause

The change of life. The end of fertility. The beginning of freedom. Whatever people call it, menopause is a unique and personal experience for every woman. **Menopause** refers to the cessation of regular menstrual cycles. It is the end of menstruation and childbearing capacity. The average age of natural menopause—defined as 1 year without a menstrual period—is 51 years old (Alexander et al., 2007). With current female life expectancy at 80, this event comes in the middle of a woman's adult life.

▶ ***Take*** *NOTE!*

Humans are virtually the only species to outlive their reproductive capacities.

Menopause signals the end of an era for many women. It concludes their ability to reproduce, and some women find advancing age, altered roles, and these physiologic changes to be overwhelming events that may precipitate depression and anxiety (Kessenich, 2007). Menopause does not happen in isolation. Midlife is often experienced as a time of change and reflection. Change happens in many arenas: children are leaving or returning home, employment pressures intensify as career moves or decisions are required, elderly parents require more care or the death of a parent may have a major impact, and partners are retrenching or undergoing their own midlife crises. Women must negotiate all these changes in addition to menopause. Managing these stressful changes can be very challenging for many women as they make the transition into midlife.

A woman is born with approximately 500,000 ova, but only 300 to 400 ever mature fully to be released during the menstrual cycle. The absolute number of ova in the ovary is a major determinant of fertility. Over the course of her premenopausal life there is a steady decline in the number of immature ova. No one understands this depletion, but it does not occur in isolation. Maturing ova are surrounded by follicles that produce two major hormones: estrogen, in the form of estradiol, and progesterone. The cyclic maturation of the ovum is directed by the hypothalamus. The hypothalamus triggers a cascade of neurohormones, which act through the pituitary and the ovaries as a pulse generator for reproduction.

This hypothalamic-pituitary-ovarian axis begins to break down long before there is any sign that menopause is imminent. Some scientists believe that the pulse generator in the hypothalamus simply degenerates; others speculate that the ovary becomes more resistant to the pituitary hormone FSH and simply shuts down (Krantz, 2007b). The final act in this well-orchestrated process is amenorrhea.

As menopause approaches, more and more of the menstrual cycles become anovulatory. This period of time, usually 2 to 8 years before cessation of menstruation, is termed perimenopause (Manson, 2006). In perimenopause, the ovary begins to sputter, producing irregular and missed periods and an occasional hot flash. When menopause finally appears, viable ova are gone. Estrogen levels plummet by 90%, and estrone, produced in fat cells, replaces estradiol as the body's main form of estrogen. The major hormone produced by the ovaries during the reproductive years is estradiol; the estrogen found in postmenopausal women is estrone. Estradiol is much more biologically active than estrone (Krantz, 2007). In addition, testosterone levels decrease with menopause.

Menopause, with its dramatic decline in estrogen, affects not only the reproductive organs, but also other body systems:

- Brain: hot flashes, disturbed sleep, mood and memory problems
- Cardiovascular: lower levels of high-density lipoprotein (HDL) and increased risk of cardiovascular disease
- Skeletal: rapid loss of bone density increases the risk of osteoporosis
- Breasts: duct and glandular tissues are replaced by fat
- Genitourinary: vaginal dryness, stress incontinence, cystitis
- Gastrointestinal: less calcium is absorbed from food, increasing the risk for fractures
- Integumentary: skin becomes dry and thin, and collagen levels decrease
- Body shape: more abdominal fat; waist size swells relative to hips

Therapeutic Management

Menopause should be managed individually. In the past, despite the wide diversity of symptoms and risks, the traditional reaction was to reach for the one-size-fits-all therapy: hormone therapy. Today the medical community is changing its thinking in light of the Women's Health Initiative (WHI) study and the Heart and Estrogen/Progestin Replacement Study Follow-Up (HERS II), which reported

that long-term hormone therapy (HT) increased the risks of heart attacks, strokes, and breast cancer; in short, the overall health risks of HT exceeded the benefits (Writing Group, 2002, p. 321). In addition, HT didn't protect against the development of coronary artery disease, nor did it prevent the progression of coronary artery disease, as it was previously touted to do (Shelby & O'Hair, 2007). As expected, the fallout from this study and others forced practitioners to re-evaluate their usual therapies and tailor treatment to each client's history, needs, and risk factors.

There is a universe of treatment options out there, but factors in the client's history should be the driving force when determining therapy. Women need to educate themselves about the latest research findings and collaborate with their health care provider on the right menopause therapy. The following factors should be considered in management:

- HT is not indicated to treat or prevent cardiovascular disease, according to WHI. Instead, consider lipid-lowering agents and lifestyle changes if risk or disease is present.
- HT should not be taken for more than 5 years for vasomotor symptoms. Use the lowest dose possible for any hormone therapy.
- HT is acceptable as long as there is a clear indication for use, the woman is under medical supervision, and she is aware of the risks and benefits (North American Menopause Society, 2004).
- Consider nonhormonal therapies such as bisphosphonates and selective estrogen receptor modulators (SERMs).
- Consider weight-bearing exercises, calcium, vitamin D, smoking cessation, and avoidance of alcohol to treat or prevent osteoporosis.
- Annual breast examinations and mammograms are essential.
- Local estrogen creams can be used for vaginal atrophy.
- Consider herbal therapies for symptoms (Krantz, 2007).

Although numerous symptoms have been attributed to menopause (Box 4.9), some of them are more closely related to the aging process than to estrogen deficiency. A few of the more common menopausal conditions and their management will be discussed.

BOX 4.9 Common Symptoms of Menopause

- Hot flashes or flushes of the head and neck
- Dryness in the eyes and vagina
- Personality changes
- Anxiety and/or depression
- Loss of libido
- Weight gain and water retention
- Night sweats
- Fatigue
- Irritability
- Insomnia
- Stress incontinence
- Heart palpitations

Source: Chedraui et al., 2007.

Managing Hot Flashes and Night Sweats

Hot flashes and night sweats are classic signs of estrogen deficiency and the predominant complaint of perimenopausal women. A hot flash is a transient and sudden sensation of warmth that spreads over the body, particularly the neck, face, and chest. Hot flashes are caused by vasomotor instability. Nearly 85% of menopausal women experience them (Alexander et al., 2007). Hot flashes are an early and acute sign of estrogen deficiency. These flashes can be mild or extreme and can last from 2 to 30 minutes (Grady, 2006).

There are many options for treating hot flashes. Treatment must be based on symptom severity, the client's medical history, and the client's values and concerns. Although the gold standard in the treatment of hot flashes is estrogen, this is not recommended for all women. The following are suggestions for the management of hot flashes:

- Pharmacologic options
  - HT unless contraindicated
  - Androgen therapy (potentiates estrogen)
  - Estrogen and androgen combinations
  - Progestin therapy (Depo-Provera injection every 3 months)
  - Clonidine (central alpha-adrenergic agonist) weekly patch
    - Neurontin (anti-seizure) decreased hot flashes
    - Acupuncture reduced frequency of hot flashes
  - Propranolol (beta-adrenergic blocker)
  - Gabapentin (Neurontin): antiseizure drug
  - SSRIs: venlafaxine (Effexor) and sertraline (Zoloft) have shown promise
  - Vitamin E: 100 mg daily (Rubin, 2007)
- Lifestyle changes
  - Lower room temperature; use fans.
  - Wear clothing in layers for easy removal.
  - Limit caffeine and alcohol intake.
  - Drink 8 to 10 glasses of water daily.
  - Stop smoking or cut back.
  - Avoid hot drinks and spicy food.
  - Take calcium (1,200 to 1,500 mg) and vitamin D (400 to 600 IU).
  - Try relaxation techniques, deep breathing, and meditation.
  - Exercise daily, but not just before bedtime.

- Maintain a healthy weight.
- Identify stressors and learn to manage them.
- Keep a diary to identify triggers of hot flashes.
- Alternative therapies
  - Phytoestrogens: isoflavones, ligands, coumenstrols
  - Black cohosh
  - Chamomile: mild sedative to alleviate insomnia
  - Unopposed transdermal progesterone
  - Compounded bioidentical hormones
    - Estrogen
    - Progesterone
    - Testosterone
    - Dehydroepiandrosterone (DHEA)
    - Pregnenolone (Campbell, 2006)
  - Chasteberry (vitex): balances progesterone and estrogen
  - Dong quai: acts as a form of phytoestrogen
  - Ginseng: purported to improve memory
  - St. John's wort: reduces depression and fatigue
  - Valerian root: induces sleep and relaxation (AAFP, 2006)

Many women are choosing alternative treatments for managing menopausal symptoms. Because of their natural origin, women perceive that alternative treatments are safer. The interest in phytoestrogens came about because of the low prevalence of hot flashes in Asian women, which was attributed to their diet being rich in phytoestrogens (Manson, 2006). Recent studies have found that black cohosh, multibotanical herbs, and increased soy intake do not reduce the frequency or severity of menopausal hot flashes or night sweats (ACOG, 2005; Huntzinger, 2006; Newton et al., 2006; Seppa, 2007). Other remedies for easing menopausal symptoms might include red clover, motherwort, ginseng, sarsaparilla root, valerian root, L-tryptophan, calcium-magnesium, and kelp tablets (Haas, 2007). Again, research thus far has been skeptical about their efficacy, but many women report they ease their symptoms and their use has skyrocketed. While there might be some benefits to their use, evidence of the efficacy of alternative products in menopause is largely anecdotal. Small, preliminary clinical trials might demonstrate the safety of some of the nonpharmacologic products. Nurses should be aware of the purported action of these agents as well as any adverse effects or drug interactions.

Managing Urogenital Changes

Menopause can be a physically and emotionally challenging time for women. In additional to the psychological burden of leaving behind the reproductive phase of life and the stigma of an "aging" body, sexual difficulties due to urogenital changes plague most women but are frequently not addressed.

Vaginal atrophy occurs during menopause because of declining estrogen levels. These changes include thinning of the vaginal walls, an increase in pH, irritation, increased susceptibility to infection, dyspareunia, loss of lubrication with intercourse, vaginal dryness, and a decrease in sexual desire related to these changes. Decreased estrogen levels can also influence a woman's sexual function as well. Delayed clitoral reaction, decreased vaginal lubrication, diminished circulatory response during sexual stimulation, and reduced contractions during orgasm have all been linked to low estrogen levels (McKinney, 2007).

Management of these changes might include the use of estrogen vaginal tablets (Vagifem) or Premarin cream; Estring, an estrogen-releasing vaginal ring that lasts for 3 months; testosterone patches; and over-the-counter moisturizers and lubricants (Astroglide). A positive outlook on sexuality and a supportive partner are also needed to make the sexual experience enjoyable and fulfilling.

▶ *Take* NOTE!

Sexual health is an important aspect of the human experience. By keeping an open mind, listening to women, and providing evidence-based treatment options, the nurse can help improve quality of life for menopausal women.

Preventing and Managing Osteoporosis

Women are greatly affected by osteoporosis after menopause. Osteoporosis is a condition in which bone mass declines to such an extent that fractures occur with minimal trauma. Bone loss begins in the third or fourth decade of a woman's life and accelerates rapidly after menopause. It affects 8 million women, with millions more at high risk for developing it. This translates to 1 in 2 women over the age of 50 having an osteoporosis-related fracture in their lifetime (Alexander et al., 2007). This condition puts many women into long-term care, with a resulting loss of independence. Figure 4.22 shows the skeletal changes associated with osteoporosis.

Most women with osteoporosis don't know they have the disease until they sustain a fracture, usually of the wrist or hip. Risk factors include:

- Increasing age
- Postmenopausal status without hormone replacement
- Small frame, thin-boned
- Caucasian or Asian
- Impaired eyesight
- Rheumatoid arthritis
- Family history of osteoporosis
- Sedentary lifestyle
- History of treatment with:
  - Antacids with aluminum
  - Heparin
  - Steroids
  - Thyroid replacement drugs

FIGURE 4.22 Skeletal changes associated with osteoporosis. (John Radcliffe Hospital/ Photo Researcher Inc.)

- Smoking and consuming alcohol
- Low calcium and vitamin D intake
- Excessive amounts of caffeine
- Anorexia nervosa or bulimia (Hansberger, 2007)

Screening tests to measure bone density are not good predictors for young women who might be at risk for developing this condition. Dual-energy x-ray absorptiometry (DXA or DEXA) is a screening test that calculates the mineral content of the bone at the spine and hip. It is highly accurate, fast, and relatively inexpensive (McNally, Kenny & Smith, 2007).

The best management for this painful, crippling, and potentially fatal disease is prevention. Women can modify many risk factors by doing the following:

- Engage in daily weight-bearing exercise, such as walking.
- Increasing calcium and vitamin D intake.
- Avoid smoking and excessive alcohol.
- Discuss your bone health with your health care provider.
- When appropriate, have a bone density test and take medication if needed (National Osteoporosis Foundation, 2007).

Medications that can help in preventing and managing osteoporosis include:

- HT (Premarin)
- SERMs (Evista)
- Calcium and vitamin D supplements (Tums)
- Bisphosphonates (Actonel or Fosamax)
- Calcitonin (Miacalcin) (Hansberger, 2007)

Preventing and Managing Cardiovascular Disease

Although cardiovascular disease is still thought of as a "man's disease," it is the major killer of postmenopausal women 50 to 75 years of age (Rosano et al., 2007). Half a million women die annually in the United States of cardiovascular disease, with strokes accounting for about 20% of the deaths (Alexander et al., 2007). This translates into approximately one death every minute. Coronary heart disease accounts for the majority of cardiovascular deaths in women, with nearly two thirds of these women dying suddenly without any previously recognized symptoms (Hackley, Kriebs & Rousseau, 2007).

For the first half of a woman's life, estrogen seems to be a protective substance for the cardiovascular system by smoothing, relaxing, and dilating blood vessels. It even helps boost HDL and lower LDL levels, helping to keep the arteries clean from plaque accumulation. But when estrogen levels plummet as women age and experience menopause, the incidence of cardiovascular disease increases dramatically.

Menopause is not the only factor that increases a woman's risk for cardiovascular disease. Lifestyle and medical history factors such as the following play a major role:

- Smoking
- Obesity
- High-fat diet
- Sedentary lifestyle
- High cholesterol levels
- Family history of cardiovascular disease
- Hypertension
- Apple-shaped body
- Diabetes

Two of the major risk factors for coronary heart disease are hypertension and dyslipidemia. Both are modifiable and can be prevented by lifestyle changes and, if needed, controlled by medication. This is why prevention is essential. In addition, women who experience early menopause lose the protection afforded by endogenous estrogen to the cardiac system and are at greater risk for more extensive atherosclerosis. Major preventive strategies include a healthy diet, increased activity, exercise, smoking cessation, decreased alcohol intake, and weight reduction.

Raising awareness of heart disease in women is an essential role for nurses. Lifestyle interventions are effective in preventing cardiovascular disease in all individuals regardless of their underlying risk (Hackley, Kriebs & Rousseau, 2007). Stressing the importance of lifestyle modifications must begin early in life and should be reinforced from the beginning of a young woman's reproductive years through menopause. Nurses are in an ideal position to teach the importance of good nutrition, healthy weight, and daily exercise before cardiovascular disease becomes clinically evident.

Nursing Assessment

Menopause is a universal and irreversible part of the overall aging process involving a woman's reproductive system. While not a disease state, menopause does place women at greater risk for the development of many conditions of aging. Nurses can help the woman become aware of her risk for postmenopausal diseases, as well as strategies to prevent them. The nurse can be instrumental in assessing risk factors and planning interventions in collaboration with the client. These might include:

- Screening for osteoporosis, cardiovascular disease, and cancer risk
  - Assessment of blood pressure to identify hypertension
  - Blood cholesterol to identify hyperlipidemia risk
  - Mammogram to find a cancerous lesion
  - Pap smear to identify cervical cancer
  - Pelvic examination to identify endometrial cancer or masses
  - Digital rectal examination to assess for colon cancer
  - Bone density testing as a baseline at menopause to identify osteopenia (low bone mass), which might lead to osteoporosis
- Assessing lifestyle to plan strategies to prevent chronic conditions:
  - Dietary intake of fat, cholesterol, and sodium
  - Weight management
  - Calcium intake
  - Use of tobacco, alcohol, and caffeine
  - Performance of breast self-examinations

Nursing Management

There is no "magic bullet" in managing menopause. Nurses can counsel women about their risks and help them to prevent disease and debilitating conditions with specific health-maintenance education. Women should make their own decisions, but the nurse should make sure they are armed with the facts to do so intelligently. Nurses can offer a thorough explanation of the menopausal process, including the latest research findings, to help women understand and make decisions about this inevitable event.

If the woman decides to use HT to control her menopausal symptoms, after being thoroughly educated, she will need frequent reassessment. There are no hard-and-fast rules that apply to meeting a woman's individual needs. The nurse can provide realistic expectations of the therapy to reduce the woman's anxiety and concern.

It is also useful to emphasize the value of friends to gain support and share information and resources. Often just talking about emotional difficulties like a death of a parent or problematic relationships helps solve problems. It also shows the woman that her emotional responses are valid.

Healthy lifestyles and stress management techniques are vital to health and longevity, and it is important to keep these on the client's agenda when discussing menopause (Staff of Boston Women's Health Book Collective, 2007). Evidence-based interventions include lifestyle modifications, risk management therapies, and preventive drug interventions, such as the following:

- Participate actively in maintaining health.
- Exercise regularly.
- Take supplemental calcium and eat appropriately to prevent osteoporosis.
- Stop smoking to prevent lung and heart disease.
- Reduce caffeine and alcohol intake to prevent osteoporosis.
- Monitor blood pressure, lipids, and diabetes (drug therapy management).
- Use low-dose aspirin.
- Reduce dietary intake of fat, cholesterol, and sodium to prevent cardiovascular disease.
- Maintain a healthy weight for body frame.
- Perform breast self-examinations to detect breast lesions.
- Control stress (Dormire & Becker, 2007).

These life approaches may seem low-tech, but they can stave off menopause-related complications such as cardiovascular disease, osteoporosis, and depression. These tips for healthy living work well, but the client needs to be motivated to stick with them.

Key Concepts

- Establishing good health habits and avoiding risky behaviors early in life will prevent chronic conditions later on.
- There are more than 200 symptoms of PMS, and at least two different syndromes have been recognized: PMS and premenstrual dysphoric disorder (PMDD).
- Endometriosis is a condition in which bits of functioning endometrial tissue are located outside their normal site, the uterine cavity.
- Infertility is a widespread problem that has an emotional, social, and economic impact on couples.
- More than half (53%) of all unintended pregnancies occur in women who report using some method of birth control during the month of conception.
- Hormonal methods include oral contraceptives, injectables, implants, vaginal rings, and transdermal patches.
- Recent studies have shown that the extension of active oral contraceptive pills carries the same safety profile as the conventional 28-day regimens.
- Currently there are three IUSs available in the United States: the copper ParaGard-T-380A; Progestasert, a progesterone device; and the levonorgestrel intrauterine system (LNG-IUS) Mirena, a levonorgestrel-releasing device.
- Sterilization is the most popular method of contraception in the United States and worldwide.
- Menopause, with a dramatic decline in estrogen levels, affects not only the reproductive organs but also other bodily systems.

- Most women with osteoporosis do not know they have the disease until they sustain a fracture, usually of the wrist or hip.
- Half a million women die annually in the United States of cardiovascular diseases, with strokes accounting for about 20% of the deaths.
- Nurses should aim to have a holistic approach to the sexual health of women from menarche through menopause.

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. A couple is considered infertile after how many months of trying to conceive?
   a. 6 months
   b. 12 months
   c. 18 months
   d. 24 months
2. A couple reports that their condom broke while they were having sexual intercourse last night. What would you advise to prevent pregnancy?
   a. Inject a spermicidal agent into her vagina immediately.
   b. Obtain emergency contraceptives and take them immediately.
   c. Douche with a solution of vinegar and hot water tonight.
   d. Take a strong laxative now and again at bedtime.
3. Which of the following combination contraceptives has been approved for extended continuous use?
   a. Seasonale
   b. NuvaRing
   c. Ortho Evra
   d. Mirena
4. Which of the following measures helps prevent osteoporosis?
   a. Iron supplementation
   b. Sleeping 8 hours nightly
   c. Eating lean meats only
   d. Walking 3 miles daily
5. Which of the following activities will increase a woman's risk of cardiovascular disease if she is taking oral contraceptives?
   a. Eating a high-fiber diet
   b. Smoking cigarettes
   c. Taking daily multivitamins
   d. Drinking alcohol
6. Hormone therapy taken by menopausal women reduces:
   a. Weight gain
   b. Bone density
   c. Hot flashes
   d. Heart disease
7. Throughout life, a woman's most proactive activity to promote her health would be to engage in:
   a. Consistent exercise
   b. Socialization with friends
   c. Quality quiet time with herself
   d. Consuming water
8. What comment by a woman would indicate that a diaphragm is not the best contraceptive device for her?
   a. "My husband says it is my job to keep from getting pregnant."
   b. "I have a hard time remembering to take my vitamins daily."
   c. "Hormones cause cancer and I don't want to take them."
   d. "I am not comfortable touching myself down there."

CRITICAL THINKING EXERCISE

1. Ms. London, 25, comes to your family planning clinic requesting to have an intrauterine system (IUS) inserted because "birth control pills give you cancer." In reviewing her history, you note she has been into the STI clinic three times in the past year with vaginal infections and was hospitalized for pelvic inflammatory disease (PID) last month. When you question her about her sexual history, she reports having sex with multiple partners and not always using protection.
   a. Is an IUS the most appropriate method for her? Why or why not?
   b. What myths/misperceptions will you address in your counseling session?
   c. Outline the safer sex discussion you plan to have with her.

Study Activities

1. Develop a teaching plan for an adolescent with premenstrual syndrome and dysmenorrhea.
2. Arrange to shadow a nurse working in family planning for the morning. What questions does the nurse ask to ascertain the kind of family planning method that is right for each woman? What teaching goes along with each method? What follow-up care is needed? Share your findings with your classmates during a clinical conference.
3. Surf the Internet and locate three resources for infertile couples to consult that provide support and resources.
4. Sterilization is the most prevalent method of contraception used by married couples in the United States. Contact a local urologist and gynecologist to learn about the procedure involved and the cost of a male and female sterilization. Which procedure poses less risk to the person and costs less?
5. Take a field trip to a local drugstore to check out the variety and costs of male and female condoms. How many different brands did you find? What was the range of costs?
6. Noncontraceptive benefits of combined oral contraceptives include which of the following? Select all that apply.
   a. Protection against ovarian cancer
   b. Protection against endometrial cancer
   c. Protection against breast cancer
   d. Reduction in incidence of ectopic pregnancy
   e. Prevention of functional ovarian cysts
   f. Reduction in deep venous thrombosis
   g. Reduction in the risk of colorectal cancer

CHAPTER 5

SEXUALLY TRANSMITTED INFECTIONS

KEY TERMS

bacterial vaginosis
gonorrhea
pelvic inflammatory disease (PID)
sexually transmitted infection (STI)
syphilis
trichomoniasis
vulvovaginal candidiasis

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms used in this chapter.
2. Discuss the spread and control of sexually transmitted infections.
3. Identify risk factors and outline appropriate client education needed in common sexually transmitted infections.
4. Discuss how contraceptives can play a role in the prevention of sexually transmitted infections.
5. Analyze the physiologic and psychological aspects of sexually transmitted infections.
6. Delineate the nursing management needed for women with sexually transmitted infections.

Sandy, a 19-year-old, couldn't imagine what these "things" were that appeared "down there" in her genital area last week. She was too embarrassed to tell anyone, so she stopped by the college health service today to find out what they were.

Wow

Unconditional self-acceptance in clients is the core to reducing risky behavior and fostering peace of mind.

Sexually transmitted infections (STIs) are infections of the reproductive tract caused by microorganisms transmitted through vaginal, anal, or oral sexual intercourse (CDC, 2006). STIs pose a serious threat not only to women's sexual health but also to the general health and well-being of millions of people worldwide. STIs constitute an epidemic of tremendous magnitude. An estimated 65 million people live with an incurable STI, and another 15 million are infected each year (CDC, 2006). The incidence of STIs continues to rise in the United States.

STIs are biologically sexist, presenting greater risk and causing more complications among women than among men. Women are diagnosed with two thirds of the estimated 15 million new cases of STIs annually in the United States. After only a single exposure, women are twice as likely as men to acquire infections from pathogens causing gonorrhea, chlamydia infection, hepatitis B, and syphilis (Johnson-Mallard et al., 2007). STIs may contribute to cervical cancer, infertility, ectopic pregnancy, chronic pelvic pain, and death. Certain infections can be transmitted in utero to the fetus or during childbirth to the newborn (Table 5.1). STIs know no class, racial, ethnic, or social barriers—all individuals are vulnerable if exposed to the infectious organism. The problem of STIs has still not been tackled adequately on a global scale, and until this is done, numbers worldwide will continue to increase.

A special section on STIs and adolescents is presented below. This is followed by discussion of specific STIs categorized according to the CDC framework, which groups STIs according to the major symptom manifested (Box 5.1). A section on preventing STIs is included at the end of the chapter.

BOX 5.1 CDC Classification of STIs

- Infections characterized by vaginal discharge
  - Vulvovaginal candidiasis
  - Trichomoniasis
  - Bacterial vaginosis
- Infections characterized by cervicitis
  - Chlamydia
  - Gonorrhea
- Infections characterized by genital ulcers
  - Genital herpes simplex
  - Syphilis
- Pelvic inflammatory disease (PID)
- Human immunodeficiency virus (HIV)
- Human papillomavirus infection (HPV)
- Vaccine-preventable STIs
  - Hepatitis A
  - Hepatitis B
- Ectoparasitic infections
  - Pediculosis pubis
  - Scabies

Sexually Transmitted Infections and Adolescents

An estimated two thirds of all STIs occur among persons under the age of 25 (Waugh, 2007). Each year there are 4 million cases of STIs among teenagers. In the United States, teens who are sexually active experience high rates of STIs, and some groups are at higher risk, including African-American youths, abused youths, homeless youths,

TABLE 5.1 STIs AND EFFECTS ON THE FETUS OR NEWBORN

STI	Effects on Fetus or Newborn
Chlamydia	Can be infected during delivery Eye infections (neonatal conjunctivitis), pneumonia, low birthweight, preterm birth, stillbirth
Gonorrhea	Can be infected during delivery Rhinitis, vaginitis, urethritis, inflammation of sites of fetal monitoring Ophthalmia neonatorum can lead to blindness and sepsis (including arthritis and meningitis).
Herpes type II (genital herpes)	Contamination can occur during birth. Mental retardation, premature birth, low birthweight, death
Syphilis	Can be passed in utero Can result in fetal or infant death Congenital syphilis symptoms include skin ulcers, rashes, fever, weakened or hoarse cry, swollen liver and spleen, jaundice and anemia, various deformations.
Trichomoniasis	Fever, irritability, preterm birth, low birthweight
Venereal warts	May develop warts in throat (laryngeal papillomatosis); uncommon but life-threatening

young men having sex with men, and gay, lesbian, bisexual, and transgendered youths.

▶ *Take* NOTE!

It is estimated that before graduating from high school, 25% of adolescents will contract an STI (Pickering, 2006).

Biological and behavioral factors place teenagers at high risk. Female adolescents are more susceptible to STIs due to their anatomy. During adolescence and young adulthood, women's columnar epithelial cells are especially sensitive to invasion by sexually transmitted organisms, such as chlamydia and gonococci, because they extend out over the vaginal surface of the cervix, where they are unprotected by cervical mucus; these cells recede to a more protected location as women age. Behaviorally, adolescent and young adults tend to think they are invincible and deny the risks of their behavior. This risky behavior exposes them to STIs and HIV/AIDS. Adolescents frequently have unprotected intercourse, they engage in partnerships of limited duration, and they face many obstacles that prevent them from using the health care system.

Nursing Assessment

Many health care providers fail to assess adolescent sexual behavior and STI risks, to screen for asymptomatic infection during clinic visits, or to counsel adolescents on STI risk reduction. Nurses need to remember that they play a key role in the detection, prevention, and treatment of STIs in adolescents. All states allow adolescents to give consent to confidential STI testing and treatment. Table 5.2 discusses clinical manifestations of common STIs in adolescents.

Nursing Management

Encourage the client to complete the antibiotic prescription (specific management for each type of STI is discussed below).

Prevention of STIs among adolescents is critical. Health care providers have a unique opportunity to provide counseling and education to their clients. Adapt the style, content, and message to the client's developmental level. Identify risk factors and risk behaviors and guide the client to develop specific individualized actions of prevention. Your interaction with the client needs to be direct and nonjudgmental.

Encourage adolescents to postpone initiation of sexual intercourse for as long as possible, but if they choose to have sexual intercourse, explain the necessity of using barrier methods, such as male and female condoms (Teaching Guidelines 5.1). For teens who have already had sexual intercourse, the clinician can encourage abstinence at this point. If adolescents are sexually active, they should be directed to teen clinics and contraceptive options should be explained. In areas where specialized teen clinics are not available, nurses should feel comfortable discussing sexuality, safety, and contraception with teens. Encourage adolescents to minimize their lifetime number of sexual partners, to use barrier methods consistently and correctly, and to be aware of the connection between drug and alcohol use and the incorrect use of barrier methods. Table 5.3 discusses barriers to condom use and means to overcome them.

Think back to Sandy, who was introduced at the beginning of the chapter. How should the nurse handle Sandy's anxious state? What specific questions should the nurse ask Sandy to determine the source of the possible infection in her genital area?

Infections Characterized by Vaginal Discharge

Vaginitis is a generic term that means inflammation and infection of the vagina. There can be hundreds of causes for vaginitis, but more often than not the cause is infection by one of three organisms:

- Candida, a fungus
- Trichomonas, a protozoan
- Gardnerella, a bacterium

The complex balance of microbiological organisms in the vagina is a key element in the maintenance of health. Subtle shifts in the vaginal environment may allow organisms with pathologic potential to proliferate, causing infectious symptoms.

The nurse's role in managing vaginitis is one of primary prevention and education to limit recurrences of these infections. Primary prevention begins with changing the sexual behaviors that place women at risk for infection. In addition to assessing women for the common signs and symptoms and risk factors, the nurse can help women to avoid vaginitis or to prevent a recurrence by teaching them to take the precautions highlighted in Teaching Guidelines 5.2.

VULVOVAGINAL CANDIDIASIS

Vulvovaginal candidiasis is one of the most common causes of vaginal discharge. It is also referred to as yeast, monilia, and a fungal infection. It is not considered an

(text continues on page 148)

TABLE 5.2 STIs Common in Adolescents

Disease	Causative Organism	Transmission Mode	Diagnostic Testing	Female Symptoms	Male Symptoms	Treatment
Chlamydia Curable STI Seen frequently among sexually active adolescents and young adults Sexually active adolescents should be screened at least annually.	*Chlamydia trachomatis* (bacteria)	Vaginal, anal, oral sex, and by childbirth	Culture fluid from urethral swabs in males or endocervical swabs for females and conjunctival secretions in neonates	May be asymptomatic Dysuria Vaginal discharge (mucus or pus) Endocervicitis May lead to pelvic inflammatory disease, ectopic pregnancy, and infertility Can cause inflammation of the rectum and lining of the eye (conjunctivitis) Can infect the throat from oral sexual contact with an infected partner	May be asymptomatic Dysuria Penile discharge (mucus or pus) Urethral tingling May lead to epididymitis (inflammation of the epididymis, the tubular structure that connects the testicle with the vas deferens) and sterility Can cause inflammation of the rectum and lining of the eye (conjunctivitis) Can infect the throat from oral sexual contact with an infected partner	Azithromycin (Zithromax) Doxycycline (Vibramycin) Erythromycin (EES) Ofloxacin (Floxin) Sexual partners need evaluation, testing, and treatment also.
Gonorrhea Curable STI Client is often co-infected with *Chlamydia tracho matis*	*Neisseria gonorrhoeae* (bacteria)	Vaginal, anal, oral sex, and by childbirth	Staining samples directly for the bacterium, detection of bacterial genes or DNA in urine, and growing the bacteria in laboratory cultures More than one test may be used.	May be asymptomatic or no recognizable symptoms until serious complications such as pelvic inflammatory disease Dysuria Urinary frequency Vaginal discharge (yellow, foul) Dyspareunia Endocervicitis Arthritis May lead to pelvic inflammatory disease, ectopic pregnancy, and infertility Symptoms of rectal infection include discharge, anal itching, and occasional painful	Most produce symptoms but can be asymptomatic Dysuria Penile discharge (pus) Arthritis May lead to epididymitis and sterility Symptoms of rectal infection include discharge, anal itching, and occasional painful bowel movements with fresh blood.	Usually a single dose of one of the following: Cefiximine (Suprax) Ciprofloxacin (Cipro) Ceftriaxone (Rocephin) Ofloxacin (Floxin) Levofloxin (Levaquin) **No Floxin or Cipro if <18 years or pregnant!** Azithromycin (Zithromax) Doxycycline (Vibramycin) Usually will be treated for co-infection with chlamydia, so a combination is given (e.g., ceftriaxone and doxycycline). Sexual partners need evaluation, testing, and treatment also.

				bowel movements with fresh blood.		
Herpes Type II (Genital Herpes) Lifelong recurrent viral disease Most people have not been diagnosed. There is no cure.	Herpes simplex virus II (HSV II)	Having sexual contact (vaginal, oral, or anal) with someone who is shedding the herpes virus either during an outbreak or during a period with no symptoms Can be transmitted through close skin-to-skin contact	Visual inspection and symptoms or culture Virologic and type-specific serologic tests can tell if herpes simplex virus II is present but does not confirm genital herpes, though most providers will assume a positive HSV II means genital herpes.	Blister-like genital lesions Dysuria Fever, headache, muscle aches	Blister-like genital lesions Dysuria Fever, headache, muscle aches	Acyclovir (Zovirax) Other antivirals DOES NOT CURE, just controls symptoms Sexual partners benefit from evaluation and counseling. If symptomatic, they need treatment. If asymptomatic, offer testing and education.
Syphilis	*Treponema pallidum* (spirochete bacteria)	Sexual contact with an infected person	Blood tests Venereal Disease Research Laboratory (VDRL), Rapid Plasma Reagin (RPR), and treponemal tests (e.g., fluorescent treponemal antibody absorbed [FTA-ABS]) can lead to a presumptive diagnosis. Darkfield examination and direct fluorescent antibody tests	Disease is divided into four stages *Primary infection* • Chancre on place of entrance of bacteria (usually vulva or vagina but can develop in other parts of the body) *Secondary infection* • Maculopapular rash (hands & feet) • Sore throat • Lymphadenopathy • Flu-like symptoms *Latent infection* • No symptoms • No longer contagious • Many people if not treated will suffer no further signs and symptoms.	Disease is divided into four stages *Primary infection* • Chancre on place of entrance of bacteria (usually on penis but can develop in other parts of the body) *Secondary, latent, and tertiary infections* All similar to female symptoms	Penicillin G inj. (if penicillin allergy, doxycycline or erythromycin) Sexual partners need evaluation and testing.

(continued)

TABLE 5.2 STIs Common in Adolescents (continued)

Disease	Causative Organism	Transmission Mode	Diagnostic Testing	Female Symptoms	Male Symptoms	Treatment
			of lesion exudate or tissue provide definitive diagnosis of early syphilis.	Some people will go on to develop tertiary or late syphilis. *Tertiary infections* • Tumors of skin, bones & liver • CNS symptoms • CV symptoms • Usually not reversible at this stage		
Trichomoniasis	*Trichomonas vaginalis* (protozoan)	Vaginal intercourse with an infected partner May be picked up from direct genital contact with damp or moist objects, such as towels, wet clothing, or a toilet seat	Microscopic evaluation of vaginal secretions or culture	Many women have symptoms but some may be asymptomatic. Dysuria Urinary frequency Vaginal discharge (yellow, green, or gray & foul odor) Dyspareunia Irritation or itching of genital area	Most infected men are asymptomatic. Dysuria Penile discharge (watery, white)	Metronidazole (Flagyl) Sexual partners need evaluation, testing, and treatment also.

Venereal Warts (condylomata acuminata) One of the most common STIs in the United States Could lead to cancers of the cervix, vulva, vagina, anus, or penis No cure; warts can be removed but virus remains	Human papillomavirus	Vaginal, anal, or oral sex with an infected partner	Visual inspection Abnormal Pap smear may indicate cervical infection of HPV.	Wart-like lesions that are soft, moist, or flesh-colored and appear on the vulva and cervix and inside and surrounding the vagina and anus Sometimes appear in clusters that resemble cauliflower-like bumps, and are either raised or flat, small or large	Wart-like lesions that are soft, moist, or flesh-colored and appear on the scrotum or penis Sometimes appear in clusters that resemble cauliflower-like bumps, and are either raised or flat, small or large	May disappear without treatment Treatment is aimed at removing the lesions rather than HPV itself No optimal treatment has been identified, but there are several ways to treat them depending on size and location. Most methods rely on chemical or physical destruction of the lesion: Imiquimod cream 20% Podophyllin antimitotic solution 0.5% Podofilox solution 5% 5-fluorouracil cream Trichloroacetic acid (TCA) Small warts can be removed by: • Freezing (cryosurgery) • Burning (electrocautery) • Laser treatment Large warts that have not responded to treatment may be removed surgically.

TEACHING GUIDELINES 5.1

Proper Condom Use

- Use latex condoms.
- Use a new condom with each act of sexual intercourse. Never reuse a condom.
- Handle condoms with care to prevent damage from sharp objects such as fingernails and teeth.
- Ensure condom has been stored in a cool, dry place away from direct sunlight. Do not store condoms in wallet or automobile or anywhere they would be exposed to extreme temperatures.
- Do not use a condom if it appears brittle, sticky, or discolored. These are signs of aging.
- Put condom on before any genital contact.
- Put condom on when penis is erect. Ensure it is placed so it will readily unroll.
- Hold the tip of the condom while unrolling. Ensure there is a space at the tip for semen to collect, but make sure no air is trapped in the tip.
- Ensure adequate lubrication during intercourse. If external lubricants are used, use only water-based lubricants such as KY jelly with latex condoms. Oil-based or petroleum-based lubricants, such as body lotion, massage oil, or cooking oil, can weaken latex condoms.
- Withdraw while penis is still erect, and hold condom firmly against base of penis.

Adapted from Pickering, L. K. (Ed.) (2006). *Red book: 2006 report of the committee on infectious diseases* (27th ed.). Elk Grove Village, IL: American Academy of Pediatrics; and Public Health Agency of Canada (2006). *Canadian guidelines on sexually transmitted infections.* Ottawa, ON: Author.

STI because Candida is a normal constituent in the vagina and becomes pathologic only when the vaginal environment becomes altered. An estimated 75% of women will have at least one episode of vulvovaginal candidiasis, and 40% to 50% will have two or more episodes in their lifetime (CDC, 2006).

Therapeutic Management

Treatment of candidiasis includes one of the following medications:

- Miconazole (Monistat) cream or suppository
- Clotrimazole (Mycelex) tablet or cream
- Terconazole (Terazol) cream or intravaginal suppository
- Fluconazole (Diflucan) oral tablet (CDC, 2006, p. 55)

Most of the above medications are used intravaginally in the form of a cream, tablet, or suppositories used for 3 to 7 days. If fluconazole (Diflucan) is prescribed, a 150-mg oral tablet is taken as a single dose.

Topical azole preparations are effective in the treatment of vulvovaginal candidiasis, relieving symptoms and producing negative cultures in 80% to 90% of women who complete therapy (CDC, 2006). If vulvovaginal candidiasis is not treated effectively during pregnancy, the newborn can develop an oral infection known as thrush during the birth process; that infection must be treated with a local azole preparation after birth.

Nursing Assessment

Assess the patient's health history for predisposing factors for vulvovaginal candidiasis, which include:

- Pregnancy
- Use of oral contraceptives with a high estrogen content
- Use of broad-spectrum antibiotics
- Diabetes mellitus
- Obesity
- Use of steroid and immunosuppressive drugs
- HIV infection
- Wearing tight, restrictive clothes and nylon underpants
- Trauma to vaginal mucosa from chemical irritants or douching

Assess the patient for clinical manifestations of vulvovaginal candidiasis. Typical symptoms, which can worsen just before menses, include:

- Pruritus
- Vaginal discharge (thick, white, curd-like)
- Vaginal soreness
- Vulvar burning
- Erythema in the vulvovaginal area
- Dyspareunia
- External dysuria

Figure 5.1 shows the typical appearance of vulvovaginal candidiasis.

Speculum examination will reveal white plaques on the vaginal walls. The vaginal pH remains within normal range. Definitive diagnosis is made by a wet smear, which reveals the filamentous hyphae and spores characteristic of a fungus when viewed under a microscope.

Nursing Management

Teach preventive measures to women with frequent vulvovaginal candidiasis infections, including:

- Reduce dietary intake of simple sugars and soda.
- Wear white, 100% cotton underpants.
- Avoid wearing tight pants or exercise clothes with spandex.
- Shower rather than taking tub baths.
- Wash with a mild, unscented soap and dry the genitals gently.
- Avoid the use of bubble baths or scented bath products.
- Wash underwear in unscented laundry detergent and hot water.

TABLE 5.3 BARRIERS TO CONDOM USE AND MEANS TO OVERCOME THEM

Perceived Barrier	Intervention Strategy
Decreases sexual pleasure (sensation)	• Encourage patient to try.
Note: Often perceived by those who have never used a condom.	• Put a drop of water-based lubricant or saliva inside the tip of the condom or on the glans of the penis before putting on the condom. • Try a thinner latex condom or a different brand or more lubrication.
Decreases spontaneity of sexual activity	• Incorporate condom use into foreplay. • Remind patient that peace of mind may enhance pleasure for self and partner.
Embarrassing, juvenile, "unmanly"	• Remind patient that it is "manly" to protect himself and others.
Poor fit (too small or too big, slips off, uncomfortable)	• Smaller and larger condoms are available.
Requires prompt withdrawal after ejaculation	• Reinforce the protective nature of prompt withdrawal and suggest substituting other postcoital sexual activities.
Fear of breakage may lead to less vigorous sexual activity.	• With prolonged intercourse, lubricant wears off and the condom begins to rub. Have a water-soluble lubricant available to reapply.
Non-penetrative sexual activity	• Condoms have been advocated for use during fellatio; unlubricated condoms may prove best for this purpose due to the taste of the lubricant. • Other barriers, such as dental dams or an unlubricated condom, can be cut down the middle to form a barrier; these have been advocated for use during certain forms of non-penetrative sexual activity (e.g., cunnilingus and anolingual sex).
Allergy to latex	• Polyurethane male and female condoms are available. • A natural skin condom can be used together with a latex condom to protect the man or woman from contact with latex.

From Public Health Agency of Canada. (2006). *Canadian guidelines on sexually transmitted infections.*

- Dry underwear in a hot dryer to kill the yeast that clings to the fabric.
- Remove wet bathing suits promptly.
- Practice good body hygiene.
- Avoid vaginal sprays/deodorants.
- Avoid wearing pantyhose (or cut out the crotch to allow air circulation).
- Use white, unscented toilet paper and wipe from front to back.
- Avoid douching (which washes away protective vaginal mucus).
- Avoid the use of super-absorbent tampons (use pads instead).

TRICHOMONIASIS

Trichomoniasis is another common vaginal infection that causes a discharge. The woman may be markedly symptomatic or asymptomatic. Men are asymptomatic carriers. Although this infection is localized, there is increasing evidence of preterm birth and postpartum endometritis in women with this vaginitis (CDC, 2006). *Trichomonas vaginalis* is an ovoid, single-cell protozoan parasite that can be observed under the microscope making a jerky swaying motion.

Therapeutic Management

A single 2-gram dose of oral metronidazole (Flagyl) or tinidazole (Tindamax) for both partners is a common treatment for this infection. Sex partners of women with trichomoniasis should be treated to avoid recurrence of infection.

Nursing Assessment

Assess the patient for clinical manifestations of trichomoniasis, which include:

- A heavy yellow/green or gray frothy or bubbly discharge
- Vaginal pruritus and vulvar soreness
- Dyspareunia
- Cervix may bleed on contact
- Dysuria
- Colpitis macularis ("strawberry" look on cervix)

Figure 5.2 shows the typical appearance of trichomoniasis.

The diagnosis is confirmed when a motile flagellated trichomonad is visualized under the microscope. In addition, a vaginal pH of greater than 4.5 is a typical finding.

HEALTHY PEOPLE 2010

Healthy People 2010 Objectives 25–1, 2, 3, 5, 11, & 19	Significance
Reduce the proportion of adolescents and young adults with *Chlamydia trachomatis* infections.	Provide confidential care to all adolescents.
Reduce gonorrhea.	Assess for sexual behaviors and STI risks during clinic visits; take every opportunity to educate on risks of STIs and risk reduction.
Eliminate sustained domestic transmission of primary and secondary syphilis.	Be direct and nonjudgmental and tailor your approach to the client.
(Developmental) Reduce the proportion of persons with human papillomavirus (HPV) infection.	Encourage adolescents to postpone initiation of sexual intercourse for as long as possible.
Increase the proportion of adolescents who abstain from sexual intercourse or use condoms if currently sexually active.	For teens who have already had sexual intercourse, encourage abstinence at this point.
(Developmental) Increase the proportion of all sexually transmitted disease clinic patients who are being treated for bacterial STDs (chlamydia, gonorrhea, and syphilis) and who are offered provider referral services for their sex partners.	Encourage adolescents to minimize their lifetime number of sexual partners.
	Educate about the importance of correct and consistent condom use.

Nursing Management

Instruct clients to avoid sex until they and their sex partners are cured (i.e., when therapy has been completed and both partners are symptom-free) and also to avoid consuming alcohol during treatment because mixing the medications and alcohol causes severe nausea and vomiting (CDC, 2006).

TEACHING GUIDELINES 5.2

Preventing Vaginitis

- Avoid douching to prevent altering the vaginal environment.
- Use condoms to avoid spreading the organism.
- Avoid tights, nylon underpants, and tight clothes.
- Wipe from front to back after using the toilet.
- Avoid powders, bubble baths, and perfumed vaginal sprays.
- Wear clean cotton underpants.
- Change out of wet bathing suits as soon as possible.
- Become familiar with the signs and symptoms of vaginitis.
- Choose to lead a healthy lifestyle.

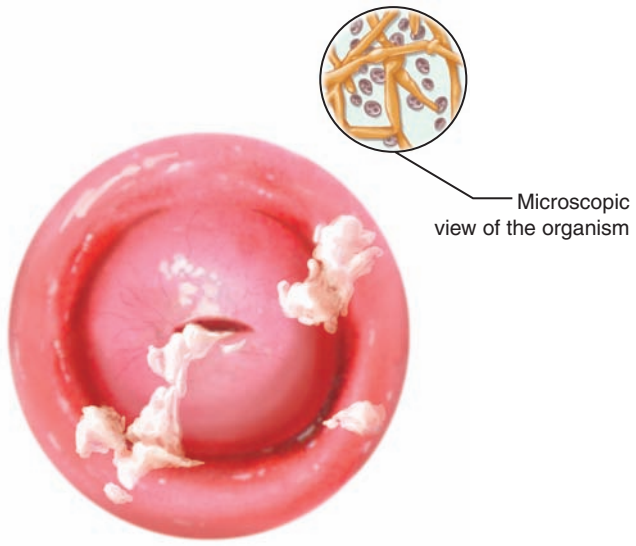

FIGURE 5.1 Vulvovaginal candidiasis. (Source: The Anatomical Chart Company. [2002]. *Atlas of pathophysiology*. Springhouse, PA: Springhouse.)

BACTERIAL VAGINOSIS

A third common infection of the vagina is **bacterial vaginosis**, caused by the gram-negative bacillus *Gardnerella vaginalis*. It is the most prevalent cause of vaginal discharge or malodor, but up to 50% of women are asymptomatic. Bacterial vaginosis is a sexually associated infection characterized by alterations in vaginal flora in which lactobacilli

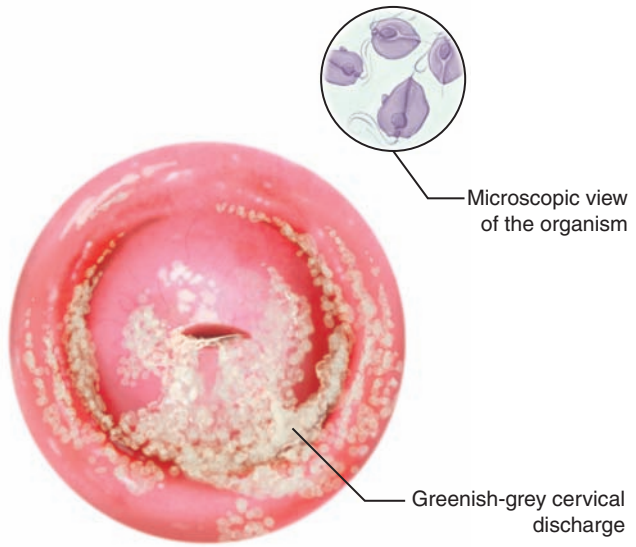

FIGURE 5.2 Trichomoniasis. (Source: The Anatomical Chart Company. [2002]. *Atlas of pathophysiology*. Springhouse, PA: Springhouse.)

EVIDENCE-BASED PRACTICE 5.1
Interventions for Trichomoniasis in Pregnancy

● Study
Trichomoniasis is a very common sexually transmitted infection. Symptoms include vaginal itching and discharge. It is not clear whether pregnant women with trichomoniasis are more likely to give birth preterm or to have other pregnancy complications. The review of trials found that the drug metronidazole is effective against trichomoniasis when taken by women and their partners during pregnancy, but it may harm the baby. Of the two clinical trials reviewed, one was stopped early because women taking metronidazole were more likely to give birth preterm and have low-birthweight babies. Further research into trichomoniasis treatments for pregnant women is needed.

▲ Findings
Metronidazole is effective against a trichomoniasis infection during pregnancy but may increase the risk of preterm and low-birthweight babies.

■ Nursing Implications
The nurse's role concerning this study's results is to counsel women diagnosed with trichomoniasis during pregnancy about the potential risks of treatment. The woman should be cautioned about taking this medication if she has a previous history of preterm births, is carrying twins, or is experiencing preterm contractions. In addition, an ultrasound should validate the fetal weight linked to the gestational age to make sure it is within normal range before this medication is prescribed.

Source: Gülmezoglu A. M. (2007). Interventions for trichomoniasis in pregnancy. *Cochrane Database of Systematic Reviews* 2006, Issue 3. Art. No.: CD000220. DOI: 10.1002/14651858.CD000220.

in the vagina are replaced with high concentrations of anaerobic bacteria. The cause of the microbial alteration is not fully understood but is associated with having multiple sex partners, douching, and lack of vaginal lactobacilli (CDC, 2006). Research suggests that bacterial vaginosis is associated with preterm labor, premature rupture of membranes, chorioamnionitis, postpartum endometritis, and pelvic inflammatory disease (CDC, 2006).

Therapeutic Management

Treatment for bacterial vaginosis includes oral metronidazole (Flagyl) or clindamycin (Cleocin) cream. Treatment of the male partner has not been beneficial in preventing recurrence because sexual transmission of bacterial vaginosis has not been proven (CDC, 2006).

Nursing Assessment

Assess the patient for clinical manifestations of bacterial vaginosis. Primary symptoms are a thin, white homogeneous vaginal discharge and a characteristic "stale fish" odor. Figure 5.3 shows the typical appearance of bacterial vaginosis.

To diagnose bacterial vaginosis, three of the four criteria must be met:

- Thin, white homogeneous vaginal discharge
- Vaginal pH > 4.5
- Positive "whiff test" (secretion is mixed with a drop of 10% potassium hydroxide on a slide, producing a characteristic stale fishy odor)
- The presence of clue cells on wet-mount examination (CDC, 2006)

Nursing Management

The nurse's role is one of primary prevention and education to limit recurrences of these infections. Primary prevention begins with changing the sexual behaviors that place women at risk for infection. In addition to assessing women for common signs, symptoms, and risk factors,

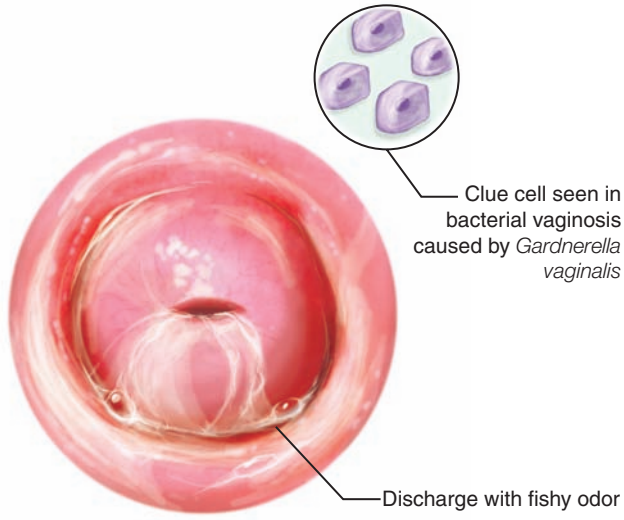

FIGURE 5.3 Bacterial vaginosis. (Source: The Anatomical Chart Company. [2002]. *Atlas of pathophysiology.* Springhouse, PA: Springhouse.)

the nurse can help women to avoid vaginitis or to prevent a recurrence by teaching them to take the precautions highlighted in Teaching Guidelines 5.2.

Infections Characterized by Cervicitis

Cervicitis is a catchall term that implies the presence of inflammation or infection of the cervix. It is used to describe everything from symptomless erosions to an inflamed cervix that bleeds on contact and produces quantities of purulent discharge containing organisms not ordinarily found in the vagina. Cervicitis is usually caused by gonorrhea or chlamydia, as well as almost any pathogenic bacterial agent and a number of viruses. The treatment of cervicitis involves the appropriate therapy for the specific organism that has caused it.

CHLAMYDIA

Chlamydia is the most common bacterial STI in the United States. The CDC estimates that there are 4 million new cases each year; the highest predictor for the infection is age. The highest rates of infection are among those ages 15 to 19, mainly because their sexual relations are often unplanned and are sometimes the result of pressure or force, and typically happen before they have the experience and skills to protect themselves. The rates are highest among this group regardless of demographics or location (CDC, 2006). The young have the most to lose from acquiring STIs, since they will suffer the consequences the longest and might not reach their full reproductive potential.

Asymptomatic infection is common among both men and women. Men primarily develop urethritis. In women, chlamydia is linked with cervicitis, acute urethral syndrome, salpingitis, ectopic pregnancy, pelvic inflammatory disease (PID), and infertility (Marrazzo & Martin, 2007). Chlamydia causes half of the 1 million recognized cases of PID in the United States each year, and treatment costs run over $1 billion yearly.

Chlamydia trachomatis is the bacterium that causes chlamydia. It is an intracellular parasite that cannot produce its own energy and depends on the host for survival. It is often difficult to detect, and this can pose problems for women due to the long-term consequences of untreated infection. Moreover, lack of treatment provides more opportunity for the infection to be transmitted to sexual partners. Newborns delivered to infected mothers may develop conjunctivitis or pneumonitis and have a 50% to 70% risk of acquiring the infection (Glasier et al., 2006).

Therapeutic Management

Antibiotics are usually used in treating this STI. The CDC treatment options for chlamydia include doxycycline (Vibromycin) 100 mg orally twice a day for 7 days or azithromycin (Zithromax) 1 gram orally in a single dose. Because of the common co-infection of chlamydia and gonorrhea, a combination regimen of ceftriaxone (Rocephin) with doxycycline or azithromycin is prescribed frequently (CDC, 2006). Additional CDC guidelines for patient management include annual screening of all sexually active women aged 20 to 25 years old; screening of all high-risk people; and treatment with antibiotics effective against both gonorrhea and chlamydia for anyone diagnosed with a gonococcal infection (CDC, 2006).

Nursing Assessment

Assess the health history for significant risk factors for chlamydia, which may include:

- Being an adolescent
- Having multiple sex partners
- Having a new sex partner
- Engaging in sex without using a barrier contraceptive (condom)
- Using oral contraceptives
- Being pregnant
- Having a history of another STI (Geisler, 2007)

Assess the client for clinical manifestations of chlamydia. The majority of women (70% to 80%) are asymptomatic (CDC, 2006). If the client is symptomatic, clinical manifestations include:

- Mucopurulent vaginal discharge
- Urethritis
- Bartholinitis
- Endometritis
- Salpingitis
- Dysfunctional uterine bleeding

The diagnosis can be made by urine testing or swab specimens collected from the endocervix or vagina. Culture, direct immunofluorescence, EIA, or nucleic acid amplification methods by polymerase chain reaction or ligase chain reaction (DNA probe, such as GenProbe or Pace2) are highly sensitive and specific when used on urethral and cervicovaginal swabs. They can also be used with good sensitivity and specificity on first-void urine specimens (Mehta, 2007). The chain reaction tests are the most sensitive and cost-effective. The CDC strongly recommends screening of asymptomatic women at high risk in whom infection would otherwise go undetected (CDC, 2006).

GONORRHEA

Gonorrhea is a serious and potentially very severe bacterial infection. It is the second most commonly reported infection in the United States. Gonorrhea is highly con-

tagious and is a reportable infection to the health department authorities. Gonorrhea increases the risk for PID, infertility, ectopic pregnancy, and HIV acquisition and transmission (CDC, 2007a, 2007b, 2007d). It is rapidly becoming more and more resistant to cure. In the United States, an estimated 600,000 new gonorrhea infections occur annually (CDC, 2006). In common with all other STIs, it is an equal-opportunity infection—no one is immune to it, regardless of race, creed, gender, age, or sexual preference.

The cause of gonorrhea is an aerobic gram-negative intracellular diplococcus, *Neisseria gonorrhoeae.* The site of infection is the columnar epithelium of the endocervix. Gonorrhea is almost exclusively transmitted by sexual activity. In pregnant women, gonorrhea is associated with chorioamnionitis, premature labor, premature rupture of membranes, and postpartum endometritis (Peterson et al., 2007). It can also be transmitted to the newborn in the form of ophthalmia neonatorum during birth by direct contact with gonococcal organisms in the cervix. Ophthalmia neonatorum is highly contagious and if untreated leads to blindness in the newborn.

Therapeutic Management

The treatment of choice for uncomplicated gonococcal infections is cefixime (Suprex) 400 mg orally in a single dose or ceftriaxone (Rocephine) 125 mg intramuscularly in a single dose. Azithromycin (Zithromax) orally or doxycycline (Vibromycin) should accompany all gonococcal treatment regimens if chlamydial infection is not ruled out (CDC, 2006). Pregnant women should not be treated with quinolones or tetracyclines. Cephalosporins or a single 2-gram intramuscular dose of spectinomycin should be used during pregnancy (CDC, 2006). To prevent gonococcal ophthalmia neonatorum, a prophylactic agent should be instilled into the eyes of all newborns; this procedure is required by law in most states. Erythromycin or tetracycline ophthalmic ointment in a single application is recommended (CDC, 2006).

Nursing Assessment

Assess the client's health history for risk factors, which may include low socioeconomic status, living in an urban area, single status, inconsistent use of barrier contraceptives, age under 20 years old, and multiple sex partners. Assess the client for clinical manifestations of gonorrhea, keeping in mind that between 50% and 90% of women infected with gonorrhea are totally symptom-free (Glasier et al., 2006). Because women are so frequently asymptomatic, they are regarded as a major factor in the spread of gonorrhea. If symptoms are present, they might include:

- Abnormal vaginal discharge
- Dysuria
- Cervicitis
- Abnormal vaginal bleeding
- Bartholin's abscess
- PID
- Neonatal conjunctivitis in newborns
- Mild sore throat (for pharyngeal gonorrhea)
- Rectal infection (asymptomatic)
- Perihepatitis (Bennett & Domachowske, 2007)

Sometimes a local gonorrhea infection is self-limiting (there is no further spread), but usually the organism ascends upward through the endocervical canal to the endometrium of the uterus, further on to the fallopian tubes, and out into the peritoneal cavity. When the peritoneum and the ovaries become involved, the condition is known as PID. The scarring to the fallopian tubes is permanent. This damage is a major cause of infertility and is a possible contributing factor in ectopic pregnancy (Mehta, 2007).

If gonorrhea remains untreated, it can enter the bloodstream and produce a disseminated gonococcal infection. This severe form of infection can invade the joints (arthritis), the heart (endocarditis), the brain (meningitis), and the liver (toxic hepatitis). Figure 5.4 shows the typical appearance of gonorrhea.

The CDC recommends screening for all women at risk for gonorrhea. Pregnant women should be screened at the first prenatal visit and again at 36 weeks of gestation. Nucleic acid hybridization tests (GenProbe) are used for diagnosis. Any woman suspected of having gonorrhea should be tested for chlamydia also because co-infection (45%) is extremely common (CDC, 2006).

Nursing Management of Chlamydia and Gonorrhea

The prevalence of chlamydia and gonorrhea is increasing dramatically, and these infections can have long-term effects on people's lives. Sexual health is an important part of a person's physical and mental health, and nurses have a professional obligation to address it. Be particularly sensitive when addressing STIs because women are often embarrassed or feel guilty. There is still a social stigma attached to STIs, so women need to be reassured about confidentiality.

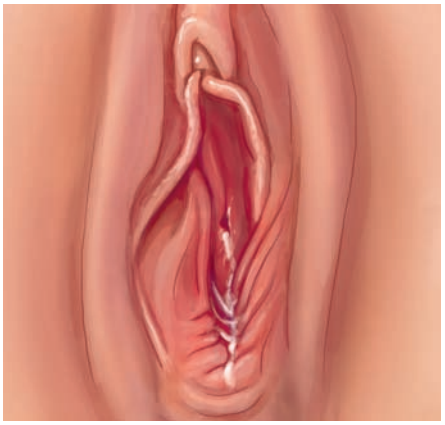

FIGURE 5.4 Gonorrhea.

The nurse's knowledge about chlamydia and gonorrhea should include treatment strategies, referral sources, and preventive measures. It is important to be skilled at patient education and counseling and to be comfortable talking with, and advising, women diagnosed with these infections.

Provide education about risk factors for these infections. High-risk groups include single women, women younger than 25 years, African-American women, women with a history of STIs, those with new or multiple sex partners, those with inconsistent use of barrier contraception, and women living in communities with high infection rates (Bennett & Domachowske, 2007). Assessment involves taking a health history that includes a comprehensive sexual history. Ask about the number of sex partners and the use of safer sex techniques. Review previous and current symptoms. Emphasize the importance of seeking treatment and informing sex partners. The four-level P-LI-SS-IT model (Box 5.2) can be used to determine interventions for various women because it can be adapted to the nurse's level of knowledge, skill, and experience. Of utmost importance is the willingness to listen and show interest and respect in a nonjudgmental manner.

In addition to meeting the health needs of women with chlamydia and gonorrhea, the nurse is responsible for educating the public about the increasing incidence of these infections. This information should include high-risk behaviors associated with these infections, signs and symptoms, and the treatment modalities available. Stress that both of these STIs can lead to infertility and long-term sequelae. Teach safer sex practices to people in nonmonogamous relationships. Know the physical and psychosocial responses to these STIs to prevent transmission and the disabling consequences.

BOX 5.2 The P-LI-SS-IT Model

P Permission—gives the woman permission to talk about her experience

LI Limited Information—information given to the woman about STIs

- Factual information to dispel myths about STIs
- Specific measures to prevent transmission
- Ways to reveal information to her partners
- Physical consequences if the infections are untreated

SS Specific Suggestions—an attempt to help women change their behavior to prevent recurrence and prevent further transmission of the STI

IT Intensive Therapy—involves referring the woman or couple for appropriate treatment elsewhere based on their life circumstances

▶ *Take* NOTE!

If the epidemic of chlamydia and gonorrhea is to be halted, nurses must take a major front-line role now.

Infections Characterized by Genital Ulcers

In the United States, the majority of young, sexually active patients who have genital ulcers have genital herpes, syphilis, or chancroid. The frequency of each condition differs by geographic area and patient population; however, genital herpes is the most prevalent of these diseases. More than one of these diseases can be present in a patient who has genital ulcers. All three of these diseases have been associated with an increased risk for HIV infection. Not all genital ulcers are caused by STIs.

GENITAL HERPES SIMPLEX

Genital herpes is a recurrent, lifelong viral infection. The CDC estimates that 50 million Americans have genital herpes simplex (HSV) infection, with a half million new cases annually (CDC, 2006). Two serotypes of HSV have been identified: HSV-1 (not sexually transmitted) and HSV-2 (sexually transmitted). Today, approximately 10% of genital herpes infections are thought to be caused by HSV-1 and 90% by HSV-2 (Paz-Baily et al., 2007). HSV-1 causes the familiar fever blisters or cold sores on the lips, eyes, and face. HSV-2 invades the mucous membranes of the genital tract and is known as herpes genitalis. Most persons infected with HSV-2 have not been diagnosed.

The herpes simplex virus is transmitted by contact of mucous membranes or breaks in the skin with visible or nonvisible lesions. Most genital herpes infections are transmitted by individuals unaware that they have an infection. Many have mild or unrecognized infections but still shed the herpes virus intermittently. HSV is transmitted primarily by direct contact with an infected individual who is shedding the virus. Kissing, sexual contact, and vaginal delivery are means of transmission.

Having sex with an infected partner places the individual at risk for contracting HSV. After the primary outbreak, the virus remains dormant in the nerve cells for life, resulting in periodic recurrent outbreaks. Recurrent genital herpes outbreaks are triggered by precipitating factors such as emotional stress, menses, and sexual intercourse, but more than half of recurrences occur without a precipitating cause. Immunocompromised women have more

frequent and more severe recurrent outbreaks than normal hosts (Paz-Bailey et al., 2007).

Living with genital herpes can be difficult due to the erratic, recurrent nature of the infection, the location of the lesions, the unknown causes of the recurrences, and the lack of a cure. Further, the stigma associated with this infection may affect the individual's feelings about herself and her interaction with partners. Potential psychosocial consequences may include emotional distress, isolation, fear of rejection by a partner, fear of transmission of the disease, loss of confidence, and altered interpersonal relationships (Alexander et al., 2007).

Along with the increase in the incidence of genital herpes has been an increase in neonatal herpes simplex viral infections, which are associated with a high incidence of mortality and morbidity. The risk of neonatal infection with a primary maternal outbreak is between 30% and 50%; it is less than 1% with a recurrent maternal infection (CDC, 2006).

Therapeutic Management

No cure exists, but antiviral drug therapy helps to reduce or suppress symptoms, shedding, and recurrent episodes. Advances in treatment with acyclovir (Zovirax) 400 mg orally three times daily for 7 to 10 days, famciclovir (Famivir) 250 mg orally three times daily for 7 to 10 days, and valacyclovir (Valtrex) 1 gram orally twice daily for 7 to 10 days have resulted in an improved quality of life for those infected with HSV. However, these drugs neither eradicate latent virus nor affect the risk, frequency, or severity of recurrences after the drug is discontinued (CDC, 2006). Suppressive therapy is recommended for individuals with six or more recurrences per year. The natural course of the disease is for recurrences to be less frequent over time.

The management of genital herpes includes antiviral therapy. The safety of antiviral therapy has not been established during pregnancy. Therapeutic management also includes counseling regarding the natural history of the disease, the risk of sexual and perinatal transmission, and the use of methods to prevent further spread.

Nursing Assessment

Assess the client for clinical manifestations of HSV. Clinical manifestations can be divided into the primary episode and recurrent infections. The first or primary episode is usually the most severe, with a prolonged period of viral shedding. Primary HSV is a systemic disease characterized by multiple painful vesicular lesions, mucopurulent discharge, superinfection with candida, fever, chills, malaise, dysuria, headache, genital irritation, inguinal tenderness, and lymphadenopathy. The lesions in the primary herpes episode are frequently located on the vulva, vagina, and perineal areas. The vesicles will open and weep and finally crust over, dry, and disappear without scar formation

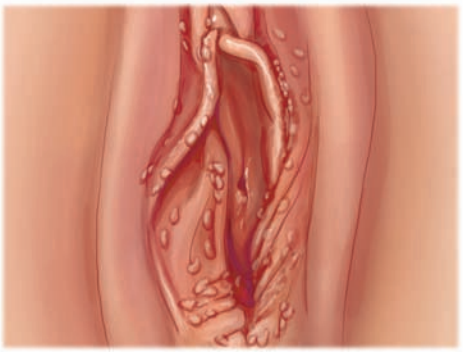

FIGURE 5.5 Genital herpes simplex.

(Fig. 5.5). This viral shedding process usually takes up to 2 weeks to complete.

Recurrent infection episodes are usually much milder and shorter in duration than the primary one. Tingling, itching, pain, unilateral genital lesions, and a more rapid resolution of lesions are characteristics of recurrent infections. Recurrent herpes is a localized disease characterized by typical HSV lesions at the site of initial viral entry. Recurrent herpes lesions are fewer in number and less painful and resolve more rapidly (Sharma & Brilliant, 2007).

Diagnosis of HSV is often based on clinical signs and symptoms and is confirmed by viral culture of fluid from the vesicle. Papanicolaou (Pap) smears are an insensitive and nonspecific diagnostic test for HSV and should not be relied on for diagnosis.

SYPHILIS

Syphilis is a complex, curable bacterial infection caused by the spirochete *Treponema pallidum.* It is a serious systemic disease that can lead to disability and death if untreated. Rates of syphilis in the United States were declining, but they remain high among young adults and African-Americans in urban areas and in the south (CDC, 2006). It continues to be one of the most important STIs both because of its biological effect on HIV acquisition and transmission and because of its impact on infant health (Stoner, 2007).

The spirochete rapidly penetrates intact mucous membranes or microscopic lesions in the skin and within hours enters the lymphatic system and bloodstream to produce a systemic infection long before the appearance of a primary lesion. The site of entry may be vaginal, rectal, or oral (Ferguson & Varnado, 2006). The syphilis spirochete can cross the placenta at any time during pregnancy. One out of every 10,000 infants born in the United States has congenital syphilis (CDC, 2006). Maternal infection

consequences include spontaneous abortion, prematurity, stillbirth, and multisystem failure of the heart, lungs, spleen, liver, and pancreas, as well as structural bone damage and nervous system involvement and mental retardation (Gilbert, 2007).

Therapeutic Management

Fortunately, there is effective treatment for syphilis. Penicillin G, administered by either the intramuscular or intravenous route, is the preferred drug for all stages of syphilis. For pregnant or nonpregnant women with syphilis of less than 1 year's duration, the CDC recommends 2.4 million units of benzathine penicillin G intramuscularly in a single dose. If the syphilis is of longer duration (more than 1 year) or of unknown duration, 2.4 million units of benzathine penicillin G is given intramuscularly once a week for 3 weeks. The preparations used, the dosage, and the length of treatment depend on the stage and clinical manifestations of disease (CDC, 2006). Other medications, such as doxycycline, are available if the client is allergic to penicillin.

Women should be re-evaluated at 6 and 12 months after treatment for primary or secondary syphilis with additional serologic testing. Women with latent syphilis should be followed clinically and serologically at 6, 12, and 24 months (McGregor & Richard, 2007).

Nursing Assessment

Assess the client for clinical manifestations of syphilis. Syphilis is divided into four stages: primary, secondary, latency, and tertiary. Primary syphilis is characterized by a chancre (painless ulcer) at the site of bacterial entry that will disappear within 1 to 6 weeks without intervention (Fig. 5.6). Motile spirochetes are present on darkfield examination of ulcer exudate. In addition, painless bilateral adenopathy is present during this highly infectious period. If left untreated, the infection progresses to the secondary stage. Secondary syphilis appears 2 to 6 months after the initial exposure and is manifested by flu-like symptoms and a maculopapular rash of the trunk, palms, and soles. Alopecia and adenopathy are both common during this stage. In addition to rashes, secondary syphilis may present with symptoms of fever, pharyngitis, weight loss, and fatigue (Waugh, 2007). The secondary stage of syphilis lasts about 2 years. Once the secondary stage subsides, the latency period begins. This stage is characterized by the absence of any clinical manifestations of disease, although the serology is positive. This stage can last as long as 20 years. If not treated, tertiary or late syphilis occurs, with life-threatening heart disease and neurologic disease that slowly destroys the heart, eyes, brain, central nervous system, and skin.

Clients with a diagnosis of HIV or another STI should be screened for syphilis, and all pregnant women should be screened at their first prenatal visit. Darkfield microscopic examinations and direct fluorescent antibody tests of lesion exudate or tissue are the definitive methods for diagnosing early syphilis. A presumptive diagnosis can be made by using two serologic tests:

- Nontreponemal tests (Venereal Disease Research Laboratory [VDRL] and rapid plasma reagin [RPR])
- Treponemal tests (fluorescent treponemal antibody absorbed [FTA-ABS] and *T. pallidum* particle agglutination [TP-PA]) (CDC, 2006)

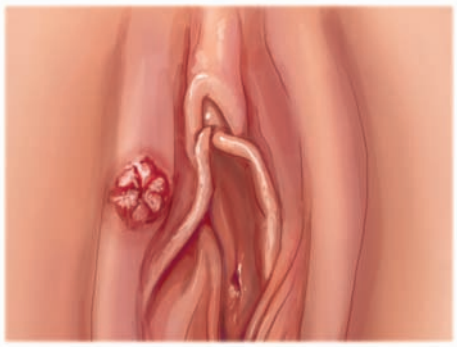

FIGURE 5.6 Chancre of primary syphilis.

Nursing Management of Herpes and Syphilis

Genital ulcers from either herpes or syphilis can be devastating to women, and the nurse can be instrumental in helping her through this difficult time. Referral to a support group may be helpful. Address the psychosocial aspects of these STIs with women by discussing appropriate coping skills, acceptance of the lifelong nature of the condition (herpes), and options for treatment and rehabilitation. Teaching Guidelines 5.3 highlights appropriate teaching points for the patient with genital ulcers.

Pelvic Inflammatory Disease

Pelvic inflammatory disease refers to an inflammatory state of the upper female genital tract and nearby structures. The fallopian tubes, ovaries, or peritoneum may be involved and endometriosis may also be present. PID results from an ascending polymicrobial infection of the upper female reproductive tract, frequently caused by untreated chlamydia or gonorrhea (Fig. 5.7). An estimated 1.5 million cases are diagnosed annually, resulting in over 250,000 hospitalizations (CDC, 2006). It is a serious health problem in the United States, costing an estimated $10 billion annually in terms of hospitalizations and surgical procedures (Crossman, 2006). Complications include ectopic pregnancy, pelvic abscess, infertility, recurrent or chronic episodes of the disease, chronic abdominal pain, pelvic adhesions, and depression (Glasier et al., 2006).

TEACHING GUIDELINES 5.3

Caring for Genital Ulcers

- Abstain from intercourse during the prodromal period and when lesions are present.
- Wash hands with soap and water after touching lesions to avoid autoinoculation.
- Use comfort measures such as wearing nonconstricting clothes, wearing cotton underwear, urinating in water if urination is painful, taking lukewarm sitz baths, and air-drying lesions with a hair dryer on low heat.
- Avoid extremes of temperature such as ice packs or hot pads to the genital area as well as application of steroid creams, sprays, or gels.
- Use condoms with all new or noninfected partners.
- Inform health care professionals of your condition.

Because of the seriousness of the complications of PID, an accurate diagnosis is critical.

Therapeutic Management

Treatment of PID must include empiric, broad-spectrum antibiotic coverage of likely pathogens. The client is treated on an ambulatory basis with oral antibiotics or is hospitalized and given antibiotics intravenously. The decision to hospitalize a woman is based on clinical judgment and the severity of her symptoms (e.g., severely ill with high fever or with protracted vomiting). Frequently, oral antibiotics are initiated, and if no improvement is seen within 72 hours, the woman is admitted to the hospital. Treatment then includes intravenous antibiotics, increased oral fluids to improve hydration, bed rest, and pain management. Follow-up is needed to validate that the infectious process is gone to prevent the development of chronic pelvic pain.

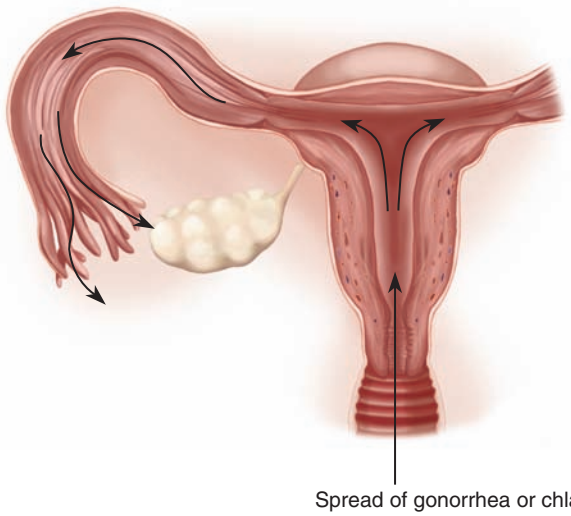

FIGURE 5.7 Pelvic inflammatory disease. Chlamydia or gonorrhea spreads up the vagina into the uterus and then to the fallopian tubes and ovaries.

Nursing Assessment

Nursing assessment of the woman with PID involves a complete health history and assessment of clinical manifestations, physical examination, and laboratory and diagnostic testing.

Health History and Clinical Manifestations

Explore the client's current and past medical health history for risk factors for PID, which may include:

- Adolescence or young adulthood
- Nonwhite female
- Having multiple sex partners
- Early onset of sexual activity
- History of PID or STI
- Sexual intercourse at an early age
- Alcohol or drug use
- Having intercourse with a partner who has untreated urethritis
- Recent insertion of an intrauterine device (IUD)
- Nulliparity
- Cigarette smoking
- Engaging in sex during menses (Reyes & Abbuhl, 2007)
- Lack of consistent condom use
- Lack of contraceptive use
- Douching
- Prostitution

Assess the client for clinical manifestations of PID, keeping in mind that, because of the wide variety of clinical manifestations of PID, clinical diagnosis can be challenging. To reduce the risk of missed diagnosis, the CDC has established criteria to establish the diagnosis of PID. Minimal criteria (all must be present) are lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness. Additional supportive criteria that support a diagnosis of PID are:

- Abnormal cervical or vaginal mucopurulent discharge
- Oral temperature above 101°F
- Elevated erythrocyte sedimentation rate (inflammatory process)
- Elevated C-reactive protein level (inflammatory process)
- *N. gonorrhoeae* or *C. trachomatis* infection documented (causative bacterial organism)
- White blood cells on saline vaginal smear (CDC, 2006)
- Prolonged or increased menstrual bleeding
- Dysmenorrhea
- Dysuria
- Painful sexual intercourse
- Nausea
- Vomiting

Physical Examination and Laboratory and Diagnostic Tests

Inspect the client for presence of fever (usually over 101°F) or vaginal discharge. Palpate the abdomen, noting tenderness over the uterus or ovaries. However, the only way to diagnose PID definitively is through an endometrial biopsy, transvaginal ultrasound, or laparoscopic examination.

Nursing Management

If the woman with PID is hospitalized, maintain hydration via intravenous fluids if necessary and administer analgesics as needed for pain. Semi-Fowler's positioning facilitates pelvic drainage. A key element to treatment of PID is education to prevent recurrence. Depending on the clinical setting (hospital or community clinic) where the nurse encounters the woman diagnosed with PID, a risk assessment should be done to ascertain what interventions are appropriate to prevent a recurrence. To gain the woman's cooperation, explain the various diagnostic tests needed. Discuss the implications of PID and the risk factors for the infection; her sexual partner should be included if possible. Sexual counseling should include practicing safer sex, limiting the number of sexual partners, using barrier contraceptives consistently, avoiding vaginal douching, considering another contraceptive method if she has an IUD and has multiple sexual partners, and completing the course of antibiotics prescribed (Reyes & Abbuhl, 2007). Review the serious sequelae that may occur if the condition is not treated or if the woman does not comply with the treatment plan. Ask the woman to have her partner go for evaluation and treatment to prevent a repeat infection. Provide nonjudgmental support while stressing the importance of barrier contraceptive methods and follow-up care. Teaching Guidelines 5.4 gives further information related to PID prevention.

Human Papillomavirus

Human papillomavirus (HPV) is the most common viral infection in the United States (CDC, 2007c). Genital warts or condylomata (Greek for warts) are caused by HPV. Conservative estimates suggest that in the United States, approximately 20 million people have productive HPV infection, and 5.5 million Americans acquire it annually (CDC, 2007c). Clinical studies have confirmed that HPV is the cause of essentially all cases of cervical cancer, which is the fourth most common cancer in women in the United States, following lung, breast, and colorectal cancer (ACS, 2007). HPV-mediated oncogenesis is responsible for up to 95% of cervical squamous cell carcinomas and nearly all preinvasive cervical neoplasms (Gearhart & Randall, 2007). More than 30 types of HPV can infect the genital tract. HPV is most prevalent in young women between the ages of 20 and 24 years old, followed closely by the 15-to-19-year-old age group (Hackley et al., 2007).

HEALTHY PEOPLE 2010

Healthy People 2010 Objectives 25-6,7	Significance
Reduce the proportion of females who have ever required treatment for pelvic inflammatory disease (PID).	Educate women that abstinence is the only way to completely avoid contracting sexually transmitted infections.
Reduce the proportion of childless females with fertility problems who have had a sexually transmitted disease or who have ever required treatment for pelvic inflammatory disease (PID).	Encourage women always to use condoms if participating in any sexual act.
	Provide an open and confidential environment so women will report symptoms and seek treatment earlier.

TEACHING GUIDELINES 5.4

Preventing Pelvic Inflammatory Disease

- Advise sexually active girls and women to insist their partners use condoms.
- Discourage routine vaginal douching, as this may lead to bacterial overgrowth.
- Encourage regular sexually transmitted infection screening.
- Emphasize the importance of having each sexual partner receive antibiotic treatment.

▶ *Take* NOTE!

The lifetime risk of HPV infection is estimated to be as high as 80% in sexually active individuals.

Nursing Assessment

Nursing assessment of the woman with HPV involves a complete health history and assessment of clinical manifestations, physical examination, and laboratory and diagnostic testing.

Health History and Clinical Manifestations

Assess the client's health history for risk factors for HPV, which include having multiple sex partners, age (15 to 25), sex with a male who has had multiple sexual partners, and first intercourse at 16 or younger (Moore & Seybold, 2007). Risk factors contributing to the development of cervical cancer include smoking, few or no screenings for cervical cancer, multiple sex partners, immunosuppressed

state, long-term contraceptive use (more than 2 years), co-infection with another STI, pregnancy, nutritional deficiencies, and early onset of sexual activity (Dunne et al., 2007).

Assess the client for clinical manifestations of HPV. Most HPV infections are asymptomatic, unrecognized, or subclinical. Visible genital warts usually are caused by HPV types 6 or 11. In addition to the external genitalia, genital warts can occur on the cervix and in the vagina, urethra, anus, and mouth. Depending on the size and location, genital warts can be painful, friable, and pruritic, although most are typically asymptomatic (Fig. 5.8). The strains of HPV associated with genital warts are considered low risk for development of cervical cancer, but other HPV types (16, 18, 31, 33, and 35) have been strongly associated with cervical cancer (CDC, 2006).

Physical Examination and Laboratory and Diagnostic Tests

Clinically, visible warts are diagnosed by inspection. The warts are fleshy papules with a warty, granular surface. Lesions can grow very large during pregnancy, affecting urination, defecation, mobility, and descent of the fetus (CDC, 2006). Large lesions, which may resemble cauliflowers, exist in coalesced clusters and bleed easily.

Serial Pap smears are performed for low-risk women. These regular Pap smears will detect the cellular changes associated with HPV. The FDA has recently approved an HPV test as a follow-up for women who have an ambiguous Pap test. In addition, this HPV test may be a helpful addition to the Pap test for general screening of women age 30 and over. The HPV test is a diagnostic test that can determine the specific HPV strain, which is useful in discriminating between low-risk and high-risk HPV types. A specimen for testing can be obtained with a fluid-phase collection system such as Thin Prep. The HPV test can identify 13 of the high-risk types of HPV associated with the development of cervical cancer and can detect high-risk types of HPV even before there are any conclusive visible changes to the cervical cells. If the test is positive for the high-risk types of HPV, the woman should be referred for colposcopy.

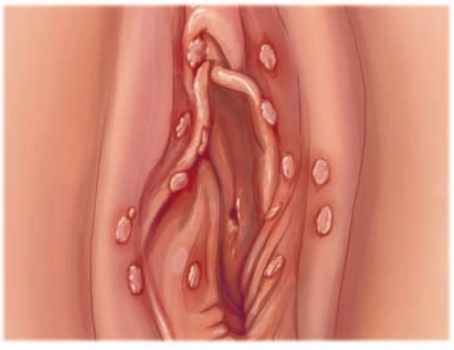

FIGURE 5.8 Genital warts.

Upon physical examination, it is determined that Sandy has genital warts. The nurse finds out that Sandy engaged in high-risk behavior with a stranger she "hooked up" with recently at college. She couldn't imagine that he would give her a STI because "he looked so clean-cut." She wonders how she could possibly have genital warts. What information should be given to Sandy about STIs in general? What specific information about HPV should be stressed?

Therapeutic Management

There is currently no medical treatment or cure for HPV. Instead, therapeutic management focuses heavily on prevention through the use of the HPV vaccine and education and on the treatment of lesions and warts caused by HPV. In summer 2006, the FDA approved the HPV vaccine (Gardasil) to prevent cervical cancer. The CDC's Advisory Committee on Immunization Practices (ACIP) has recommended the vaccine for routine administration to 11- and 12-year-old girls. The ACIP also endorsed the use of Gardasil for girls as young as 9 and recommended that women between the ages of 13 and 26 receive the vaccination series, which consists of three injections over 6 months. The vaccine has been found 100% effective in preventing precancerous lesions of the cervix and genital warts (Wald, 2007). The duration of protection afforded by this vaccine, as well as its impact on long-term outcomes, is not yet known (Kennedy, 2007).

The vaccine is administered intramuscularly in three separate 0.5-mL doses. The first dose may be given to any individual 9 to 26 years old prior to infection with HPV. The second dose is administered 2 months after the first, and the third dose is given 6 months after the initial dose. The deltoid region of the upper arm or anterolateral area of the thigh may be used (Leggatt & Frazer, 2007).

If the woman doesn't receive primary prevention with the vaccine, then secondary prevention would focus on education about the importance of receiving regular Pap smears and, for women over 30, including an HPV test to determine whether the woman has a latent high-risk virus that could lead to precancerous cervical changes. Finally, treatment options for precancerous cervical lesions or genital warts caused by HPV are numerous and may include:

- Topical trichloroacetic acid (TCA) 80% to 90%
- Liquid nitrogen cryotherapy
- Topical imiquimod 5% cream (Aldara)
- Topical podophyllin 10% to 25%
- Laser carbon dioxide vaporization
- Client-applied Podofilox 0.5% solution or gel
- Simple surgical excision
- Loop electrosurgical excisional procedure (LEEP)

- Intralesional interferon therapy (National Institute of Allergy and Infectious Diseases, 2007b)

The goal of treating genital warts is to remove the warts and induce wart-free periods for the client. Treatment of genital warts should be guided by the preference of the client and available resources. No single treatment has been found to be ideal for all clients, and most treatment modalities appear to have comparable efficacy. Because genital warts can proliferate and become friable during pregnancy, they should be removed using a local agent. A cesarean birth is not indicated solely to prevent transmission of HPV infection to the newborn, unless the pelvic outlet is obstructed by warts (Gearhart & Randall, 2007).

Nursing Management

An HPV infection has many implications for the woman's health, but most women are unaware of HPV and its role in cervical cancer. The average age of sexual debut is in early adolescence; therefore, it is important to target this population for use of the HPV/cervical cancer vaccine.

Key nursing roles are teaching about prevention of HPV infection and patient education and promotion of vaccines and screening tests in order to reduce the morbidity and mortality associated with cervical cancer caused by HPV infection. Teach all women that the only way to prevent HPV is to refrain from any genital contact with another individual. Although the effect of condoms in preventing HPV infection is unknown, latex condom use has been associated with a lower rate of cervical cancer. Teach women about the link between HPV and cervical cancer. Explain that, in most cases, there are no signs or symptoms of infection with HPV. Strongly encourage all young women between 9 and 26 to consider getting Gardasil, the vaccine against HPV. For all women, promote the importance of obtaining regular Pap smears and, for women over 30, suggest an HPV test to rule out the presence of a latent high-risk strain of HPV.

Education and counseling are important aspects of managing women with genital warts. Teach the woman that:

- Even after genital warts are removed, HPV still remains and viral shedding will continue.
- The likelihood of transmission to future partners and the duration of infectivity after treatment for genital warts are unknown.
- The recurrence of genital warts within the first few months after treatment is common and usually indicates recurrence rather than reinfection (CDC, 2006).

Sandy is being treated for HPV and is anxious for her "things" to disappear and never return. What education is needed to prevent further transmission from Sandy to any future sexual partners?

Vaccine-Preventable STIs: Hepatitis A and B

Hepatitis is an acute, systemic, viral infection that can be transmitted sexually. The viruses associated with hepatitis or inflammation of the liver are hepatitis A, B, C, D, E, and G. Hepatitis A (HAV) is spread via the gastrointestinal tract. It can be acquired by drinking polluted water, by eating uncooked shellfish from sewage-contaminated waters or food handled by a hepatitis carrier with poor hygiene, and from oral/anal sexual contact. Approximately 33% of the U.S. population has serologic evidence of prior hepatitis A infection; the rate increases directly with age (Wasley et al., 2007). A person with hepatitis A can easily pass the disease to others within the same household.

Hepatitis B (HBV) is transmitted through saliva, blood serum, semen, menstrual blood, and vaginal secretions (Assan & Kraszewski, 2006). In the early 2000s, transmission among heterosexual partners accounted for 40% of infections, and transmission among men who have sex with men accounted for 20% of infections. The World Health Organization (WHO) estimates the prevalence of hepatitis B worldwide is 350 million chronically infected people. Worldwide, hepatitis B has the highest death rate of any STI except HIV (WHO, 2007a). Risk factors for infection include having multiple sex partners, engaging in unprotected receptive anal intercourse, and having a history of other STIs (CDC, 2006). The most effective means to prevent the transmission of hepatitis A or B is pre-exposure immunization. Vaccines are available for the prevention of HAV and HBV, both of which can be transmitted sexually. Every person seeking treatment for an STI should be considered a candidate for hepatitis B vaccination, and some individuals (e.g., men who have sex with men, and injection-drug users) should be considered for hepatitis A vaccination (CDC, 2006).

Therapeutic Management

Unlike other STIs, HBV and HAV are preventable through immunization. HAV is usually self-limiting and does not result in chronic infection. HBV can result in serious, permanent liver damage. Treatment is generally supportive. No specific treatment for acute HBV infection exists.

Nursing Assessment

Assess the client for clinical manifestations of hepatitis A and B. Hepatitis A produces flu-like symptoms with malaise, fatigue, anorexia, nausea, pruritus, fever, and upper right quadrant pain. Symptoms of hepatitis B are similar to those of hepatitis A, but with less fever and skin involvement. The diagnosis of hepatitis A cannot be made based on clinical manifestations alone and requires serologic testing. The presence of IgM antibody to HAV

is diagnostic of acute HAV infection. Hepatitis B is detected by a blood test that looks for antibodies and proteins produced by the virus and is positively diagnosed by the presence of hepatitis B surface antibody (HBsAg) (Pyrsopoulos & Reddy, 2007).

Nursing Management

Nurses should encourage all women to be screened for hepatitis when they have their annual Pap smear, or sooner if high-risk behavior is identified. Nurses should also encourage women to undergo HBV screening at their first prenatal visit and repeat screening in the last trimester for women with high-risk behaviors (Assan & Kraszewski, 2006). Nurses can also explain that hepatitis B vaccine is given to all infants after birth in most hospitals. The vaccination consists of a series of three injections given within 6 months. The vaccine has been shown to be safe and well tolerated by most recipients (CDC, 2006). Hepatitis A vaccine is strongly encouraged for children between 12 and 23 months; persons 1 year of age and older traveling to countries with a high prevalence of hepatitis A, such as Central or South America, Mexico, Asia, Africa, and eastern Europe; men who have sex with men; persons who use street drugs; and persons with chronic liver disease (CDC, 2007c). For others, hepatitis A vaccine series (two doses 6 months apart) may be started whenever a person is at risk of infection.

Ectoparasitic Infections

Ectoparasites are a common cause of skin rash and pruritus throughout the world, affecting persons of all ages, races, and socioeconomic groups. Overcrowding, delayed diagnosis and treatment, and poor public education contribute to the prevalence of ectoparasites in both industrial and nonindustrial nations. Approximately 300 million cases of ectoparasitic cases are reported worldwide each year (CDC, 2006). These infections include infestations of scabies and pubic lice. Since these parasites are easily passed from one person to another during sexual intimacy, clients should be assessed for them when receiving care for other STIs. Scabies is an intensely pruritic dermatitis caused by a mite. The female mite burrows under the skin and deposits eggs, which hatch. The lesions start as a small papule that reddens, erodes, and sometimes crusts. Diagnosis is based on history and appearance of burrows in the webs of the fingers and the genitalia (Cordoro & Wilson, 2007). Aggressive infestation can occur in immunodeficient, debilitated, or malnourished people, but healthy people do not usually suffer sequelae.

Clients with pediculosis pubis (pubic lice) usually seek treatment because of the pruritus, because of a rash brought on by skin irritation from scratching, or because they notice lice or nits in their pubic hair, axillary hair, abdominal and thigh hair, and sometimes in the eyebrows, eyelashes, and beards. Infestation is usually asymptomatic until after a week or so, when bites cause pruritus and secondary infections from scratching (Fig. 5.9). Diagnosis is based on history and the presence of nits (small, shiny, yellow, oval, dewdrop-like eggs) affixed to hair shafts or lice (a yellowish, oval, wingless insect) (Wolfram, 2007).

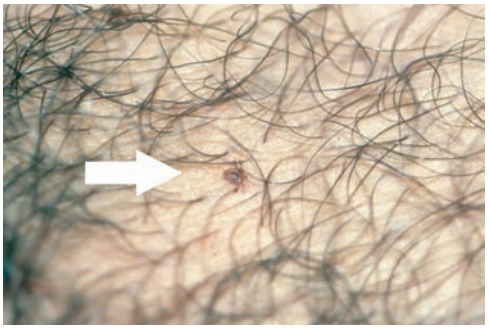

FIGURE 5.9 Pubic lice. A small brown living crab louse is seen at the base of hairs (*arrow*). (Source: Goodheart, H. [2003]. *Goodheart's photoguide of common skin disorders.* Philadelphia: Lippincott Williams & Wilkins.)

Treatment is directed at the infested area, using permethrin cream or lindane shampoo (CDC, 2006). Bedding and clothing should be washed in hot water to decontaminate it. Sexual partners should be treated also, as well as family members who live in close contact with the infected person.

Nursing care of a woman infested with lice or scabies involves a three-tiered approach: eradicating the infestation with medication, removing nits, and preventing spread or recurrence by managing the environment. Over-the-counter products containing pyrethrins (RID, Triple X, Pronto, and Kwell) are safe for use and kill the active lice or mites. Nurses should provide education about these products (Teaching Guidelines 5.5). The nurse can follow these same guidelines to prevent the health care facility from becoming infested.

TEACHING GUIDELINES 5.5

Treating and Minimizing the Spread of Scabies and Pubic Lice

- Use the medication according to the manufacturer's instructions.
- Remove nits with a fine-toothed nit comb.
- Do not share any personal items with others or accept items from others.
- Treat objects, clothing, and bedding and wash them in hot water.
- Meticulously vacuum carpets to prevent a recurrence of infestation.

Human Immunodeficiency Virus (HIV)

An estimated 1 million people currently live with HIV and an estimated 50,000 new HIV infections have occurred annually in the United States (CDC, 2007b). In terms of epidemiology, fatality rate, and its social, legal, ethical, and political aspects, HIV/AIDS has become a public health crisis and has generated more concern than any other infectious disease in modern medical history (Mullan, 2007). To date, there is no cure for this fatal viral infection.

The HIV virus is transmitted by intimate sexual contact, by sharing needles for intravenous drug use, from mother to fetus during pregnancy, or by transfusion of blood or blood products. Men who have sex with men represent the largest proportion of new infections, followed by men and women infected through heterosexual sex (CDC, 2007b).

The number of women with HIV infection and AIDS has been increasing steadily worldwide. WHO estimates that over 25 million women are living with HIV/AIDS worldwide, accounting for approximately 50% of the 40 million adults living with HIV/AIDS (National Institute of Allergy and Infectious Diseases, 2007a). HIV disproportionately affects African-American and Hispanic women: together they represent less than 25% of all U.S. women, yet they account for more than 82% of AIDS cases in women (CDC, 2007b). Worldwide, more than 90% of all HIV infections have resulted from heterosexual intercourse. Women are particularly vulnerable to heterosexual transmission of HIV due to substantial mucosal exposure to seminal fluids. This biological fact amplifies the risk of HIV transmission when coupled with the high prevalence of nonconsensual sex, sex without condoms, and the unknown and/or high-risk behaviors of their partners (National Institute of Allergy and Infectious Diseases, 2007a). Therefore, the face of HIV/AIDS is becoming the face of young women. That shift will ultimately exacerbate the incidence of HIV because women spread it not only through sex, but also through nursing and childbirth.

AIDS is a breakdown in the immune function caused by HIV, a retrovirus. The infected person develops opportunistic infections or malignancies that become fatal. Progression from HIV infection to AIDS occurs a median of 11 years after infection (Mullan, 2007).

Twenty years have passed since HIV/AIDS began to affect our society. Since then, 50 million people have been infected by the virus, with AIDS being the fourth leading cause of death globally (CDC, 2007b). The morbidity and mortality of HIV continue to hold the attention of the medical community. While there has been a dramatic improvement in both morbidity and mortality with the use of highly active antiretroviral therapy (HAART), the incidence of HIV infection continues to rise.

▶ *Take* NOTE!

More than 90% of individuals infected with HIV worldwide do not know they are infected (Dubin, 2007).

The fetal and neonatal effects of acquiring HIV through perinatal transmission are devastating and eventually fatal. An infected mother can transmit HIV infection to her newborn before or during birth and through breastfeeding. Most cases of mother-to-child HIV transmission, the cause of more than 90% of pediatric-acquired infections worldwide, occur late in pregnancy or during delivery. Transmission rates vary from 25% in untreated nonbreastfeeding populations in industrialized countries to about 40% among untreated breastfeeding populations in developing countries (National Institute of Allergy and Infectious Diseases, 2007a). Despite the dramatic reduction in perinatal transmission, hundreds of infants will be born infected with HIV.

HIV and Adolescents

The effects of HIV and AIDS on adolescents and young adults is of increasing concern, but it is difficult to get accurate data due to varying ways this population seeks health care services. Some adolescents continue to receive care through pediatricians and adult services, but many do not have access to health care. HIV infections are increasing in adolescents and young adults (13 to 24 years). Also, the proportion of adolescents diagnosed with AIDS has increased from 4% in 1999 to 6% in 2006 (NIH, 2008). At least one adolescent in the United States is infected with HIV each hour. Since it takes an average of 10 years for AIDS symptoms to appear when HIV is left untreated, it is obvious that many adults with AIDS were infected as adolescents.

Most HIV-infected adolescents are exposed to the virus though sexual intercourse. Recent data suggest that the majority of HIV-infected adolescent males are infected through sex with men. A small number of adolescent males appear to be exposed through injection of drugs or heterosexual contact. Adolescent females are mostly exposed through heterosexual contact, with a small percentage becoming infected through injected drug use (www.niaid.hih.gov/factsheets/hivadolescent.htm). African-American and Hispanic adolescents between the ages of 13 and 19 account for 66% and 21%, respectively, of reported AIDS cases in 2003. Because adolescents think they are invincible, they may delay testing, and if they test positive, they may delay treatment or refuse treatment. The inability to trace this population for medical care can lead to increased transmission of HIV.

▶ *Consider THIS!*

I was thinking of my carefree college days, when the most important thing was having an active sorority life and meeting guys. I had been raised by very strict parents and was never allowed to date under their watch. Since I attended an out-of-state college, I figured that my parents' outdated advice and rules no longer applied. Abruptly, my thoughts of the past were interrupted by the HIV counselor asking about my feelings concerning my positive diagnosis. What was there to say at this point? I had a lot of fun but never dreamed it would haunt me for the rest of my life, which was going to be shortened considerably now. I only wish I could turn back the hands of time and listen to my parents' advice, which somehow doesn't seem so outdated now.

Thoughts: All of us have thought back on our lives to better times and wondered how our lives would have changed if we had made better choices or gone down another path. It is a pity that we have only one chance to make good, sound decisions at times. What would you have changed in your life if given a second chance? Can you still make a change for the better now?

Clinical Manifestations

When a person is initially infected with HIV, he or she goes through an acute primary infection period for about 3 weeks. The HIV viral load drops rapidly because the host's immune system works well to fight this initial infection. The onset of the acute primary infection occurs 2 to 6 weeks after exposure. Symptoms include fever, pharyngitis, rash, and myalgia. Most people do not associate this flu-like condition with HIV infection. After initial exposure, there is a period of 3 to 12 months before seroconversion. The person is considered infectious during this time.

After the acute phase, the infected person becomes asymptomatic, but the HIV virus begins to replicate. Even though there are no symptoms, the immune system runs down. A normal person has a CD4 T-cell count of 450 to 1,200 cells per microliter. When the CD4 T-cell count reaches 200 or less, the person has reached the stage of AIDS. The immune system begins a constant battle to fight this viral invasion, but over time it falls behind. A viral reservoir occurs in T cells that can store various stages of the virus. The onset and severity of the disease correlate directly with the viral load: the more HIV virus that is present, the worse the person will feel.

As profound immunosuppression begins to occur, an opportunistic infection will occur, qualifying the person for the diagnosis of AIDS. The diagnosis is finally confirmed when the CD4 count is below 200. As of now, AIDS will eventually develop in everyone who is HIV-positive.

Because HIV over time depletes the CD4 cell population, infected people become more susceptible to opportunistic infections. Currently, the AIDS virus and response to treatment are tracked based on CD4 count rather than viral load. Untreated HIV will progress to AIDS in about 11 years, but this progression can be delayed by antiretroviral therapy (Dubin, 2007).

Diagnosis

Newly approved quick tests for HIV produce results in 20 minutes and also lower the health care worker's risk of occupational exposure by eliminating the need to draw blood. The CDC's Advancing HIV Prevention initiative, launched in 2003, has made increased testing a national priority. The initiative calls for testing to be incorporated into routine medical care and to be delivered in more nontraditional settings.

Fewer than half of adults between the ages of 18 and 64 have ever had an HIV test, according to the CDC. The agency estimates that one fourth of the million HIV-infected people in the United States do not know they are infected. This means they are not receiving treatment that can prolong their lives, and they may be unknowingly infecting others. In addition, even when people do get tested, one in three failed to return to the testing site to learn their results when there was a 2-week wait. The CDC hopes that the new "one-stop" approach to HIV testing changes that pattern. About 50,000 new HIV cases are reported each year in the United States, and that number has held steady for the past few years despite massive efforts in prevention education (CDC, 2007b).

The OraQuick Rapid HIV-1 Antibody Test detects the HIV antibody in a blood sample taken with a fingerstick or from an oral fluid sample. Both can produce results in as little as 20 minutes with more than 99% accuracy (Aaron et al., 2006). The FDA has approved two other rapid blood tests: the Reveal Rapid HIV-1 Antibody Test and the Uni-Gold Recombigen HIV Test.

Testing for HIV should be offered to anyone seeking evaluation and treatment for STIs. Counseling before and after testing is an integral part of the testing procedure. Informed consent must be obtained before an HIV test is performed. HIV infection is diagnosed by tests for antibodies against HIV-1 and HIV-2 (HIV-1/2). Antibody testing begins with a sensitive screening test (e.g., the enzyme immunoassay [ELISA]). This is a specific test for antibodies to HIV that is used to determine whether the person has been exposed to the HIV retrovirus. Reactive screening tests must be confirmed by a more specific test (e.g., the Western blot [WB]) or an immunofluorescence assay (IFA). This is a highly specific test that is used to validate a positive ELISA test finding. If the supplemental test (WB or IFA) is positive, it confirms that the person is infected with HIV and is capable of transmitting the

virus to others. HIV antibody is detectable in at least 95% of people within 3 months after infection (CDC, 2006).

Therapeutic Management

The goals of HIV drug therapy are to:

- Decrease the HIV viral load below the level of detection
- Restore the body's ability to fight off pathogens
- Improve the client's quality of life
- Reduce HIV morbidity and mortality (Cressey & Lallemant, 2007)

Highly active antiretroviral therapy (HAART), which combines at least three antiretroviral drugs, has dramatically improved the prognosis of HIV/AIDS. Often treatment begins with combination HAART therapy at the time of the first infection, when the person's immune system is still intact. The current HAART therapy standard is a triple combination therapy, but some clients may be given a fourth or fifth agent.

There are obvious challenges involved in meeting these goals. The viral load can be reduced much more quickly than the T-cell count can be increased, and this disparity leaves the woman vulnerable to opportunistic infections.

Current therapy to prevent the transmission of HIV to the newborn includes a three-part regimen of having the mother take an oral antiretroviral agent at 14 to 34 weeks of gestation; it is continued throughout pregnancy. During labor, an antiretroviral agent is administered intravenously until delivery. An antiretroviral syrup is administered to the infant within 12 hours after birth.

Dramatic new treatment advances with antiretroviral medications have turned a disease that used to be a death sentence into a chronic, manageable one for individuals who live in countries where antiretroviral therapy is available. Despite these advances in treatment, however, only a minority of HIV-positive Americans who take antiretroviral medications are receiving the full benefits because they are not adhering to the prescribed regimen. Successful antiretroviral therapy requires nearly perfect adherence to a complex medication regimen; less-than-perfect adherence leads to drug resistance (Battaglioli-Denero, 2007).

Adherence is difficult because of the complexity of the regimen and the lifelong duration of treatment. A typical antiretroviral regimen may consist of three or more medications taken twice daily. Adherence is made even more difficult because of the unpleasant side effects, such as nausea and diarrhea. Women in early pregnancy already experience these, and the antiretroviral medication only exacerbates them.

Nursing Management

Nurses can play a major role in caring for the HIV-positive woman by helping her accept the possibility of a shortened life span, cope with others' reactions to a stigmatizing illness, and develop strategies to maintain her physical and emotional health. Educate the woman about changes she can make in her behavior to prevent spreading HIV to others, and refer her to appropriate community resources such as HIV medical care services, substance abuse, mental health services, and social services. See Nursing Care Plan 5.1: Overview for the Woman With HIV.

Providing Education About Drug Therapy

The goal of antiretroviral therapy is to suppress viral replication so that the viral load becomes undetectable (below 400). This is done to preserve immune function and delay disease progression but is a challenge because of the side effects of nausea and vomiting, diarrhea, altered taste, anorexia, flatulence, constipation, headaches, anemia, and fatigue. Although not everyone experiences all of the side effects, the majority do have some of them. Current research hasn't documented the long-term safety of exposure of the fetus to antiretroviral agents during pregnancy, but collection of data is ongoing.

Help to reduce the development of drug resistance and thus treatment failure by identifying the barriers to adherence; identifying these barriers can help the woman to overcome them. Some of the common barriers exist because the woman:

- Does not understand the link between drug resistance and nonadherence
- Fears revealing her HIV status by being seen taking medication
- Hasn't adjusted emotionally to the HIV diagnosis
- Doesn't understand the dosing regimen or schedule
- Experiences unpleasant side effects frequently
- Feels anxious or depressed (Dubin, 2007)

Depending on which barriers are causing nonadherence, work with the woman by educating her about the dosing regimen, helping her find ways to integrate the prescribed regimen into her lifestyle, and making referrals to social service agencies as appropriate. By addressing barriers on an individual level, the nurse can help the woman to overcome them.

Educate the woman about the prescribed drug therapy and stress that it is very important to take the regimen as prescribed. Offer suggestions about how to cope with anorexia, nausea, and vomiting by:

- Separating the intake of food and fluids
- Eating dry crackers upon arising
- Eating six small meals daily
- Using high-protein supplements (Boost, Ensure) to provide quick and easy protein and calories
- Eating "comfort foods," which may appeal when other foods don't

Promoting Compliance

Remaining compliant with drug therapy is a huge challenge for many HIV-infected people. Compliance becomes diffi-

Nursing Care Plan 5.1

OVERVIEW OF THE WOMAN WHO IS HIV-POSITIVE

Annie, a 28-year-old African-American woman, is HIV-positive. She acquired HIV through unprotected sexual contact. She has been inconsistent in taking her antiretroviral medications and presents today stating she is tired and doesn't feel well.

NURSING DIAGNOSIS: Risk for infection related to positive HIV status and inconsistent compliance with antiretroviral therapy

Outcome Identification and Evaluation

Client will remain free of opportunistic infections as evidenced by temperature within acceptable parameters and absence of signs and symptoms of opportunistic infections.

Interventions: Minimizing the Risk of Opportunistic Infections

- Assess CD4 count and viral loads *to determine disease progression* (CD4 counts <500/L and viral loads >10,000 copies/L = increased risk for opportunistic infections).
- Assess complete blood count *to identify presence of infection* (>10,000 cells/mm^3 may indicate infection).
- Assess oral cavity and mucous membranes for painful white patches in mouth *to evaluate for possible fungal infection.*
- Teach client to monitor for general signs and symptoms of infections, such as fever, weakness, and fatigue, *to ensure early identification.*
- Provide information explaining the importance of avoiding people with infections when possible *to minimize risk of exposure to infections.*
- Teach importance of keeping appointments so her CD4 count and viral load can be monitored *to alert the health care provider about her immune system status.*
- Instruct her to reduce her exposure to infections via:
  - Meticulous handwashing
  - Thorough cooking of meats, eggs, and vegetables
  - Wearing shoes at all times, especially when outdoors
- Encourage a balance of rest with activity throughout the day *to prevent overexertion.*
- Stress importance of maintaining prescribed antiretroviral drug therapies *to prevent disease progression and resistance.*
- If necessary, refer Annie to a nutritionist to help her understand what constitutes a well-balanced diet with supplements *to promote health and ward off infection.*

NURSING DIAGNOSIS: Knowledge deficit related to HIV infection and possible complications

Outcome Identification and Evaluation

Client will demonstrate increased understanding of HIV infection as evidenced by verbalizing appropriate health care practices and adhering to measures to comply with therapy and reduce her risk of further exposure and reduce risk of disease progression.

Interventions: Providing Patient Education

- Assess her understanding of HIV and its treatment *to provide a baseline for teaching.*
- Establish trust and be honest with Annie; encourage her to talk about her fears and the impact of the disease *to provide an outlet for her concerns.* Encourage her to discuss reasons for her noncompliance.
- Provide a nonjudgmental, accessible, confidential, and culturally sensitive approach *to promote Annie's self-esteem and allow her to feel that she is a priority.*
- Explain measures, including safer sex practices and birth control options, to prevent disease transmission; determine her willingness to practice safer sex to protect others *to determine further teaching needs.*
- Discuss the signs and symptoms of disease progression and potential opportunistic infections *to promote early detection for prompt intervention.*
- Outline with the client the availability of community resources and make appropriate referrals as needed *to provide additional education and support.*
- Encourage Annie to keep scheduled appointments *to ensure follow-up and allow early detection of potential problems.*

cult when the same pills that are supposed to thwart the disease are making the person sick. Nausea and diarrhea are just two of the possible side effects. It is often difficult to increase the client's quality of life when so much oral medication is required. The combination medication therapy is challenging for many people, and staying compliant over a period of years is extremely difficult. Stress the importance of taking the prescribed antiretroviral drug therapies by explaining that they help prevent replication of the retroviruses and subsequent progression of the disease, as well as decreasing the risk of perinatal transmission of HIV. In addition, provide written materials describing diet, exercise, medications, and signs and symptoms of complications and opportunistic infections. Reinforce this information at each visit.

Preventing HIV Infection

The lack of information about HIV infection and AIDS causes great anxiety and fear of the unknown. It is vital to take a leadership role in educating the public about risky behaviors in the fight to control this disease. The core of HIV prevention is to abstain from sex until marriage, to be faithful, and to use condoms. This is all good advice for many women, but some simply do not have the economic and social power or choices or control over their lives to put that advice into practice. Recognize that fact, and address the factors that will give women more control over their lives by providing anticipatory guidance, giving ample opportunities to practice negotiation techniques and refusal skills in a safe environment, and encouraging the use of female condoms to protect against this deadly virus. Prevention is the key to reversing the current infection trends.

Providing Care During Pregnancy and Childbirth

Voluntary counseling and HIV testing should be offered to all pregnant women as early in the pregnancy as possible to identify HIV-infected women so that treatment can be initiated early. Once a pregnant woman is identified as being HIV-positive, she should be informed about the risk for perinatal infection. Current evidence indicates that in the absence of antiretroviral medications, 25% of infants born to HIV-infected mothers will become infected with HIV (CDC, 2007b). If women do receive a combination of antiretroviral therapies during pregnancy, however, the risk of HIV transmission to the newborn drops below 2% (National Institute of Allergy and Infectious Disease, 2007a). In addition, HIV can be spread to the infant through breastfeeding, and thus all HIV-infected pregnant women should be counseled to avoid breastfeeding and use formula instead. A recent maternal infection with HIV may raise the risk of transmission through breastfeeding to twice that of a woman with earlier established infection, owing probably to the high viral load associated with recent infection (WHO, 2007b).

In addition, the woman needs instructions on ways to enhance her immune system by following these guidelines during pregnancy:

- Getting adequate sleep each night (7 to 9 hours)
- Avoiding infections (e.g., staying out of crowds, handwashing)
- Decreasing stress in her life
- Consuming adequate protein and vitamins
- Increasing her fluid intake to 2 liters daily to stay hydrated
- Planning rest periods throughout the day to prevent fatigue

Despite the dramatic reduction in perinatal transmission, hundreds of infants will be born infected with HIV. The birth of each infected infant is a missed prevention opportunity. To minimize perinatal HIV transmission, identify HIV infection in women, preferably before pregnancy; provide information about disease prevention; and encourage HIV-infected women to follow the prescribed drug therapy.

Providing Appropriate Referrals

The HIV-infected woman may have difficulty coping with the normal activities of daily living because she has less energy and decreased physical endurance. She may be overwhelmed by the financial burdens of medical and drug therapies and the emotional responses to a life-threatening condition, as well as concern about her infant's future, if she is pregnant. A case management approach is needed to deal with the complexity of her needs during this time. Be an empathetic listener and make appropriate referrals for nutritional services, counseling, homemaker services, spiritual care, and local support groups. Many community-based organizations have developed programs to address the numerous issues regarding HIV/AIDS. The national AIDS hotline (1-800-342-AIDS) is a good resource.

Preventing Sexually Transmitted Infections

Education about safer sex practices—and the resulting increase in the use of condoms—can play a vital role in reducing STI rates all over the world. Clearly, knowledge and prevention are the best defenses against STIs. The prevention and control of STIs is based on the following concepts (CDC, 2006):

1. Education and counseling of persons at risk about safer sexual behavior
2. Identification of asymptomatic infected individuals and of symptomatic individuals unlikely to seek diagnosis and treatment
3. Effective diagnosis and treatment of infected individuals

4. Evaluation, treatment, and counseling of sex partners of people who are infected with an STI
5. Pre-exposure vaccination of people at risk for vaccine-preventable STIs

Nurses play an integral role in identifying and preventing STIs. They have a unique opportunity to educate the public about this serious public health issue by communicating the methods of transmission and symptoms associated with each condition, tracking the updated CDC treatment guidelines, and offering clients strategic preventive measures to reduce the spread of STIs.

It is not easy to discuss STI prevention when globally we are failing at it. Knowledge exists on how to prevent every single route of transmission, but the incidence continues to climb. Challenges to prevention of STIs include lack of resources and difficulty in changing the behaviors that contribute to their spread. Regardless of the challenging factors involved, nurses must continue to educate and to meet the needs of all women to promote their sexual health. Successful treatment and prevention of STIs is impossible without education. Successful teaching approaches include giving clear, accurate messages that are age-appropriate and culturally sensitive.

Primary prevention strategies include education of all women, especially adolescents, regarding the risk of early sexual activity, the number of sexual partners, and STIs. Sexual abstinence is ideal but often not practiced; therefore, the use of barrier contraception (condoms) should be encouraged (see Teaching Guidelines 5.1).

Secondary prevention involves the need for annual pelvic examinations with Pap smears for all sexually active women, regardless of age. Many women with STIs are asymptomatic, so regular screening examinations are paramount for early detection. Understanding the relationship between poor socioeconomic conditions and poor patterns of sexual and reproductive self-care is significant in disease-prevention and health-promotion strategies.

Every successful form of prevention requires a change in behavior. The nursing role in teaching and rendering quality health care is invaluable evidence that the key to reducing the spread of STIs is through behavioral change. Nurses working in these specialty areas have a responsibility to educate themselves, their clients, their families, and the community about STIs and to provide compassionate and supportive care to clients. Some strategies nurses can use to prevent the spread of STIs are detailed in Box 5.3.

Behavior Modification

Research validates that changing behaviors does result in a decrease in new STI infections, but it must encompass all levels—governments, community organizations, schools, churches, parents, and individuals (Peterson et al., 2007). Education must address ways to prevent becoming infected, ways to prevent transmitting infection, symptoms of STIs, and treatment. At this point in the STI epidemic, nurses do not have time to debate the relative merits of prevention versus treatment: both are underused and underfunded, and one leads to the other. But being serious about prevention and focusing on the strategies outlined above will bring about a positive change on everyone's part.

BOX 5.3 Selected Nursing Strategies to Prevent the Spread of STIs

- Provide basic information about STI transmission.
- Outline safer sexual behaviors for people at risk for STIs.
- Refer clients to appropriate community resources to reduce risk.
- Screen asymptomatic persons with STIs.
- Identify barriers to STI testing and remove them.
- Offer pre-exposure immunizations for vaccine-preventable STIs.
- Respond honestly about testing results and options available.
- Counsel and treat sexual partners of persons with STIs.
- Educate school administrators, parents, and teens about STIs.
- Support youth development activities to reduce sexual risk-taking.
- Promote the use of barrier methods (condoms, diaphragms) to prevent the spread of STIs.
- Assist clients to gain skills in negotiating safer sex.
- Discuss reducing the number of sexual partners to reduce risk

Contraception

The spread of STIs could be prevented by access to safe, efficient, appropriate, modern contraception for everyone who wants it. Nurses can play an important role in helping women to identify their risk of STIs and to adopt preventive measures through the dual protection that contraceptives offer. Traditionally, family planning and STI services have been separate entities. Family planning services have addressed a woman's need for contraception without considering her or her partner's risk of STI; meanwhile, STI services have been heavily slanted toward men, ignoring the contraceptive needs of men and their partners.

Many women are at significant risk for unintended pregnancy and STIs, yet with this separation of services, there is limited evaluation of whether they need dual protection—that is, concurrent protection from STIs and unintended pregnancy. This lack of integration of services represents a missed opportunity to identify many at-risk women and to offer them counseling on dual protection (Hogben, 2007).

Nurses can expand their scopes in either setting by discussing dual protection by use of a male or female condom alone or by use of a condom along with a nonbarrier contraceptive. Because barrier methods are not the most effective means of fertility control, they have not been typically recommended as a method alone for dual protection. Unfortunately, the most effective pregnancy prevention methods—sterilization, hormonal methods, and intrauterine devices—do not protect against STIs. Dual-method use protects against STIs and pregnancy.

Key Concepts

- Avoiding risky sexual behaviors may preserve fertility and prevent chronic conditions later in life.
- An estimated 65 million people live with an incurable STI, and another 15 million are infected each year.
- The most reliable way to avoid transmission of STIs is to abstain from sexual intercourse (i.e., oral, vaginal, or anal sex) or to be in a long-term, mutually monogamous relationship with an uninfected partner.
- Barrier methods of contraception are recommended because they increase protection from contact with urethral discharge, mucosal secretions, and lesions of the cervix or penis.
- The high rate of asymptomatic transmission of STIs calls for teaching high-risk women the nature of transmission and how to recognize infections.
- The CDC and ACOG recommend that all women be offered group B streptococcal screening by rectovaginal culture at 35 to 37 weeks of gestation, and that colonized women be treated with intravenous antibiotics at the time of labor or ruptured membranes.
- Nurses should practice good handwashing techniques and follow standard precautions to protect themselves and their patients from STIs.
- Nurses are in an important position to promote the sexual health of all women. Nurses should make their clients and the community aware of the perinatal implications and life-long sequelae of STIs.

Chapter Worksheet

Multiple Choice Questions

1. Which of the following contraceptive methods offers protection against sexually transmitted infections (STIs)?
   a. Oral contraceptives
   b. Withdrawal
   c. Latex condom
   d. Intrauterine device
2. In teaching about HIV transmission, the nurse explains that the virus cannot be transmitted by:
   a. Shaking hands
   b. Sharing drug needles
   c. Sexual intercourse
   d. Breastfeeding
3. A woman with HPV is likely to present with which nursing assessment finding?
   a. Profuse, pus-filled vaginal discharge
   b. Clusters of genital warts
   c. Single painless ulcer
   d. Multiple vesicles on genitalia
4. The nurse's discharge teaching plan for the woman with PID should reinforce which of the following potentially life-threatening complications?
   a. Involuntary infertility
   b. Chronic pelvic pain
   c. Depression
   d. Ectopic pregnancy
5. To confirm a finding of primary syphilis, the nurse would observe which of the following on the external genitalia?
   a. A highly variable skin rash
   b. A yellow-green vaginal discharge
   c. A nontender, indurated ulcer
   d. A localized gumma formation

Critical Thinking Exercise

1. Sally, age 17, comes to the teen clinic saying that she is in pain and has some "crud" between her legs. The nurse takes her into the examining room and questions her about her symptoms. Sally states she had numerous genital bumps that had been filled with fluid, then ruptured and turned into ulcers with crusts. In addition, she has pain on urination and overall body pain. Sally says she had unprotected sex with several men when she was drunk at a party a few weeks back, but she thought they were "clean."
   a. What STI would the nurse suspect?
   b. The nurse should give immediate consideration to which of Sally's complaints?
   c. What should be the goal of the nurse in teaching Sally about STIs?

Study Activities

1. Select a website at the end of the chapter to explore. Educate yourself about one specific STI thoroughly and share your expertise with your clinical group.
2. Contact your local health department and request current statistics regarding three STIs. Ask them to compare the current number of cases reported to last year's. Are they less or more? What may be some of the reasons for the change in the number of cases reported?
3. Request permission to attend a local STI clinic to shadow a nurse for a few hours. Describe the nurse's counseling role with patients and what specific information is emphasized to patients.
4. Two common STIs that appear together and commonly are treated together regardless of identification of the secondary one are _____ and _____.
5. Genital warts can be treated with which of the following? Select all that apply.
   a. Penicillin
   b. Podophyllin
   c. Imiquimod
   d. Cryotherapy
   e. Antiretroviral therapy
   f. Acyclovir

CHAPTER 6

Disorders of the Breasts

Nancy hasn't been able to sleep well since she felt the lump in her left breast over a month ago, just after her 60th birthday. She knows she is at high risk because her mother died of breast cancer, but she can't bring herself to have it checked out.

KEY TERMS

benign breast disorder
breast cancer
breast-conserving surgery
breast self-examination
carcinoma
chemotherapy
duct ectasia
endocrine therapy
fibroadenomas
fibrocystic breast changes
intraductal papilloma
mammography
mastitis
modified radical mastectomy
simple mastectomy

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms used in this chapter.
2. Identify the incidence, risk factors, screening methods, and treatment modalities for benign breast conditions.
3. Outline preventive strategies for breast cancer through lifestyle changes and health screening.
4. Explain the incidence, risk factors, treatment modalities, and nursing considerations related to breast cancer.
5. Develop an educational plan to teach breast self-examination to a group of young women.

Wow

Focus on reducing fear, anxiety, pain, and aloneness in all women diagnosed with a breast disorder.

The female breast is closely linked to womanhood in American culture. Women's breasts act as physical markers for transitions from one stage of life to another, and although the primary function of the breasts is lactation, they are perceived as a symbol of beauty and sexuality.

This chapter will discuss assessments, screening procedures, and management of specific benign and malignant breast disorders. Nurses play a key role in helping women maintain breast health by education and screening. A good working knowledge of early detection techniques, diagnosis, and treatment options is essential.

Benign Breast Disorders

A **benign breast disorder** is any noncancerous breast abnormality. Though not life-threatening, benign disorders can cause pain and discomfort, and they account for a large number of visits to primary care providers.

Depending on the type of benign breast disorder, treatment might or might not be necessary. Although these disorders are benign, the emotional trauma women experience is phenomenal. Fear, anxiety, disbelief, helplessness, and depression are just a few of the reactions that a woman may have when she discovers a lump in her breast. Many women believe that all lumps are cancerous, but actually more than 90% of the lumps discovered are benign and need no treatment (Alexander et al., 2007). Patience, support, and education are essential components of nursing care.

Consider THIS!

It was pouring down rain and I was driving alone along dark wet streets to my 8 a.m. appointment for a breast ultrasound. I recently had my annual mammogram and the radiologist thought he saw something suspicious on my right breast. I was on my way to confirm or refute his suspicions, and I couldn't keep focused on the road ahead. For the past few days I had been a basket case, fearing the worst. I was playing in my mind, what I would do if . . . ? What changes would I make in my life and how would I react when told? I have been through such personal turmoil since that doctor announced he wanted "more tests."

Thoughts: This woman is worrying and is emotionally devastated before she even has a conclusive diagnosis. Is this a typical reaction to a breast disorder? Why do women fear the worst? Many women use denial to mask their feelings and hope against hope the doctor made a mistake or misread their mammogram. How would you react if you or your sister, girlfriend, or mother were confronted with a breast disorder?

The most commonly encountered benign breast disorders in women include fibrocystic breasts, fibroadenomas, intraductal papilloma, mammary duct ectasia, and mastitis. Although these breast disorders are considered benign, fibrocystic breasts and intraductal papillomas carry a cancer risk, with prolific masses and hyperplastic changes within the breasts. Generally speaking, fibroadenomas, mastitis, and mammary duct ectasia carry little cancer risk (Sukumvanich & Borgen, 2007). Table 6-1 summarizes benign breast conditions.

FIBROCYSTIC BREAST CHANGES

Fibrocystic breast changes do not refer to a disease; rather, they represent a variety of changes in the glandular and structural tissues of the breast. Because this condition affects many women at some point, it is more accurately defined as a "change" rather than a "disease." The cause of fibrocystic changes is related to the way breast tissue responds to monthly levels of estrogen and progesterone. During the menstrual cycle, hormonal stimulation of the breast tissue causes the glands and ducts to enlarge and swell. One or both breasts can be involved, and any part of the breast can become tender (Hackley, Kriebs, & Rousseau, 2007). Fibrocystic changes do not increase the risk of breast cancer for most women except when the breast biopsy shows "atypia" or abnormal breast cells. The cause for concern for many women with fibrocystic changes is that breast examinations and mammography become more difficult to interpret with multiple cysts present, and early cancerous lesions that occur may occasionally be overlooked (American Cancer Society [ACS], 2007a).

Fibrocystic breast changes are most common in women between the ages of 30 and 50. The condition is rare in postmenopausal women not taking hormone replacement therapy. According to the ACS, fibrocystic breast changes affect at least half of all women at some point in their lives and are the most common breast disorder today (ACS, 2007a).

Therapeutic Management

Management of the symptoms of fibrocystic breast changes begins with self-care. In severe cases drugs, including bromocriptine, tamoxifen, or danazol, can be used to reduce the influence of estrogen on breast tissue. However, several undesirable side effects, including masculinization, have been documented. Aspiration or surgical removal of breast lumps will reduce pain and swelling by removing the space-occupying mass.

Nursing Assessment

Nursing assessment consists of a health history, physical examination, and laboratory and diagnostic tests.

TABLE 6.1 SUMMARY OF BENIGN BREAST DISORDERS

Breast Condition	Nipple Discharge	Site	Characteristics/ Age of Client	Tenderness	Diagnosis & Treatment
Fibrocystic breast changes	+ or –	Bilateral; upper outer quadrant	Round, smooth Several lesions Cyclic, palpable 30 to 50 years old	+	Aspiration and biopsy Limit caffeine; ibuprofen; supportive bra
Fibroadenomas	–	Unilateral; nipple area or upper outer quadrant	Round, firm, movable Palpable, rubbery Well delineated Single lesion 15 to 30 years old	–	Mammogram "Watchful waiting" Aspiration and biopsy Surgical excision
Intraductal papilloma	+	Unilateral; near nipple	Small, wart-like Poorly delineated Nonpalpable Can become large 40 to 60 years old	+	Culture discharge Mammogram Ultrasound Surgical excision
Duct ectasia	+	Unilateral; behind nipple	Inflammation Pasty, greenish discharge Nonmobile Burning, itching Perimenopausal women	+	Mammogram Ultrasound Culture Antibiotics Surgical excision
Mastitis	–	Unilateral; outer quadrant	Wedge-shaped Warmth, redness Swelling Nipple cracked Breast engorged	+	Antibiotics Warm shower Supportive bra Breastfeeding Increase fluids

Sources: ACS, 2007a; Alexander et al., 2007; Blackburn, 2007; Sukumvanich & Borgen, 2007

Health History

Ask the woman about common clinical manifestations, which include lumpy, tender breasts, particularly during the week before menses. Changes in breast tissue produce pain by nerve irritation from edema in connective tissue and by fibrosis from nerve pinching. The pain is cyclic and frequently dissipates after the onset of menses. The pain is described as a dull, aching feeling of fullness. Masses or nodularities usually appear in both breasts and are often found in the upper outer quadrants. Some women also experience spontaneous clear to yellow nipple discharge when the breast is squeezed or manipulated.

Physical Examination

It is best to examine a woman's breast a week after menses, when swelling has subsided. Observe the breasts for fibrosis, or thickening of the normal breast tissues, which occurs in the early stages. Cysts form in the later stages and feel like multiple, smooth, well-delineated tiny pebbles or bumpy oatmeal under the skin (Fig. 6.1). On physical examination of the breasts, a few characteristics might be helpful in differentiating a cyst from a cancerous lesion. Cancerous lesions typically are fixed and painless and may cause skin retraction (pulling). Cysts tend to be mobile and tender and do not cause skin retraction in the surrounding tissue.

Laboratory and Diagnostic Tests

Mammography can be helpful in distinguishing fibrocystic changes from breast cancer. Ultrasound is a useful adjunct to mammography for breast evaluation because it helps to differentiate a cystic mass from a solid one (Aliotta & Schaeffer, 2006). Ultrasound produces images of the breasts by sending sound waves through a gel applied to the breasts. Fine-needle aspiration biopsy can also be done to differentiate a solid tumor, cyst, or malignancy. A fine-needle aspiration biopsy uses a thin needle guided by ultrasound to the mass. In a method called stereotactic needle biopsy, a computer maps the exact location of the mass using mammograms taken from two angles, and the map is used to guide the needle.

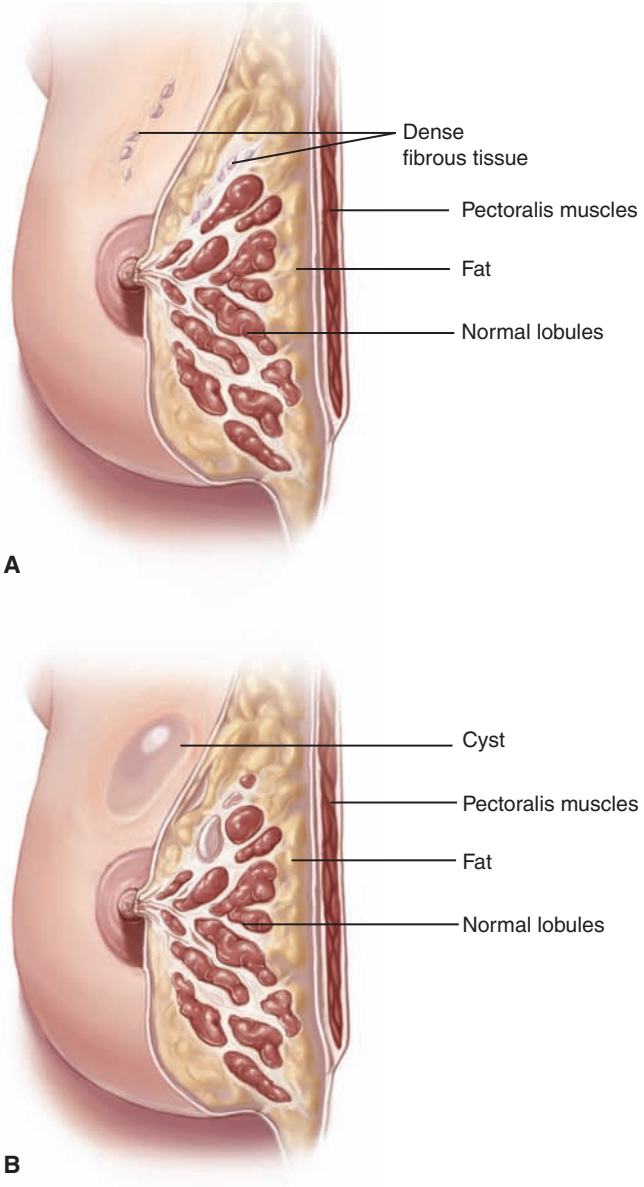

FIGURE 6.1 (**A**) Fibrocystic breast changes. (**B**) Cysts. (Source: The Anatomical Chart Company. [2002]. *Atlas of pathophysiology.* Springhouse, PA: Springhouse Corporation.)

Nursing Management

A nurse caring for a woman with fibrocystic breast changes can teach her about the condition, provide tips for self-care (Teaching Guidelines 6.1), suggest lifestyle changes, and demonstrate how to perform monthly breast self-examination after her menses to monitor the changes. Nursing Care Plan 6.1 presents a plan of care for a woman with fibrocystic breast changes.

TEACHING GUIDELINES 6.1

Relieving Symptoms of Fibrocystic Breast Changes

- Wear an extra-supportive bra to prevent undue strain on the ligaments of the breasts to reduce discomfort.
- Avoid caffeine, which is a stimulant. This reduces discomfort for some women.
- Take oral contraceptives, as recommended by a health care practitioner, to stabilize the monthly hormonal levels.
- Eat a low-fat diet rich in fruits, vegetables, and grains to maintain a healthy nutritional lifestyle and ideal weight.
- Apply heat to the breasts to help reduce pain via vasodilation of vessels.
- Take diuretics, as recommended by a health care practitioner, to counteract fluid retention and swelling of the breasts.
- Reduce salt intake to reduce fluid retention and swelling in the breasts.
- Take OTC medications, such as aspirin or ibuprofen (Motrin, Advil, Nuprin), to reduce inflammation and discomfort.
- Use thiamine and vitamin E therapy. This has been found helpful for some women, but research has failed to demonstrate a direct benefit from either therapy.
- Take medications as prescribed (e.g., bromocriptine, tamoxifen, or danazol).
- Discuss the possibility of aspiration or surgical removal of breast lumps with a health care practitioner.

FIBROADENOMAS

Fibroadenomas are common benign solid breast tumors that occur in about 10% of all women and account for up to half of all breast biopsies. They are the most common mass in women (Harris, 2007). They are considered hyperplastic lesions associated with an aberration of normal development and involution rather than a neoplasm. Fibroadenomas can be stimulated by external estrogen, progesterone, lactation, and pregnancy (Sukumvanich & Borgen, 2007). They are composed of both fibrous and glandular tissue and usually occur in women between 20 and 40 years of age (Alexander et al., 2007). Giant fibroadenomas account for approximately 10% of cases. These masses are frequently larger than 5 cm and occur most often in pregnant or lactating women. These large lesions may regress in size once hormonal stimulation subsides (Hackley, Kriebs, & Rousseau, 2007). Fibroadenomas are rarely associated with cancer.

Therapeutic Management

Treatment may include a period of "watchful waiting" because many fibroadenomas stop growing or shrink on their own without any treatment. Other growths may need to be

Nursing Care Plan 6.1

OVERVIEW OF THE WOMAN WITH FIBROCYSTIC BREAST CHANGES

Sheree Rollins is a 37-year-old woman who comes to the clinic for her routine check-up. During the examination, she says, "Sometimes my breasts feel so heavy and they ache a lot. I noticed a couple of lumpy areas in my breast last week just before I got my period. Is this normal? Now they feel like they're almost gone. Should I be worried?" Clinical breast examination reveals two small (pea-sized), mobile, slightly tender nodules in each breast bilaterally. No skin retraction noted. Previous mammogram revealed fibrocystic breast changes.

NURSING DIAGNOSIS: Pain related to changes in breast tissue

Outcome Identification and Evaluation

Client will demonstrate a decrease in breast pain as evidenced by a pain rating of 1 or 2 on a pain rating scale of 0 to 10 and statements that pain is lessened.

Interventions: Relieving Pain

- Ask client to rate her pain using a numeric pain rating scale *to establish a baseline.*
- Discuss with client any measures used to relieve pain *to determine effectiveness of the measures.*
- Encourage use of a supportive bra *to aid in reducing discomfort.*
- Instruct client in use of over-the-counter analgesics *to promote pain relief.*
- Advise the client to apply warm compresses or allow warm water from the shower to flow over her breasts *to promote vasodilation and subsequent pain relief.*
- Tell client to reduce her intake of salt to reduce risk of fluid retention and swelling leading *to increased pain.*

NURSING DIAGNOSIS: Deficient knowledge related to fibrocystic breast changes and appropriate care measures

Outcome Identification and Evaluation

Client will verbalize understanding of condition as evidenced by statements about the cause of breast changes and appropriate choices for lifestyle changes, and demonstration of self-care measures.

Interventions: Providing Patient Education

- Assess client's knowledge of fibrocystic breast changes *to establish a baseline for teaching.*
- Explain the role of monthly hormonal level changes and describe the signs and symptoms *to promote understanding of this condition.*
- Teach the client how to perform breast self-examination after her menstrual period *to monitor for changes.*
- Encourage client to report any changes promptly *to ensure early detection of problems.*
- Suggest client speak with her primary care provider about the use of oral contraceptives *to help stabilize monthly hormonal levels.*
- Review lifestyle choices, such as avoiding caffeine, eating a low-fat diet rich in fruits, vegetables, and grains, and adhering to screening recommendations *to promote health.*
- Discuss measures for pain relief *to minimize discomfort associated with breast changes.*

surgically removed if they do not regress or if they remain unchanged. Cryoablation, an alternative to surgery, can also be used to remove a tumor. In this procedure, extremely cold gas is piped into the tumor using ultrasound guidance. The tumor freezes and dies. The current trend is toward a more conservative approach to treatment after careful evaluation and continued monitoring.

Nursing Assessment

Ask the woman about clinical manifestations of fibroadenomas. These lumps are felt as firm, rubbery, well-circumscribed, freely mobile nodules that might or might not be tender when palpated.

Breast fibroadenomas are usually detected incidentally during clinical or self-examinations and are usually located in the upper outer quadrant of the breast; more than one may be present (Fig. 6.2). Several other breast lesions have similar characteristics, so every woman with a breast mass should be evaluated to exclude cancer. A clinical breast examination by a health care professional is critical. In addition, diagnostic studies include imaging studies (mammography, ultrasound, or both) and some form of biopsy, most often a fine-needle aspiration, core needle biopsy, or stereotactic needle biopsy. The core needle biopsy removes a small cylinder of tissue from the breast mass, more than the fine-needle aspiration biopsy.

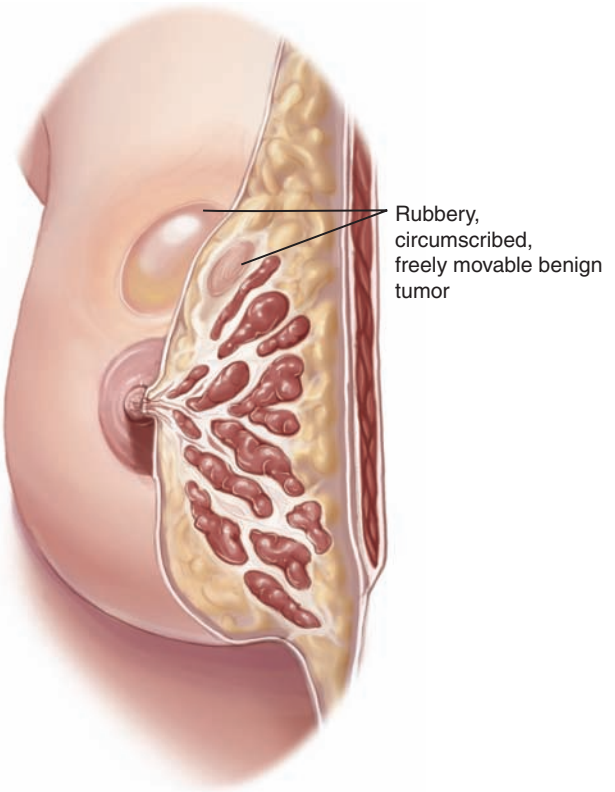

FIGURE 6.2 Fibroadenoma. (Source: The Anatomical Chart Company. [2002]. *Atlas of pathophysiology.* Springhouse, PA: Springhouse Corporation.)

If additional tissue needs to be evaluated, the advanced breast biopsy instrument (ABBI) is used. This instrument removes a larger cylinder of tissue for examination by using a rotating circular knife. The ABBI procedure removes more tissue than any of the other methods except a surgical biopsy (ACS, 2007b).

Nursing Management

The nurse should urge the client to return for re-evaluation in 6 months, perform monthly breast self-examinations, and return annually for a clinical breast examination.

INTRADUCTAL PAPILLOMA

An **intraductal papilloma** is a benign, wart-like growth found in the mammary ducts, usually near the nipple. This benign growth is thought to be caused by a proliferation and overgrowth of ductal epithelial tissue. An intraductal papilloma is generally less than 1 cm in diameter and might not be palpable. It produces a spontaneous serous, serosanguineous, or watery nipple discharge (Graham, 2006). It mostly affects women between the ages of 40 and 60. A single duct or several ducts may be involved. Women with solitary papilloma without atypia carry a minimal increase of developing breast cancer over the general population. These women are not classified as high risk. However, the risk of subsequent breast cancer is increased by four- to fivefold in the presence of atypia (Sukumvanich & Borgen, 2007).

Therapeutic Management

Treatment consists of surgical removal of the papilloma and a part of the duct it is found in, usually through an incision at the edge of the areola. The excised papilloma and duct are sent to the pathology laboratory to rule out cancer (ACS, 2007a).

Nursing Assessment

The woman might report a feeling of fullness in the breast and may state that she can manually express a serous, serosanguineous, or watery discharge from the nipple. If the papilloma is large enough, it can be palpated in the nipple area as a soft, nontender, mobile, poorly delineated mass.

Laboratory and diagnostic testing is important to rule out cancer. The nipple discharge is evaluated for the presence of occult blood using a Hemoccult card; a blue coloration on the card indicates the presence of blood. In addition, a sample of the discharge may be sent for cytologic evaluation to screen for cancer cells. Mammography, ultrasound, or ductography (radiographic dye is instilled into a duct; it outlines the breast ductal system on radiographs) is used to diagnose or differentiate this lesion from a cancerous one. An intraductal papilloma appears as a smooth, lobulated filling defect or a solitary obstructed duct on ductography (Aliotta & Schaeffer, 2006).

Nursing Management

The nurse should advise the woman to continue monthly breast self-examinations and yearly clinical breast examinations.

DUCT ECTASIA

Duct ectasia is a dilation and inflammation of the ducts behind the nipple. It is most common in perimenopausal women. This benign condition frequently occurs in women who have breastfed their children. The cause is unclear; however, chronic periductal inflammation, fibrosis, and ductal dilatation are associated factors. This condition results in noncyclic breast pain, nipple retraction, and discharge (Hackley, Kriebs, & Rousseau, 2007).

Therapeutic Management

This condition frequently improves without any specific treatment, or with warm compresses and antibiotics. If symptoms persist, the abnormal duct is removed through a local incision at the border of the areola. The tissue is sent to the pathology laboratory for evaluation.

Nursing Assessment

Assess the patient for clinical manifestations of duct ectasia. If the ducts have been chronically infected, an erythematous lesion will be present at the edge of the nipple area (ACS, 2007a). The woman may complain of nipple discharge, which can be green, brown, straw-colored, reddish, gray, or cream-colored, with the consistency of toothpaste. In addition, the woman may report a dull nipple pain, subareolar swelling, or a burning sensation accompanied by pruritus around the nipple (Richards et al., 2007).

Physical examination of the breasts might reveal subareolar redness and swelling, with mild to moderate tenderness on palpation. In addition, palpation will reveal the presence of tortuous tubular swellings beneath the areola, along with nipple retraction and dimpling in some postmenopausal women (Graham, 2006). Diagnostic and laboratory testing includes mammography, ultrasound, and cytology and testing for occult blood on a nipple discharge sample, and ductography may be used to assist in the diagnosis of this lesion.

Nursing Management

The nurse should reassure the woman that this condition is benign and should reinforce the importance of monthly self-examinations as well as annual clinical breast examinations by the woman's health care provider. This benign breast condition is typically self-limiting; the only intervention needed is reassurance.

MASTITIS

Mastitis is an infection of the connective tissue in the breast that occurs primarily in lactating or engorged women. Mastitis is divided into lactational or nonlactational. The usual causative organisms for lactational mastitis are *Staphylococcus aureus, Haemophilus influenzae,* and *Haemophilus* and *Streptococcus* species, the source of which is the baby's flora. One or more of the ducts drain poorly or become blocked, resulting in bacterial growth in the retained milk (Sukumvanich & Borgen, 2007).

Nonlactational mastitis can be caused by duct ectasia, which occurs when the milk ducts become congested with secretions and debris, resulting in periductal inflammation. These women present with greenish nipple discharge, nipple retraction, and noncyclical pain.

Therapeutic Management

Management of both types of mastitis involves the use of oral antibiotics (usually a penicillinase-resistant penicillin or cephalosporin) and acetaminophen (Tylenol) for pain and fever.

Nursing Assessment

Assess the patient's health history for risk factors for mastitis, which include poor handwashing, ductal abnormalities, nipple cracks and fissures, lowered maternal defenses due to fatigue, tight clothing, poor support of pendulous breasts, failure to empty the breasts properly while breastfeeding, or missing breastfeedings.

Assess the patient for clinical manifestations of mastitis, which include flu-like symptoms of malaise, leukocytosis, fever, and chills. Physical examination of the breasts reveals increased warmth, redness, tenderness, and swelling. The nipple is usually cracked or abraded and the breast is distended with milk (Fig. 6.3). The diagnosis is made based on history and examination.

Nursing Management

Teach the woman about the etiology of mastitis and encourage her to continue to breastfeed, emphasizing that the prescribed medication is safe to take during lactation. Continued emptying of the breast or pumping improves the outcome, decreases the duration of symptoms, and decreases the incidence of breast abscess. Thus, continued breastfeeding is recommended in the presence of mastitis (Reddy et al., 2007). Instructions for the woman with mastitis are detailed in Teaching Guidelines 6.2.

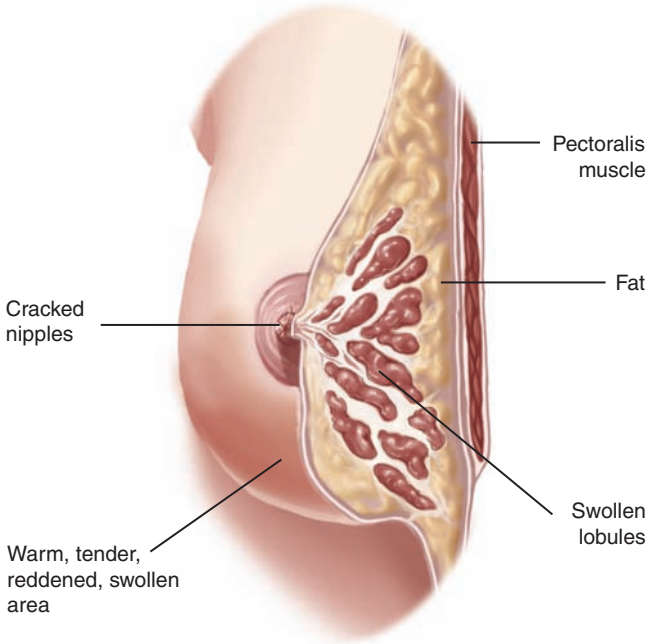

FIGURE 6.3 Mastitis.

TEACHING GUIDELINES 6.2

Caring for Mastitis

- Take medications as prescribed.
- Continue breastfeeding, as tolerated.
- Wear a supportive bra 24 hours a day to support the breasts.
- Increase fluid intake.
- Make sure infant is positioned correctly on the nipple.
- Practice good handwashing techniques.
- Apply warm compresses to the affected breast or take a warm shower before breastfeeding.
- Frequently change positions while nursing.
- Get adequate rest and nutrition to support or improve the immune system.

Sources: ACS, 2007a; Blackburn, 2007; Eglash, Plane, & Mundt, 2006.

Malignant Breast Disorders

Breast cancer is a neoplastic disease in which normal body cells are transformed into malignant ones (Opatt & Chung, 2007). It is the most common cancer in women and the second leading cause of cancer deaths (lung cancer is first) among American women. Breast cancer accounts for one of every three cancers diagnosed in the United States (ACS, 2007c). A new case is discovered every 2 minutes. It is estimated that one out of every seven women will develop the disease at some time during her life, and the mortality rate of those with breast cancer is 1 in 30 (National Cancer Institute [NCI], 2007b).

Over 200,000 cases of invasive breast cancer are diagnosed in the United States each year (ACS, 2007c). Breast cancer can also affect men, but only 1% of all individuals diagnosed with breast cancer annually are men (ACS, 2007). Because men are not routinely screened for breast cancer, the diagnosis is often delayed. The most common clinical manifestation of male breast cancer is a painless, firm, subareolar breast mass. Any suspicious breast mass in a male should undergo diagnostic biopsy. If a malignancy is diagnosed, typical treatment is mastectomy with assessment of the axillary nodes.

The cause of breast cancer, while not well understood, is thought to be a complex interaction between environment, genetic, and hormonal factors. Breast cancer is a progressive rather than a systemic disease, meaning that most cancers grow from small size with low metastatic potential to larger size and greater metastatic potential (Opatt & Chung, 2007).

Pathophysiology

Cancer is not just one disease, but rather a group of diseases that result from unregulated cell growth. Without regulation, cells divide and grow uncontrollably until they eventually form a tumor. Extensive research has determined that all cancer is the result of changes in DNA or chromosome structure that cause the mutation of specific genes. Most genetic mutations that cause cancer are acquired sporadically, which means they occur by chance and are not necessarily due to inherited mutations (Law & Alcamo, 2007). Cancer development is thought to be clonal in nature, which means that each cell is derived from another cell. If one cell develops a mutation, any daughter cell derived from that cell will have that same mutation, and this process continues until a malignant tumor forms.

Breast cancer starts in the epithelial cells that line the mammary ducts within the breast. The growth rate depends on hormonal influences, mainly estrogen and progesterone. The two major categories of breast cancer are noninvasive and invasive. Noninvasive, or in situ, breast cancers are those that have not extended beyond their duct, lobule, or point of origin into the surrounding breast tissue. Conversely, invasive, or infiltrating, breast cancers have extended into the surrounding breast tissue, with the potential to metastasize. Many researchers believe that most invasive cancers probably originate as noninvasive cancers (Underwood, 2006).

By far the most common breast cancer is invasive ductal carcinoma, which represents 85% of all cases (ACS, 2007f). **Carcinoma** is a malignant tumor that occurs in epithelial tissue; it tends to infiltrate and give rise to metastases. The incidence of this cancer peaks in the sixth decade of life (>60 years old). It spreads rapidly to axillary and other lymph nodes, even while small. Infiltrating ductal carcinoma may take various histologic forms—well differentiated and slow-growing, poorly differentiated and infiltrating, or highly malignant and undifferentiated with numerous metastases. This common type of breast cancer starts in the ducts, breaks through the duct wall, and invades the fatty breast tissue (Aliotta & Schaeffer, 2006).

Invasive lobular carcinomas, which originate in the terminal lobular units of breast ducts, account for 10% to 15% of all cases of breast cancer. The tumor is frequently located in the upper outer quadrant of the breast, and by the time it is discovered the prognosis is usually poor (Underwood, 2006). Other invasive types of cancer include tubular carcinoma (29%), which is fairly uncommon and typically occurs in women aged 55 and older. Colloid carcinoma (2% to 4%) occurs in women 60 to 70 years of age and is characterized by the presence of large pools of mucus interspersed with small islands of tumor cells. Medullary carcinoma accounts for 5% to 7% of malignant breast tumors; it occurs frequently in younger women (<50 years of age) and grows into large tumor masses. Inflammatory breast cancer (<4%) often presents with skin edema, redness, and warmth and is associated with a poor prognosis. Paget's disease (2% to 4%) originates in the nipple and typically occurs with invasive ductal carcinoma (Sukumvanich & Borgen, 2007).

Breast cancer is considered to be a highly variable disease. While the process of metastasis is a complex and poorly understood phenomenon, there is evidence to suggest that new vascularization of the tumor plays an important role in the biological aggressiveness of breast cancer (Hackley, Kriebs, & Rousseau 2007). Breast cancer metastasizes widely and to almost all organs of the body, but primarily to the bone, lungs, lymph nodes, liver, and brain. The first sites of metastases are usually local or regional, involving the chest wall or axillary supraclavicular lymph nodes or bone (ACS, 2007f).

Breast cancers are classified into three stages based on:

1. Tumor size
2. Extent of lymph node involvement
3. Evidence of metastasis

The purposes of tumor staging are to determine the probability the tumor has metastasized, to decide on an appropriate course of therapy, and to assess the client's prognosis. Table 6.2 gives details and characteristics of each stage. The overall 10-year survival rate for a woman with stage I breast cancer is 80% to 90%; for a woman with stage II, it is about 50%. The outlook is not as good for women with stage III or IV disease (Alexander et al., 2007).

There is no completely accurate way to know whether the cancer has micrometastasized to distant organs, but certain tests can help determine if the cancer has spread. A bone scan can be performed to assess the bones. Magnetic resonance imaging (MRI) can be used to detect metastases to the liver, abdominal cavity, lungs, or brain.

Risk Factors

An estimated 80% of women in whom breast cancer develops have no documented risk factors (Sukumvanich & Borgen, 2007). Breast cancer is thought to develop in response to a number of related factors: aging, delayed childbearing or never bearing children, high breast density, family history of cancer, late menopause, and hormonal factors (ACS, 2007e). Other factors might contribute to breast cancer but have not been scientifically proven.

In 1970, the lifetime risk for developing breast cancer was one in ten; since then, the risk has gradually risen (NCI, 2007b). This slight increase in incidence might be explained in a variety of ways—better detection and screening tools are available, which have identified more cases; women are living to an older age, when their risk increases; and lifestyle changes in American women (having their first pregnancy at an older age, having fewer children, and using hormonal therapy to treat the symptoms of menopause) might have produced the higher numbers. Age is a significant risk factor. Because rates of breast cancer increase with age, estimates of risk at specific ages are more meaningful than estimates of lifetime risk. The estimated chances of a woman being diagnosed with breast cancer between the ages of 30 and 70 are detailed in Table 6.3.

Risk factors for breast cancer can be divided into those that cannot be changed (nonmodifiable risk factors) and those that can be changed (modifiable risk factors). Nonmodifiable risk factors (ACS, 2007e) are:

- Gender (female)
- Aging (>50 years old)
- Genetic mutations (BRCA-1 and BRCA-2 genes)
- Personal history of ovarian or colon cancer
- Increased breast density
- Family history of breast cancer (mother, sister, daughter, grandmother, or aunt)
- Personal history of breast cancer (three- to fourfold increase in risk for recurrence)
- Race (higher in Caucasian women, but African-American women are more likely to die of it)
- Previous abnormal breast biopsy (atypical hyperplasia)
- Exposure to chest radiation (radiation damages DNA)
- Previous breast radiation (12 times normal risk)
- Early menarche (<12 years old) or late onset of menopause (>55 years old), which represents increased estrogen exposure over the lifetime

Modifiable risk factors related to lifestyle choices (ACS, 2007e) include:

- Not having children at all or not having children until after age 30—this increases the risk of breast cancer by not reducing the number of menstrual cycles
- Postmenopausal use of estrogens and progestins—the Women's Health Initiative study (2002) reported increased risks with long-term (>5 years) use of hormone replacement therapy

TABLE 6.2 STAGING OF BREAST CANCER

Stage	Characteristics
0	In situ, early type of breast cancer
I	Localized tumor <1 inch in diameter
II	Tumor 1–2 inches in diameter; spread to axillary lymph nodes
III	Tumor 2 inches or larger; spread to other lymph nodes and tissues
IV	Cancer has metastasized to other body organs

Source: ACS, 2007c.

TABLE 6.3 ESTIMATED RISK OF BREAST CANCER AT SPECIFIC AGES

Age 30 to 40	1 out of 262
Age 40 to 50	1 out of 68
Age 50 to 60	1 out of 35
Age 60 to 70	1 out of 27

Modified from National Cancer Institute (NCI). (2007). Probability of breast cancer in American women. Available at: http://cis.nci.nih.gov/fact/5_6.htm

- Failing to breastfeed for up to a year after pregnancy—increases the risk of breast cancer because it does not reduce the total number of lifetime menstrual cycles
- Alcohol consumption—boosts the level of estrogen in the bloodstream
- Smoking—exposure to carcinogenic agents found in cigarettes
- Obesity and consumption of high-fat diet—fat cells produce and store estrogen, so more fat cells create higher estrogen levels
- Sedentary lifestyle and lack of physical exercise—increases body fat, which houses estrogen

The presence of risk factors, especially several of them, calls for careful ongoing monitoring and evaluation to promote early detection. Even though risk factors are important considerations, many women with newly diagnosed breast cancer have no known risk factors. While routine mammography and self-examination are prudent for everyone, these precautions may become lifesavers for at-risk individuals.

Diagnosis

There are many studies performed to make an accurate diagnosis of a malignant breast lump. Diagnostic tests may include:

- Diagnostic mammography
- Magnetic resonance mammography (MRM)
- Fine-needle aspiration
- Stereotactic needle-guided biopsy
- Sentinel lymph node biopsy
- Hormone receptor status
- DNA ploidy status
- Cell proliferative indices
- HER-2/neu genetic marker (Opatt & Chung, 2007)

Mammography

Mammography involves taking x-ray pictures of the bare breasts while they are compressed between two plastic plates. This procedure is performed to identify and characterize a breast mass and to detect an early malignancy.

EVIDENCE-BASED PRACTICE 6.1
Can a Low-Fat Diet Reduce Breast Cancer Risk in Postmenopausal Women?

The hypothesis that a low-fat diet can reduce breast cancer risk has existed for decades but has never been tested in a controlled intervention trial.

● Study

To assess the effects of a low-fat diet on breast cancer incidence, a randomized, controlled, primary prevention trial was conducted at 40 U.S. clinical centers from 1993 to 2005. A total of 48,835 postmenopausal women, aged 50 to 79 years, without prior breast cancer, including 18.6% of minority race/ethnicity, were enrolled. Women were randomly assigned to the dietary modification intervention group (40% [n = 19,541]) or the comparison group (60% [n = 29,294]). The intervention was designed to promote dietary change with the goals of reducing intake of total fat to 20% of energy and increasing consumption of vegetables and fruit to at least five servings daily and grains to at least six servings daily. Comparison group participants were not asked to make dietary changes.

Dietary fat intake was significantly lower in the dietary modification intervention group compared with the comparison group. Vegetable and fruit consumption was higher in the intervention group by at least one serving per day and a smaller, more transient difference was found for grain consumption.

▲ Findings

The number of women who developed invasive breast cancer (annualized incidence rate) over the 8-year average follow-up period was 655 (0.42%) in the intervention group and 1,072 (0.45%) in the comparison group (hazard ratio, 0.91; 95% confidence interval, 0.83–1.01 for the comparison between the two groups). Secondary analyses suggested a lower hazard ratio among adherent women, provided greater evidence of risk reduction among women who ate a high-fat diet at baseline, and suggested a dietary effect that varies by hormone receptor characteristics of the tumor. Among postmenopausal women, a low-fat diet did not result in a statistically significant reduction in invasive breast cancer risk over an 8-year average follow-up period.

■ Nursing Implications

Although the results didn't confirm that eating a low-fat diet reduces the risk of breast cancer, nurses need to counsel their patients about the other benefits derived from a low-fat diet: weight loss, lower cholesterol levels, and decreased risk for cardiovascular disease. These additional benefits should be emphasized as part of an overall healthy lifestyle.

Source: Prentice RL, Caan B, Chlebowski RT, et al. (2006). Low-fat dietary pattern and risk of invasive breast cancer: The Women's Health Initiative Randomized Controlled Dietary Modification Trial. *JAMA, 295*(6), 629–642.

A screening mammogram typically consists of four views, two per breast (Fig. 6.4). It can detect lesions as small as 0.5 cm (the average size of a tumor detected by a woman practicing occasional breast self-examination is approximately 2.5 cm) (Kubota et al., 2007). A diagnostic mammogram is performed when the woman has suspicious clinical findings on a breast examination or an abnormality has been found on a screening mammogram. A diagnostic mammogram uses additional views of the affected breast as well as magnification views. Diagnostic mammography provides the radiologist with additional detail to render a more specific diagnosis. A digital mammography, which records images in computer code instead of on x-ray film, can also be used so that images can be transmitted and easily stored.

Most women find the 10-minute mammography procedure uncomfortable but not painful. Teaching Guidelines 6.3 offers tips for a patient to follow before she undergoes this procedure.

TEACHING GUIDELINES 6.3

Preparing for a Screening Mammogram

- Schedule the procedure just after menses, when breasts are less tender.
- Don't use deodorant or powder the day of the procedure, because they can appear on the x-ray film as calcium spots.
- Acetaminophen (Tylenol) or aspirin can relieve any discomfort after the procedure.
- Remove all jewelry from around your neck, because the metal can cause distortions on the film image.
- Select a facility that is accredited by the American College of Radiology (ACR) to ensure appropriate credentialed staff.

Magnetic Resonance Mammography

MRM is a relatively new procedure that might allow for earlier detection because it can detect smaller lesions and provide finer detail. MRM is a highly accurate (>90% sensitivity for invasive carcinoma) but costly tool. Contrast infusion is used to evaluate the rate at which the dye initially enters the breast tissue. The basis of the high sensitivity of MRM is the tumor angiogenesis (vessel growth) that accompanies a majority of breast cancers, even early ones. Malignant lesions tend to exhibit increased enhancement within the first 2 minutes (Preda et al., 2006). Currently MRM is used only as a complement to mammography and clinical breast examination because it is expensive, but it may move into the diagnostic arena in the near future (Smith, 2007).

FIGURE 6.4 Mammography. (**A**) A top-to-bottom view of the breast. (**B**) A side view of the breast.

Fine-Needle Aspiration

Fine-needle aspiration (FNA) is done to identify a solid tumor, cyst, or malignancy. It is a simple office procedure that can be performed with or without anesthesia. A small (20- to 22-gauge) needle connected to a 10-cc or larger syringe is inserted into the breast mass and suction is applied to withdraw the contents. The aspirate is then sent to the cytology laboratory to be evaluated for abnormal cells.

Stereotactic Needle-Guided Biopsy

This diagnostic tool is used to target and identify mammographically detected nonpalpable lesions in the breast. This procedure is less expensive than an excisional biopsy. The procedure takes place in a specially equipped room and generally takes about an hour. When proper placement of the breast mass is confirmed by digital mammograms, the breast is locally anesthetized and a spring-loaded biopsy gun is used to obtain two or three core biopsy tissue samples. After the procedure is finished, the biopsy area is cleaned and a sterile dressing is applied.

Sentinel Lymph Node Biopsy

The status of the axillary lymph nodes is an important prognostic indicator in early-stage breast cancer. The pres-

ence or absence of malignant cells in lymph nodes is highly significant: the more lymph nodes involved and the more aggressive the cancer, the more powerful chemotherapy will have to be, both in terms of the toxicity of drugs and the duration of treatment (Teal, Tabbara, & Kelly, 2007). With a sentinel lymph node biopsy, the clinician can determine whether breast cancer has spread to the axillary lymph nodes without having to do a traditional axillary lymph node dissection. Experience has shown that the lymph ducts of the breast typically drain to one lymph node first before draining through the rest of the lymph nodes under the arm. The first lymph node is called the sentinel lymph node.

This procedure can be performed under local anesthesia. A radioactive blue dye is injected 2 hours before the biopsy to identify the afferent sentinel lymph node. The surgeon usually removes one to three nodes and sends them to the pathologist to determine whether cancer cells are present. The sentinel lymph node biopsy is usually performed before a lumpectomy to make sure the cancer has not spread. Removing only the sentinel lymph node can allow women with breast cancer to avoid many of the side effects (lymphedema) associated with a traditional axillary lymph node dissection (Underwood, 2006).

Hormone Receptor Status

Normal breast epithelium has hormone receptors and responds specifically to the stimulatory effects of estrogen and progesterone. Most breast cancers retain estrogen receptors, and for those tumors estrogen will retain proliferative control over the malignant cells. It is therefore useful to know the hormone receptor status of the cancer to predict which women will respond to hormone manipulation. Hormone receptor status reveals whether the tumor is stimulated to grow by estrogen and progesterone. Tumors that have estrogen receptors are said to be "ER positive" (ER+) and tumors that do not have estrogen receptors are "ER negative" (ER–). The same terminology applies to progesterone (PR+ or PR–). ER+ and PR+ tumors have a better than 75% response to endocrine therapy in comparison to tumors that are ER+ and PR–, whose response rate is under 35%. Postmenopausal women tend to be ER+; premenopausal women tend to be ER– (Opatt & Chung, 2007). To determine hormone receptor status, a sample of breast cancer tissue obtained during a biopsy or a tumor removed surgically during a lumpectomy or mastectomy is examined by a cytologist.

DNA Ploidy Status

DNA ploidy status, which correlates with tumor aggressiveness, indicates the amount of DNA in cancer cells. Cancer cells that have the correct amount of DNA (diploid) in contrast with too much or too little DNA (aneuploid) tend not to spread. An aneuploid DNA pattern denotes a greater tendency to metastasize than a diploid one (Sukumvanich & Borgen, 2007). A sample of breast cancer tissue obtained during a biopsy or a tumor removed surgically during a lumpectomy or mastectomy is examined for abnormal amounts of DNA. Using flow cytometry (process of counting and measuring cells), it is possible to measure the DNA content and proliferative activity of a tumor. The number of chromosome sets in the nucleus indicates the speed of cell replication and tumor growth; a high number predicts a poor outcome.

Cell Proliferative Indices

Research indicates that cell proliferation potential may have prognostic significance. Cell proliferative indices indirectly measure the rate of cell division, which is an indication of how fast the cancer is growing. Flow and image cytometry techniques are used to measure the tumor's cell cycle rate. The percentage of tumor cells in S phase (synthesis stage of cell division) of the cell cycle is assessed. S-phase percentages below 10% are considered low, and the tumor has less of a chance of spreading than one with a higher percentage. A tumor with high proliferative activity has a more aggressive metastatic potential (ACS, 2007f).

HER-2/neu Genetic Marker

Molecular and biologic factors are increasingly being used as indicators for prognosis and treatment. HER-2 is a human epidermal growth factor receptor whose biological function is associated with cell growth, resulting in loss of cell regulation and uncontrolled cell proliferation.

HER-2/neu oncoprotein is a protein that is significant, especially in large tumors. Overexpression of this protein results from an acquired genetic mutation and occurs in approximately 30% of women with metastatic breast cancer. Women whose tumors have high levels of HER-2/neu oncoprotein have a poor prognosis: they have rapid tumor progression, an increased rate of recurrence, a poor response to standard therapies, and a lower survival rate (Chernecky & Berger, 2007). The presence or absence of this oncoprotein helps determine which chemotherapy treatment will be most effective. A breast tissue sample is obtained by a fine-needle or open biopsy and treated with a material that binds to HER-2/neu oncoprotein. A dye is added to the tissue sample: the more uptake of the dye, the higher amount present (Chernecky & Berger, 2007).

Therapeutic Management

Women diagnosed with breast cancer have many treatments available to them. Generally, treatments fall into two categories: local and systemic. Local treatments are surgery and radiation therapy. Effective systemic treatments include chemotherapy, hormonal therapy, and immunotherapy.

Treatment plans are based on multiple factors, primarily on whether the cancer is invasive or noninvasive, the tumor's size and grade, the number of cancerous axillary lymph nodes, the hormone receptor status, and the ability to obtain clear surgical margins (ACS, 2007f). A combination of surgical options and adjunctive therapy is often recommended.

Another consideration in making decisions about a treatment plan is genetic testing for BRCA-1 and BRCA-2. This genetic testing became available in 1995 and can pinpoint women who have a significantly increased risk for breast and ovarian cancer: individuals with BRCA-1 and BRCA-2 mutations have a 75% lifetime risk of breast cancer and a 30% lifetime risk of ovarian cancer. Most cases of breast and ovarian cancer are sporadic in nature, but approximately 7% of breast cancers and 10% of ovarian cancers are thought to result from genetic inheritance (Kell & Burke, 2007).

Testing positive for a BRCA-1 or BRCA-2 mutation can significantly alter health care decisions. In some cases, before genetic testing was available, lumpectomy with radiation or mastectomy was the treatment most often recommended. However, if the woman is found to have a BRCA-1 mutation, she is most likely to be offered the option of contralateral prophylactic mastectomy and possible bilateral oophorectomy (Kell & Burke, 2007).

Severe psychological distress can occur as a result of genetic testing. Also, many women perceive their breasts as intrinsic to their femininity, self-esteem, and sexuality, and the risk of losing a breast can provoke extreme anxiety (Alexander et al., 2007). Nurses need to address the physical, emotional, and spiritual needs of the women they care for, as well as their families, since this mutation is inherited in an autosomal dominant fashion. Based on Mendelian genetics, first-degree relatives of affected women have a 50% risk of having inherited the mutation (Kell & Burke, 2007).

Surgical Options

Generally, the first treatment option for the woman diagnosed with breast cancer is surgery. A few women with tumors larger than 5 cm or inflammatory breast cancer may undergo neoadjuvant chemotherapy or radiotherapy to shrink the tumor before surgical removal is attempted (Opatt & Chung, 2007). The surgical options depend on the type and extent of cancer. The choices are typically either breast-conserving surgery (lumpectomy with radiation) or mastectomy with or without reconstruction. The overall survival rate with lumpectomy and radiation is about the same as that with modified radical mastectomy (ACS, 2007f). Research has shown that the survival rates in women who have had mastectomies versus those who have undergone breast-conserving surgery followed by radiation are the same. However, lumpectomy may not be an option for some women, including those:

- Who have two or more cancer sites that cannot be removed through one incision
- Whose surgery will not result in a clean margin of tissue
- Who have active connective tissue conditions (lupus or scleroderma) that make body tissues especially sensitive to the side effects of radiation
- Who have had previous radiation to the affected breast
- Whose tumors are larger than 5 cm (2 inches) (National Comprehensive Cancer Network, 2007)

These decisions are made jointly between the woman and her surgeon. If mastectomy is chosen, either by tumor characteristics or patient preference, then discussion needs to include breast reconstruction and regional lymph node biopsy versus sentinel lymph node biopsy. The mastectomy techniques are a simple mastectomy with sentinel node biopsy or a radical mastectomy with regional node biopsy. Removal of numerous lymph nodes places the patient at high risk for lymphedema.

Breast-Conserving Surgery

Breast-conserving surgery, the least invasive procedure, is the wide local excision (or lumpectomy) of the tumor along with a 1-cm margin of normal tissue. A lumpectomy is often used for early-stage localized tumors. The goal of breast-conserving surgery is to remove the suspicious mass along with tissue free of malignant cells to prevent recurrence. The results are less drastic and emotionally less scarring to the woman. Women undergoing breast-conserving therapy receive radiation after lumpectomy with the goal of eradicating residual microscopic cancer cells to limit locoregional recurrence. In women who do not require adjuvant chemotherapy, radiation therapy typically begins 2 to 4 weeks after surgery to allow healing of the lumpectomy incision site. Radiation is administered to the entire breast at daily doses over a period of several weeks (Rao et al., 2007).

A sentinel lymph node biopsy may also be performed since the lymph nodes draining the breast are located primarily in the axilla. Theoretically, if breast cancer is to metastasize to other parts of the body, it will probably do so via the lymphatic system. If malignant cells are found in the nodes, more aggressive systemic treatment may be needed.

Mastectomy

A **simple mastectomy** is the removal of all breast tissue, the nipple, and the areola. The axillary nodes and pectoral muscles are spared. This procedure would be used for a large tumor or multiple tumors that have not metastasized to adjacent structures or the lymph system.

A **modified radical mastectomy** is another surgical option; survival rates are comparable to those of radical mastectomy, but it is more conducive to breast reconstruction and results in greater mobility and less lymphedema (Alexander et al., 2007). This procedure involves removal of breast tissue, the axillary nodes, and some chest muscles, but not the pectoralis major, thus avoiding a concave anterior chest (DiSaia & Creasman, 2007).

In conjunction with the mastectomy, lymph node surgery (removal of underarm nodes) may need to be done to reduce the risk of distant metastasis and improve a woman's chance of long-term survival. For women with a positive sentinel node biopsy, 10 to 20 underarm lymph nodes may need to be removed. Complications associated with axillary lymph node surgery include nerve damage during surgery, causing temporary numbness down the upper aspect of the arm; seroma formation followed by wound infection; restrictions in arm mobility (some women

need physiotherapy); and lymphedema. In many women lymphedema can be avoided by:

- Avoiding using the affected arm for drawing blood, inserting intravenous lines, or measuring blood pressure (can cause trauma and possible infection)
- Seeking medical care immediately if the affected arm swells
- Wearing gloves when engaging in activities such as gardening that might cause injury
- Wearing a well-fitted compression sleeve to promote drainage return

Women having mastectomies must decide whether to have further surgery to reconstruct the breast. If the woman decides to have reconstructive surgery, it ideally is performed immediately after the mastectomy. The woman must also determine whether she wants the surgeon to use saline implants or natural tissue from her abdomen (TRAM flap method) or back (LAT flap method).

In the transverse rectus abdominis myocutaneous (TRAM) flap method, the rectus abdominis muscle is transferred from the abdomen via a tunnel under the skin and brought out through a new excision in the breast area. The blood supply is maintained. This tissue is used to reconstruct the breast that has been removed. In the latissimus dorsi (LAT) flap method, tissue from the latissimus dorsi muscle in the upper back is tunneled subcutaneously up to the chest area.

If reconstructive surgery is desired, the ultimate decision regarding the method will be determined by the woman's anatomy (e.g., is there sufficient fat and muscle to permit natural reconstruction) and her overall health status. Both procedures require a prolonged recovery period.

Some women opt for no reconstruction, and many of them choose to wear breast prostheses. Some prostheses are worn in the bra cup and others fit against the skin or into special pockets made into clothing.

Whether to have reconstructive surgery is an individual and very complex decision. Each woman must be presented with all of the options and then allowed to decide. The nurse can play an important role here by presenting the facts to the woman so that she can make an intelligent decision to meet her unique situation.

Adjunctive Therapy

Adjunctive therapy is supportive or additional therapy that is recommended after surgery. Adjunctive therapies include local therapy such as radiation therapy and systemic therapies using chemotherapy, hormonal therapy, and immunotherapy.

Radiation Therapy

Radiation therapy uses high-energy rays to destroy cancer cells that might have been left behind in the breast, chest wall, or underarm area after the tumor has been removed surgically. Usually serial radiation doses are given 5 days a week to the tumor site for 6 to 8 weeks postoperatively. Each treatment takes only a few minutes, but the dose is cumulative. Women undergoing breast-conserving therapy receive radiation to the entire breast after lumpectomy with the goal of eradicating residual microscopic cancer cells to reduce the chance of recurrence (Holcomb, 2006).

Side effects of traditional radiation therapy include inflammation, local edema, anorexia, swelling, and heaviness in the breast; sunburn-like skin changes in the treated area; and fatigue. Changes to the breast tissue and skin usually resolve in about a year (Willett, Czito, & Tyler, 2007). This type of therapy can be given several ways: external beam radiation, which delivers a carefully focused dose of radiation from a machine outside the body, or internal radiation, in which tiny pellets that contain radioactive material are placed into the tumor.

Several advances have taken place in the field of radiation oncology for the treatment of women with early-stage breast cancer that assist in reducing the side effects. The treatment position for external radiation has changed from supine to prone, with the arm on the affected side raised above the head, so that the treated breast hangs dependently through the opening of the treatment board. Treatment in the prone position improves dose distribution within the breast and allows for a decrease in the dose delivered to the heart, lung, chest wall, and other breast (National Comprehensive Cancer Network, 2007).

High-dose brachytherapy is another advance that is an alternative to traditional radiation treatment. A balloon catheter is used to insert radioactive seeds into the breast after the tumor is removed surgically. The seeds deliver a concentrated dose directly to the operative site; this is important because most cancer recurrences in the breast (67% to 100%) occur at or near the lumpectomy site. This allows a high dose of radiation to be delivered to a small target volume with a minimal dose to the surrounding normal tissue. This procedure takes 4 to 5 days as opposed to the 4 to 6 weeks that traditional radiation therapy takes; it also eliminates the need to delay radiation therapy to allow for wound healing. Brachytherapy is now used as a primary radiation treatment after breast-conserving surgery in selected women as an alternative to whole breast irradiation (Sanders et al., 2007). Side effects of brachytherapy include redness or discharge around catheters, fever, and infection. Daily cleansing of the catheter insertion site with a mild soap and application of an antibiotic ointment will minimize the risk of infection.

Intensity-modulated radiation therapy (IMRT) offers still another new approach to the delivery of treatment to reduce the dose within the target area while sparing surrounding normal structures. A computed tomography scan is used to create a three-dimensional model of the breast. Based on this model, a series of intensity-modulated beams are produced to the desired dose distribution to

reduce radiation exposure to underlying structures. Acute toxicity is thus minimized (Willett, Czito, & Tyler, 2007). Research is ongoing to evaluate the impact of all of these advances in radiation therapy.

Chemotherapy

Chemotherapy refers to the use of drugs that are toxic to all cells and interfere with a cell's ability to reproduce. They are particularly effective against malignant cells but affect all rapidly dividing cells, especially those of the skin, the hair follicles, the mouth, the gastrointestinal tract, and the bone marrow. Breast cancer is a systemic disease in which micrometastases are already present in other organs by the time the breast cancer is diagnosed. Chemotherapeutic agents perform a systemic "sweep" of the body to reduce the chances that distant tumors will start growing.

Chemotherapy may be indicated for women with tumors larger than 1 cm, positive lymph nodes, or cancer of an aggressive type. Chemotherapy is prescribed in cycles, with each period of treatment followed by a rest period. Treatment typically lasts 3 to 6 months, depending on the dose used and the woman's health status.

Different classes of drugs affect different aspects of cell division and are used in combinations or "cocktails." The most active and commonly used chemotherapeutic agents for breast cancer include alkylating agents, anthracyclines, antimetabolites, and vinca alkaloids. Fifty or more chemotherapeutic agents can be used to treat breast cancer; however, a combination drug approach versus a single drug treatment appears to be more effective (ACS, 2007f).

Side effects of chemotherapy depend on the agents used, the intensity of dosage, the dosage schedule, the type and extent of cancer, and the client's physical and emotional status (Boehmke & Dickerson, 2006). However, typical side effects include nausea and vomiting, diarrhea or constipation, hair loss, weight loss, stomatitis, fatigue, and immunosuppression. The most serious is bone marrow suppression (myelosuppression). This causes an increased risk of infection, bleeding, and a reduced red-cell count, which can lead to anemia. Treatment of the side effects can generally be addressed through appropriate support medications such as antinausea drugs like granisetron hydrochloride (Kytril) or ondansetron (Zofran). In addition, growth-stimulating factors, such as epoetin alfa (Procrit) and filgrastim (Neupogen), help keep blood counts from dropping too low. Counts that are too low would stop or delay the use of chemotherapy.

An aggressive systemic option, when other treatments have failed or when there is a strong possibility of relapse or metastatic disease, is high-dose chemotherapy with bone marrow and/or stem cell transplant. This therapy involves the withdrawal of bone marrow before the administration of toxic levels of chemotherapeutic agents. The marrow is frozen and then returned to the client after the high-dose chemotherapy is finished. Clinical trials are still researching this experimental therapy (Guarneri et al., 2007).

Endocrine Therapy

One of estrogen's normal functions is to stimulate the growth and division of healthy cells in the breasts. However, in some women with breast cancer, this normal function contributes to the growth and division of cancer cells.

The objective of **endocrine therapy** is to block or counter the effect of estrogen. Estrogen plays a central role in the pathogenesis of cancer, and treatment with estrogen deprivation has proven to be effective (Bush, 2007). Several different drug classes are used to interfere or block estrogen receptors. They include selective estrogen receptor modulators (SERMs), estrogen receptor down-regulators, aromatase inhibitors, luteinizing hormone-releasing hormone, progestin, and biologic response modifiers (Underwood, 2006). Current recommendations for most women with ER+ breast cancer are to take a hormone-like medication—known as a SERM anti-estrogenic agent—daily for up to 5 years after initial treatment. Certain areas in the female body (breasts, uterus, ovaries, skin, vagina, and brain) contain specialized cells called hormone receptors that allow estrogen to enter the cell and stimulate it to divide. SERMs enter these same receptors and act like keys, turning off the signal for growth inside the cell (Bush, 2007). The best-known SERM is tamoxifen (Nolvadex, 20 mg daily for 5 years). Although it works well in preventing further spread of cancer, it is also associated with an increased incidence of endometrial cancer, pulmonary embolus, deep vein thrombosis, hot flashes, vaginal discharge and bleeding, stroke, and cataract formation (Bush, 2007).

A relatively new SERM is the anti-osteoporosis drug raloxifene (Evista), which has shown promising results. It has anti-estrogen effects on the breast and uterus. In a recent study involving more than 20,000 postmenopausal women at high risk for breast cancer, raloxifene worked as well as tamoxifen in preventing breast cancer, but with fewer serious adverse effects. Both drugs cut the cancer risk in half (Medical Letter, 2006). It was originally marketed solely for the prevention and treatment of osteoporosis but is now used as adjunctive breast cancer therapy.

Another class of endocrine agents, aromatase inhibitors, work by inhibiting the conversion of androgens to estrogens. Aromatase inhibitors include letozole (Femara, 2.5 mg daily), exemestane (Aromasin, 25 mg daily), and anastrozole (Arimidex, 1 mg daily for 5 years), all of which are taken orally. These are usually given to women with advanced breast cancer or cancer that recurs despite the use of tamoxifen (Holcomb, 2006).

The side effects associated with these endocrine therapies include hot flashes, bone pain, fatigue, nausea, cough, dyspnea, and headache (Hackley, Kriebs, & Rousseau, 2007). Women with hormone-sensitive cancers can live for long periods without any intervention other than hormonal manipulation, but quality-of-life issues need to be addressed in the balance between treatment and side effects.

Immunotherapy

Immunotherapy, used as an adjunct to surgery, represents an attempt to stimulate the body's natural defenses to recognize and attack cancer cells. Trastuzumab (Herceptin, 2- to 4-mg/kg intravenous infusion) is the first monoclonal antibody approved for breast cancer (National Comprehensive Cancer Network, 2007). Some tumors produce excessive amounts of HER-2/neu protein, which regulates cancer cell growth. Breast cancers that overexpress the protein HER-2/neu are associated with a more aggressive form of disease and a poorer prognosis. Trastuzumab blocks the effect of this protein to inhibit the growth of cancer cells. It can be used alone or in combination with other chemotherapy to treat clients with metastatic breast disease (Opatt & Chung, 2007). Adverse effects of trastuzumab include cardiac toxicity, vascular thrombosis, hepatic failure, fever, chills, nausea, vomiting, and pain with first infusion (Skidmore-Roth, 2007).

NURSING PROCESS FOR THE PATIENT WITH BREAST CANCER

When a woman is diagnosed with breast cancer, she faces treatment that may alter her body shape, may make her feel unwell, and may not carry a certainty of cure. Nurses can support women from the time of diagnosis, through the treatments, and through follow-up after the surgical and adjunctive treatments have been completed. Allowing patients time to ask questions and to discuss any necessary preparations for treatment is critical. As our understanding of breast disorders keeps improving, treatments continue to change. Although the goal of treatment remains improved survival, increasing emphasis is focused on prevention (Stephenson, 2007). Nurses can have an impact on early detection of breast disorders, treatment, and symptom management (Underwood, 2006). A nurse who is involved in the woman's treatment plan from the beginning can effectively offer support throughout the whole experience.

Teamwork is important in breast screening and caring for women with breast disorders. Treatment is often fragmented between the hospital and community treatment centers, which can be emotionally traumatic for the woman and her family. The advances being made in the diagnosis and treatment of breast disorders mean that guidelines are constantly changing, requiring all health care professionals to keep up to date. Informed nurses can provide support and information and, most importantly, continuity of care for the woman undergoing treatment for a breast problem.

The nurse plays a particularly important role in providing psychological support and self-care teaching to patients with breast cancer. Nurses can influence both physical and emotional recovery, which are both important aspects of care that help in improving the woman's quality of life and the ability to survive. The nurse's role should extend beyond helping clients; spreading the word in the community about screening and prevention is a big part in the ongoing fight against cancer. The community should see nurses as both educators and valued sources of credible information. This role will help improve clinical outcomes while achieving high levels of client satisfaction.

Remember Nancy from the chapter opener? Is her response typical of many women upon discovering a lump in their breast? Nancy confides her discovery of the lump and her worries to you. What advice would you give her?

Assessment

Early breast cancer has no symptoms. The earliest sign of breast cancer is often an abnormality seen on a screening mammogram before the woman or the health care professional feels it. In the woman presenting with a breast disorder, take a thorough history of the problem and explore the woman's risk factors for breast cancer. Assess the woman for clinical manifestations of breast cancer, such as changes in breast appearance and contour, which become apparent with advancing breast cancer (ACS, 2007d). These changes include:

- Continued and persistent changes in the breast
- A lump or thickening in one breast
- Persistent nipple irritation
- Unusual breast swelling or asymmetry
- A lump or swelling in the axilla
- Changes in skin color or texture
- Nipple retraction, tenderness, or discharge (Fig. 6.5)

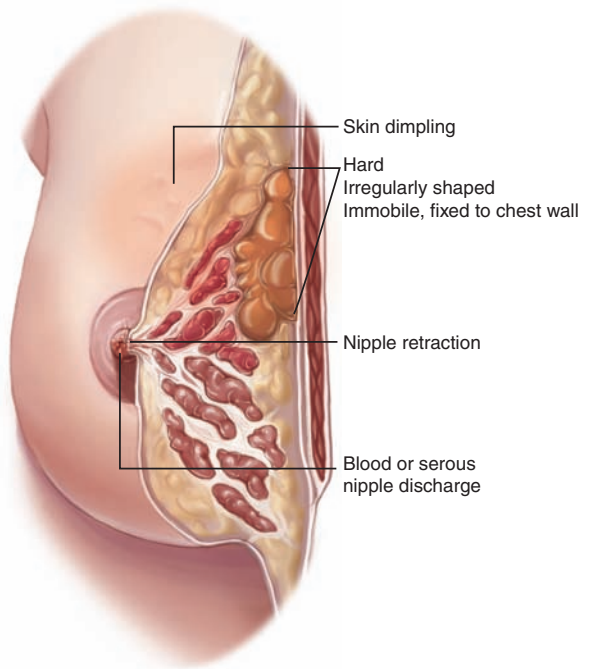

FIGURE 6.5 Malignant breast tumor.

Complete a breast examination to validate the clinical manifestations and findings of the health history and risk factor assessment. The clinical breast examination involves both inspection and palpation (Nursing Procedure 6.1). Helpful characteristics in evaluating palpable breast masses are described in Box 6.1. If a lump can be palpated, the cancer has been there for quite some time.

Be cognizant of the impact that breast cancer has on a woman's emotional state, coping ability, and quality of life. Women may experience sadness, anger, fear, and guilt as a result of breast cancer. However, despite potential negative outcomes, many women have a positive outlook for their futures and adapt to treatment modalities with a good quality of life (Holcomb, 2006). Closely monitor clients for their psychosocial adjustment to diagnosis and treatment and be able to identify those who need further psychological intervention. By giving practical advice, the nurse can help the woman adjust to her altered body image and to accept the changes to her life.

Because family members play a significant role in supporting women through breast cancer diagnosis and treatment, assess the emotional distress of both partners during the course of treatment and, if needed, make a referral for psychological counseling. By identifying interpersonal strains, negative psychosocial side effects of cancer treatment can be minimized.

Nursing Diagnosis

Appropriate nursing diagnoses for a woman with a diagnosis of breast cancer might include:

- Disturbed body image related to:
  - Loss of body part (breast)
  - Loss of femininity
  - Loss of hair due to chemotherapy
- Fear related to:
  - Diagnosis of cancer
  - Prognosis of disease
- Educational deficit related to:
  - Cancer treatment options
  - Reconstructive surgery decisions
  - Breast self-examination

Nursing Interventions

Offer information, support, and perioperative care to women diagnosed with breast cancer who are undergoing treatment. Implement health-promotion and disease-prevention strategies to minimize the risk for developing breast cancer and to promote optimal outcomes.

Remember Nancy, who discovered a breast lump? You offer to go with her to the doctor. After a full examination and several diagnostic tests, the results come back positive for breast cancer. What treatment options does Nancy have, and what factors need to be considered in selecting those options?

Providing Patient Education

Help the woman and her partner to prioritize the voluminous amount of information given to them so that they can make informed decisions. Explain all treatment options in detail so the patient and her family understand them. By preparing an individualized packet of information and reviewing it with the woman and her partner, the nurse can help them understand her specific type of cancer, the diagnostic studies and treatment options she may choose, and the goals of treatment. For example, nurses play an important role in educating women about the use of endocrine therapies, observing women's experiences with treatment, and communicating those observations to their primary care professionals to make dosage adjustments, in addition to contributing to the knowledge base of endocrine therapy in the treatment of breast cancer.

Providing information is a central role of the nurse in caring for the woman with a diagnosis of breast cancer. This information can be given via telephone counseling, one-to-one contact, and pamphlets. Telephone counseling with women and their partners may be an effective method to improve symptom management and quality of life (Knobf, 2007).

Providing Emotional Support

The diagnosis of cancer affects all aspects of life for a woman and her family. The threatening nature of the disease and feelings of uncertainty about the future can lead to anxiety and stress. Address the woman's needs for:

- Information about diagnosis and treatment
- Physical care while undergoing treatments
- Contact with supportive people
- Education about disease, options, and prevention measures
- Discussion and support by a caring, competent nurse

Reassure the client and her family that the diagnosis of breast cancer does not necessarily mean imminent death, a decrease in attractiveness, or diminished sexuality. Encourage the woman to express her fears and worries. Be available to listen and address the woman's concerns in an open manner to help her toward recovery. All aspects of care must include sensitivity to the patient's personal efforts to cope and heal. Some women will become involved in organizations or charities that support cancer research; they may participate in breast cancer walks to raise awareness or become a Reach for Recovery volunteer to help others. Each woman copes in her own personal manner, and all of these efforts can be positive motivators for her own healing.

To help women cope with the diagnosis of breast cancer, the American Cancer Society launched Reach to Recovery more than 30 years ago. Specially trained breast cancer survivors give women and their families opportunities to express their feelings, verbalize their fears, and get answers. Most importantly, Reach to Recovery vol-

(text continues on page 190)

Nursing Procedure 6.1

CLINICAL BREAST EXAMINATION

Purpose: To Assess Breasts for Abnormal Findings

1. Inspect the breast for size, symmetry, and skin texture and color. Inspect the nipples and areola. Ask the client to sit at the edge of the examination table, with her arms resting at her sides.

2. Inspect the breast for masses, retraction, dimpling, or ecchymosis.
   - The client places her hands on her hips.

   - She then raises her arms over her head so the axillae can also be inspected.

   - The client then stands, places her hands on her hips, and leans forward.

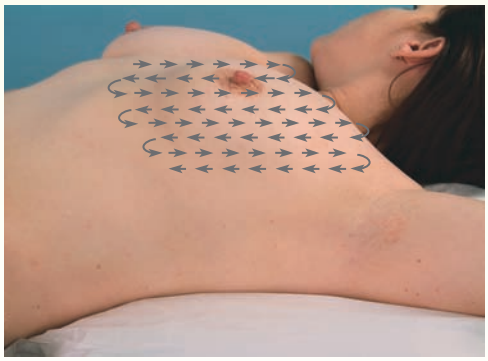
3. Palpate the breasts. Assist the client into a supine position with her arms above her head. Place a pillow or towel under the client's head to help spread the breasts. Three patterns might be used to palpate the breasts:

   - Spiral

Nursing Procedure 6.1 (continued)

- Pie-shaped wedges

- Vertical strip



4. Compress the nipple gently between the thumb and index finger to evaluate for masses and squeeze to check for any discharge.

5. Palpate the axillary area for any tenderness or lymph node enlargement. Have the client sit up and move to the edge of the examination table. While supporting the client's arm, palpate downward from the armpit, palpating toward the ribs just below the breast.

Adapted from Rhoads, J. (2006). *Advanced health assessment and diagnostic reasoning.* Philadelphia: Lippincott Williams & Wilkins.

BOX 6.1 Characteristics of Benign vs. Malignant Breast Masses

- **Benign breast masses are described as:**
  - Frequently painful
  - Firm, rubbery mass
  - Bilateral masses
  - Induced nipple discharge
  - Regular margins (clearly delineated)
  - No skin dimpling
  - No nipple retraction
  - Mobile, not affixed to the chest wall
  - No bloody discharge
- **Malignant breast masses are described as:**
  - Hard to palpation
  - Painless
  - Irregularly shaped (poorly delineated)
  - Immobile, fixed to the chest wall
  - Skin dimpling
  - Nipple retraction
  - Unilateral mass
  - Bloody, serosanguineous, or serous nipple discharge
  - Spontaneous nipple discharge

unteers offer understanding, support, and hope through face-to-face visits or by telephone; they are proof that people can survive breast cancer and live productive lives. National contact information is 1-800-ACS-2345.

Providing Postoperative Care

For the woman who has had surgery to remove a malignant breast lump or an entire breast, excellent postoperative nursing care is crucial. Tell the woman what to expect in terms of symptoms and when they usually occur during treatment and after surgery. This allows women to anticipate these symptoms and proactively employ management strategies to improve their cancer experience. Postoperative care includes immediate postoperative care, pain management, care of the affected arm, wound care, mobility care, respiratory care, emotional care, educational needs, and referrals.

Immediate Postoperative Care

Assess the client's respiratory status by auscultating the lungs and observing the breathing pattern. Assess circulation; note vital signs, skin color, and skin temperature. Observe the client's neurologic status by evaluating the level of alertness and orientation. Monitor the wound for amount and color of drainage. Monitor the intravenous lines for patency, correct fluid, and rate. Assess the drainage tube for amount, color, and consistency of drainage.

Pain Management

Provide analgesics as needed. Reassure the woman that her pain will be controlled. Teach the woman how to communicate her pain intensity on a scale of 0 to 10, with 10 being the worst pain imaginable. Assess the client's pain level frequently and anticipate pain before assisting the woman to ambulate.

Affected Arm Care

Elevate the affected arm on a pillow to promote lymph drainage. Make sure that no treatments are performed on the affected arm, including laboratory draws, intravenous lines, blood pressures, and so on. Place a sign above the bed to warn others not to touch the affected arm.

Wound Care

Observe the wound often and empty drainage reservoirs as needed. Tell the client to report any evidence of infection early, such as fever, chills, or any area of redness or inflammation along the incision line. Also tell the client to report any increase in drainage, foul odor, or separation at the incision site.

Mobility Care

Perform active range-of-motion and arm exercises as ordered. Encourage self-care activities for successful rehabilitation. Perform dressing and drainage care; explain the care during the procedure.

Respiratory Care

Assist with turning, coughing, and deep breathing every 2 hours. Explain that this helps to expand collapsed alveoli in the lungs, promotes faster clearance of inhalation agents from the body, and prevents postoperative pneumonia and atelectasis.

Emotional Care and Referrals

Encourage the client to participate in her care. Assess her coping strategies preoperatively. Explain possible body image concerns after discharge. Promote the ACS websites, which provide the latest cancer therapy news. Encourage the client to attend local support groups for breast cancer survivors, such as Reach to Recovery, an ACS program in which trained volunteers provide support and up-to-date information for spouses, children, friends, and other loved ones. Reach to Recovery volunteers can also, when appropriate, provide a temporary breast form and give information on types of permanent prostheses, as well as lists of where those items are available in the community.

Educational Needs

Provide follow-up information about adjunctive therapy. Explain that radiation therapy may start within weeks postoperatively. Discuss chemotherapy, its side effects and cycles, home care during treatment, and future monitoring strategies. Explain hormonal therapy, including antiestrogens or aromatase inhibitors. Teach progressive arm exercises to minimize lymphedema. Explain that ongoing surveillance is needed to detect recurrence of cancer or a new primary site and that the patient will typically see the health care provider every 6 months.

Nancy underwent a mastectomy with radiation and chemotherapy. What follow-up care is needed? How can the nurse assist Nancy to cope with her uncertain future? What community resources might help her?

Implementing Health-Promotion and Disease-Prevention Strategies

In the past, most women assumed that there was little they could do to reduce their risk of developing breast cancer. However, research has found that the daily choices women make concerning breast cancer screening, diet, exercise, and other health practices have a profound impact on cancer risk. In the fight against cancer, nurses often assume a variety of roles, such as educator, counselor, advocate, and role model. Nurses can offer education about the following:

- Prevention
- Early detection
- Screening
- Dispelling myths and fears

- Self-examination techniques
- Individual risk status and strategies for risk reduction

It is important to be knowledgeable about the most current evidence-based practices and cognizant of how the media presents this information. Offer prevention strategies within the context of a woman's life. Factors such as lifestyle choices, economic status, and multiple roles need to be taken into consideration when counseling women. Advocate for healthy lifestyles and making sound choices to prevent cancer. Nurses, like all health care professionals, should offer guidance from a comprehensive perspective that acknowledges the unique needs of each individual (Banning, 2007).

Breast cancer is a frightening experience for women. Like a black cloud hanging over their heads, with little regard for any victim, breast cancer stalks women everywhere they go. Many have a close friend or relative who is battling the disease; many have watched their mothers and sisters die of this dreaded disease. Those with risk factors live with even greater anxiety and fear. No woman wants to hear those chilling words: "The biopsy is positive. You have breast cancer." Provide women with information about detection and risk factors, inform them about the new ACS screening guidelines, instruct them on breast self-examination, and outline dietary changes that might reduce their risk of breast cancer.

Awareness is the first step toward a change in habits. Raising the level of awareness about breast cancer is of paramount importance, and nurses can play an important role in health promotion, disease prevention, and education.

Breast Cancer Screening

The three components of early detection are breast self-examination, clinical breast examination, and mammography.

The ACS (2007b) has issued breast cancer screening guidelines that, for the first time, offer specific guidance for the women and greater clarification of the role of breast examinations (Table 6.4). ACS screening guidelines are revised about every 5 years to include new scientific findings and developments.

Women are exposed to multiple sources of cancer prevention information, and much of it may not be sound. Discuss the benefits, risks, and potential limitations of breast self-examination, clinical breast examination, and mammography with each woman and tailor the information to her specific risk factors (ACS, 2007b). Based on the new guidelines, make clinical judgments as to the appropriateness of recommending breast self-examination, and re-evaluate the need to teach the procedure to all women; the focus might instead be on encouraging regular mammograms (depending, of course, on the woman's individual risk factors).

TABLE 6.4 AMERICAN CANCER SOCIETY BREAST CANCER SCREENING GUIDELINES

Woman's Age	Screening Activity
20–39	Breast self-examination (BSE) is optional Clinical breast examination every 3 years
40+	BSE every month is optional Clinical breast examination every year Mammogram every year, continuing for as long as the woman is in good health

Women at increased risk (e.g., family history, genetic tendency, past history of cancer) should discuss with their health care professionals the pros and cons of starting mammography screening earlier, undergoing additional diagnostic tests (e.g., ultrasound or MRI), or increasing the frequency of examinations.

Source: ACS, 2007c.

Breast self-examination is a technique that enables a woman to detect any changes in her breasts; this could result in early cancer detection. The emphasis is now on awareness of breast changes, not just discovery of cancer. Research has shown that breast self-examination plays a small role in detecting breast cancer compared with self-awareness. However, doing breast self-examination is one way for a woman to know how her breasts normally feel so that she can notice any changes that do occur (ACS, 2007g).

There are two steps to conducting breast self-examination: visual inspection and tactile palpation. The visual part should be done in three separate positions: with the arms up behind the head, with the arms down at the sides, and bending forward. Instruct the woman to look for:

- Changes in shape, size, contour, or symmetry
- Skin discoloration or dimpling, bumps/lumps
- Sores or scaly skin
- Discharge or puckering of the nipple

In the second part, the tactile examination, the woman feels her breasts in one of three specific patterns: spiral, pie-shaped wedges, or up and down. When using any of the three patterns, the woman should use a circular rubbing motion (in dime-sized circles) without lifting the fingers. She checks not only the breasts but also between the breast and the axilla, the axilla itself, and the area above the breast up to the clavicle and across the shoulder. The pads of the three middle fingers on the right hand are used to assess the left breast; the pads of the three middle fingers on the left hand are used to assess the right

breast. Instruct the woman to use three different degrees of pressure:

- Light (move the skin without moving the tissue underneath)
- Medium (midway into the tissue)
- Hard (down to the ribs)

Once the tactile examination has been completed while standing in front of a mirror, it should be repeated while lying down. Teaching Guidelines 6.4 details breast self-examination.

Nutrition

Nutrition plays a critical role in health promotion and disease prevention (Escott-Stump, 2007). Being overweight or obese is a risk factor for breast cancer in postmenopausal women (Wright, 2007). *Healthy People 2010* identified being overweight or obese as one of the 10 leading health indicators and a major health concern (USDHHS, 2000). Almost 62% of women over the age of 20 years are overweight; of these, 33.4% are obese (Smith-Warner & Stampfer, 2007). A diet high in fruits, vegetables, and high-fiber carbohydrates and low in animal fats seems to offer protection against breast cancer as well as weight control. Women who followed these dietary guidelines decreased their risk of breast cancer (Escott-Stump, 2007).

The Women's Health Initiative Dietary Modification Trial (Prentice et al., 2006) was designed to study a low-fat diet, a nutritional approach to prevention of chronic diseases. It found a marginally statistically significant reduction in breast cancer incidence among women in the low-fat dietary pattern group.

The American Institute for Cancer Research (AICR), which conducts extensive research, made the following

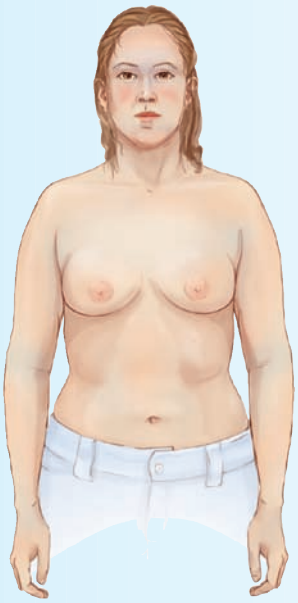
TEACHING GUIDELINES 6.4

How to Perform Breast Self-Examination

Step 1

- Stand before a mirror.
- Check both breasts for anything unusual.
- Look for discharge from the nipple and puckering, dimpling, or scaling of the skin.

The next two steps check for any changes in the contour of your breasts. As you do them, you should be able to feel your muscles tighten.



Step 2

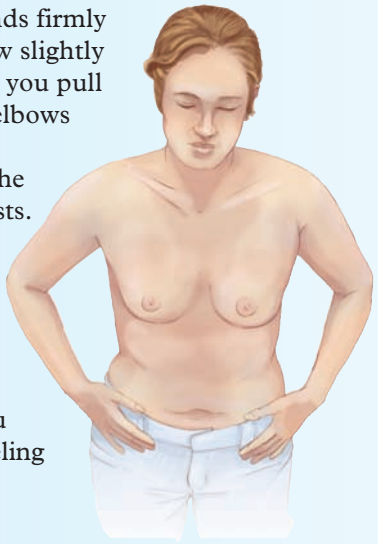
- Watch closely in the mirror as you clasp your hands behind your head and press your hands forward.
- Note any change in the contour of your breasts.

TEACHING GUIDELINES 6.4 (continued)

How to Perform Breast Self-Examination

Step 3

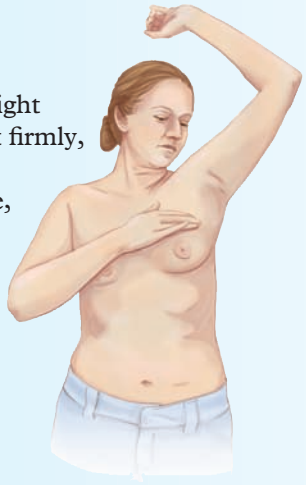
- Next, press your hands firmly on your hips and bow slightly toward the mirror as you pull your shoulders and elbows forward.
- Note any change in the contour of your breasts.



Some women perform the next part of the examination in the shower. Your fingers will glide easily over soapy skin, so you can concentrate on feeling for changes inside the breast.

Step 4

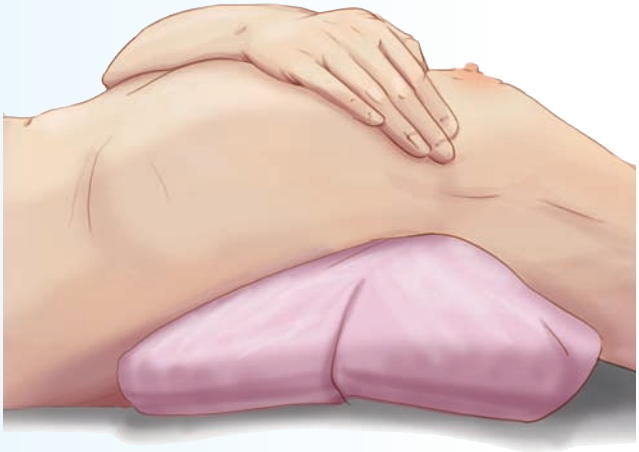
- Raise your left arm.
- Use 3 or 4 fingers of your right hand to feel your left breast firmly, carefully, and thoroughly.
- Beginning at the outer edge, press the flat part of your fingers in small circles, moving the circles slowly around the breast.
- Gradually work toward the nipple.
- Be sure to cover the whole breast.



- Pay special attention to the area between the breast and the underarm, including the underarm itself.
- Feel for any unusual lumps or masses under the skin.
- If you have any spontaneous discharge during the month—whether or not it is during your BSE—see your doctor.
- Repeat the examination on your right breast.

Step 5

- Lie flat on your back with your left arm over your head and a pillow or folded towel under your left shoulder. (This position flattens your breast and makes it easier to check.)
- Repeat the actions of Step 4 in this position for each breast.



Source: American Cancer Society. (2007). *How to perform a breast self exam.* Available online at http://www.cancer.org/docroot/cri/content/cri_2_6x_how_to_perform_a_breast_self_exam_5.asp

recommendations to reduce a woman's risk for developing breast cancer:

- Engaging in daily moderate exercise and weekly vigorous physical activity
- Consuming at least five servings of fruits and vegetables daily
- Not smoking or using any tobacco products
- Keeping a maximum body mass index (BMI) of 25 and limiting weight gain to no more than 11 pounds since age 18
- Consuming seven or more daily portions of complex carbohydrates, such as whole grains and cereals
- Limiting intake of processed foods and refined sugar
- Restricting red meat intake to approximately 3 ounces daily
- Limiting intake of fatty foods, particularly those of animal origin
- Restricting intake of salted foods and use of salt in cooking (Wright, 2007)

The medical community is also starting to study the role of phytochemicals in health. The unique geographic variability of breast cancer around the world and the low rate of breast cancer in Asian compared to Western countries prompted this interest. This area of research appears

hopeful for women seeking to prevent breast cancer as well as those recovering from it. Although the mechanism isn't clear, certain foods demonstrate anticancer properties and boost the immune system. Phytochemical-rich foods include:

- Green tea and herbal teas
- Garlic
- Whole grains and legumes
- Onions and leeks
- Soybeans and soy products
- Fruits (citrus, apricots, pumpkin, berries)
- Green leafy vegetables (spinach, collards, romaine)
- Colorful vegetables (carrots, squash, tomatoes)
- Cruciferous vegetables (broccoli, cabbage, cauliflower)
- Flax seeds (Escott-Stump, 2007)

Adopt a holistic approach when addressing the nutritional needs of women with breast cancer. Incorporate nutritional assessment into the general overall assessment of all women. Culturally sensitive nutritional assessment tools need to be developed and used to enhance this process. Providing examples of appropriate foods associated with the woman's current dietary habits, relating current health status to nutritional intake, and placing proposed modifications within a realistic personal framework may increase a woman's willingness to incorporate needed changes in her nutritional behavior. Be able to interpret research results and stay up to date on nutritional influences so that you can transmit this key information to the public.

Key Concepts

- Many women believe that all lumps are cancerous, but actually more than 90% of the lumps discovered are benign and need no treatment.
- The most commonly encountered benign breast disorders in women include fibrocystic breasts, fibroadenomas, intraductal papilloma, mammary duct ectasia, and mastitis.
- Current research suggests that women with fibrocystic breast disease or other benign breast conditions are more likely to develop breast cancer later only if a breast biopsy shows "atypia" or abnormal breast cells.
- Fibroadenomas are common benign solid breast tumors that can be stimulated by external estrogen, progesterone, lactation, and pregnancy.
- An intraductal papilloma is generally less than 1 cm in diameter, not palpable, and produces a spontaneous serous, serosanguineous, or watery nipple discharge.
- Duct ectasia is a dilation and inflammation of the ducts behind the nipple that results in noncyclic breast pain, nipple retraction, and discharge.
- Mastitis is an infection of the connective tissue in the breast that occurs primarily in lactating or engorged women; it is divided into lactational or nonlactational types.
- Management of both types of mastitis involves the use of oral antibiotics (usually a penicillinase-resistant penicillin or cephalosporin) and acetaminophen (Tylenol) for pain and fever.
- Breast cancer is the most common cancer in women and the second leading cause of cancer deaths (lung cancer is first) among American women.
- Breast cancer metastasizes widely and to almost all organs of the body, but primarily to the bone, lungs, lymph nodes, liver, and brain.
- The etiology of breast cancer is unknown, but the disease is thought to develop in response to a number of related factors: aging, delayed childbearing or never bearing children, high breast density, family history of cancer, late menopause, and hormonal factors.
- Breast cancer treatments fall into two categories: local and systemic. Local treatments are surgery and radiation therapy. Effective systemic treatments include chemotherapy, hormonal therapy, and immunotherapy.
- Women perceive their breasts as intrinsic to their femininity, self-esteem, and sexuality, and the risk of losing a breast can provoke extreme anxiety.
- Nurses can influence both physical and emotional recovery, which are both important aspects of care that help in improving the woman's quality of life and the ability to survive.
- Providing up-to-date information and emotional support are central roles of the nurse in caring for the woman with a diagnosis of breast cancer.

Chapter Worksheet

Multiple Choice Questions

1. Breast self-examinations involve both touching of breast tissue and:
   a. Palpation of cervical lymph nodes
   b. Firm squeezing of both breast nipples
   c. Visualizing both breasts for any change
   d. A mammogram to evaluate breast tissue
2. Which of the following is the strongest risk factor for breast cancer?
   a. Advancing age and being female
   b. High number of children
   c. Genetic mutations in BRCA-1 and BRCA-2
   d. Family history of colon cancer
3. A biopsy procedure that traces radioisotopes and blue dye from the tumor site through the lymphatic system into the axillary nodes is:
   a. Stereotactic biopsy
   b. Sentinel node biopsy
   c. Axillary dissection biopsy
   d. Advanced breast biopsy
4. The most serious potential adverse reaction from chemotherapy is:
   a. Thrombocytopenia
   b. Deep vein thrombosis
   c. Alopecia
   d. Myelosuppression
5. What suggestion would be helpful for the client experiencing painful fibrocystic breast changes?
   a. Increase her caffeine intake.
   b. Take a mild analgesic when needed.
   c. Reduce her intake of leafy vegetables.
   d. Wear a bra bigger than she needs.
6. A postoperative mastectomy client should be referred to which of the following organizations for assistance?
   a. National Organization for Women (NOW)
   b. Food and Drug Administration (FDA)
   c. March of Dimes Foundation (MDF)
   d. Reach to Recovery volunteers

Critical Thinking Exercises

1. Mrs. Gordon, 48, presents to the women's community clinic where you work as a nurse. She is very upset and crying. She tells you that she found lumps in her breast: "I know that it's cancer and I will die." When you ask her about her problem, she says she does not check her breasts monthly and hasn't had a mammogram for years because "they're too expensive." She also describes the intermittent pain she experiences.
   a. What specific questions would you ask this client to get a clearer picture?
   b. What education is needed for this client regarding breast health?
   c. What community referrals are needed to meet this client's future needs?
2. Ruth Davis, 51, stops in at the urgent care facility with an anxious look on her face. She tells the nurse practitioner that she has green discharge coming from her right breast and discomfort intermittently. She can't understand how this would happen since she hasn't previously had any nipple discharge or pain.
   a. What benign breast condition might the nurse practitioner suspect based on her description?
   b. What specific information should the nurse practitioner give Mrs. Davis about duct ectasia?
   c. The typical treatment of this benign breast condition would include what?

Study Activities

1. Discuss with a group of women what their breasts symbolize to them and to society. Do they symbolize something different to each one?
2. When a woman experiences a breast disorder, what feelings might she be experiencing and how can a nurse help her sort them out?
3. Interview a woman who has fibrocystic breast changes and find out how she manages this condition.
4. An infection of the breast connective tissue that frequently occurs in the lactating woman is _____.

CHAPTER 7

Benign Disorders of the Female Reproductive Tract

KEY TERMS

cystocele
enterocele
Kegel exercises
ovarian cyst
pelvic organ prolapse
pessary
polyps
polycystic ovary syndrome
rectocele
urinary incontinence
uterine fibroids
uterine prolapse

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms.
2. Identify the major pelvic relaxation disorders in terms of etiology, management, and nursing interventions.
3. Outline the nursing management needed for the most common benign reproductive disorders in women.
4. Discuss urinary incontinence in terms of pathology, clinical manifestations, treatment options, and effect on quality of life.
5. Compare the various benign growths in terms of their symptoms and management.
6. Discuss the emotional impact of polycystic ovarian syndrome and the nurse's role as a counselor, educator, and advocate.

Liz, a 26-year-old, overweight woman, presented to the clinic with hirsutism and facial acne and told the nurse she was concerned about her irregular menstrual periods. She also said her hair seemed to be falling out on top of her head recently. What diagnostic tests might the nurse anticipate with this patient? How can the nurse prepare Liz for them?

Wow

Women can influence their aging process by making wise lifestyle choices early on.

The incidence of several benign pelvic disorders increases as women age. For instance, women may experience pelvic support disorders related to pelvic relaxation or urinary incontinence. These disorders generally develop after years of wear and tear on the muscles and tissues that support the pelvic floor—such as that which occurs with childbearing, chronic coughing, straining, surgery, or simply aging. In addition to pelvic support disorders, woman may also experience various benign neoplasms of the reproductive tract, such as cervical polyps, uterine leiomyomas (fibroids), ovarian cysts, genital fistulas, and Bartholin's cysts. This chapter provides an overview of various pelvic support disorders and benign neoplasms, discussing the assessment, treatment, and prevention strategies for each.

Pelvic Support Disorders

Pelvic support disorders such as pelvic organ prolapse (POP) and urinary and fecal incontinence are common in aging women. The majority of the more than 13 million people in the United States who experience urinary incontinence are women with POP (Smith, 2007). Pelvic support disorders cause significant physical and psychological morbidity and can diminish women's social interactions, emotional well-being, and overall quality of life. Because pelvic support disorders increase with age, the problem will grow worse as our population ages. These disorders occur as a result of weakness of the connective tissue and muscular support of pelvic organs due to a number of factors: vaginal childbirth, obesity, lifting, chronic cough, straining at defecation secondary to constipation, and estrogen deficiency (ACOG, 2007). The bony pelvis has an exaggerated lumbar spine curve and downward tilt to it. The bladder rests on the symphysis and the posterior organs rest on the sacrum and coccyx. The pelvis holds the organs, but a woman's erect posture causes a funneling effect and constant downward pressure.

PELVIC ORGAN PROLAPSE

Pelvic organ prolapse (from the Latin *prolapsus*, a slipping forth) refers to the abnormal descent or herniation of the pelvic organs from their original attachment sites or their normal position in the pelvis. POP occurs when structures of the pelvis shift and protrude into or outside of the vaginal canal. The Egyptians were the first to describe prolapse of the genital organs. Hippocrates made reference to placing a pomegranate half into the vagina to treat organ prolapse. A disorder exclusive to women, POP rarely results in severe morbidity or mortality but can affect a woman's daily activities and quality of life.

It is difficult to determine the incidence of POP, as the disorder is often asymptomatic and many women do not seek treatment. It has been estimated, however, that up to 75% of all women who have given birth experience POP (ACOG, 2007). With the aging of the population, POP and its associated symptoms are becoming increasingly common (Bartoletti, 2007).

The treatment and diagnosis of POP is challenging and problematic.

Types of Pelvic Organ Prolapse

The four most common types of genital prolapse are cystocele, rectocele, enterocele, and uterine prolapse (Fig. 7.1):

- **Cystocele** occurs when the posterior bladder wall protrudes downward through the anterior vaginal wall.
- **Rectocele** occurs when the rectum sags and pushes against or into the posterior vaginal wall.
- **Enterocele** occurs when the small intestine bulges through the posterior vaginal wall (especially common when straining).
- **Uterine prolapse** occurs when the uterus descends through the pelvic floor and into the vaginal canal. Multiparous women are at particular risk for uterine prolapse.

The extent of uterine prolapse is described in terms of degree:

- First degree: prolapse of the organ into the vaginal canal
- Second degree: cervix descends to the vaginal introitus
- Third degree: cervix is below the vaginal introitus (Berzuk, 2007)

Etiology

Anatomic support of the pelvic organs is mainly provided by the levator ani muscle complex and the connective tissue attachments of the pelvic organ fascia. Dysfunction of one or both of these components can lead to loss of support and eventually POP. Weakened pelvic floor muscles also prevent complete closure of the urethra, resulting in urine leakage during physical stress. This problem is not limited to older women: urinary incontinence has been documented in women of varying ages, including very young women (Smith, 2007).

Many risk factors for POP have been suggested, but the true cause is likely to be multifactorial. Causes might include:

- Constant downward gravity because of erect human posture
- Atrophy of supporting tissues with aging and decline of estrogen levels
- Weakening of pelvic support related to childbirth trauma
- Reproductive surgery
- Family history of POP
- Young age at first birth

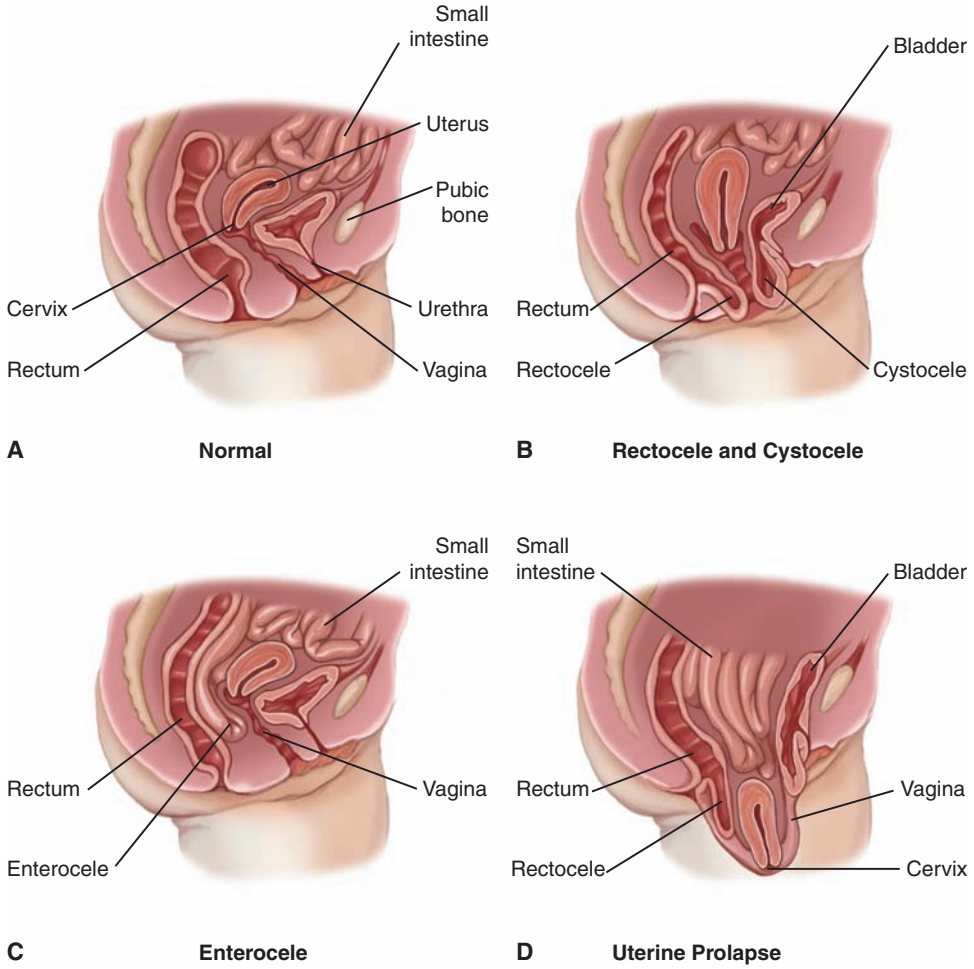

FIGURE 7.1 Types of pelvic prolapses. (**A**) Normal. (**B**) Rectocele and cystocele. (**C**) Enterocele. (**D**) Uterine prolapse.

- Connective tissue disorders
- Infant birthweight of more than 4,500 g
- Pelvic radiation
- Increased abdominal pressure secondary to:
  - Lifting of children or heavy objects
  - Straining due to chronic constipation
  - Respiratory problems or chronic coughing
  - Obesity (Jelovsek, Maher, & Barber, 2007)

Therapeutic Management

Treatment options for POP depend on the symptoms and their effect on the woman's quality of life. Important considerations when deciding on nonsurgical or surgical options include the severity of symptoms, the woman's preferences, the woman's health status, age, and suitability for surgery, and the presence of other pelvic conditions (urinary or fecal incontinence). When surgery is being considered, the nature of the procedure and the likely outcome must be fully explained and discussed with the woman and her partner. Treatment options for POP include Kegel exercises, estrogen replacement therapy, dietary and lifestyle modifications, use of pessaries or the Colpexin Sphere, and surgery (see Evidence-Based Practice 7.1).

Kegel Exercises

Kegel exercises strengthen the pelvic floor muscles to support the inner organs and prevent further prolapse. The purpose of pelvic floor exercises is to increase the muscle volume, which will result in a stronger muscular contraction. Kegel exercises might limit the progression of mild prolapse and alleviate mild prolapse symptoms, including low back pain and pelvic pressure. They will not, however, help severe uterine prolapse.

Hormone Replacement Therapy

Hormone replacement therapy (orally, transdermally, or vaginally) may improve the tone and vascularity of the supporting tissue in perimenopausal and menopausal women by increasing blood perfusion and the elasticity of the vaginal wall.

EVIDENCE-BASED PRACTICE 7.1
Is Conservative Management of Pelvic Organ Prolapse Effective in Women?

● Study
Pelvic organ prolapse (protrusion of the uterus, cervix, bladder, or bowel into the vagina because of weakness in the tissues that normally support them) is common; in fact, some degree of prolapse is seen in 50% of parous women. The symptoms vary depending on the type of prolapse. Treatments include surgery, mechanical devices, and conservative management. Conservative treatments, such as pelvic floor muscle training or lifestyle change, are commonly recommended for women with mild or moderate prolapse. A study was done to assess the effects of conservative management (physical and lifestyle interventions) for women with pelvic organ prolapse in comparison with no treatment or other treatment options (e.g., mechanical devices or surgery).

▲ Findings
This review found three randomized trials of conservative management for pelvic organ prolapse.

One relatively large trial of an exercise program for elderly Thai women living in the community was not sufficiently well conducted or reported to provide reliable findings.

A feasibility study (n = 47 women) found that pelvic floor muscle training, delivered by a physiotherapist to symptomatic women in an outpatient setting, may reduce the severity of prolapse. The study provided some evidence of benefit, which was sufficient to justify the large trial that is planned to follow it.

The third trial claimed benefits but was reported in a way that could not be used in the analysis.

Overall, the evidence found in this review was not sufficient to judge the value of conservative management of pelvic organ prolapse. Large, better-quality, randomized controlled trials are still needed.

■ Nursing Implications
Pelvic organ prolapse is a significant clinical issue among women of all ages, and it often results in discomfort, altered lifestyle, and urinary incontinence. Although this review did not identify a clear-cut first-line treatment, nurses can continue to stress lifestyle changes such as weight loss and daily pelvic floor strengthening exercises to improve the client's quality of life.

Hagen, S., Stark, D., Maher. C., & Adams, E. (2006). Conservative management of pelvic organ prolapse in women. *Cochrane Database of Systematic Reviews* 2006, Issue 4. Art. No.: CD003882. DOI: 10.1002/14651858.CD003882.pub3.

▶ *Take* NOTE!

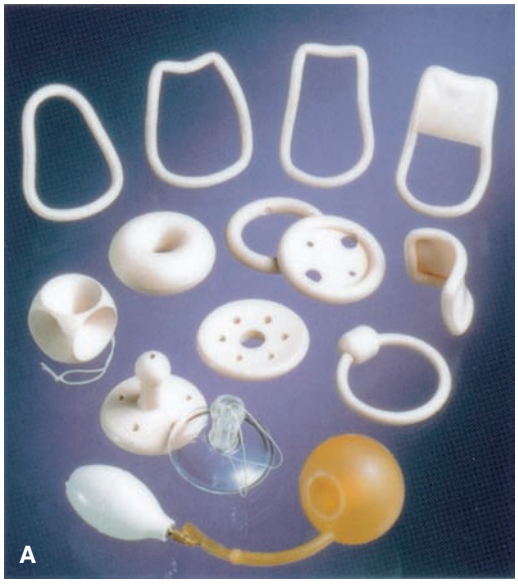
Before hormone therapy is considered, a thorough medical history must be taken to assess her risk for complications (e.g., endometrial cancer, myocardial infarction, stroke, breast cancer, pulmonary emboli, and deep vein thrombosis). Because of these risks, estrogens, with or without progestins, should be given at the lowest effective dose and for the shortest duration consistent with the treatment goals and risks for the individual woman (ACOG, 2007).

Dietary and Lifestyle Modifications
Dietary and lifestyle modifications may help prevent pelvic relaxation and chronic problems later in life. Dietary habits can exacerbate the prolapse by causing constipation and consequently chronic straining. The stools of a constipated woman are hard and dry, and typically she must strain while bearing down to defecate. This straining to pass a hard stool increases intra-abdominal pressure, which over time causes the pelvic organs to prolapse. Dietary modifications can help to establish regular bowel movements without discomfort and eliminate flatus and bloating.

Pessaries
A **pessary** is a silicone or plastic device that is placed into the vagina to support the uterus, bladder, and rectum as a space-filling device, replacing normal pressure on the vaginal walls when levator ani support is unreliable (Fig. 7.2). Although there are many types and shapes, the most commonly used pessary is a firm ring that presses against the wall of the vagina and urethra to help decrease leakage and support a prolapsed vagina or uterus. Pessaries are of two main types:

- Support pessaries, which rest under the symphysis and sacrum and elevate the vagina (e.g., Ring, Gehrung, and Hodge pessaries)
- Space-occupying pessaries, which are designed to manage severe prolapse by supporting the uterus even with a lack of vaginal tone (e.g., cube, doughnut, and inflatable Gellhorn pessaries)

Indications for pessary use include uterine prolapse or cystocele, especially among elderly clients for whom surgery is contraindicated; younger women with prolapse



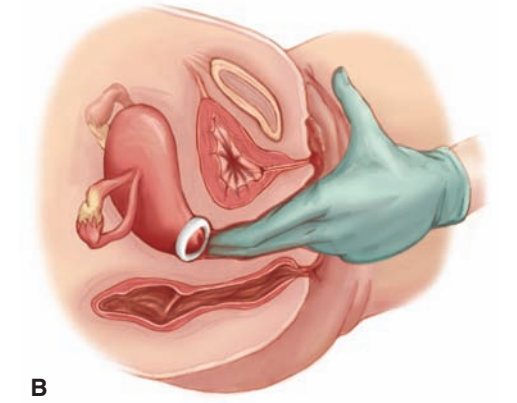


FIGURE 7.2 Examples of pessaries. (**A**) Various shapes and sizes of pessaries available. (**B**) Insertion of one type of pessary.

who plan to have additional children; and women with marked prolapse who prefer to use a pessary rather than undergo surgery (Newman, 2007). Many women use pessaries for only a short period of time and become free of symptoms. Long-term use can lead to pressure necrosis in some women; in this situation other methods of support should be explored.

Pessaries are fitted by trial and error; the woman often needs to try several sizes or styles. The largest pessary that the woman can wear comfortably is generally the most effective. The woman should be instructed to report any discomfort or difficulty with urination or defecation while wearing the pessary.

Colpexin Sphere

A new intravaginal device, the Colpexin Sphere, which became available in 2006, supports the pelvic floor muscle and facilitates rehabilitation of the pelvic floor muscles. Although pessaries may support a prolapsed pelvic organ, they do not allow for concomitant strengthening of pelvic floor musculature and they do not reduce urine leakage (Smith, 2007). The Colpexin Sphere is a polycarbonate sphere with a locator string that is fitted above the hymenal ring to support the pelvic floor muscle. The sphere is used in conjunction with pelvic floor muscle exercises, which should be performed daily.

Surgical Interventions

Surgical interventions for genital organ prolapse are designed to correct specific defects, with the goals being to restore normal anatomy and to preserve function (ACOG, 2007). Surgery is not an option for all women. Women who are at high risk of suffering recurrent prolapse after a surgical repair or who have morbid obesity, chronic obstructive pulmonary disease, or medical conditions in which general anesthesia would be risky are not good candidates for surgical repair (Bartoletti, 2007), and noninvasive treatment strategies should be discussed with them.

Surgical interventions might include anterior or posterior colporrhaphy (to repair a cystocele or rectocele) and vaginal hysterectomy (for uterine prolapse).

An anterior and posterior colporrhaphy may be effective for a first-degree prolapse. This surgical procedure tightens the anterior and posterior vaginal wall, thus repairing a cystocele or rectocele. The pubocervical fascia (supportive tissue between the vagina and bladder) is folded and sutured to bring the bladder and urethra in proper position (Lazarou & Scotti, 2007).

A vaginal hysterectomy is the treatment of choice for uterine prolapse because it removes the prolapsed organ that is bringing down the bladder and rectum with it. It can be combined with an anterior and posterior repair if a cystocele or rectocele is present.

Nursing Assessment

Nursing assessment for women with POP includes a thorough health history and physical examination and several laboratory and diagnostic tests.

Health History and Clinical Manifestations

The cause of prolapse is multifactorial, with vaginal childbirth, advancing age, and increasing body mass index as the most consistent risk factors (Jelovsek, Maher, & Barber, 2007). Assessment of risk factors (chronic straining, hysterectomy, normal aging, and abnormalities of connective tissue) in the woman's history will assist the health care provider in the diagnosis and treatment of POP. The history should include questions about:

- The woman's obstetrical history (number of pregnancies, weight of newborns, pregnancy spacing)
- Chronic respiratory condition (chronic coughing)
- Menopausal status
- Weight history (loss or gain)

- Constipation (frequency and chronicity)
- Age
- Family history (family member with POP)
- Urinary incontinence
- Previous pelvic surgeries

Assess for clinical manifestations of POP. POP is often asymptomatic, but when symptoms do occur, they are often related to the site and type of prolapse. Symptoms common to all types of prolapses are a feeling of dragging, a lump in the vagina, or something "coming down." Women with POP can present either with one symptom, such as vaginal bulging or pelvic pressure, or with several complaints, including many bladder, bowel, and pelvic symptoms. Symptoms associated with POP are summarized in Box 7.1.

Women present with varying degrees of descent. Uterine prolapse is the most troubling type of pelvic relaxation because it is often associated with concomitant defects of the vagina in the anterior, posterior, and lateral compartments (Lazarou & Scotti, 2007).

BOX 7.1 Symptoms Associated With Pelvic Organ Prolapse

- Urinary symptoms
  - Stress incontinence
  - Frequency (diurnal and nocturnal)
  - Urgency and urge incontinence
  - Hesitancy
  - Poor or prolonged stream
  - Feeling of incomplete emptying
- Bowel symptoms
  - Difficulty in defecation
  - Incontinence of flatus or liquid or solid stool
  - Urgency of defecation
  - Feeling of incomplete evacuation
  - Rectal protrusion or prolapse after defecation
- Sexual symptoms
  - Inability to have frequent intercourse
  - Dyspareunia
  - Lack of satisfaction or orgasm
  - Incontinence during sexual activity
- Other local symptoms
  - Pressure or heaviness in the vagina
  - Pain in the vagina or perineum
  - Low back pain after long periods of standing
  - Palpable bulge in the vaginal vault
  - Difficulty walking due to a protrusion from the vagina
  - Difficulty inserting or keeping a tampon in place
  - Vaginal-cervical mucosa hypertrophy, excoriation, ulceration, and bleeding
  - Abdominal pressure or pain (Jelovsek, Maher, & Barber, 2007; Smith, 2007)

Physical Examination

The pelvic examination performed by the health care provider includes an external genital inspection to visualize any obvious protrusion of the uterus, bladder, urethra, or vaginal wall occurring at the vaginal opening. Usually the woman is asked to perform the Valsalva maneuver (bearing down) while the examiner notes which organ prolapses first and the degree to which it occurs. Any urine leakage during the examination is important to note. The woman is asked to contract the pubococcygeal muscles (Kegel exercise); the health care provider inserts two fingers into the vagina to assess the strength and symmetry of the contraction. Since genital organ prolapse can cause urinary symptoms such as incontinence, bladder function should be assessed by determining postvoid residual with a catheter. If the woman has more than 100 mL of retained urine, she should be referred for further urodynamic evaluation and testing.

Laboratory and Diagnostic Tests

Common laboratory tests that may be ordered to determine the cause of POP might include a urinalysis to rule out a bacterial infection, urine culture to identify the specific organism if present, visualization of urine loss during the pelvic examination, and measurement of postvoid urine volume.

Nursing Management

Help the woman understand the nature of the condition, the treatment options, and the likely outcomes. Nursing considerations might include the following:

- Describe normal anatomy and causes of pelvic prolapse.
- Assess how this condition has affected the woman's life.
- Outline the options, with the advantages and disadvantages of each.
- Allow the client to make the decision that is right for her.
- Provide education.
- Schedule preoperative activities needed for surgery.
- Reassure the client that there is a solution for her symptoms.
- Provide community education about genital prolapse.

Nursing Care Plan 7.1 provides an overview of care for a woman with POP.

Encourage Pelvic Floor Muscle Training

Encourage the woman to perform Kegel exercises daily (Teaching Guidelines 7.1). Discuss current research findings and educate the woman about hormone therapy, allowing the woman to make her own decision on whether to use hormones. Controversy still exists regarding the benefits versus the risks of taking hormones, so the woman must weigh this option carefully (Luft, 2006).

Encourage Dietary and Lifestyle Modifications

Instruct clients to increase dietary fiber and fluids to prevent constipation. A high-fiber diet with an increase in

Nursing Care Plan 7.1

OVERVIEW OF A WOMAN WITH PELVIC ORGAN PROLAPSE (POP)

Katherine, a 62-year-old multiparous woman, came to her gynecologist with complaints of a chronic dragging or heavy painful feeling in her pelvis, lower backache, constipation, and urine leakage. Her symptoms increase when she stands for long periods. She hasn't had menstrual cycles for at least a decade. She tells you, "I'm not taking any of those menopausal hormones."

NURSING DIAGNOSIS: Pain related to relaxation of pelvic support and elimination difficulties

Outcome Identification and Evaluation

Client will report an acceptable level of discomfort within 1 to 2 hours of intervention as evidenced by a rating of less than 4 on a 0-to-10 pain scale.

Interventions: Providing Pain Management

- Obtain a thorough pain history, including ongoing pain experiences, methods of pain control used, what worked, what didn't, any allergies to pain medications, and the effect of pain on her activities of daily living *to provide a baseline and enable a systematic approach to pain management.*
- Assess the location, frequency, severity, duration, precipitating factors, and aggravating/alleviating factors *to identify characteristics of the client's pain to plan appropriate interventions.*
- Educate client about any medications prescribed (correct dosage, route, side effects, and precautions) *to increase the client's understanding of the therapy and promote compliance.*
- Assess problematic elimination patterns *to identify underlying factors from which to plan appropriate prevention strategies.*
- Encourage client to increase fluids and fiber in diet and increase physical activity daily *to promote peristalsis.*
- Assist client with establishing regular toileting patterns by setting aside time daily for bowel elimination *to promote regular bowel function and evacuation.*
- Urge client to avoid the routine use of laxatives *to reduce risk of compounding constipation.*

NURSING DIAGNOSIS: Knowledge deficit related to causes of structural disorders and treatment options

Outcome Identification and Evaluation

Client will demonstrate understanding of current condition and treatments as evidenced by identifying treatment options, making health-promoting lifestyle choices, verbalizing appropriate health care practices, and adhering to treatment plan.

Interventions: Provide Client Education

- Assess client's understanding of pelvic organ prolapse and its treatment options *to provide a baseline for teaching.*
- Review information provided about surgical procedures and recommendations for healthy lifestyle, obtaining feedback frequently, *to validate client's understanding of instructions.*
- Discuss association between uterine, bladder, and rectal prolapse and symptoms *to help client understand the etiology of her symptoms and pain.*
- Have client verbalize and discuss information related to diagnosis, surgical procedure, preoperative routine, and postoperative regimen *to ensure adequate understanding and provide time for correcting or clarifying any misinformation or misconceptions.*
- Provide written material with pictures *to promote learning and help client visualize what has occurred to her body secondary to aging, weight gain, childbirth, and gravity.*
- Discuss pros and cons of hormone replacement therapy, osteoporosis prevention, and cardiovascular events common in postmenopausal women *to promote informed decision making by the client about available menopausal therapies.*
- Inform client about the availability of community resources and make appropriate referrals as needed *to provide additional education and support.*
- Document details of teaching and learning *to allow for continuity of care and further education, if needed.*

TEACHING GUIDELINES 7.1

Performing Kegel Exercises

- Squeeze the muscles in your rectum as if you are trying to prevent passing flatus.
- Stop and start urinary flow to help identify the pubococcygeus muscle.
- Tighten the pubococcygeus muscle for a count of three, and then relax it.
- Contract and relax the pubococcygeus muscle rapidly 10 times.
- Try to bring up the entire pelvic floor and bear down 10 times.
- Repeat Kegel exercises at least five times daily.

fluid intake alleviates constipation by increasing stool bulk and stimulating peristalsis. It is accomplished by replacing refined, low-fiber foods with high-fiber foods. The recommended daily intake of fiber for women is 25 g (Dudek, 2006). In addition to increasing the amount of fiber in her diet, also encourage the woman to drink eight 8-oz glasses of fluid daily and to engage in regular aerobic exercise, which promotes muscle tone and stimulates peristalsis.

Educate the client about other lifestyle changes that will assist with prolapse, such as:

- Achieve ideal weight to reduce intra-abdominal pressure and strain on pelvic organs, including pressure on the bladder.
- Wear a girdle or abdominal support to support the muscles surrounding the pelvic organs.
- Avoid lifting heavy objects to reduce the risk of increasing intra-abdominal pressure, which can push the pelvic organs downward.
- Avoid high-impact aerobics, jogging, or jumping repeatedly to minimize the risk of increasing intra-abdominal pressure, which places downward pressure on the organs.
- Give up smoking to minimize the risk for a chronic "smoker's cough," which increases intra-abdominal pressure and forces the pelvic organs downward.

Provide Teaching for Pessary Use

Educate the woman about pessary use. Discuss complications as part of the instruction. Although the pessary is a safe device, it is still a foreign body in the vagina. Because of this, the most common side effects of the pessary are increased vaginal discharge, urinary tract infections, vaginitis, and odor. This can be reduced by douching with dilute vinegar or hydrogen peroxide. Postmenopausal women with thin vaginal mucosa are susceptible to vaginal ulceration with the use of a pessary. Advise the woman to use estrogen cream to make the vaginal mucosa more resistant to erosion and to strengthen the vaginal walls.

The woman must be capable of managing use of the pessary, either alone or with the help of a caretaker. The most common recommendations for pessary care include removing the pessary twice weekly and cleaning it with soap and water; using a lubricant for insertion; and having regular follow-up examinations every 6 to 12 months after an initial period of adjustment. Educate the woman in the care of her pessary so she feels comfortable with all aspects of care before leaving the health care facility.

Provide Perioperative Care

Prepare the woman for surgery by reinforcing the risks and benefits of surgery and describing the postoperative course. Explain that a Foley catheter will be in place for up to 1 week, and that she might not be able to urinate due to the swelling after the catheter has been removed. Provide home care instructions for the Foley catheter. She should cleanse the perineal area daily with mild soap and water, especially around where the catheter enters the urinary meatus. If the woman is provided with a leg bag to be worn during waking hours, instruct her to empty it frequently and keep it below the level of the bladder to prevent backflow. The same principles are applied to the primary Foley bag when emptying.

During the recovery period, instruct the client to avoid for several weeks activities that cause an increase in abdominal pressure, such as straining, sneezing, and coughing. In addition, advise her to avoid lifting anything heavy or straining to push anything. Explain to the woman that stool softeners and gentle laxatives might be prescribed to prevent constipation and straining with bowel movements. Pelvic rest will be prescribed until the operative area is healed in 6 weeks.

Promote Prevention Strategies

Limited data are available on ways to prevent POP. Approaches include lifestyle changes that reduce modifiable risk factors, such as losing weight, avoiding heavy lifting, and relieving constipation. Explore with the woman what factors in her lifestyle might be modified to reduce her risk of developing POP (primary prevention), or improve her quality of life after receiving treatment (secondary prevention).

URINARY INCONTINENCE

Urinary incontinence is the involuntary loss of urine sufficient enough to be a social or hygiene problem (Reena, Kekre, & Kekre, 2007). This disorder affects approximately 25 million people in the United States, about 12 million of them women (Berzuk, 2007). It has been

estimated that one in four women experience urinary incontinence at some time in their life, varying in severity from mild to severe (Selby, 2006). It is more common than diabetes and Alzheimer's disease, both of which receive a great deal of press attention. About half the women with incontinence have never discussed the problem with their health care provider because they feel ashamed, embarrassed, guilty, or lacking control (Wallace, 2007).

▶ *Take* NOTE!

Incontinence is preventable, treatable, and often curable. However, many women believe that loss of bladder function is a normal and expected part of aging.

Incontinence can have far-reaching effects. Some women experience anxiety, depression, social isolation, and disruptions in their self-esteem and dignity. It can cause the woman to stop working, traveling, socializing, and enjoying sexual relationships. In addition, incontinence can create a tremendous burden for caretakers and is a common reason for admission to a long-term care facility (Lemack, 2007).

The three most common types of incontinence are urge incontinence (overactive bladder caused by detrusor muscle contractions), stress incontinence (inadequate urinary sphincter function), and mixed incontinence (involves both stress and urge incontinence) (Ogundele & Silverberg, 2007). Comparison Chart 7.1 details these types.

Pathophysiology and Etiology

Urinary continence requires several factors, including effective functioning of the bladder, adequate pelvic floor muscles, neural control from the brain, and integrity of the neural connections that facilitate voluntary control. The bladder neck and proximal urethra function as a sphincter. During urination the sphincter relaxes and the bladder empties. The ability to control urination requires the integrated function of numerous components of the lower urinary tract, which must be structurally sound and function normally. Incontinence can develop if the bladder muscles become overactive due to weakened sphincter muscles, if the bladder muscles become too weak to contract properly, or if signals from the nervous system to the urinary structures are interrupted. A major factor in women that contributes to urinary continence is the estrogen level, because this hormone helps maintain bladder sphincter tone. In perimenopausal or menopausal women, incontinence can be a problem as estrogen levels begin to decline and genitourinary changes occur. In simple terms, the bladder is the reservoir, the urethra is the seal, and the levator ani muscle is the gate that holds pressure against the outflow of urine by supporting the urethra and bladder from below. When there is a dysfunction of any of the three structures, incontinence occurs.

Contributing factors in urinary incontinence include:

- Fluid intake, especially alcohol, carbonated drinks, and caffeinated beverages
- Constipation: alters the position of the pelvic organs and puts pressure on the bladder
- Habitual "preventive" emptying: may result in training the bladder to hold only small amounts of urine
- Advancing age: age-related anatomic changes provide less pelvic support
- Pregnancy and childbirth: damage to pelvic structures during childbirth
- Obesity: increases abdominal pressure (Hines & Miller, 2006)

Therapeutic Management

Treatment options depend on the type of urinary incontinence. In general, the least invasive procedure with the

COMPARISON CHART 7.1 **Urge Incontinence vs. Stress Incontinence**

	Urge Incontinence	Stress Incontinence
Description	Precipitous loss of urine, preceded by a strong urge to void, with increased bladder pressure and detrusor contraction	Accidental leakage of urine that occurs with increased pressure on the bladder from coughing, sneezing, laughing, or physical exertion
Etiology	Causes might be neurologic, idiopathic, or infectious	Develops commonly in women in their 40s and 50s, usually as the result of weakened muscles and ligaments in the pelvis following childbirth
Signs and Symptoms	Urgency, frequency, nocturia, and a large amount of urine loss	Involuntary loss of a small amount of urine in response to physical activity that raises intra-abdominal pressure

fewest risks is the first choice for treatment. Surgery is used only if other methods have failed. There is a widespread belief that urinary incontinence is an inevitable problem of getting older and that little or nothing can be done to relieve symptoms or reverse it. Nothing is further from the truth, and attitudes must change so that women feel comfortable seeking help for this embarrassing condition.

For many women with urge incontinence, simple reassurance and lifestyle interventions might help. However, if more than simple lifestyle measures are needed, effective treatments might include:

- Bladder training to establish normal voiding intervals (every 3 to 5 hours)
- Kegel exercises to strengthen the pelvic floor musculature
- Pessary ring to support pelvic structures that have weakened
- Pharmacotherapy to reduce the urge to void. Anticholinergic agents such as oxybutynin (Ditropan) or tolterodine (Detrol) might be prescribed. The most common side effects of anticholinergic agents are dry mouth, blurred vision, constipation, nausea, dizziness, and headaches (Lemack, 2007).

For women with stress incontinence, treatment is not always a cure, but it can minimize the impact of this condition on the woman's quality of life. Some treatment options for stress incontinence might include:

- Weight loss if needed
- Avoidance of constipation
- Smoking cessation
- Kegel exercises to strengthen the pelvic floor
- Pessaries
- Weighted vaginal cones to improve the tone of pelvic floor muscles
- Periurethral injection (injecting a bulking agent [collagen] to form a bulge that brings the urethral walls closer together to achieve a better closure)
- Medications such as duloxetine (Cymbalta, Yentreve) to increase urethral sphincter contractions during the storage phase of the urination cycle
- Estrogen replacement therapy to improve bladder sphincter tone
- Surgery to correct genital prolapse and improve urethral and bladder tone

Nursing Assessment

The assessment of the incontinent woman includes a history, physical examination, laboratory tests, and possibly urodynamic testing. The onset, frequency, severity, and pattern of incontinence should be determined, as well as any associated symptoms such as frequency, dysuria, urgency, and nocturia. Incontinence may be quantified by asking the woman if she wears a pad and how often the pad is changed. A review of the woman's current medications, including over-the-counter medications, should be included in the history.

A complete physical examination should be carried out by the health care provider; it should include a neurologic assessment and pelvic and rectal examinations. The presence of associated POP should be noted because it can contribute to the woman's voiding problems and may have an impact on diagnosis and treatment. A rectal examination is done to evaluate sphincter tone and perineal sensation.

A urinalysis is performed to look for hematuria, pyuria, glucosuria, or proteinuria. A urine culture is done if there is pyuria or bacteriuria. Postvoid residual should be measured either with pelvic ultrasound or directly with a catheter. If the residual exceeds the limit set, urodynamic testing is then used to diagnose the incontinence.

Nursing Management

Incontinence can be devastating and can cause psychosocial concerns and isolation. Nurses can encourage women with troublesome symptoms to seek help. Discuss the treatment options with the client, including benefits and potential outcomes, and encourage her to select the continence treatment best for her lifestyle. Provide education about good bladder habits and strategies to reduce the incidence or severity of incontinence (Teaching Guidelines 7.2). Provide support and encouragement to ensure compliance. Remember that aging can increase the risk of incontinence,

TEACHING GUIDELINES 7.2

Managing Urinary Incontinence

- Avoid drinking too much fluid (i.e., 1.5 L total daily limit), but do not decrease your intake of fluids.
- Reduce intake of fluids and foods that are bladder irritants and precipitate urgency, such as chocolate, caffeine, sodas, alcohol, artificial sweetener, hot spicy foods, orange juice, tomatoes, and watermelon (Lemack, 2007).
- Increase fiber and fluids in your diet to reduce constipation.
- Control blood glucose levels to prevent polyuria.
- Treat chronic cough.
- Remove any barriers that delay you from reaching the toilet.
- Practice good perineal hygiene by using mild soap and water. Wipe from front to back to prevent urinary tract infections.
- Become aware of adverse drug effects.
- Take your medications as prescribed.
- Continue to do pelvic floor (Kegel) exercises.

but incontinence is not an inevitable part of aging. Review the anatomy and physiology of the urinary system and offer simple explanations to help the woman cope with urinary alterations. Therapeutic listening is important. Be aware of the courage it takes for a woman to disclose an embarrassing condition.

▸ *Consider* THIS!

Life can be complicated and embarrassing at times when we least expect it. I met a man in church who seemed interested in me, and he asked me out for coffee after Sunday services. I have been alone for 10 years and this prospect seemed exciting to me. We talked for hours over coffee and seemed to have a great deal in common, especially since both of us had lost our spouses to cancer. He asked me to go square dancing with him, since that was an activity we both had enjoyed in the past with our spouses. I hadn't been out or physically active for ages and didn't realize how my body had changed with age.

It was during the first dance that I noticed a wet sensation between my legs, which I was unable to control. I managed to continue on and pretend that all was fine, but then realized what many of my friends were talking about—stress incontinence. Not being able to control one's urine is very embarrassing and it complicates your life, but I made up my mind that it wasn't going to control me!

Thoughts: Gravity and childbirth take a toll on women's reproductive organs by bringing them downward. This woman is not going to let stress incontinence curtail her outside activity, which demonstrates a good attitude. What can be done about her embarrassing accidents? Were there any preventive strategies she could have used at an earlier age?

▸ *Take* NOTE!

Simple diet and lifestyle alterations, combined with a proper pelvic floor muscle strengthening program, can often produce significant improvements for women of all ages.

Benign Growths

The most common benign growths of the reproductive tract include cervical, endocervical, and endometrial polyps; uterine fibroids (leiomyomas); ovarian cysts; genital fistulas; and Bartholin's cysts.

POLYPS

Polyps are small benign growths. The cause of polyp growth is not well understood, but they are frequently the result of infection. Polyps might be associated with chronic inflammation, an abnormal local response to increased levels of estrogen, or local congestion of the cervical vasculature (Kaminski & Hoffman, 2007). Single or multiple polyps might occur. They are most common in multiparous women. Polyps can appear anywhere but are most common on the cervix and in the uterus (Fig. 7.3).

Cervical polyps often appear after menarche. They occur in 2% to 5% of women, and approximately 2% of these polyps have cancerous changes (Verga, 2006). Endocervical polyps are commonly found in multiparous women age 40 to 60. Endocervical polyps are more common than cervical polyps, with a stalk of varied width and length. Endometrial polyps are benign tumors or localized overgrowths of the endometrium. Most endometrial polyps are solitary, and they rarely occur in women younger than 20 years of age. The incidence of these polyps rises steadily with increasing age, peaks in the fifth decade of life, and gradually declines after menopause. They are present in up to 25% of women being seen for abnormal bleeding (Verga, 2006).

Therapeutic Management

Treatment of polyps usually consists of simple removal with small forceps done on an outpatient basis, removal during hysteroscopy, or dilatation and curettage (D&C). The polyp base can be removed by laser vaporization. Because many polyps are infected, an antibiotic may be

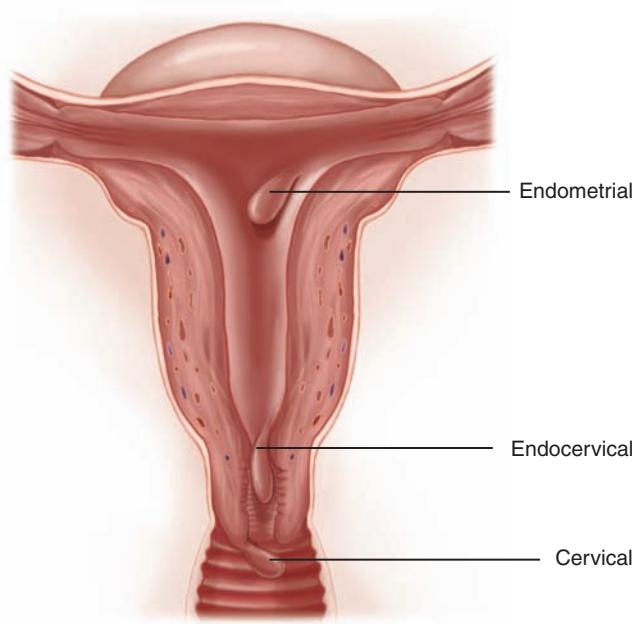

FIGURE 7.3 Cervical, endocervical, and endometrial polyps.

ordered after removal as a preventive measure or to treat early signs of infection.

Although polyps are rarely cancerous, a specimen should be sent after surgery to a pathology laboratory to exclude malignancy. A cervical biopsy typically reveals mildly atypical cells and signs of infection. Polyps rarely return after they are removed. Regularly scheduled Pap smears are suggested for women with cervical polyps to detect any future abnormal growths that may be malignant.

Nursing Assessment

Nursing assessment for a woman with polyps includes assisting with the physical examination and preparing the collected specimen to be sent to the cytologist.

Clinical Manifestations

Assess for clinical manifestations of polyps. Most endocervical polyps are cherry red, while most cervical polyps are grayish-white (Verga, 2006). Cervical and endocervical polyps are often asymptomatic, but they can produce mild symptoms such as abnormal vaginal bleeding (after intercourse or douching, between menses) or discharge. The most common clinical manifestation of endometrial polyps is metrorrhagia (irregular, acyclic uterine bleeding).

Physical Examination and Laboratory and Diagnostic Studies

Typically, cervical polyps are diagnosed when the cervix is visualized through a speculum during the woman's annual gynecologic examination (Kaminski & Hoffman, 2007). Endometrial polyps are not detected on physical examination, but rather with ultrasound or hysteroscopy (introduction of a small camera through the cervix to visualize the uterine cavity).

Nursing Management

Nursing management of polyps involves explaining the condition and the rationale for removal and giving follow-up care instructions. The nurse also assists the health care provider with the removal procedure.

UTERINE FIBROIDS

Uterine fibroids, or leiomyomas, are benign proliferations composed of smooth muscle and fibrous connective tissue in the uterus. Fibroids can occur in the submucous layer, the intramural layer, or the subserous layer of the uterus (Fig. 7.4). They are estrogen-dependent and thus grow rapidly during the childbearing years, when estrogen is plentiful, but they shrink during menopause, when estrogen levels decline. It is believed that these benign tumors develop in up to 50% of all women older than age 30 (Thomason, 2007). Fibroids are the most common indication for hysterectomy in the United States. The peak incidence occurs around the age of 45, and they are two to three times more prevalent in African-American women (Verga, 2006).

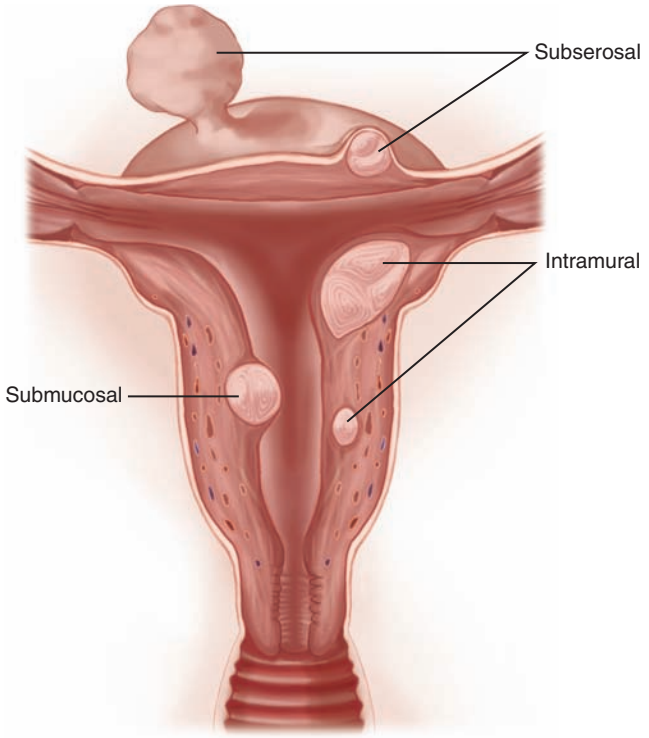

FIGURE 7.4 Submucosal, intramural, and subserosal fibroids.

Etiology

Although the cause of fibroids is unknown, several predisposing factors have been identified, including:

- Age (late reproductive years)
- Genetic predisposition
- African-American ethnicity
- Nulliparity
- Obesity (Alexander et al., 2007)

Therapeutic Management

Treatment depends on the size of the fibroids and the woman's symptoms. There are several options, from watchful waiting to surgery.

Medical Management

The goals of medical therapy are to reduce symptoms and to reduce the tumor size. This can be accomplished with gonadotropin-releasing hormone (GnRH) agonists such as Lupron (leuprolide), Synarel (nafarelin), or Zoladex (goserelin), which induce reversible menopause, or low-dose mifepristone, a progestin antagonist. Both have produced regression and reduced the size of the tumors without surgery, but long-term therapy is expensive and

not tolerated by most women. The side effects of GnRH medications include hot flashes, headaches, mood changes, vaginal dryness, musculoskeletal malaise, bone loss, and depression (Thomason, 2007). Long-term mifepristone therapy can result in endometrial hyperplasia, which increases the risk of endometrial malignancy. Once either therapy is stopped, the fibroids typically recur.

Uterine artery embolization (UAE) is an option in which polyvinyl alcohol pellets are injected into selected blood vessels via a catheter to block circulation to the fibroid, causing it to shrink and producing symptom resolution. After treatment, most fibroids are reduced by 50% within 3 months, but they might recur (Edwards et al., 2007). The failure rate is approximately 10% to 15%, and this therapy should not be performed on women desiring to retain their fertility.

Surgical Management

For women with large fibroids or severe menorrhagia, surgery is preferred over medical treatment. Surgical management might involve myomectomy, laser surgery, or hysterectomy.

Myomectomy involves removing the fibroid alone. A myomectomy is performed via laparoscopy, through an abdominal incision, or through a vaginal approach. The advantage is that only the fibroid is removed; fertility is not jeopardized because this procedure leaves the uterine muscle walls intact. Myomectomy relieves symptoms but does not affect the underlying process; thus, fibroids grow back and further treatment will be needed in the future.

Laser surgery (or electrocauterization) involves destroying small fibroids with lasers. Laser therapy can be done using a vaginal approach or laparoscopically. The laser treatment preserves the uterus, but the process may cause scarring and adhesions, thus impairing fertility (Verga, 2006). Fibroids can return after this procedure. Controversy remains as to whether laser treatment weakens the uterine wall and thus may contribute to uterine rupture in the future.

A hysterectomy is the surgical removal of the uterus. After cesarean section, it is the second most frequently performed surgical procedure for women in the United States. Approximately 600,000 hysterectomies are performed annually in the United States (CDC, 2007). The top three conditions associated with hysterectomies are fibroids, endometriosis, and uterine prolapse (CDC, 2007). A hysterectomy to remove fibroids eliminates both the symptoms and the risk of recurrence, but it also terminates the woman's ability to bear children. Three types of hysterectomy surgeries are available: vaginal hysterectomy, laparoscopically assisted vaginal hysterectomy, and abdominal hysterectomy.

In a vaginal hysterectomy, the uterus is removed through an incision in the posterior vagina. Advantages include a shorter hospital stay and recovery time and no abdominal scars. Disadvantages include a limited operating space and poor visualization of other pelvic organs.

In a laparoscopically assisted vaginal hysterectomy, the uterus is removed through a laparoscope, through which structures within the abdomen and pelvis are visualized. Small incisions are made in the abdominal wall to permit the laparoscope to enter the surgical site. Advantages include a better surgical field, less pain, lower cost, and a shorter recovery time. Disadvantages include potential injury to the bladder and the inability to remove enlarged uteruses and scar tissue.

In abdominal hysterectomy, the uterus and other pelvic organs are removed through an incision in the abdomen. This procedure allows the surgeon to visualize all pelvic organs and is typically used when a malignancy is suspected or a very large uterus is present. Disadvantages include the need for general anesthesia, a longer hospital stay and recovery period, more pain, higher cost, and a visible scar on the abdomen.

Nursing Assessment

Nursing assessment for the woman with uterine fibroids includes a thorough health history and physical examination.

Health History and Clinical Manifestations

The history should include questions about the woman's menstrual cycle, including alterations in the menstrual pattern (e.g., pain or pressure, aggravating and alleviating factors), history of infertility, and any history of spontaneous abortion, which might indicate a space-occupying uterine lesion. Ask if any female relatives have had fibroids, as there is a familial predisposition. Assess for clinical manifestations of uterine fibroids. Symptoms of fibroids depend on their size and location and may include:

- Chronic pelvic pain
- Low back pain
- Iron deficiency anemia secondary to bleeding
- Bloating
- Infertility (with large tumors)
- Dysmenorrhea
- Dyspareunia
- Urinary frequency, urgency, incontinence
- Irregular vaginal bleeding (menorrhagia)
- Feeling of heaviness in the pelvic region

Physical Examination and Laboratory and Diagnostic Studies

The bimanual examination performed by the health care provider typically shows an enlarged, irregular uterus. The uterus may be palpable abdominally if the fibroid is very large. Ultrasound may be used to confirm the diagnosis.

Nursing Management

Provide information about surgery so the woman can make an informed decision. Offer a thorough explanation of the

BOX 7.2 Nursing Interventions for a Woman Undergoing a Hysterectomy

Preoperative Care

- Instruct the patient and her family about the procedure and aftercare.
- Provide interventions to reduce anxiety (due to perceived threats to the woman's self-concept and role functioning) and fear of alteration in body image, complications, and pain. Prepare the woman so she knows what to expect throughout her perioperative experience. Explain postoperative pain management procedures that will be used. Identify the high-risk woman early to reduce her stress.
- Teach turning, deep breathing, and coughing before surgery to prevent postoperative atelectasis and respiratory complications such as pneumonia.
- Encourage the woman to discuss her feelings. Some women equate their femaleness with their reproductive capability, and loss of the uterus could evoke grieving.
- Complete all preoperative orders in a timely manner to allow for rest.

Postoperative Care

- Provide comfort measures.
- Administer analgesics promptly or use a PCA pump.
- Administer antiemetics to control nausea and vomiting per order.
- Change the client's linens and gown frequently to promote hygiene.
- Change the client's position frequently and use pillows for support to promote comfort and pain management.
- Assess the incision, the dressing, and vaginal bleeding and report if bleeding is excessive (soaking perineal pad within an hour).
- Monitor elimination and provide increased fluids and fiber to prevent constipation and straining.
- Encourage ambulation and active range-of-motion exercises when in bed to prevent thrombophlebitis and venous stasis.
- Monitor vital signs to detect early complications.
- Be comfortable discussing sexual concerns with the client.

Discharge Planning

- Advise the client to reduce her activity level to avoid fatigue, which might inhibit healing.
- Advise the client to rest when she is tired and to increase her activity level slowly.
- Educate the client on the need for pelvic rest (nothing in the vagina) for 6 weeks.
- Instruct the client to avoid heavy lifting or straining for about 6 weeks to prevent an increase in intra-abdominal pressure, which could weaken her sutures.
- Teach the client the signs and symptoms of infection.
- Advise the woman to take showers instead of tub baths to reduce the risk for infection.
- Encourage the client to eat a healthy diet with increased intake of fluids to prevent dehydration and fluid and electrolyte imbalance.
- Instruct the client to change her perineal pad frequently to prevent infection.
- Explain and schedule follow-up care appointments as needed.
- Provide information about community resources for support/help.

procedure and aftercare (Box 7.2). A woman undergoing a hysterectomy for the treatment of fibroids often needs special care.

GENITAL FISTULAS

Genital fistulas are abnormal openings between a genital tract organ and another organ, such as the urinary tract or the gastrointestinal tract. A fistula can result from a congenital anomaly, surgical complications, Bartholin's gland abscesses, radiation, or malignancy, but the majority of fistulas that occur worldwide are related to obstetric trauma (Husain et al., 2007). During normal labor, the bladder is displaced upward into the abdomen and the anterior vaginal wall, the base of the bladder, and the urethra are compressed between the fetal head and the posterior pubis. When labor is obstructed or prolonged, this unrelieved compression causes ischemia, which causes pressure necrosis and subsequent fistula formation.

Common types of fistulas include:

- Vesicovaginal: communication between the bladder and genital tract
- Urethrovaginal: communication between the urethra and the vagina
- Rectovaginal: communication between the rectum or sigmoid colon and the vagina

The direct consequences of this damage include urinary incontinence and fecal incontinence if the rectum is involved. This tragic condition has plagued women since the beginning of history (Hamilton, Spencer, & Evans, 2007).

Therapeutic Management

Many small fistulas will heal without treatment, but large fistulas often require surgical repair; surgery may be postponed until the edema or inflammation in the surrounding tissues has dissipated. Surgical repair of fistulas is associated with a high success rate if it is done in a timely

manner, but larger fistulas and those of long duration have a poorer prognosis (Kriplani et al., 2007).

Nursing Assessment

The history should include questions about any changes in the woman's urinary and bowel patterns. Assess for common signs and symptoms of fistulas, which are related to the type of fistula. If the opening involves the rectum, feces and flatus will leak through the vagina. If it involves the bladder, urine will leak from the vagina. Depending on the location and size of the fistula, the woman may or may not experience discomfort. The health care provider can detect these abnormal openings through inspection and palpation during the pelvic examination. Diagnostic or laboratory tests are generally not ordered once this condition is found.

Nursing Management

Provide guidance and support. Offer information to help the woman learn about her condition and, with appropriate intervention, to improve her quality of life. Begin by making sure the woman understands her anatomy and why she is having such symptoms. Provide a thorough explanation of the treatment options so that she can make an informed decision. Be sensitive to the woman's feeling of shame and fear about her incontinence; these feelings may be why she delayed seeking treatment. Address all of the woman's needs, both physical and emotional.

BARTHOLIN'S CYSTS

A Bartholin's cyst is a swollen, fluid-filled, sac-like structure that results when one of the ducts of the Bartholin's gland becomes blocked. The cyst may become infected and an abscess may develop in the gland. The Bartholin's glands are two mucus-secreting glandular structures with duct openings bilaterally at the base of the labia minora near the opening of the vagina that provide lubrication during sexual arousal. Bartholin's cysts are the most common cystic growths in the vulva, affecting approximately 2% of women at some time in their life (Patil, Sultan, & Thakar, 2007).

Therapeutic Management

Treatment can be conservative or surgical depending on the symptoms, the size of the cyst, and whether it is infected or not. Small asymptomatic cysts do not require treatment. Sitz baths along with analgesics are used to reduce discomfort. Antibiotics are prescribed if the gland is infected. The aim of treatment for a cyst or abscess is to create a fistulous tract from the dilated duct to the outside vulva by incision and drainage (I&D). However, cysts or abscesses tend to return if this option is used.

Other treatment options beyond I&D include placement of a Word catheter to prevent closure and to allow drainage and use of a carbon dioxide laser to remove the cyst. After the Word catheter is inserted, the balloon tip is inflated and it is left in place for 4 to 6 weeks. This procedure is a safe and effective alternative to surgery (Haider et al., 2007). Treatment for a pregnant woman with a Bartholin's cyst depends on the severity of the symptoms and whether an infection is present. Surgery may be delayed until after the woman gives birth if there are no symptoms.

Nursing Assessment

Nursing assessment for the woman with a Bartholin's cyst includes a thorough health history and physical examination and laboratory and diagnostic tests.

Health History

The history should include questions about the woman's sexual practices and protective measures used. Assess for common signs and symptoms of Bartholin's cysts. The woman may be asymptomatic if the cyst is small (less than 5 cm) and not infected. If infection is present, symptoms include varying degrees of pain, especially when walking or sitting; unilateral edema; redness around the gland; and dyspareunia. Extensive inflammation may cause systemic symptoms. Abscess formation occurs when the cystic fluid becomes infected. An abscess usually develops rapidly over a 2- to 3-day period and may spontaneously rupture. A history of sudden relief of pain following profuse discharge is highly suggestive of spontaneous rupture (Schuiling & Likis, 2006).

Physical Examination and Laboratory and Diagnostic Studies

The diagnosis of Bartholin's cysts or abscesses is primarily made during a physical examination when a protruding tender labial mass is located. In women over the age of 40, there is an increased risk of malignancy, accounting for 2% to 7% of all invasive vulvar malignancies (Patil, Sultan, & Thakar, 2007). Cultures of the purulent abscess fluid and of the cervix should be obtained for *Neisseria gonorrhea* and *Chlamydia trachomatis* to rule out a sexually transmitted infection.

Nursing Management

Nurses must be aware of and knowledgeable about vulvar cysts and treatment options. The woman may be aware of a vulvar cyst secondary to the pain or may be unaware of it if it is asymptomatic. A Bartholin's cyst may be an incidental finding during a routine pelvic examination. Explain the cause of the cyst and assist with cultures if needed. Provide reassurance and support.

OVARIAN CYSTS

An **ovarian cyst** is a fluid-filled sac that forms on the ovary (Fig. 7.5). These very common growths are benign 90% of the time and are asymptomatic in many women (Hackley, Kriebs, & Rousseau, 2007). Ovarian cysts occur in 30% of women with regular menses, 50% of women with irregular menses, and 6% of postmenopausal women (Verga, 2006). When the cysts grow large and exert pressure on surrounding structures, women often seek medical help.

Types of Ovarian Cysts

The most common benign ovarian cysts are follicular cysts, corpus luteum (lutein) cysts, theca-lutein cysts, and polycystic ovarian syndrome (PCOS).

Follicular Cysts

Follicular cysts are caused by the failure of the ovarian follicle to rupture at the time of ovulation. Follicular cysts seldom grow larger than 5 cm in diameter; most regress and require no treatment. They can occur at any age but are more common in reproductive-aged women and are rare after menopause. They are detected by vaginal ultrasound.

Corpus Luteum (Lutein) Cysts

A corpus luteum cyst forms when the corpus luteum becomes cystic or hemorrhagic and fails to degenerate after 14 days. These cysts might cause pain and delay the next menstrual period. A pelvic ultrasound helps to make this diagnosis. Typically these cysts appear after ovulation and resolve without intervention.

Theca-Lutein Cysts

Prolonged abnormally high levels of human chorionic gonadotropin (hCG) stimulate the development of theca-lutein cysts. Although rare, these cysts are associated with hydatidiform mole, choriocarcinoma, PCOS, and Clomid therapy.

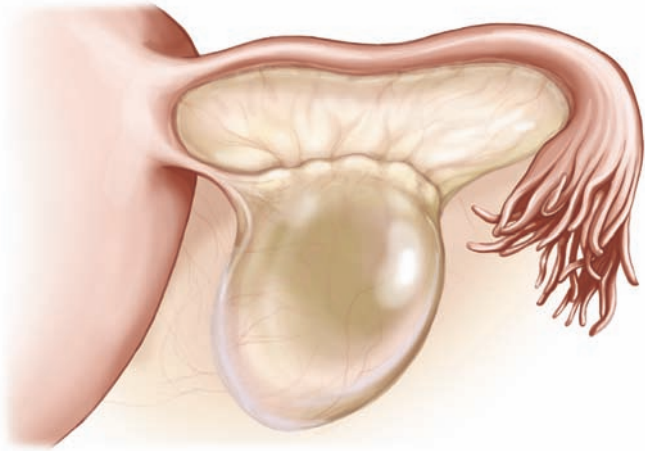

FIGURE 7.5 Ovarian cyst.

Polycystic Ovarian Syndrome

Polycystic ovary syndrome (PCOS) involves the presence of multiple inactive follicle cysts within the ovary that interfere with ovarian function. It is associated with obesity, hyperinsulinemia, elevated luteinizing hormone levels (linked to ovulation), elevated androgen levels (virilization), hirsutism (male-pattern hair growth), follicular atresia (ovarian growth failure), ovarian growth and cyst formation, anovulation (failure to ovulate), and amenorrhea (absence of menstruation or irregular periods). Recent studies also indicate that PCOS is associated with an increase in the risk of uterine fibroids (Wise et al., 2007). It is the most common endocrine disorder in reproductive-age women, affecting 1 in 15 women in the United States (Panidis & Farmakiotis, 2007).

Take NOTE!

Careful attention should be given to this condition because affected women are at increased risk for long-term health problems such as cardiovascular disease, hypertension, dyslipidemia, type 2 diabetes (half of all women), and cancer (endometrial, breast, and ovarian) (Lorenz & Wild, 2007).

Initially PCOS was called Stein-Leventhal syndrome after its researchers, but it is now recognized to be an anabolic syndrome (Vignesh & Mohan, 2007). Its etiology is not clearly understood, but studies suggest a genetic (autosomal-dominant) component (Speroff & Mishell, 2007).

Therapeutic Management

Treatment of ovarian cysts focuses on differentiating a benign cyst from a solid ovarian malignancy. Transvaginal ultrasound is useful in distinguishing fluid-filled cysts from solid masses. Laparoscopy may be needed to remove the cyst, if it is large and pressing on surrounding structures. For smaller cysts, monitoring with repeat ultrasounds every 3 to 6 months might be in order (Helm, 2007). Oral contraceptives are often prescribed to suppress gonadotropin levels, which may help resolve the cysts. Pain medication is also prescribed if needed.

Management of PCOS includes both drug and nondrug therapy, along with lifestyle modifications. Goals of therapy focus on reducing the production and circulating levels of androgens, protecting the endometrium against the effects of unopposed estrogens, supporting lifestyle changes to achieve ideal body weight, lowering the risk of cardiovascular disease, avoiding the effects of hyperinsulinemia on the risk of cardiovascular disease and diabetes, and inducing ovulation to achieve pregnancy if desired (see Evidence-Based Practice 7.2). Treatment modalities for PCOS are highlighted in Box 7.3.

EVIDENCE-BASED PRACTICE 7.2

Are Insulin-Sensitizing Drugs More Effective Than the Combined Oral Contraceptive Pill in Minimizing Hirsutism, Acne, Risk of Diabetes, Cardiovascular Disease, and Endometrial Cancer in PCOS?

● Study

Women with polycystic ovary syndrome (PCOS) have excessive hairiness (hirsutism), irregular periods, and acne. They are also at greater risk of developing diabetes, cardiovascular disease, and endometrial cancer. Insulin-sensitizing drugs (ISDs) have recently been advocated as a safer and more effective long-term treatment than the oral contraceptive pill (OCP) in women with PCOS. A study was conducted to assess the effectiveness and safety of ISDs versus the OCP (alone or in combination) in improving clinical, hormonal, and metabolic features of PCOS.

▲ Findings

In women with PCOS, the OCP is more effective than ISDs in improving menstrual pattern and reducing serum androgen (male hormone) levels, whereas the ISD metformin is more effective than the OCP in reducing fasting insulin levels and not increasing triglyceride levels. There is insufficient evidence in favor of either metformin or the OCP in treating hirsutism or acne, or in preventing diabetes, heart disease, or endometrial cancer. The limited data available do not support the preferential use of either ISDs or the OCP (alone or in combination) for the long-term medical management of PCOS.

■ Nursing Implications

Oral contraceptives have been the mainstay of long-term management of PCOS by decreasing LH and FSH secretion and ovarian production of androgens to reduce symptoms. This study compared the ISD metformin to the traditional therapy without conclusive results. PCOS is associated with increased insulin resistance and increased unbound androgen levels. Since this study was inconclusive, nurses can continue to counsel women to improve their lifestyle (e.g., diet, exercise, weight management) to avoid health problems later in life related to diabetes and heart disease.

Costello, M., Shrestha, B., Eden, J., Sjoblom, P., & Johnson, N. (2007). Insulin-sensitizing drugs versus the combined oral contraceptive pill for hirsutism, acne and risk of diabetes, cardiovascular disease, and endometrial cancer in polycystic ovary syndrome. *Cochrane Database of Systematic Reviews* 2007, Issue 1. Art. No.: CD005552. DOI: 10.1002/14651858.CD005552.pub2.

Nursing Assessment

Nursing assessment for the woman with PCOS includes a thorough health history and physical examination and laboratory and diagnostic tests.

Health History

The history should include questions about the woman's symptoms, including onset, location, frequency, quality, intensity, and aggravating and alleviating factors of her discomfort. Note the last menstrual period and whether or not her cycles are regular. Ask about her overall general health and any changes recently noticed, such as a change in abdominal girth without a concomitant weight gain.

Assess for common signs and symptoms of ovarian cysts. Findings might include:

- Hirsutism (face and chin, upper lip, areola, lower abdomen and perineum)
- Alopecia (frontal region and crown of head)
- Virilization (clitoral hypertrophy, deepening of voice, increased muscle mass, breast atrophy, male-pattern baldness)
- Menstrual irregularity and infertility (menorrhagia, anovulation)
- Polycystic ovaries (12 or more follicles on ovaries)
- Obesity (occurs in more than 50% of women with PCOS; occurs in abdominal region, with an increase in the waist–hip ratio)
- Insulin resistance (chronic hyperinsulinemia leads to type 2 diabetes)
- Metabolic syndrome (elevated cholesterol, triglycerides, low-density lipoprotein; risk of cardiovascular disease)
- Increased risk for endometrial cancer, ovarian cancer, breast cancer
- Psychological impact (depression, frustration, anxiety, eating disorders)
- Acne (face and shoulders) (Krantz, 2007)

BOX 7.3 Treatment Modalities for PCOS

- Oral contraceptives to treat menstrual irregularities and acne
- Mechanical hair removal (shaving, waxing, plucking, or electrolysis) to treat hirsutism
- Glucophage (metformin), which improves insulin uptake by fat and muscle cells, to treat hyperinsulinemia; thiazolinediones (Actos, Avandia) to decrease insulin resistance
- Ovulation induction agents (Clomid) to treat infertility
- Lifestyle changes (e.g., weight loss; exercise; balanced, low-fat diet)
- Referral to support groups to help improve emotional state and build self-esteem

Physical Examination and Laboratory and Diagnostic Studies

The physical examination includes inspection, auscultation, and palpation of the abdomen because large ovarian masses may cause visible changes in the abdomen. A complete pelvic examination is performed to assess the location, size, shape, texture, mobility, and tenderness of any palpable mass.

Diagnostic tests include a pregnancy test to rule out ectopic pregnancy. Gonorrhea and chlamydia testing is warranted if an ovarian abscess is suspected. An ultrasound may be ordered to differentiate between functional or simple ovarian cysts and a solid tumor. Additional tests may be performed depending on the findings.

Remember Liz, the client with irregular menses, facial hair, and acne? Her glucose level is elevated, multiple cysts were felt on her ovaries during the pelvic examination, and laboratory tests found elevated lipid and lipoprotein levels. What education should the nurse provide Liz regarding her PCOS diagnosis? What medications might be prescribed to address her abnormal laboratory values?

Nursing Management

Nursing care should include education about the condition, treatment options, diagnostic test arrangements, and referral for surgery if needed. Provide support and reassurance during the diagnostic period to allay anxiety in the client and her family. Reassure the woman that the majority of ovarian cysts are benign, but regardless stress the importance of follow-up care. Listen to the woman's concerns about her appearance, infertility, and facial hair growth. Offer suggestions to help the woman feel better about herself and her health.

Nurses can have a positive impact on women with PCOS through counseling and education. Provide support for women dealing with negative self-image secondary to the physical manifestations of PCOS. Through education, help the woman understand the syndrome and its associated risk factors to prevent long-term health problems. Encourage the woman to make positive lifestyle changes. Make community referrals to local support groups to help the woman build her coping skills.

Liz returns to the clinic a month later for re-evaluation of her PCOS. She has been taking metformin to reduce her insulin resistance and has followed her exercise regimen and reduced her caloric intake to lose weight, but she still complains about her facial hair and acne. What interventions might be helpful to address this problem? What medication might also be prescribed to regularize her menses and relieve the hirsutism?

Key Concepts

- Pelvic support disorders such as pelvic organ prolapse and urinary and fecal incontinence are prevalent conditions in aging women. They cause significant physical and psychological morbidity, with obvious detriment to women's social interactions, emotional well-being, and overall quality of life.
- The four most common types of genital prolapse are cystocele, rectocele, enterocele, and uterine prolapse.
- The purpose of pelvic-floor exercises is to increase the muscle volume, which will result in a stronger muscular contraction. Kegel exercises might limit the progression of mild prolapse and alleviate mild prolapse symptoms, including low back pain and pelvic pressure.
- Urinary incontinence is the involuntary loss of urine sufficient enough to be a social or hygiene problem. It affects approximately 18 million people in the United States, about 11 million of them women.
- The three most common types of incontinence are urge incontinence (overactive bladder caused by detrusor muscle contractions), stress incontinence (inadequate urinary sphincter function), and mixed incontinence (involves both stress and urge incontinence).
- The most common benign growths of the reproductive tract include cervical, endocervical, and endometrial polyps; uterine fibroids (leiomyomas); and ovarian cysts.
- PCOS involves the presence of multiple inactive follicle cysts within the ovary that interfere with ovarian function. Hyperandrogenism, insulin resistance, and chronic anovulation characterize PCOS. Careful attention should be given to this condition because women with it are at increased risk for long-term health problems such as cardiovascular disease, hypertension, dyslipidemia, type 2 diabetes, and cancer (endometrial, breast, and ovarian).

Chapter Worksheet

Multiple Choice Questions

1. When you are interviewing a patient with uterine fibroids, what subjective data would you expect to find in her history?
   a. Cyclic migraine headaches
   b. Urinary urgency
   c. Chronic pelvic pain
   d. Chronic constipation
2. Treatment options available for women with pelvic organ prolapse are:
   a. Pessaries and Kegel exercises
   b. External pelvic fixation devices
   c. Weight gain and yoga
   d. Firm panty-and-girdle garments
3. Which of the following dietary and lifestyle modifications might the nurse recommend to help prevent pelvic relaxation as women age?
   a. Eat a high-fiber diet to avoid constipation and straining.
   b. Avoid sitting for long periods; get up and walk around frequently.
   c. Limit the amount of exercise to prevent overdeveloping muscles.
   d. Space children a year apart to reduce wear and tear on the uterus.
4. Women with polycystic ovarian syndrome (PCOS) are at increased risk for developing which of the following long-term health problems?
   a. Osteoporosis
   b. Lupus
   c. Type 2 diabetes
   d. Migraine headaches
5. Side effects experienced by women taking gonadotropin-releasing hormone (GnRH) agonists for the treatment of fibroids closely resemble those of:
   a. Osteoporosis
   b. Osteoarthritis
   c. Depression
   d. Menopause

Critical Thinking Exercise

1. Faith, a 42-year-old multiparous woman, presents to the women's health clinic complaining of pelvic pain, menorrhagia, and vaginal discharge. She says she has been having these problems for several months. On examination, her uterus is enlarged and irregular in shape. Her blood studies reveal anemia.
   a. What condition might Faith have, based on her symptoms?
   b. What treatment options are available to address this condition?
   c. What educational interventions should the nurse discuss with Faith?

Study Activities

1. Prepare an educational session to teach women how to do Kegel exercises to prevent stress incontinence and pelvic floor relaxation.
2. In a small group, discuss the personal, social, and sexual issues that might affect a woman with pelvic organ prolapse. How might these issues affect her socialization? How might a support group help?
3. List the symptoms that a woman with uterine fibroids might have. Discuss how these symptoms might mimic a more frightening condition and why the woman might delay seeking treatment.
4. A bladder that herniates into the vagina is a _____.
5. A rectum that herniates into the vagina is a _____.

CHAPTER 8

Cancers of the Female Reproductive Tract

KEY TERMS

cervical cancer
cervical dysplasia
colposcopy
cone biopsy
cryotherapy
endometrial cancer
human papillomavirus
ovarian cancer
Papanicolaou (Pap) test
vaginal cancer
vulvar cancer

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms in the chapter.
2. Identify the major modifiable risk factors for reproductive tract cancers.
3. Discuss the risk factors, screening methods, and treatment modalities for cancers of the female reproductive tract.
4. Outline the nursing management needed for the most common malignant reproductive tract cancers in women.
5. Discuss lifestyle changes and health screenings that can reduce the risk of or prevent reproductive tract cancers.
6. List the community resources available for a woman undergoing surgery for cancer of the reproductive tract.
7. Explain the psychological distress felt by women diagnosed with cancer, and outline information that can help them to cope.

Carmella is an obese, 55-year-old woman who presents to her woman's health care provider with vaginal bleeding. She has been through menopause and wonders why she is having a period again. Her history includes infertility and hypertension. Three years ago she had a mastectomy for breast cancer, and she has been taking tamoxifen (Nolvadex) to prevent recurrent breast cancer since her surgery. What risk factors in Carmella's history might predispose her to a reproductive tract cancer? What additional information is needed to make a diagnosis?

Wow

The word "cancer" can strike fear into anyone who hears it. But when it involves a reproductive organ, this fear is often magnified.

Cancer is the second leading cause of death for women in the United States, surpassed only by cardiovascular disease (Centers for Disease Control and Prevention [CDC], 2007b). Cardiovascular disease is and should continue to be a major focus of efforts in women's health. However, this should not overshadow the fact that many women between the ages of 35 and 74 are developing and dying of cancer (National Cancer Institute [NCI], 2007a). Women have a one-in-three lifetime risk of developing cancer, and one out of every four deaths is from cancer (Alexander et al., 2007). African-American women have the highest death rates from both heart disease and cancer (CDC, 2007b). According to the American Cancer Society (2008), it is estimated that over 39,000 new cases of uterine cancer (6% of all cancers) and over 22, 000 cases of ovarian cancer (3% of all cancers) will be diagnosed in 2007, with the number of estimated deaths to be over 7,000 and 15,000 respectively.

It has been estimated that in the United States half of all premature deaths, one third of acute disabilities, and one half of chronic disabilities are preventable (NCI, 2007a). Nurses need to focus their energies on screening, education, and early detection to reduce these numbers. Because cancer risk is strongly associated with lifestyle and behavior, screening programs are of particular importance for early detection. There is evidence that prevention and early detection have reduced cancer mortality rates and prevented reproductive cancers (CDC, 2007b).

This chapter begins with a nursing process overview of the care of women with reproductive cancer. It then describes selected cancers of the reproductive system—ovarian, endometrial, cervical, vaginal, and vulvar cancer. The chapter discusses the nurse's role through diagnosis, intervention, and follow-up care. Cancer management requires a multidisciplinary approach, including specialists in surgical, medical, and radiation oncology. The nurse can provide guidance and support to the client as she finds her way through the health care maze.

Nursing Process Overview for the Woman With Cancer of the Reproductive Tract

The word "cancer" is laden with fear and dread. These feelings may be worsened when the cancer involves a woman's reproductive tract. The diagnosis of a reproductive tract cancer can have a profound impact on a woman's sexuality because it affects the very core of her identity as a female. The loss of the reproductive body part as well as the possible loss of childbearing ability can have a significant effect on women and their partners. Nurses need to remember this impact when counseling women and their partners about cancer treatment and side effects and changes in gender roles and sexuality.

When a woman is first diagnosed with a reproductive tract cancer, two primary needs arise: information and emotional support. When the diagnosis is made, the woman typically has many questions, such as, "What is going to happen to me?", "How will this change my life?," and "Will I survive?" Nurses can play a major role in helping women find the answers to their questions and directing them to the resources they need. Two reliable sources of general cancer information are the National Cancer Institute (NCI) and the American Cancer Society (ACS). They can be reached via the Internet or by phone.

The nurse also plays a key role in offering emotional support, determining appropriate sources of support, and helping the woman use effective coping strategies. Many research studies have found that social support from the woman's family, friends, and coworkers is one of the strongest predictors of how well she will cope (Fieler & Henry, 2007). Women without a social support network may need a social work referral or may need to be guided toward support groups to receive the emotional support they need.

In addition, cancer clients have a strong need for hope. Strategies for inspiring hope may include active listening, touch, presence, and helping clients overcome communication barriers. Often it is not what nurses say or do but just their presence that counts.

Assessment

Assessment of a woman with cancer of the reproductive tract involves a thorough history and physical examination. In addition, various laboratory and diagnostic tests may be done to evaluate for a malignancy.

Health History and Physical Examination

Interview the woman carefully to determine any current or past factors that might increase her risk of cancer, such as early menarche, late menopause, sexually transmitted infections, use of hormonal agents, or infertility. Find out if the woman has a family history of cancer. Be thorough in obtaining the woman's past medical history, especially her reproductive, obstetric, and gynecologic history. Ask about her lifestyle and behaviors, including risky behaviors such as engaging in unprotected sexual intercourse or sexual intercourse with multiple partners. Find out if she has had routine or recommended screening procedures.

Ask if the woman has had any symptoms, such as abnormal vaginal bleeding or discharge or vaginal discomfort. Often the symptoms of cancer are vague and nonspecific and the woman may attribute them to another problem, such as aging, stress, or improper diet.

Perform a complete physical examination, including a review of body systems and a pelvic examination. Observe for lesions or masses in the perineal area. Note any masses when palpating the abdomen or when performing the pelvic examination.

Laboratory and Diagnostic Testing

Some of the laboratory and diagnostic tests used to help diagnose cancer of the reproductive tract are discussed in Common Laboratory and Diagnostic Tests 8.1.

Nursing Diagnoses and Related Interventions

Upon completion of a thorough assessment, the nurse might identify several nursing diagnoses, including:

- Deficient knowledge
- Disturbed body image
- Anxiety
- Fear
- Pain

Nursing goals, interventions, and evaluation for the woman with a reproductive cancer are based on the nursing diagnoses. Nursing Care Plan 8.1 may be used as a guide in planning nursing care for the woman with a reproductive cancer. It should be individualized based on the woman's symptoms and needs.

Nurses have traditionally served as advocates in the health care arena and should continue to be on the forefront of health education and diagnosis, acting as leaders in the fight against cancer. Over a half-million women in the United States will be diagnosed with cancer this year alone, and more than half will die of it. The public needs to know that not only are these deaths preventable, but many of the cancers themselves are preventable. Nurses need to work to improve the availability and quality of cancer-screening services, making them accessible to underserved and socioeconomically disadvantaged clients. Through a unified effort by health care professionals, health policy experts, government agencies, health insurance companies, the

COMMON LABORATORY TESTS 8.1

Test	Explanation	Indications	Nursing Implications
Clinical breast examination	Assessment of the breast for abnormal findings; patient may discover lump herself; high-risk history for breast cancer	Identifies palpable mass, skin change, inverted nipple, or unresolved rash	• Educate client to perform breast self-examination and report any abnormalities. • Reinforce need for frequent clinical breast examinations if risk factors are present.
Mammography	Screening modality for breast cancer or any distortion in breast tissue architecture	Detects calcifications, densities, and nonpalpable cancer lesions	Stress importance of annual mammograms for all women after the age of 40 or 50, depending on their risk history.
Pap smear	Cervical cytology screening to diagnose cervical cancers	Aids in detecting abnormal cells of the cervix (from squamocolumnar junction of the cervix; most cervical cancers arise here)	Encourage all sexually active women to receive an annual pelvic examination, including a Pap smear, to promote early detection of cervical cancer.
Transvaginal ultrasound	Screening for pelvic pathology to assist in diagnosing endometrial cancers	Allows measurement of endometrial thickness to determine if endometrial biopsy is needed for postmenopausal bleeding	• Review the risk factors for the development of endometrial cancer and reason for this screening test. • Assist in preparing the patient for this examination.
CA-125	Nonspecific blood test used as a tumor marker	Elevation of marker suggests malignancy but is not specific to ovarian cancer.	• Review risk factors for ovarian cancer and explain that a series of diagnostic tests may be performed (transvaginal ultrasound, CT scan, CA-125) to assist in the diagnosis and treatment plan. • Elevated marker levels are not specific to ovarian cancer; they can be elevated in other types of cancer.

Nursing Care Plan 8.1

OVERVIEW OF A WOMAN WITH A REPRODUCTIVE TRACT CANCER

Molly, a thin 28-year-old woman, comes to the free health clinic complaining of a thin, watery vaginal discharge and spotting after sex. She says she is homeless and has lived "on the streets" for years. Molly says she has had multiple sex partners to pay for her food and cigarettes. She had an abnormal Pap smear "a while back" but didn't return to the clinic for follow-up. She hopes nothing "bad" is wrong with her because she just found a job that will allow her to get off the streets. "I'm worried that I won't be the same if there is something wrong. I don't know what I'd do if there is a problem," she tells you. Cervical cancer is suspected.

NURSING DIAGNOSIS: Anxiety related to uncertainty of diagnosis, possible diagnosis of cancer, and eventual outcome as evidenced by client's report of signs and symptoms, statements of being worried and not knowing what she would do

Outcome Identification and Evaluation

Client will demonstrate measures to cope with anxiety *as evidenced by statements acknowledging anxiety, use of positive coping strategies, and verbalization that anxiety has decreased.*

Interventions: Reducing Anxiety

- Encourage client to express her feelings and concerns *to reduce her anxiety and to determine appropriate interventions.*
- Assess the meaning of the diagnosis to the client, clarify misconceptions, and provide reliable, realistic information *to enhance her understanding of her condition, subsequently reducing her anxiety.*
- Assess client's psychological status *to determine degree of emotional distress related to diagnosis and treatment options.*
- Identify and address verbalized concerns, providing information about what to expect *to decrease uncertainty about the unknown.*
- Assess the client's use of coping mechanisms in the past and their effectiveness *to foster use of positive strategies.*
- Teach client about early signs of anxiety and help her recognize them (e.g., fast heartbeat, sweating, or feeling flushed) *to minimize escalation of anxiety.*
- Provide positive reinforcement that the client's condition can be managed *to relieve her anxiety.*

NURSING DIAGNOSIS: Deficient knowledge related to diagnosis, prevention strategies, disease course, and treatment as evidenced by client's statements about hoping nothing bad is wrong, lack of follow-up for previous abnormal Pap test, and high-risk behaviors

Outcome Identification and Evaluation

Client will demonstrate understanding of diagnosis, *as evidenced by making health-promoting lifestyle choices, verbalizing appropriate health care practices, describing condition once diagnosed, and adhering to measures to comply with therapy.*

Interventions: Providing Client Teaching

- Assess client's current knowledge about her diagnosis and proposed therapeutic regimen *to establish a baseline from which to develop a teaching plan.*
- Review contributing factors associated with development of reproductive tract cancer, including lifestyle behaviors, *to foster an understanding of the etiology of cervical cancer.*
- Review information about treatments and procedures and recommendations for healthy lifestyle, obtaining feedback frequently *to validate adequate understanding of instructions.*
- Discuss strategies, including using condoms and limiting the number of sexual partners, *to reduce the risk of transmission of STIs,* including human papillomavirus (HPV), which is associated with cervical cancer.
- Encourage client to obtain prompt treatment of any vaginal or cervical infections *to minimize the risk for cervical cancer.*
- Urge the client to have an annual Pap smear *to allow screening and early detection.*
- Describe the treatment measures used *to provide client with knowledge of what may be necessary.*
- Provide written material with pictures *to allow for client review and help her visualize what is occurring in her body.*
- Inform client about available community resources and make appropriate referrals as needed *to provide additional education and support.*
- Document details of teaching and learning *to allow for continuity of care and further education, if needed.*

Nursing Care Plan 8.1 (continued)

NURSING DIAGNOSIS: Disturbed body image related to suspected reproductive tract cancer and impact on client's sexuality and sense of self as evidenced by statement of being worried about not being the same

Outcome Identification and Evaluation

Client will verbalize or demonstrate a positive self-esteem in relation to body image as evidenced by positive statements about self, sexuality, and participation in activities with others.

Interventions: Promoting Healthy Body Image

- Assess client's use of self-criticism *to determine client's current state of coping and adjustment.*
- Determine if the client's change in body image has contributed to social isolation *to provide a direction for care.*
- Provide opportunities for client to explore her feelings related to issues of sexuality, including past behaviors that may have placed her at risk, *to minimize feelings of guilt about her condition.*
- Acknowledge the client's feelings about possible changes in her body and sexuality and her illness *to foster trust and allow client to ventilate feelings and concerns.*
- Facilitate contact with other clients with the same type of cancer *to promote sharing of feelings and decrease feelings of isolation.*
- Initiate referrals for counseling and community support groups as necessary *to assist client in gaining a positive image of herself.*

media, educational institutions, and women themselves, along with consistency and continuity, nurses can offer quality care to all women with cancer.

Educating to Prevent Cancer

Nurses need to provide clients with information to help prevent disease and enhance quality of life. Educate women about the importance of consistent and timely screenings to identify cancer early. Emphasize the importance of having an annual pelvic examination. Also stress the need for follow-up screenings as recommended. Provide clients with information if further diagnostic testing is required.

Nurses also play a key role in promoting cancer awareness, prevention, and control. Advocate to improve the availability of cancer-screening services and work to provide public education about risk factors for cancer.

Nurses can be instrumental in helping women to identify and change behaviors that put them at risk for various reproductive tract cancers (Teaching Guidelines 8.1). Do not limit your interventions to providing preventive education only: inform women about the consequences of doing nothing about their conditions and what the long-range outcomes might be without treatment. For example, stress the importance of visiting a health care professional if certain signs and symptoms appear:

- Blood in a bowel movement
- Unusual vaginal discharge or chronic vulvar itching
- Persistent abdominal bloating or constipation
- Irregular vaginal bleeding
- Persistent low backache not related to standing
- Elevated or discolored vulvar lesions
- Bleeding after menopause
- Pain or bleeding after sexual intercourse

Teaching the Client About Her Diagnosis

Provide information about tests that may be required to confirm or rule out the diagnosis. Review with the woman what she has been told about her diagnosis and her understanding of her condition. It is not unusual for the woman to hear the diagnosis and then become overwhelmed by the thought of cancer, blocking out whatever is said after

TEACHING GUIDELINES 8.1

Reducing Your Risk for Cancer

- Don't smoke.
- Drink alcohol only in moderation (no more than one drink daily).
- Be physically active daily.
- Eat a healthy diet.
- Stay current with immunizations.
- Reach and maintain a healthy weight.
- Take preventive medicines if needed.
- Get recommended screening tests:
  - Body mass index (BMI) to identify obesity
  - Mammogram every 1 to 2 years starting at age 40
  - Pap smear every 1 to 3 years if sexually active, between the ages of 21 and 65
  - Cholesterol checked annually starting at age 45
  - Blood pressure checked at least every 2 years
  - Diabetes test if hypertensive or hypercholesterolemic
  - Check for sexually transmitted infections (STIs) if sexually active

Sources: AHRQ, 2007; Mayo Clinic, 2008; WHO, 2008.

that. Answer any questions she may have. Go slowly and repeat the information as necessary. Use written materials to explain and reinforce the teaching. Provide information about her condition and recommended therapies. For example, if a client is undergoing surgery, discuss postoperative issues such as incision care, pain, and activity level. Instruct the client on health maintenance activities after treatment, and inform her and her family about available support resources.

Providing Emotional Support

Once the diagnosis is made, provide the woman and her family with emotional support. Validate the client's feelings and provide realistic hope, using a nonjudgmental approach and therapeutic communication skills during all interactions. Individualize the care based on the client's cultural traditions and beliefs.

Ensuring Culturally Competent Cancer Care

Cultural diversity in America is increasing, and as diverse cultures interact, conflicts inevitably ensue. These conflicts can affect health care outcomes. Providing culturally competent cancer care can improve outcomes and decrease disparities in care. Work to develop cultural competence by learning about and showing respect for all cultures. Be aware of the client's cultural background, religion, migration history, degree of acculturation, living conditions, educational level, and legal status, because each of these factors can affect the client's understanding of her diagnosis and the eventual outcome (Jenko & Moffitt, 2006).

In some cultures, sharing news of a serious illness like cancer is considered disrespectful and impolite. For example, some Europeans view such sharing as inhumane; the Asian culture views a cancer diagnosis as unnecessarily cruel. The Chinese, out of respect for aging family members, withhold discussions of serious illness to avoid causing unnecessary anxieties (Surbone, 2006). Integrate this knowledge in your care to ensure a culturally competent approach.

▶ ***Take*** *NOTE!*

When a diagnosis of cancer is made, assessing an individual's strengths and weaknesses from a cultural perspective will help the nurse to provide culturally competent care.

As life becomes increasingly multilingual, multicultural, and multi-faith, learning about clients' values and cultural beliefs becomes challenging. Be willing to learn about client preferences; doing so promotes caring and nurturing.

Supporting the Pregnant Woman With Cancer

Theoretically, changes in the mother's immune system during pregnancy can increase the risk of malignancy because cell-mediated immunity, which is suppressed in pregnant women, normally protects against cancerous tumors (Blackburn, 2007). Some research has hinted at an increased rate of progression and decreased survival times in women who develop breast and cervical cancer and then become pregnant, but this generally has not been validated by research studies.

Ovarian cancer during pregnancy is rare because the disease typically occurs in older women. Because most pregnant women receive frequent medical care, including pelvic examinations, most ovarian cancers in pregnant women are found at early stages; this carries a good prognosis for both the mother and the newborn (Machado et al., 2007). Since routine screening for endometrial cancer is currently not recommended in the general population, few cases would be detected in the relatively young pregnant population (Sonoda & Barakat, 2006). Cervical cancer is more common in the pregnant population than other reproductive malignancies, and it can affect the woman's health status and the pregnancy.

Women diagnosed with any malignancy during pregnancy must confront the reality of the disease and its impact on their future fertility and live with the risk of recurrence (Roberts, Rezai, & Edmondson, 2007). The wishes of the pregnant woman and her family are of paramount importance when making decisions about continuing the pregnancy and undergoing cancer treatment. Some women will decide to terminate the pregnancy for the sake of their own health; others will undergo treatment during the pregnancy to preserve the life of the unborn child. Regardless of the woman's decision, provide support and education during treatment, birth, and beyond.

Ovarian Cancer

Ovarian cancer is malignant neoplastic growth of the ovary (Fig. 8.1). It is the eighth most common cancer among women and the fifth most common cause of cancer deaths for women in the United States. It accounts for more deaths than any other cancer of the reproductive system (ACS, 2007c). The ACS estimates that about 23,000 new cases of ovarian cancer will be diagnosed in the United States during 2007 and 15,000 deaths will occur. A woman's risk of getting ovarian cancer during her lifetime is 1.5%, or about 1 in 67. About 76% of women with ovarian cancer survive 1 year after diagnosis; only 45% survive longer than 5 years (ACS, 2007c). Older women are at highest risk. Ovarian cancer occurs most frequently in women between 55 and 75 years of age, and approximately 25% of ovarian cancer deaths occur in women between 35 and 54 years old (ACS, 2007c).

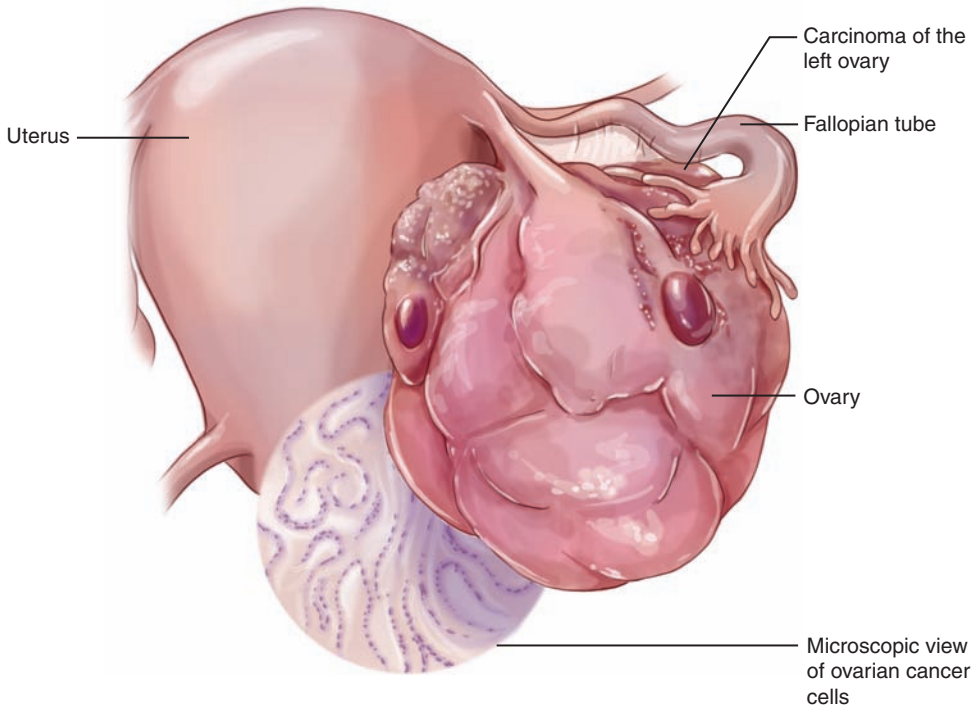

FIGURE 8.1 Ovarian cancer. (The Anatomical Chart Company. [2005]. *Atlas of pathophysiology* [2nd ed.]. Philadelphia: Lippincott Williams & Wilkins.)

The most important variable influencing the prognosis is the extent of the disease. Survival depends on the stage of the tumor, grade of differentiation, gross findings at surgery, amount of residual tumor after surgery, and effectiveness of any adjunct treatment postoperatively. Many women with ovarian cancer will experience recurrence despite the best efforts of eradicating the cancer through surgery, radiation, or chemotherapy to eliminate residual tumor cells. The likelihood of long-term survival in the event of recurrence is dismal (Eaton, 2007). The 5-year survival rates (the percentage of women who live at least 5 years after their diagnosis) are shown in Table 8.1 according to stage.

TABLE 8.1 FIVE-YEAR SURVIVAL RATES FOR OVARIAN CANCER

Stage	Five-Year Relative Survival Rates
I	80% to 90%
II	65% to 70%
III	30% to 60%
IV	20%

American Cancer Society (ACS). (2007c). *What are the key statistics about ovarian cancer?* American Cancer Society, Inc. [Online] Available at: http://www.cancer.org/docroot/CRI/content/CRI_2_4_1X_What_are_the_key_statistics_for_ovarian_cancer_33.asp?sitearea=&level=.

Pathophysiology

Ovarian cancer, the cause of which is unknown, can originate from different cell types. Most ovarian cancers originate in the ovarian epithelium. They usually present as solid masses that have spread beyond the ovary and seeded into the peritoneum prior to diagnosis. An inherited genetic mutation is the causative factor in 5% to 10% of cases of epithelial ovarian cancer.

Screening and Diagnosis

Seventy-five percent of ovarian cancers are not diagnosed until the cancer has advanced to stage III or IV, primarily because there is still no adequate screening test. Two genes, BRCA-1 and BRCA-2, are linked with hereditary breast and ovarian cancers. Blood tests can be performed to assess DNA in white blood cells to detect mutations in the BRCA genes. These genetic markers do not predict whether the person will develop cancer; rather, they provide information regarding the risk of developing cancer: a woman who is BRCA positive may have up to an 80% chance of developing breast cancer and a 40% chance of developing ovarian cancer (Eaton, 2007).

To assist in screening, researchers have been developing an ovarian cancer symptom index that includes pelvic and abdominal pain, urinary frequency and urgency, increased abdominal size (bloating), and difficulty eating (feeling full) (Goff et al., 2007). The symptom index is considered positive if any of these symptoms occur more

than 12 times a month and persist for more than 1 year. The utility of this symptom index as a general screening tool remains to be assessed.

Specific clinical guidelines for ovarian cancer screening have not been developed, so the disease is often not diagnosed until it has metastasized. The U.S. Preventive Services Task Force (USPSTF) recommends against routine screening for ovarian cancer with serum CA-125 or transvaginal ultrasound because earlier detection would have a small effect, at best, on mortality. CA-125 is a biologic tumor marker associated with ovarian cancer. Although levels are elevated in many women with ovarian cancer, CA-125 is not specific for this cancer and levels may be elevated with other malignancies (pancreatic, liver, colon, breast, and lung cancers). Currently, it is not sensitive enough to serve as a screening tool (Speroff & Fritz, 2005). The USPSTF concluded that the harm from the invasive nature of the diagnostic tests would outweigh the benefits (USPSTF, 2006).

Therapeutic Management

Treatment options for ovarian cancer vary depending on the stage and severity of the disease. Usually a laparoscopy (abdominal exploration with an endoscope) is performed for diagnosis and staging, as well as evaluation for therapy. In stage I the cancer is limited to the ovaries. In stage II the growth involves one or both ovaries, with pelvic extension. Stage III cancer has spread to the lymph nodes and other organs or structures inside the abdominal cavity. In stage IV, the cancer has metastasized to distant sites (Alexander et al., 2007). Figure 8.2 shows the likely metastatic sites for ovarian cancer.

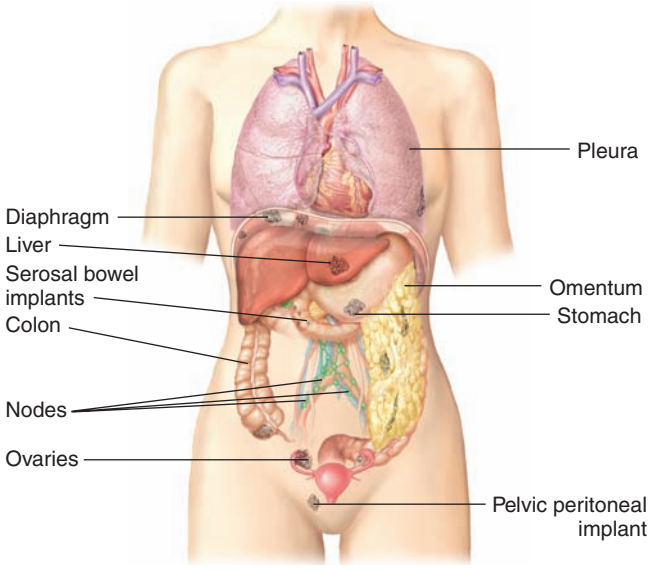

FIGURE 8.2 Common metastatic sites for ovarian cancer. (The Anatomical Chart Company. [2005]. *Atlas of pathophysiology* [2nd ed.]. Philadelphia: Lippincott Williams & Wilkins)

Surgical intervention remains the mainstay of management of ovarian cancer. Surgery generally includes a total abdominal hysterectomy, bilateral salpingo-oophorectomy, peritoneal biopsies, omentectomy, and pelvic para-aortic lymph node sampling to evaluate cancer extension (Martin, 2007). Because most women are diagnosed with advanced-stage ovarian cancer, aggressive management involving debulking or cytoreductive surgery is commonly performed. This surgery involves resecting all visible tumors from the peritoneum, taking peritoneal biopsies, sampling lymph nodes, and removing all reproductive organs and the omentum. This aggressive surgery has been shown to improve long-term survival rates.

Additional therapy with radiation may be warranted. Chemotherapy is recommended for all stages of ovarian cancer.

Nursing Assessment

Ovarian cancers are considered the worst of all the gynecologic malignancies, primarily because they develop slowly and remain silent and without symptoms until the cancer is far advanced. It has been described as "the overlooked disease" or "the silent killer" because women and health care practitioners often ignore or rationalize early symptoms. For example, women may attribute gastrointestinal problems to stress and midlife changes. However, these vague complaints may precede more obvious symptoms by months. The most common early symptoms include abdominal bloating, early satiety, fatigue, vague abdominal pain, urinary frequency, diarrhea or constipation, and unexplained weight loss or gain. The later symptoms include anorexia, dyspepsia, ascites, a palpable abdominal mass, pelvic pain, and back pain (Wallace & Sanford, 2006).

▸ *Consider* THIS!

I felt I was a lucky woman because I had been in remission from breast cancer for 12 years, and I had been given the gift of life to share with my beloved family. Recently I became ill with stomach problems: pain, indigestion, bloating, and nausea. My doctor treated me for GERD (acid reflux disease), but the symptoms persisted. I then was referred to a gastroenterologist, an urologist, and then a gynecologist, who did an ultrasound, which was negative. I received reassurance from all three that there was nothing wrong with me. As time went by, I experienced more pain, more symptoms, and increased frustration. Six months after seeing all three specialists, a repeat ultrasound revealed I had ovarian cancer, and I needed surgery as soon as possible. I underwent a complete hysterectomy

(continued)

Consider THIS! *(continued)*

and my surgeon found I was in stage 3. Since then, I have undergone chemotherapy and participated in a clinical cancer study that wasn't successful for me, and now I am facing the fact that I am going to die soon.

Thoughts: This woman has tried everything to save her life, but, alas, time has run out for her with advanced ovarian cancer. Women diagnosed with breast cancer are at a significant risk for developing ovarian cancer later in life. Of the string of doctors she saw, one has to ponder why none ordered a CA-125 blood test with her history of breast cancer. We are haunted with the question: If they had and it was elevated, would she be in stage 3 now? I guess we will never know.

Obtain a thorough history of the woman's symptoms, including their onset, duration, and frequency. Review the woman's history for risk factors such as:

- Nulliparity
- Early menarche (before 12 years old)
- Late menopause (after 55 years old)
- Increasing age (over 50 years of age)
- High-fat diet
- Obesity
- Persistent ovulation over time
- First-degree relative with ovarian cancer
- Use of perineal talcum powder or hygiene sprays
- Older than 30 years at first pregnancy
- Positive BRCA-1 and BRCA-2 mutations
- Personal history of breast, bladder, or colon cancer
- Hormone replacement therapy for more than 10 years
- Infertility (CDC, 2007c)

Perform a complete physical examination. Inspect the abdomen, noting any distention or bloating. Palpate the abdomen. Be alert for a mass or pain on palpation. Anticipate further testing to confirm the diagnosis.

Nursing Management

The complexities of ovarian cancer make a multidisciplinary approach necessary for optimal management. With the subtle nature and high risk of recurrence and mortality of this condition, most women find it an emotionally exhausting and devastating experience. Nursing management focuses on measures to promote early detection, educate the woman about the disease and its treatments, and provide emotional support. Nurses should show a positive attitude that communicates understanding and reassurance.

Promoting Early Detection

Nurses need to ensure that women are aware of the risk factors for ovarian cancer. Urge women not to dismiss seemingly innocuous symptoms as "just a part of aging." Encourage women to describe such nonspecific complaints at health visits.

Assess the woman's family and personal history for risk factors and encourage genetic testing for women with affected family members. Outline screening guidelines for women with hereditary cancer syndrome and inform women at high risk about the appropriate screening strategies.

Urge women to have yearly bimanual pelvic examinations and a transvaginal ultrasound to allow identification of ovarian masses in their early stages. After menopause, a mass on an ovary is not a cyst: physiologic cysts can arise only from a follicle that has not ruptured or from the cystic degeneration of the corpus luteum.

Take NOTE!

A small ovarian "cyst" found on ultrasound in an asymptomatic postmenopausal woman should arouse suspicion. Any mass or ovary palpated in a postmenopausal woman should be considered cancerous until proven otherwise (Cherry, DeGaetano, & Martin, 2007).

Educating the Client

Education is a major focus of nursing care. This teaching involves risk reduction and health promotion. Teach the woman about risk-reduction strategies; for instance, pregnancy, use of oral contraceptives, and breastfeeding reduce the risk of ovarian cancer. Instruct women to avoid using talc and hygiene sprays on their genitals. Review the lifetime risks related to BRCA-1 and BRCA-2 genes and options available should the woman test positive for these genes. Help to promote community awareness of ovarian cancer by educating the public about risk-reducing behaviors.

Instruct the woman about the importance of healthy lifestyles. Stress the importance of maintaining a healthy weight to reduce risk. Encourage women to eat a low-fat diet.

For the woman who is diagnosed with ovarian cancer, describe in simple terms the tests, treatment modalities, and follow-up needed. For example, if the woman will be having surgery, provide thorough teaching about what to expect before, during, and after surgery. Outline treatment options and the implications of choices. Assist the woman and her family to decipher the myriad of information related to staging, tests, and treatments. Teach the woman about additional treatment measures, such as radiation therapy or chemotherapy, including how to handle the common adverse effects of treatment.

Supporting the Client and Family

The diagnosis of ovarian cancer, like any cancer, can be overwhelming. In addition, the treatments and their effects can be highly stressful, both physically and emotionally. Provide one-to-one support for women facing treatment for ovarian cancer. Ovarian cancer involves the reproductive system, which has a direct impact on the woman's view of herself. Encourage open discussion of sexuality and the impact of cancer. Listen and support the woman and her family as they try to cope with this disease. Encourage the use of appropriate coping strategies to allow for the best quality of life. Try to restore hope to women with ovarian cancer, and stress treatment compliance. If appropriate, encourage participation in clinical trials to offer hope for all women. Continue to offer support to the woman and her family members as they experience sadness and grief.

Endometrial Cancer

Endometrial cancer (also known as uterine cancer) is malignant neoplastic growth of the uterine lining. It is the most common gynecologic malignancy and accounts for 6% of all cancers in women in the United States. The NCI estimates that there will be over 40,000 new cases in 2007; approximately 8,000 of these women will die (NCI, 2007b). It is uncommon before the age of 40, but as women age, their risk of endometrial cancer increases. Approximately 95% of these malignancies are carcinomas of the endometrium. Because endometrial cancer is usually diagnosed in the early stages, it has a better prognosis than cervical or ovarian cancer (ACS, 2007f).

Pathophysiology

Two mechanisms are believed to be involved in the development of endometrial cancer. A history of exposure to unopposed estrogen is the cause in 75% of women. Those that are spontaneous and are unrelated to estrogen or endometrial hyperplasia represent the other 25% of endometrial cancers.

Endometrial cancer may originate in a polyp or in a diffuse multifocal pattern. The pattern of spread partially depends on the degree of cellular differentiation. Well-differentiated tumors tend to limit their spread to the surface of the endometrium. Metastatic spread occurs in a characteristic pattern and most commonly involves the lungs, inguinal and supraclavicular nodes, liver, bones, brain, and vagina (NCI, 2007b). Early tumor growth is characterized by friable and spontaneous bleeding. Later tumor growth is characterized by myometrial invasion and growth toward the cervix (Fig. 8.3).

Adenocarcinoma of the endometrium is typically preceded by hyperplasia. Carcinoma in situ is found only on the endometrial surface. In stage I, it has spread to the muscle wall of the uterus. In stage II, it has spread to the cervix. In stage III, it has spread to the bowel or vagina, with metastases to pelvic lymph nodes. In stage IV, it has invaded the bladder mucosa, with distant metastases to the lungs, liver, and bone (Burke & Gallup, 2007).

Type I carcinomas, the most common, begin as endometrial hyperplasia and progress to carcinomas. Giving estrogen preparations without progestin for hormone replacement therapy leads to an increased risk for endometrial cancer. Type I is generally found at an earlier stage and treatment results are more favorable.

Unlike type I endometrial carcinoma, type II carcinomas appear spontaneously, are associated with a poorly differentiated cell type, and have a poor prognosis (Burke & Gallup, 2007). They account for less than 10% of all endometrial cancers but contribute to the majority of all endometrial deaths.

Screening and Diagnosis

Remember Carmella, the woman with postmenopausal bleeding? In postmenopausal women, any bleeding is abnormal and warrants further assessment. What testing would the nurse anticipate as being ordered to confirm the diagnosis? What would be the nurse's role during this testing?

Screening for endometrial cancer is not routinely done because it is not practical or cost-effective. The ACS recommends that women should be informed about the risks and symptoms of endometrial cancer at the onset of menopause and strongly encouraged to report any unexpected bleeding or spotting to their health care provider (ACS, 2007f). A pelvic examination is frequently normal in the early stages of the disease. Changes in the size, shape, or consistency of the uterus or its surrounding support structures may exist when the disease is more advanced.

An endometrial biopsy is the diagnostic procedure of choice. It can be done in the health care provider's office without anesthesia. A slender suction catheter is used to obtain a small sample of tissue for pathology. This test can detect up to 90% of cases of endometrial cancer in women with postmenopausal bleeding, depending on the technique and experience of the health care provider (Wallace & Sanford, 2006). The woman may experience mild cramping and bleeding after the procedure for about 24 hours, but typically mild pain medication will reduce this discomfort.

Transvaginal ultrasound can be used to evaluate the endometrial cavity and measure the thickness of the endometrial lining. It can be used to detect endometrial hyperplasia. If the endometrium measures less than 4 mm, then the client is at low risk for malignancy (Sonoda & Barakat, 2006).

Therapeutic Management

Typically, the stage of the disease directs treatment. It usually involves surgery with adjunct therapy based on pathologic findings. Surgery most often involves removal

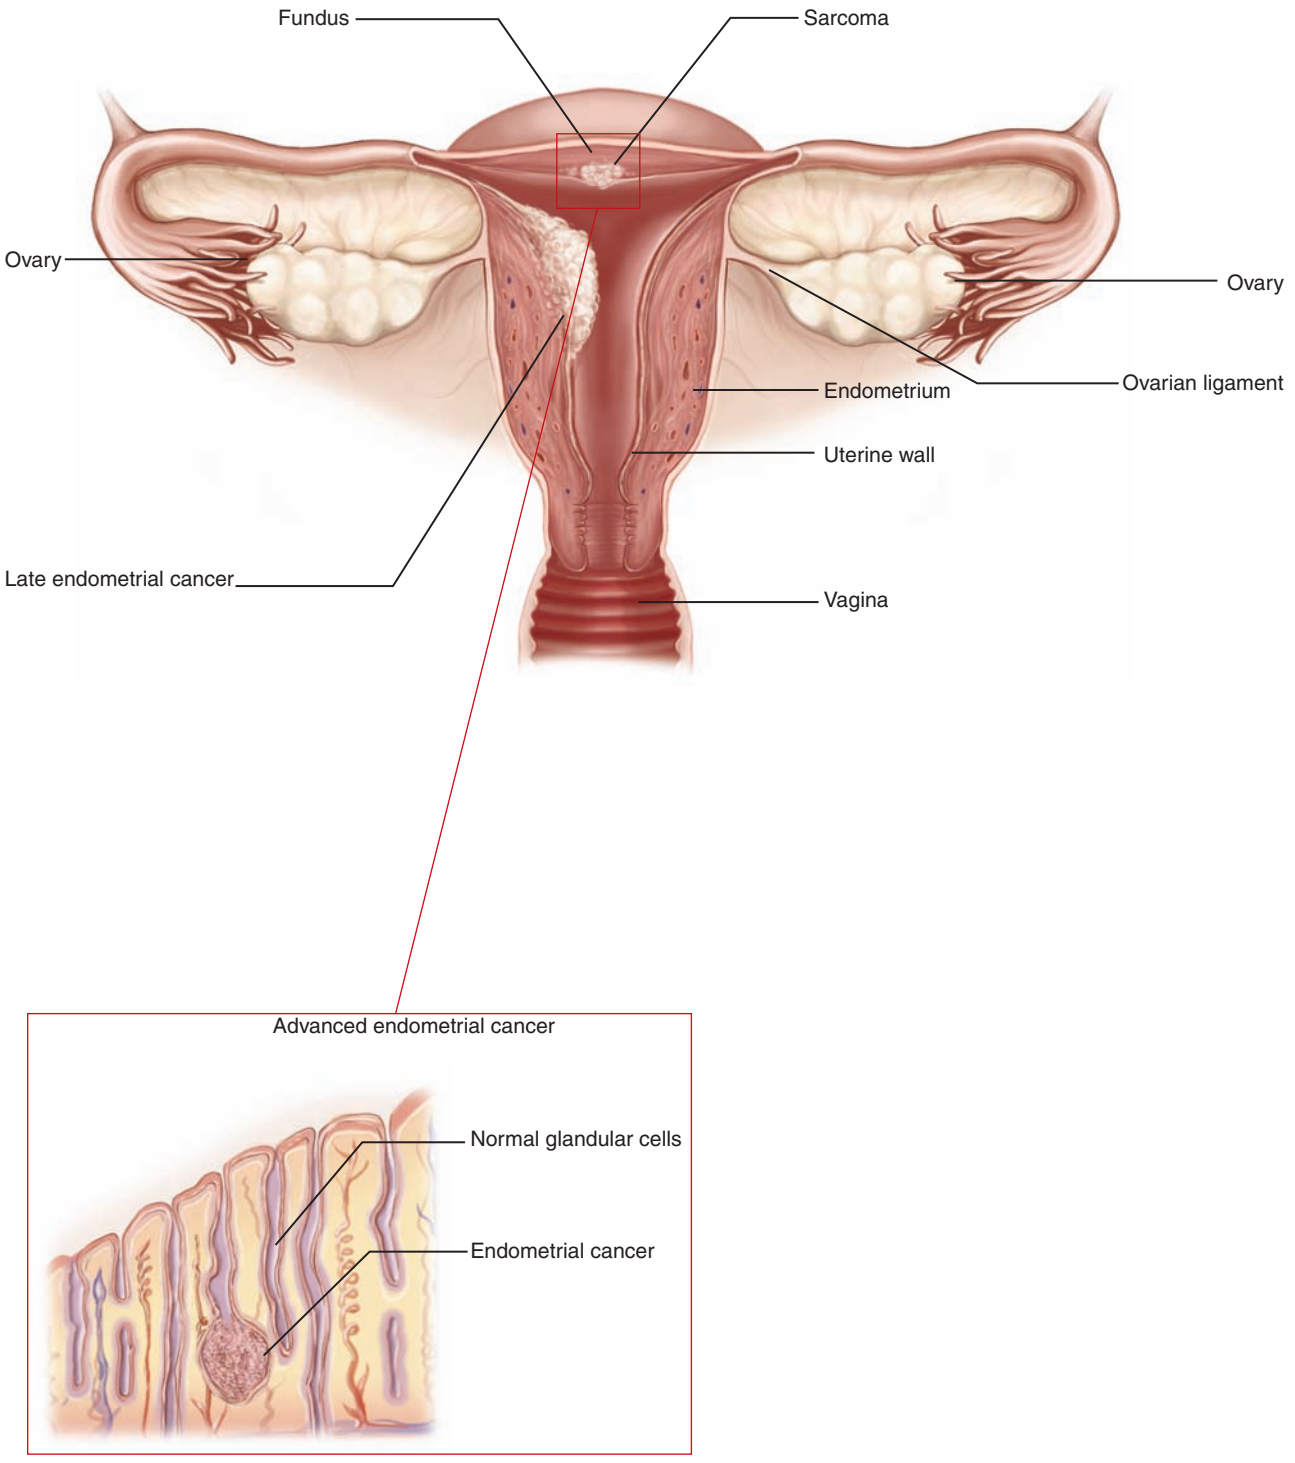

FIGURE 8.3 Progression of endometrial cancer. (The Anatomical Chart Company. [2005]. *Atlas of pathophysiology* [2nd ed.]. Philadelphia: Lippincott Williams & Wilkins)

of the uterus (hysterectomy) and the fallopian tubes and ovaries (salpingo-oophorectomy). Removal of the tubes and ovaries is recommended because tumor cells spread early to the ovaries, and any dormant cancer cells could be stimulated to grow by ovarian estrogen. In more advanced cancers, radiation and chemotherapy are used as adjuncts to surgery. Routine surveillance intervals for follow-up care are typically every 3 to 4 months for the first 2 years, since 85% of recurrences occur in the first 3 years after diagnosis (Burke & Gallup, 2007).

Nursing Assessment

Obtain a thorough history from the woman, ascertaining her primary complaint. Most commonly, the major initial symptom of endometrial cancer is abnormal and painless vaginal bleeding.

▶ *Take* NOTE!

Any episode of bright-red bleeding that occurs after menopause should be investigated. Abnormal uterine bleeding is rarely the result of uterine malignancy in a young woman, but in the postmenopausal woman it should be regarded with suspicion.

Also review the woman's history for any risk factors, including:

- Nulliparity
- Obesity (more than 50 pounds overweight)
- Liver disease
- Infertility
- Diabetes mellitus
- Hypertension
- History of pelvic radiation
- Polycystic ovary syndrome
- Infertility
- Early menarche (before 12 years old)
- High-fat diet
- Use of prolonged exogenous unopposed estrogen with an intact uterus
- Endometrial hyperplasia
- Family history of endometrial cancer
- Personal history of hereditary nonpolyposis colon cancer
- Personal history of breast or ovarian cancer
- Late onset of menopause (after age 52 years)
- Tamoxifen use
- Chronic anovulation (Tiffen & Mahon, 2006)

Assess the woman for additional manifestations, such as dyspareunia, low back pain, purulent genital discharge, dysuria, pelvic pain, weight loss, and a change in bladder and bowel habits. These may suggest advanced disease.

Perform a physical examination and assist with or perform, as appropriate, a pelvic examination. Observe for vaginal discharge. Note any changes in the size, shape, or consistency of the uterus or surrounding structures or client reports of pain during examination. Anticipate the need for transvaginal ultrasound to identify endometrial hyperplasia (usually greater than 4 mm) and endometrial biopsy to identify malignant cells.

Nursing Management

Ensure that the woman understands all the treatment options. Address any concerns the woman expresses, including those of a sexual nature. Ensure that follow-up appointments are scheduled appropriately. Refer the client to a support group. Offer the woman and family explanations and emotional support throughout.

Educate the client about preventive measures or follow-up care if she has been treated for cancer. Education may be the most important tool currently available for the early detection of endometrial cancer. Many risk factors for endometrial cancer are modifiable, including obesity, hypertension, and diabetes. Educating women about risk factors and ways to decrease the risks is essential so that women can learn about their own risk and can become partners in the fight against the number-one gynecologic cancer (Teaching Guidelines 8.2).

TEACHING GUIDELINES 8.2

Preventive and Follow-Up Measures for Endometrial Cancer

- Schedule regular pelvic examinations after the age of 21.
- Visit health care practitioner for early evaluation of any abnormal bleeding after menopause.
- Maintain a low-fat diet throughout life.
- Exercise daily.
- Manage weight to discourage hyperestrogenic states, which predispose to endometrial hyperplasia.
- Pregnancy serves as a protective factor by reducing estrogen.
- Ask your doctor about the use of combination estrogen and progestin pills.
- When combination oral contraceptives are taken to facilitate the regular shedding of the uterine lining, take risk-reduction measures.
- Be aware of risk factors for endometrial cancer and make modifications as needed.
- Report any of the following symptoms immediately:
  - Bleeding or spotting after sexual intercourse
  - Bleeding that lasts longer than a week
  - Reappearance of bleeding after 6 months or more of no menses
- After cancer therapy, schedule follow-up appointments for the next few years.
- After cancer therapy, frequently communicate with your health care provider concerning your status.
- After surgery, maintain a healthy weight.

Carmella's endometrial biopsy indicates endometrial adenocarcinoma. Her health care provider recommends surgery and adjuvant radiation therapy. How long will Carmella need to follow up after surgery? What lifestyle changes will the nurse need to stress with Carmella?

Cervical Cancer

Cervical cancer is cancer of the uterine cervix. The ACS estimates that over 12,000 cases of invasive cervical cancer will be diagnosed in the United States in 2007; approximately 3,000 of these women will die. Some researchers estimate that noninvasive cervical cancer (carcinoma in situ) is about four times more common than invasive cervical cancer. The 5-year survival rate for all stages of cervical cancer is 72% (ACS, 2007a). It is five to eight times more common in women affected with HIV or AIDS than those who do not have this virus. The probability of a woman in the United States developing cervical cancer is approximately 1 in 120, but this statistic is age-dependent; the highest incidence is in women 40 to 49 years of age (Hopkins & Sawa, 2007).

The incidence and mortality rates of cervical cancer have decreased noticeably in the past several decades, with most of the reduction attributed to the **Papanicolaou (Pap) test**, which detects cervical cancer and precancerous lesions. Cervical cancer is one of the most treatable cancers when detected at an early stage (ACS, 2007a). *Healthy People 2010* identifies two goals that address cervical cancer (Healthy People 2010 8.1; USDHHS, 2000).

HEALTHY PEOPLE 2010

Objective	Significance
Reduce the death rate from cancer of the uterine cervix from 3 per 100,000 females (1998) to 2 per 100,000 females in 2010.	• Will help improve mortality rates and quality of life for women, and reduce health care costs related to treatment of malignancies.
Increase the proportion of women who received a Pap smear within the preceding 3 years from 79% to 90% by 2010.	• Will help to promote screening and early detection. The National Institutes of Health (NIH) reported that half of women diagnosed with invasive cervical cancer have never had a Pap smear and 10% have not had Pap smears during the past 5 years (NIH, 2007).

Pathophysiology

Cervical cancer starts with abnormal changes in the cellular lining or surface of the cervix. Typically these changes occur in the squamous–columnar junction of the cervix. Here, cylindrical secretory epithelial cells (columnar) meet the protective flat epithelial cells (squamous) from the outer cervix and vagina in what is termed the transformation zone. The continuous replacement of columnar epithelial cells by squamous epithelial cells in this area makes these cells vulnerable to take up foreign or abnormal genetic material (ACS, 2007a). Figure 8.4 shows the pathophysiology of cervical cancer.

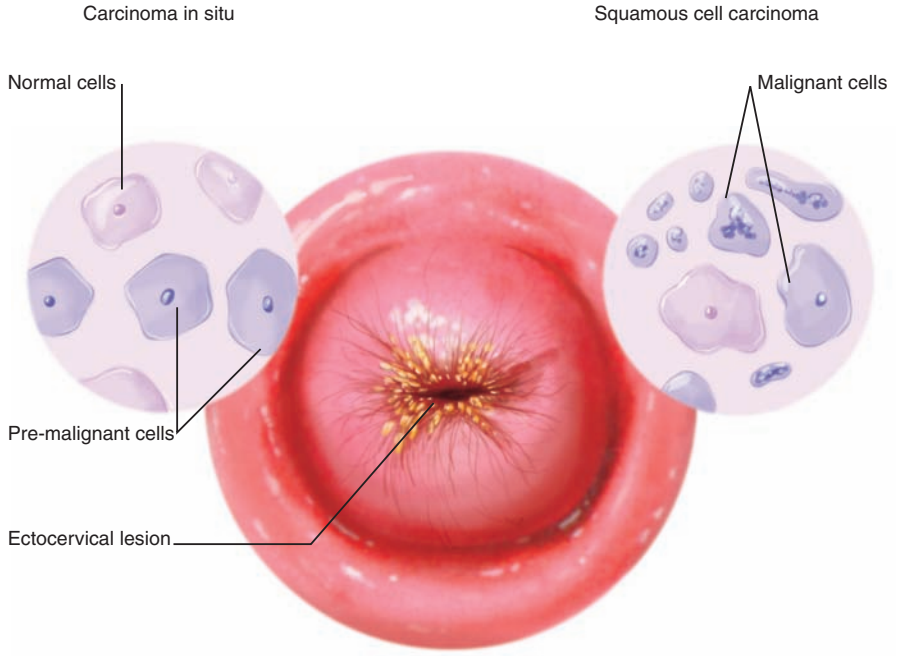

FIGURE 8.4 Cervical cancer. (The Anatomical Chart Company. [2005]. *Atlas of pathophysiology* [2nd ed.]. Philadelphia: Lippincott Williams & Wilkins)

The development of cervical cancer has been linked to the **human papillomavirus (HPV)**, which is acquired through sexual activity (Torpy, 2007). More than 90% of squamous cervical cancers contain HPV DNA, and the virus is now accepted as a major causative factor in the development of cervical cancer and its precursor, **cervical dysplasia** (disordered growth of abnormal cells).

Screening and Diagnosis

Screening for cervical cancer is very effective because the presence of a precursor lesion, cervical intraepithelial neoplasia (CIN), helps determine whether further tests are needed. Lesions start as dysplasia and progress in a predictable fashion over a long period, allowing ample opportunity for intervention at a precancerous stage. Progression from low-grade to high-grade dysplasia takes an average of 9 years, and progression from high-grade dysplasia to invasive cancer takes up to 2 years (Hopkins & Sawa, 2007).

Widespread use of the Pap test (also known as a Pap smear), a procedure used to obtain cells from the cervix for cytology screening, is credited with saving tens of thousands of women's lives and decreasing deaths from cervical cancer by more than 70% (ACS, 2007a). Despite its outstanding record of success as a screening tool for cervical cancer (it detects approximately 90% of early cancer changes), the conventional Pap smear has a 20% false-negative rate. High-grade abnormalities missed by human screening are frequently detected by computerized instruments (NCI, 2007a). Thus, many technologies have been developed to improve the sensitivity and specificity of Pap testing, including:

- Thin-Prep: In this liquid-based technique, the cervical specimen is placed into a vial of preservative solution rather than on a glass slide.
- Computer-assisted automated Pap test rescreening (Autopap): An algorithm-based decision-making technology identifies slides that should be rescreened by cytopathologists by selecting samples that exceed a certain threshold for the likelihood of abnormal cells.
- HPV-DNA typing (Hybrid Capture): This system uses the association between certain types of HPV (16, 18, 31, 33, 35, 45, 51, 52, and 56) and the development of cervical cancer. This system can identify high-risk HPV types and improves detection and management.
- Computer-assisted technology (Cytyc CDS-1000, AutoCyte, AcCell): These computerized instruments can detect abnormal cells that are sometimes missed by technologists (Wallace & Sanford, 2006).

The high rate of false-negative results may also be due to other factors, including errors in sampling the cervix, in preparing the slide, and in client preparation.

Although professional medical organizations disagree as to the recommended frequency of screening for cervical cancer, the ACS 2007 guidelines suggest that women should begin annual screening for cervical cancer via a Pap test after they initiate sexual activity or at 21 years of age, whichever comes first. If three consecutive Pap smears are negative, a trained health care provider may suggest that screening can be performed less frequently. Women ages 65 to 70 with no abnormal tests in the previous 10 years may choose to stop screenings (ACS, 2007a). High-risk women should continue to have annual Pap smears throughout their life (Table 8.2).

Pap smear results are classified using the Bethesda System (Box 8.1), which provides a uniform diagnostic terminology that allows clear communication between the laboratory and the health care provider. The information provided by the laboratory is divided into three categories: specimen adequacy, general categorization of cytologic findings, and interpretation/result (ACS, 2007b).

Therapeutic Management

Treatment for abnormal Pap smears depends on the severity of the results and the health history of the woman. Therapeutic choices all involve destroying as many affected cells as possible. Box 8.2 describes treatment options.

Using the Bethesda system, the following management guidelines for abnormal Pap results were developed by the NCI to provide direction to health care providers and clients:

- ASC-US: Repeat the Pap smear in 4 to 6 months or refer for colposcopy.
- ASC-H: Refer for colposcopy without HPV testing.
- Atypical glandular cells (AGC) and adenocarcinoma in situ (AIS): Immediate colposcopy; follow-up is based on the findings.

Colposcopy is a microscopic examination of the lower genital tract using a magnifying instrument called a colposcope. Specific patterns of cells that correlate well with certain histologic findings can be visualized.

TABLE 8.2 **PAP SMEAR GUIDELINES**

First Pap	Age 21 or within 3 years of first sexual intercourse
Until age 30	Yearly—using glass slide method Every 2 years—using liquid-based method
Age 30–70	Every 2–3 years if last 3 Paps were normal
After age 70	May discontinue if: - Past 3 Paps were normal and - No Paps in the past 10 years were abnormal

American Cancer Society (ACS). (2007b). *How Pap test results are reported*. American Cancer Society, Inc. [Online] Available at: http://www.cancer.org/docroot/PED/content/PED_2_3X_Pap_Test.asp.

BOX 8.1 The 2001 Bethesda System for Classifying Pap Smears

Specimen Type: Conventional Pap smear vs. liquid-based
Specimen Adequacy: Satisfactory or unsatisfactory for evaluation
General Categorization: (optional)
• Negative for intraepithelial lesion or malignancy
• Epithelial cell abnormality. See interpretation/result
Automated Review: If case was examined by automated device or not
Ancillary Testing: Provides a brief description of the test methods and report results so health care provider understands
Interpretation/Result:
• Negative for intraepithelial lesion or malignancy
• Organisms: *Trichomonas vaginalis;* fungus; bacterial vaginosis; herpes simplex
• Other non-neoplastic findings: Reactive cellular changes associated with inflammation, radiation, IUDs, atrophy
• Other: Endometrial cells in a woman >40 years of age
• Epithelial cell abnormalities:
• *Squamous cell*
- Atypical squamous cells
  - Of undetermined significance (ASC-US)
  - Cannot exclude HSIL (ASC-H)
- Low-grade squamous intraepithelial lesion (LSIL)
  - Encompassing HPV/mild dysplasia/CIN-1
- High-grade squamous intraepithelial lesion (HSIL)
  - Encompassing moderate and severe dysplasia CIS/CIN-2 and CIN-3
  - With features suspicious for invasion
- Squamous cell carcinoma
• *Glandular Cell:* Atypical
- Endocervical, endometrial, or glandular cells
  - Endocervical cells—favor neoplastic
  - Glandular cells—favor neoplastic
  - Endocervical adenocarcinoma in situ
- Adenocarcinoma
  - Endocervical, endometrial, extrauterine
• Other malignant neoplasms (specify)
Educational Notes and Suggestions: (optional)

Sources: NIH, 2007; ACS, 2007b; Schuiling & Likis, 2006; Sherman et al., 2007.

BOX 8.2 Treatment Options for Cervical Cancer

• ***Cryotherapy***—destroys abnormal cervical tissue by freezing with liquid nitrogen, Freon, or nitrous oxide. Studies show a 90% cure rate (Persinger & Beal, 2007). Healing takes up to 6 weeks, and the client may experience a profuse, watery vaginal discharge for 3 to 4 weeks.
• ***Cone Biopsy*** or ***conization***—removes a cone-shaped section of cervical tissue. The base of the cone is formed by the ectocervix (outer part of the cervix) and the point or apex of the cone is from the endocervical canal. The transformation zone is contained within the cone sample. The cone biopsy is also a treatment and can be used to completely remove any precancers and very early cancers. There are two methods commonly used for cone biopsies:
  • LEEP (loop electrosurgical excision procedure) or LLETZ (large loop excision of the transformation zone)—the abnormal cervical tissue is removed with a wire that is heated by an electrical current. For this procedure, a local anesthetic is used. It is performed in the health care provider's office in approximately 10 minutes. Mild cramping and bleeding may persist for several weeks after the procedure.
  • Cold knife cone biopsy—a surgical scalpel or a laser is used instead of a heated wire to remove tissue. This procedure requires general anesthesia and is done in a hospital setting. After the procedure, cramping and bleeding may persist for a few weeks.
• ***Laser therapy***—destroys diseased cervical tissue by using a focused beam of high-energy light to vaporize it (burn it off). After the procedure, the woman may experience a watery brown discharge for a few weeks. Very effective in destroying precancers and preventing them from developing into cancers.
• ***Hysterectomy***—removes the uterus and cervix surgically
• ***Radiation therapy***—delivered by internal radium applications to the cervix or external radiation therapy that includes lymphatics of the pelvis
• ***Chemoradiation***—weekly cisplatin therapy concurrent with radiation. Investigation of this therapy is ongoing (ACS, 2007).

Nursing Assessment

Obtain a thorough history and physical examination of the woman. Investigate her history for risk factors such as:

• Early age at first intercourse (within 1 year of menarche)
• Lower socioeconomic status
• Promiscuous male partners
• Unprotected sexual intercourse
• Family history of cervical cancer (mother or sisters)
• Sexual intercourse with uncircumcised men
• Female offspring of mothers who took diethylstilbestrol (DES)
• Infections with genital herpes or chronic chlamydia
• Multiple sex partners
• Cigarette smoking
• Immunocompromised state
• HIV infection
• Oral contraceptive use

- Moderate dysplasia on Pap smear within past 5 years
- HPV infection (CDC, 2007b)

Question the woman about any signs and symptoms. Clinically, the first sign is abnormal vaginal bleeding, usually after sexual intercourse. Also be alert for reports of vaginal discomfort, malodorous discharge, and dysuria. In some cases the woman is asymptomatic, with detection occurring at an annual gynecologic examination and Pap test.

Perform a physical examination. Inspect the perineal area for vaginal discharge or genital warts. Perform or assist with a pelvic examination, including the collection of a Pap smear as indicated (Nursing Procedure 8.1).

Nursing Procedure 8.1

ASSISTING WITH COLLECTION OF A PAP SMEAR

Purpose: To Obtain Cells From the Cervix for Cervical Cytology Screening

1. Explain procedure to the client (Fig. A).
2. Instruct client to empty her bladder.
3. Wash hands thoroughly.
4. Assemble equipment, maintaining sterility of equipment (Fig. B).
5. Position client on stirrups or foot pedals so that her knees fall outward.
6. Drape client with a sheet for privacy, covering the abdomen but leaving the perineal area exposed.
7. Open packages as needed.
8. Encourage client to relax.
9. Provide support to client as the practitioner obtains a sample by spreading the labia; inserting the speculum; inserting the cytobrush and swabbing the endocervix; and inserting the plastic spatula and swabbing the cervix (Fig. C–H).
10. Transfer specimen to container (Fig. I) or slide. If a slide is used, spray the fixative on the slide.
11. Place sterile lubricant on the practitioner's fingertip when indicated for the bimanual examination.
12. Wash hands thoroughly.
13. Label specimen according to facility policy.
14. Rinse reusable instruments and dispose of waste appropriately (Fig. J).
15. Wash hands thoroughly.

▶ *Take* NOTE!

Suspect advanced cervical cancer in women with pelvic, back, or leg pain, weight loss, anorexia, weakness and fatigue, and fractures.

Prepare the woman for further diagnostic testing if indicated, such as a colposcopy. In a colposcopy, the woman is placed in the lithotomy position and her cervix is cleansed with acetic acid solution. Acetic acid makes abnormal cells appear white, which is referred to as acetowhite. These white areas are then biopsied and sent to the pathologist for assessment. Although this test is not painful, has no side effects, and can be performed safely in the clinic or office setting, women may be apprehensive or anxious about it because it is done to identify and confirm potential abnormal cell growth. Provide appropriate physical and emotional preparation for this test (Evidence-Based Practice 8.1).

Nursing Management

The nurse's role involves primary prevention by educating women about risk factors and ways to prevent cervical

EVIDENCE-BASED PRACTICE 8.1
Anxiety Reduction for Women Undergoing a Colposcopy

● Study
Getting abnormal Pap smear results can be upsetting for a woman. A colposcopy is a follow-up examination that is commonly used to identify these suspicious cells and obtain a specimen for biopsy. A woman's anxiety about this examination is increased by the possibility of a cancer diagnosis. Studies have shown that anxiety can heighten discomfort, so researchers sought to discover which method of preparation for colposcopy best reduces a woman's anxiety. They conducted a detailed search of databases, clinical trial registers, and protocols to evaluate all randomized and quasi-randomized controlled trials involving interventions to reduce anxiety during colposcopy. Eleven trials involving 1,441 women were identified. The trials compared the anxiety levels of the intervention group with those of a control group. The methods used to reduce anxiety were informational leaflets, counseling, informational videos, video during colposcopy, music, and verbal information.

▲ Findings
Three methods were found to significantly reduce anxiety during colposcopy: listening to music, watching informational videos, and viewing the video during the procedure. Other methods, such as informational leaflets, counseling, and verbal information, were not found to reduce anxiety vs. control groups.

■ Nursing Implications
Nurses can use the information from this study to design appropriate strategies for client teaching and can encourage women to use these measures to reduce anxiety. For example, the nurse can suggest that the client listen to her favorite music during the procedure to help her relax. Nurses can urge women to seek agencies or settings that include these measures as part of their procedure, and nurses can work with their facilities to ensure that music, informational videos, and videotape equipment are available for use during this procedure.

Galaal, K. A., Deane, K., Sangal, S., & Lopes, A. D. (2007). Interventions for reducing anxiety in women undergoing colposcopy. *Cochrane Database of Systematic Reviews 2007,* Issue 3, Art.No.: CD006013.DOI:10.1002/14651858.CD006013.pub2.

dysplasia. Cervical cancer rates have decreased in the United States because of the widespread use of Pap testing, which can detect precancerous lesions of the cervix before they develop into cancer. Nevertheless, during 2007, an estimated 12,000 new cases will be diagnosed and approximately 3,800 women will die from cervical cancer (CDC, 2007a, 2007b; Advisory Committee on Immunization Practices [ACIP], 2007).

Gardasil, the first vaccine developed to protect girls and women from HPV, is now available. The vaccine prevents infection from four HPV types: HPV 6, 11, 16, and 18. Theses types are responsible for 70% of cervical cancers and 90% of genital warts (Snow, 2007). Clinical trials indicate that the vaccine has high efficacy in preventing persistent HPV infection, cervical cancer precursor lesions, vaginal and vulvar cancer precursor lesions, and genital warts (Bryan, 2007). The vaccine is administered by intramuscular injection, and the recommended schedule is a three-dose series with the second and third doses administered 2 and 6 months after the first dose. The recommended age for vaccination of females is 11 to 12 years old, but the vaccine can be administered to girls as young as 9 years old (Pichichero, 2007). The long-term efficacy of HPV vaccines remains to be determined. Sustained efficacy up to 4.5 years has been documented, but it could be that boosters will be needed (CDC, 2007a). However, the vaccine is not a substitute for routine cervical cancer screening, and vaccinated women should have Pap smears as recommended.

Focus primary prevention education on the following:

- Identify high-risk behaviors in clients and teach them how to reduce them:
  - Take steps to prevent STIs.
  - Avoid early sexual activity.
  - Faithfully use barrier methods of contraception.
  - Avoid smoking and drinking.
  - Receive the HPV vaccine.
- Instruct women on the importance of screening for cervical cancer by annual Pap smears. Outline the proper preparation before having a Pap smear (Teaching Guidelines 8.3). Reinforce specific guidelines for screening.

Nurses also can advocate for clients by making sure that the Pap smear is sent to an accredited laboratory for interpretation. Doing so reduces the risk of false-negative results.

Secondary prevention focuses on reducing or limiting the area of cervical dysplasia. Tertiary prevention focuses on minimizing disability or spread of cervical cancer. Explain in detail all procedures that might be needed. Encourage the client who has undergone any cervical treatment to allow the pelvic area to rest for approximately 1 month. Discuss this rest period with the client and her partner to

TEACHING GUIDELINES 8.3

Strategies to Optimize Pap Smear Results

- Schedule your Pap smear appointment about 2 weeks (10 to 18 days) after the first day of your last menses to increase the chance of getting the best sample of cervical cells without menses.
- Refrain from intercourse for 48 hours before the test because additional matter such as sperm can obscure the specimen.
- Do not douche within 48 hours before the test to prevent washing away cervical cells that might be abnormal.
- Do not use tampons, birth control foams, jellies, vaginal creams, or vaginal medications for 72 hours before the test, as they could cover up or obscure the cervical cell sample.
- Cancel your Pap appointment if vaginal bleeding occurs, because the presence of blood cells interferes with visual evaluation of the sample (Schuiling & Likis, 2006).

gain his cooperation. Outline alternatives to vaginal intercourse, such as cuddling, holding hands, and kissing. Remind the woman about any follow-up procedures that are needed and assist her with scheduling if necessary.

Throughout the process, provide emotional support to the woman and her family. During the decision-making process, the woman may be overwhelmed by the diagnosis and all the information being presented. Refer the woman and her family to appropriate community resources and support groups as indicated.

Vaginal Cancer

Vaginal cancer is malignant tissue growth arising in the vagina. It is rare, representing less than 3% of all genital cancers. The ACS estimates that in 2007, over 2,000 new cases of vaginal cancer will be diagnosed in the United States, and approximately 800 will die of this cancer (ACS, 2007d). The peak incidence of vaginal cancer occurs at 60 to 65 years of age. The prognosis of vaginal cancer depends largely on the stage of disease and the type of tumor. The overall 5-year survival rate for squamous cell carcinoma is about 42%; that for adenocarcinoma is about 78% (NCI, 2007c). Vaginal cancer can be effectively treated, and when found early it is often curable.

Pathophysiology

The etiology of vaginal cancer has not been identified. Malignant diseases of the vagina are either primary vaginal cancers or metastatic forms from adjacent or distant organs. About 80% of vaginal cancers are metastatic, primarily from the cervix and endometrium. These cancers invade the vagina directly. Cancers from distant sites that metastasize to the vagina through the blood or lymphatic system are typically from the colon, kidneys, skin (melanoma), or breast. Tumors in the vagina commonly occur on the posterior wall and spread to the cervix or vulva (NCI, 2007c).

Squamous cell carcinomas that begin in the epithelial lining of the vagina account for about 85% of vaginal cancers. This type of cancer usually occurs in women over age 50. They develop slowly over a period of years, commonly in the upper third of the vagina. They tend to spread early by directly invading the bladder and rectal walls. They also metastasize through blood and lymphatics. The remaining 15% are adenocarcinomas, which differ from squamous cell carcinoma by an increase in pulmonary metastases and supraclavicular and pelvic node involvement (ACS, 2007d).

Therapeutic Management

Treatment of vaginal cancer depends on the type of cells involved and the stage of the disease. If the cancer is localized, radiation, laser surgery, or both may be used. If the cancer has spread, radical surgery might be needed, such as a hysterectomy, or removal of the upper vagina with dissection of the pelvic nodes in addition to radiation therapy.

Nursing Assessment

Begin the history and physical examination by reviewing for risk factors. Although direct risk factors for the initial development of vaginal cancer have not been identified, associated risk factors include advancing age (over 60 years old), previous pelvic radiation, exposure to diethylstilbestrol (DES) in utero, vaginal trauma, history of genital warts (HPV infection), HIV infection, cervical cancer, chronic vaginal discharge, smoking, and low socioeconomic level (ACS, 2007d).

Question the woman about any complaints. Most women with vaginal cancer are asymptomatic. Those with symptoms have painless vaginal bleeding (often after sexual intercourse), abnormal vaginal discharge, dyspareunia, dysuria, constipation, and pelvic pain (NCI, 2007c). During the physical examination, observe for any obvious vaginal discharge or genital warts, or changes in the appearance of the vaginal mucosa. Anticipate colposcopy with biopsy of suspicious lesions to confirm the diagnosis.

Nursing Management

Nursing management for this cancer is similar to that for other reproductive cancers, with emphasis on sexuality counseling and referral to local support groups. Women undergoing radical surgery need intensive counseling about

the nature of the surgery, risks, potential complications, changes in physical appearance and physiologic function, and sexuality alterations.

Vulvar Cancer

Vulvar cancer is an abnormal neoplastic growth on the external female genitalia (Fig. 8.5). It is responsible for 0.6% of all malignancies in women and 4% of all female genital cancers. It is the fourth most common gynecologic cancer, after endometrial, ovarian, and cervical cancers (Naumann & Higgins, 2007). The ACS estimates that in 2007, about 4,000 cancers of the vulva will be diagnosed in the United States and over 900 women will die of this cancer (ACS, 2007e). When detected early, it is highly curable.

Vulvar cancer is found most commonly in older women in their mid-60s to 70s, but the incidence in women younger than 35 years old has increased over the past few decades. The overall 5-year survival rate when lymph nodes are not involved is 90%, but it drops to 50% to 70% when the lymph nodes have been invaded (ACS, 2007e).

Pathophysiology

Approximately 90% of vulvar tumors are squamous cell carcinomas. This type of cancer forms slowly over several years and is usually preceded by precancerous changes. These precancerous changes are termed vulvar intraepithelial neoplasia (VIN). The two major types of VIN are classic (undifferentiated) and simplex (differentiated). Classic VIN, the more common one, is associated with HPV infection (genital warts due to types 16, 18, 31, 33, 35, and 51) and smoking (Wallace & Sanford, 2006). It typically occurs in women between 30 and 40 years old. In contrast to classic VIN, simplex VIN usually occurs in

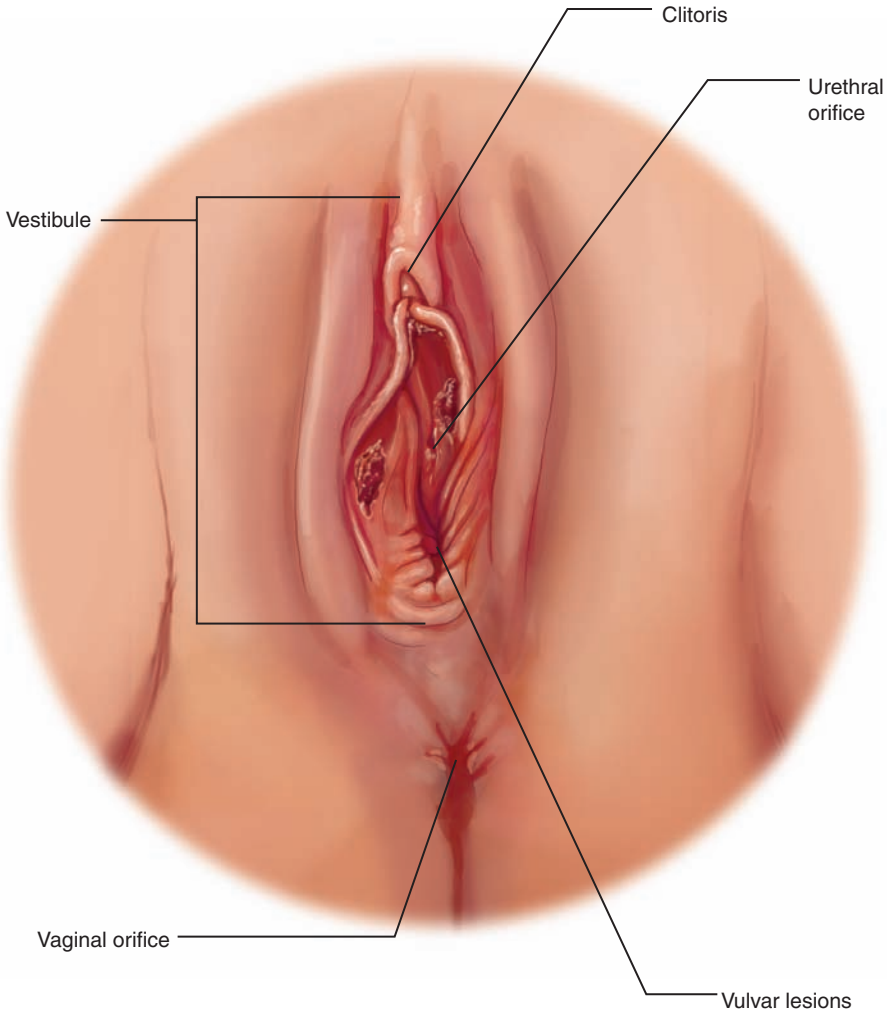

FIGURE 8.5 Vulvar cancer. (The Anatomical Chart Company. [2005]. *Atlas of pathophysiology* [2nd ed.]. Philadelphia: Lippincott Williams & Wilkins)

postmenopausal women and is not associated with HPV (Davidson, 2007).

Screening and Diagnosis

Annual vulvar examination is the most effective way to prevent vulvar cancer. Careful inspection of the vulva during routine annual gynecologic examinations remains the most productive diagnostic technique. Liberal use of biopsies of any suspicious vulvar lesion is usually necessary to make the diagnosis and to guide treatment. However, many women do not seek health care evaluation for months or years after noticing an abnormal lump or lesion.

The diagnosis of vulvar cancer is made by a biopsy of the suspicious lesion, which is usually found on the labia majora.

▶ *Take NOTE!*

Vulvar pruritus or a lump is present in the majority of women with vulvar cancer. Lumps should be biopsied even if the woman is asymptomatic.

Therapeutic Management

Treatment varies depending on the extent of the disease. Laser surgery, cryosurgery, or electrosurgical incision may be used. Larger lesions may need more extensive surgery and skin grafting. The traditional treatment for vulvar cancer has been radical vulvectomy, but more conservative techniques are being used to improve psychosexual outcomes.

Nursing Assessment

Typically, no single specific clinical symptom heralds this disease, so diagnosis is often delayed significantly. Therefore, it is important to review the woman's history for risk factors such as:

- Exposure to HPV type 16
- Age over 50
- HIV infection
- VIN
- Lichen sclerosus
- Melanoma or atypical moles
- Exposure to HSV II
- Multiple sex partners
- Smoking
- History of breast cancer
- Immune suppression
- Hypertension
- Diabetes mellitus
- Obesity (ACS, 2007e)

In most cases, the woman reports persistent vulvar itching that does not improve with the use of creams or ointments. During the physical examination, observe for any masses or thickening of the vulvar area. A vulvar lump or mass most often is noted. The vulvar lesion is usually raised and may be fleshy, ulcerated, leukoplakic, or warty (Naumann & Higgins, 2007). Less commonly, the woman may present with vulvar bleeding, discharge, dysuria, and pain.

Nursing Management

Women with vulvar cancer must clearly understand their disease, treatment options, and prognosis. To accomplish this, provide information and establish effective communication with the client and her family. Act as an educator and advocate.

Teach the woman about healthy lifestyle behaviors, such as smoking cessation and measures to reduce risk factors. For example, instruct the woman how to examine her genital area, urging her to do so monthly between menstrual periods. Tell her to look for any changes in appearance (e.g., whitened or reddened patches of skin); changes in feel (e.g., areas of the vulva becoming itchy or painful); or the development of lumps, moles (e.g., changes in size, shape, or color), freckles, cuts, or sores on the vulva. Urge the woman to report these changes to the health care provider (ACS, 2007e).

Teach the woman about preventive measures such as not wearing tight undergarments and not using perfumes and dyes in the vulvar region. Also educate her about the use of barrier methods of birth control (e.g., condoms) to reduce the risk of contracting HIV, HSV, and HPV.

For the woman diagnosed with vulvar cancer, provide information and support. Discuss potential changes in sexuality if radical surgery is performed. Encourage her to communicate openly with her partner. Refer her to appropriate community resources and support groups.

Key Concepts

- Women have a one-in-three lifetime risk of developing cancer, and one out of every four deaths is from cancer; thus, nurses must focus on screening and educating all women regardless of risk factors.
- The nurse plays a key role in offering emotional support, determining appropriate sources of support, and helping the woman use effective coping strategies when facing a diagnosis of cancer of the reproductive tract. Although reproductive tract cancer is rare during pregnancy, the woman's vigilance and routine screenings should continue throughout.
- A woman's sexuality and culture are inextricably interwoven, and it is essential that nurses working with

women of various cultures recognize this and remain sensitive to the vast changes that will take place when the diagnosis of cancer is made.

- Ovarian cancer is the eighth most common cancer among women and the fourth most common cause of cancer deaths for women in the United States, accounting for more deaths than any other cancer of the reproductive system.
- Ovarian cancer has been described as "the overlooked disease" or "silent killer," because women and/or health care practitioners often ignore or rationalize early symptoms. It is typically diagnosed in advanced stages.
- Unopposed endogenous and exogenous estrogens, obesity, nulliparity, menopause after the age of 52 years, and diabetes are the major etiologic risk factors associated with the development of endometrial cancer.
- The American Cancer Society (ACS) recommends that women should be informed about risks and symptoms of endometrial cancer at the onset of menopause and strongly encouraged to report any unexpected bleeding or spotting to their health care providers.
- Malignant diseases of the vagina are either primary vaginal cancers or metastatic forms from adjacent or distant organs. Vaginal cancer tumors can be effectively treated and, when found early, are often curable.
- Cervical cancer incidence and mortality rates have decreased noticeably in the past several decades, with most of the reduction attributed to the Pap test, which detects cervical cancer and precancerous lesions.
- The nurse's role involves primary prevention of cervical cancer through education of women regarding risk factors and preventive techniques to avoid cervical dysplasia.
- Diagnosis of vulvar cancer is often delayed significantly because there is no single specific clinical symptom that heralds it. The most common presentation is persistent vulvar itching that does not improve with the application of creams or ointments.

Chapter Worksheet

Multiple Choice Questions

1. When describing ovarian cancer to a local women's group, the nurse states that ovarian cancer often is not diagnosed early because:
   a. The disease progresses very slowly.
   b. The early stages produce very vague symptoms.
   c. The disease usually is diagnosed only at autopsy.
   d. Clients don't follow up on acute pelvic pain.
2. A postmenopausal woman reports that she has started spotting again. Which of the following would the nurse do?
   a. Instruct the client to keep a menstrual diary for the next few months.
   b. Tell her not to worry, since this a common but not serious event.
   c. Have her start warm-water douches to promote healing.
   d. Anticipate that the doctor will do an endometrial biopsy.
3. Which of the following would the nurse identify as the priority psychosocial need for a women diagnosed with reproductive cancer?
   a. Clear information
   b. Hand-holding
   c. Cheerfulness
   d. Offering of hope
4. When teaching a group of women about screening and early detection of cervical cancer, the nurse would include which of the following as most effective?
   a. Fecal occult blood test
   b. CA-125 blood test
   c. Pap smear
   d. Sigmoidoscopy
5. After teaching a group of students about reproductive tract cancers, the nursing instructor determines that the teaching was successful when the students identify which of the following as the deadliest type of female reproductive cancer?
   a. Vulvar
   b. Ovarian
   c. Endometrial
   d. Cervical

Critical Thinking Exercises

1. Tammy Scott, a 27-year-old sexually active Caucasian woman, visits the Health Department family planning clinic and requests information about the various methods available. In taking her history, the nurse learns that she started having sex at age 15 and has had multiple sex partners since then. She smokes two packs of cigarettes daily. Because she has been unemployed for a few months, her health insurance policy has lapsed. She has never previously obtained any gynecologic care.
   a. Based on her history, which risk factors for cervical cancer are present?
   b. What recommendations would you make for her, and why?
   c. What are this client's educational needs concerning health maintenance?
2. Jennifer Nappo, a 60-year-old nulliparous woman, presents to the gynecologic oncology clinic after her health care provider palpated an adnexal mass on her right ovary. In taking her history, the nurse learns that she has experienced mild abdominal bloating and weight loss for the past several months but felt fine otherwise. She was diagnosed with breast cancer 15 years ago and was treated with a lumpectomy and radiation. She has occasionally used talcum powder in her perineal area over the past 20 years.

   A transvaginal ultrasound reveals a complex mass in the right adnexa. She undergoes a total abdominal hysterectomy and bilateral salpingo-oophorectomy and lymph node biopsy. Pathology confirms a diagnosis of stage III ovarian cancer with abdominal metastasis and positive lymph nodes.
   a. Is this client's profile typical for a woman with this diagnosis?
   b. What in her history might increase her risk for ovarian cancer?
   c. What can the nurse do to increase awareness of this cancer for all women?

STUDY ACTIVITIES

1. During your surgical clinical rotation, interview a female client undergoing surgery for cancer of her reproductive organs. Ask her to recall the symptoms that brought her to the health care provider. Ask her what thoughts, feelings, and emotions went through her mind before and after her diagnosis. Finally, ask her how this experience will change her life in the future.
2. Visit an oncology and radiology treatment center to find out about the various treatment modalities available for reproductive cancers. Contrast the various treatment methods and report your findings to your class.
3. Visit one of the websites listed at the end of the chapter to explore a topic of interest concerning reproductive cancers. How correct and current is the content? What is its level? Share your assessment with your classmates.
4. Taking oral contraceptives provides protection against _____ cancer.
5. Two genes, BRCA-1 and BRCA-2, are linked with hereditary _____ and _____ cancers.

CHAPTER 9

VIOLENCE AND ABUSE

KEY TERMS

acquaintance rape
battered women syndrome
cycle of violence
date rape
female genital mutilation
human trafficking
incest
intimate partner violence
post-traumatic stress disorder
rape
sexual abuse
statutory rape

LEARNING OBJECTIVES

After completion of the chapter, the student should be able to:

1. Define the key terms.
2. Discuss the incidence of violence in women.
3. Outline the cycle of violence and appropriate interventions.
4. Discuss the myths and facts about violence.
5. Analyze the dynamics of rape and sexual abuse.
6. Describe the resources available to women experiencing abuse.
7. Discuss the role of the nurse who cares for abused women.

Dorothy came to the prenatal clinic with a complaint of recurring headaches. She had been in twice this week already, but insisted she be seen today and started to cry. When the nurse called her into the examination room, Dorothy's cell phone rang. She hurried to answer it and told the person on the other end that she was at the store. When the nurse asked if she was afraid at home, Dorothy answered "at times." What cues did the nurse pick up on to ask that question? How frequent is this problem in women?

Wow

After being traumatized, women can decide to stay in the shallow end of the pool or they can find support and swim in the ocean.

Violence against women is a significant health and social problem affecting virtually all societies, but often it goes unrecognized and unreported. For all the strides American women have made in the past 100 years, obliterating violence against themselves isn't one of them. Violence against women is a growing problem. In many countries it is still accepted as part of normal behavior. According to the Federal Bureau of Investigation, one third to one half of all women in the United States will experience some form of physical violence during their lifetime (FBI, 2007). Forty percent to 60 percent of murders of women in North America are committed by intimate partners (FBI, 2007). Federal funding for the problem is trickling down to local programs, but it isn't reaching victims fast enough. In the United States, there are three times more shelters for animals than for battered women (Dutton, 2007). In many cases, a victim escapes her abuser only to be turned away from a local shelter because it is full. The number of abused women is staggering: one woman is being battered every 12 seconds in the United States (CDC, 2007a).

Nurses play a major role in assessing women who have suffered some type of violence. Often, after a woman is victimized, she will complain about physical ailments that will give her the opportunity to visit a health care setting. A visit to a health care agency is an ideal time for women to be assessed for violence. Because nurses are viewed as trustworthy and sensitive about very personal subjects, women often feel comfortable in confiding or discussing these issues with them.

▶ ***Take*** NOTE!

Nurses will come in contact with violence and sexual abuse no matter what health care setting they work in. Nurses must be ready to ask the right questions and to act on the answers, because such action could be life-saving.

This chapter will address two types of violence against women: intimate partner violence and sexual abuse. Both types of violence against women have devastating and costly consequences for all of society.

Intimate Partner Violence

Intimate partner violence is actual or threatened physical or sexual violence or psychological/emotional abuse. It includes threats of physical or sexual violence when the threat is used to control a person's actions (CDC, 2007a). Intimate partners include individuals who are currently in dating, cohabitating, or marital relationships, or those who have been in such relationships in the past. Some of the common terms used to describe intimate partner violence are domestic abuse, spouse abuse, domestic violence, battering, and rape. Intimate partner violence affects a distressingly high percentage of the population and has physical, psychological, social, and economic consequences (Fig. 9.1).

A nurse may be the first health care professional to assess and identify the signs of intimate partner violence and can have a profound impact on a woman's decision to seek help. Thus, it is important for nurses to be able to identify abuse and aid the victim. Intimate partner violence can leave significant psychological scars, and a well-trained nurse can have a positive impact on the victim's mental and emotional health.

Incidence

Although estimates vary, as many as 6 million women are abused annually (CDC, 2007a). Even more shocking, 75% of the abused women initially identified in a medical setting go on to suffer repeated abuse, including homicide (CDC, 2007a). This may include physical violence, emotional abuse, sexual assault, rape, incest, or elder abuse. Each year, intimate partner violence results in an estimated 1,200 deaths and 2 million injuries among women (CDC, 2008).

Women are at risk for violence at nearly every stage of their lives. Old, young, beautiful, unattractive, married, single—no woman is completely safe from the risk of intimate partner violence. Current or former husbands or lovers kill over half of the murdered women in the United States. Intimate partner violence against women causes more serious injuries and deaths than automobile accidents, rapes, and muggings combined. The medical cost of intimate partner violence approaches $6 billion each year to pay for medical and surgical care, counseling, child care, incarceration, attorney fees, and loss of work productivity (Kelly, 2007).

Abuse occurs in both heterosexual and homosexual relationships. Violence within gay and lesbian relationships may go unreported for fear of harassment or ridicule. In addition, since gay and lesbian partnerships are not seen

FIGURE 9.1 Intimate partner violence has significant physical, psychological, social, and economic consequences. An important role of the health care provider is to identify abusive or potentially abusive situations as soon as possible and provide support for the victim.

as legal in many states, there are few statistics gathered on incident rates.

Background

Until the mid-1970s, our society tended to legitimize a man's power and control over a woman. The U.S. legal and judicial systems considered intervention into family disputes wrong and a violation of the family's right to privacy. Intimate partner violence was often tolerated and even socially acceptable. Fortunately, attitudes and laws have changed to protect women and punish abusers. In *Healthy People 2010,* two key objectives address violence against women.

Characteristics of Intimate Partner Violence

Although more research is needed in this area, studies have found certain risk factors for intimate partner violence:

- Use and abuse of substances such as alcohol (this increases the risk of perpetration and victimization for both men and women)
- Negative affect (e.g., hostility and depression)
- History of childhood abuse
- History of antisocial behavior
- Current unemployment
- Neighborhood norms that accept violence and drug use
- Traditional gender role expectations (Herrenkohl et al., 2007)

Generation-to-Generation Continuum of Violence

Violence is a learned behavior that, without intervention, is self-perpetuating. It is a cyclical health problem. The long-term effects of violence on victims and children can be profound. Children who witness one parent abuse another are more likely to become delinquents or batterers themselves because they see abuse as an integral part of a close relationship. Thus, an abusive relationship between father and mother can perpetuate future abusive relationships. Research has found that children who witness intimate partner violence are at risk for developing psychiatric disorders, developmental problems, school failure, violence against others, and low self-esteem (Paluzzi, 2007).

Childhood maltreatment is a major health problem that is associated with a wide range of physical conditions and leads to high rates of psychiatric morbidity and social problems in adulthood. Women who were physically or sexually abused as children have an increased risk of victimization and experience adverse mental health conditions such as depression, anxiety, and low self-esteem as adults (Ferris, 2007).

In 50% to 75% of the cases when a parent is abused, the children are abused as well (Paluzzi, 2007). Exposure to violence has a negative impact on children's physical, emotional, and cognitive well-being. The cycle continues into another generation through learned responses and violent acting out. While there are always exceptions, most children deprived of their basic physical, psychological, and spiritual needs do not develop healthy personalities. They grow up with feelings of fear, inadequacy, anxiety, anger, hostility, guilt, and rage. They often lack coping skills, blame others, demonstrate poor impulse control, and generally struggle with authority. Unless this cycle is broken, more than half become abusers themselves (CDC, 2007a).

HEALTHY PEOPLE 2010

Objective	Significance
1. Reduce the rate of physical assault by current or former intimate partners. 2. Reduce the annual rate of rape or attempted rape.	• Will increase women's quality and years of healthy life • Eliminate health disparities for survivors of violence • Goal is to have 90% compliance in screening for intimate partner violence by health professionals. • Meeting these objectives will reflect the importance of early detection, intervention, and evaluation.

The Cycle of Violence

In an abusive relationship, the **cycle of violence** comprises three distinct phases: the tension-building phase, the acute battering phase, and the honeymoon phase (Dutton, 2007). The cyclical behavior begins with a time of tension-building arguments, progresses to violence, and settles into a making-up or calm period. This cycle of violence increases in frequency and severity as it is repeated over and over again. The cycle can cover a long or short period of time. The honeymoon phase gradually shortens and eventually disappears altogether. Abuse in relationships typically becomes accelerated and thus more dangerous over time. The abuser no longer feels the need to apologize and indulge in a honeymoon phase as the woman becomes increasingly disempowered in the relationship.

Phase 1: Tension-Building

During the first—and usually the longest—phase of the cycle, tension escalates between the couple. Excessive drinking, jealousy, or other factors might lead to name-calling, hostility, and friction. The woman might sense that her partner is reacting to her more negatively, that he is on edge and reacts heatedly to any trivial frustration. A woman often will accept her partner's building anger as legitimately directed toward her. She internalizes what she perceives as her responsibility to keep the situation from exploding. In her mind, if she does her job well, he remains calm. But if she fails, the resulting violence is her fault.

Phase 2: Acute Battering

The second phase of the cycle is the explosion of violence. The batterer loses control both physically and emotionally. This is when the victim may be assaulted or murdered. After a battering episode, most victims consider themselves lucky that the abuse was not worse, no matter how severe their injuries. They often deny the seriousness of their injuries and refuse to seek medical treatment.

Phase 3: Honeymoon

The third phase of the cycle is a period of calm, loving, contrite behavior on the part of the batterer. He may be genuinely sorry for the pain he caused his partner. He attempts to make up for his brutal behavior and believes he can control himself and never hurt the woman he loves. The victim wants to believe that her partner really can change. She feels responsible, at least in part, for causing the incident, and she feels responsible for her partner's well-being (Box 9.1).

Types of Abuse

Abusers may use whatever it takes to control a situation—from emotional abuse and humiliation to physical assault. Victims often tolerate emotional, physical, financial, and sexual abuse. Many remain in abusive relationships because they believe they deserve the abuse.

Emotional Abuse

Emotional abuse includes:

- Promising, swearing, or threatening to hit the victim
- Forcing the victim to perform degrading or humiliating acts
- Threatening to harm children, pets, or close friends
- Humiliating the woman by name-calling and insults
- Threatening to leave her and the children
- Destroying valued possessions
- Controlling the victim's every move

BOX 9.1 Cycle of Violence

- Phase 1: Tension-building: Verbal or minor battery occurs. Almost any subject, such as housekeeping or money, may trigger the buildup of tension. The victim attempts to calm the abuser.
- Phase 2: Acute battering: Characterized by uncontrollable discharge of tension. Violence is rarely triggered by the victim's behavior: she is battered no matter what her response.
- Phase 3: Reconciliation (honeymoon)/calm phase: The batterer becomes loving, kind, and apologetic and expresses guilt. Then the abuser works on making the victim feel responsible.

Sources: AWHONN, 2007; Aggeles, 2007; Burgess, 2007.

Physical Abuse

Physical abuse includes:

- Hitting or grabbing the victim so hard that it leaves marks
- Throwing things at the victim
- Slapping, spitting at, biting, burning, pushing, choking, or shoving the victim
- Kicking or punching the victim, or slamming her against things
- Attacking the victim with a knife, gun, rope, or electrical cord
- Controlling access to health care for injury

Financial Abuse

Financial abuse includes:

- Preventing the woman from getting a job
- Sabotaging a current job
- Controlling how all money is spent
- Failing to contribute financially

Sexual Abuse

Sexual abuse includes:

- Forcing the woman to have vaginal, oral, or anal intercourse against her will
- Biting the victim's breasts or genitals
- Shoving objects into the victim's vagina
- Forcing the victim to perform sexual acts on other people or animals

Myths and Facts About Intimate Partner Violence

There are many myths about intimate partner violence (Table 9.1). Health care providers should take steps to dispel these myths.

Abuse Profiles

Victims

Ironically, victims rarely describe themselves as abused. In **battered woman syndrome**, the woman has experienced deliberate and repeated physical or sexual assault by an intimate partner. She is terrified and feels trapped, helpless, and alone. She reacts to any expression of anger or threat by avoidance and withdrawal behavior.

Some women believe that the abuse is caused by a personality flaw or inadequacy in themselves (e.g., inability to keep the man happy). These feelings of failure are reinforced and exploited by their partners. After being told repeatedly that they are "bad," some women begin to believe it. Many victims were abused as children and may have poor self-esteem, depression, insomnia, or a history of suicide attempts, injury, or drug and alcohol abuse (Aggeles, 2007).

Abusers

Abusers come from all walks of life and often feel insecure, powerless, and helpless, feelings that are not in line with the macho image they would like to project. The abuser

TABLE 9.1 COMMON MYTHS AND FACTS ABOUT VIOLENCE

Myths	Facts
Battering of women occurs only in lower socioeconomic classes.	Violence occurs in all socioeconomic classes.
Substance abuse causes the violence.	Violence is a learned behavior and can be changed. The presence of drugs and alcohol can make a bad problem worse.
Violence occurs to only a small percentage of women.	One in four women will be victims of violence.
Women can easily choose to leave the abusive relationship.	Women stay in the abusive relationship because they feel they have no options.
Only men with mental health problems commit violence against women.	Abusers often seem normal and don't appear to suffer from personality disorders or other forms of mental illness.
Pregnant women are protected from abuse by their partners.	One in five women is physically abused during pregnancy. The effects of violence on infant outcomes can include preterm delivery, fetal distress, low birthweight, and child abuse.
Women provoke their partners to abuse them.	Women may be willing to blame themselves for someone else's bad behavior, but nobody deserves to be beaten.
Violent tendencies have gone on for generations and are accepted.	The police, justice system, and society are beginning to make domestic violence socially unacceptable.

Sources: Aggeles, 2007; AWHONN, 2007; Giardino, 2007; Kelly, 2007.

expresses his feelings of inadequacy through violence or aggression toward others (Du Plat-Jones, 2006).

Violence typically occurs at home and is usually directed toward the man's intimate partner or the children who live there. Abusers refuse to share power and choose violence to control their victims. They often exhibit child-like aggression or antisocial behaviors. They may fail to accept responsibility or blame others for their own problems. They might also have a history of substance abuse problems, mental illness, arrests, troubled relationships, obsessive jealousy, controlling behaviors, erratic employment history, and financial problems.

Violence Against Pregnant Women

Many think of pregnancy as a time of celebration and planning for the unborn child's future, but in a troubled relationship it can be a time of escalating violence. The strongest predictor of abuse during pregnancy is prior abuse (Giardino, 2007). For women who have been abused before, beatings and violence during pregnancy are "business as usual" for them.

Women are at a higher risk for violence during pregnancy. Pregnant women are vulnerable during this time, and abusers can take advantage of it. An estimated 325,000 pregnant women are abused by their partners each year (CDC, 2007a). Abuse during pregnancy poses special risks and dynamics.

Various factors may lead to battering during pregnancy, including:

- Inability of the couple to cope with the stressors of pregnancy
- Resentment toward the interference of the growing fetus and change in the woman's shape
- Doubts about paternity or the expectant mother's fidelity during pregnancy
- Perception that the baby will be a competitor
- Outside attention the pregnancy brings to the woman
- Unwanted pregnancy
- The woman's new interest in herself and her unborn baby
- Insecurity and jealousy about the pregnancy and the responsibilities it brings
- Financial burden related to expense of pregnancy and loss of income
- Stress of role transition from adult man to becoming the father of a child
- Physical and emotional changes of pregnancy that make the woman vulnerable
- Previous isolation from family and friends that limit the couple's support system

Abuse during pregnancy threatens the well-being of the mother and fetus. Physical violence may involve injuries to the head, face, neck, thorax, breasts, and abdomen (Casanueva & Martin, 2007). The mental health consequences are also significant. Several studies have confirmed the relationship between abuse and poor mental health, especially depression (Giardino, 2007). For the pregnant woman, this most often manifests itself as postpartum depression.

▶ **Take** NOTE!

Frequently the fear of harm to her unborn child will motivate a woman to escape an abusive relationship.

Women assaulted during pregnancy are at risk for:

- Injuries to themselves and the fetus
- Depression
- Chronic anxiety
- Miscarriage
- Stillbirth
- Poor nutrition
- Insomnia
- Placental abruption
- Uterine rupture
- Excessive weight gain or loss
- Smoking and substance abuse
- Delayed or no prenatal care
- Preterm labor
- Chorioamnionitis
- Vaginitis
- Sexually transmitted infections
- Urinary tract infections
- Premature and low-birthweight infants (Sharps, Laughon, & Giangrande, 2007)

Signs of abuse can emerge during pregnancy and may include poor attendance at prenatal visits, unrealistic fears, weight fluctuations, difficulty with pelvic examinations, and noncompliance with treatment.

Uncovering abuse in pregnant women requires a consistent and direct approach to every client by the nurse. Multiple assessments may enhance reporting by enabling the nurse to establish trust and rapport with the woman and identify changes in her behavior. Once abuse is discovered in a pregnant woman, interventions should include safety assessment, emotional support, counseling, referral to community services, and ongoing prenatal care (Burgess, 2007).

Violence Against Older Women

Intimate partner violence affects women of all ages, but often the literature focuses on women in the childbearing years, ignoring the problems of aging women experiencing abuse. There are laws in all 50 states requiring health care professionals to report elder or vulnerable person abuse. Estimates suggest that 500,000 to 1.5 million cases of elder abuse and neglect occur annually in the United States (Bonomi et al., 2007).

Although an injury may bring the older woman into the health care system, the physical and emotional sequelae of intimate partner violence may be more subtle: they may include depression, insomnia, chronic pain, atypical chest pain, or other kinds of somatic symptoms (Thackeray et al., 2007). Accurate detection and assess-

EVIDENCE-BASED PRACTICE 9.1
Nurse Case Management for Pregnant Women Experiencing or at Risk for Abuse

The goal of this randomized controlled trial was to determine whether individualized nursing case management can decrease stress among pregnant women at risk for abuse or in abusive relationships.

● Study

The study was conducted at two prenatal clinics in the Pacific Northwest and rural Midwest. Participants were 1,000 women who spoke English and were 13 to 23 weeks pregnant at time of recruitment. All intervention group women (n = 499) were offered an abuse video and had access to a nurse case manager 24/7. Participants at risk for abuse or in abusive relationships also received individualized nursing care management throughout the pregnancy.

▲ Findings

The most common nursing activities were providing support (38%) and assessing needs (32%). The nursing care management group received an average of 22 contacts, most (80%) by telephone, and had a significant reduction in stress scores as measured by the Prenatal Psychosocial Profile. Compared to the control group, the differences were in the predicted direction but were not statistically different. A major finding was the choice by abused women to focus on basic needs and their pregnancies rather than the abuse, although all received safety planning.

■ Nursing Implications

Pregnant women at risk for abuse or in abusive relationships experience very stressful and complex lives. Nurses need to focus on the needs they identify, which may not be the abusive relationship.

Curry, M. A., Durham, L., Bullock, L., Bloom, T., & Davis, J. (2006). Nurse case management for pregnant women experiencing or at risk for abuse. *Journal of Obstetric, Gynecologic, and Neonatal Nursing, 35*(2), 181–192.

ment of abuse in elderly women are essential duties of all nurses.

Nursing Management

Nurses encounter thousands of abuse victims each year in their practice settings, but many victims slip through the cracks. There are many things that nurses can do to help victims. Early recognition and intervention can significantly reduce the morbidity and mortality associated with intimate partner violence. To stop the cycle of violence, nurses need to know how to assess for and identify violence and implement appropriate actions. The key is astute assessment and identification.

Assessment

Routine screening for intimate partner violence is the first way to detect abuse. The nurse should build rapport by showing an interest in the concerns of the woman, listening, and creating an atmosphere of openness. Communicating support through a nonjudgmental attitude, or telling her that no one deserves to be abused, is the first step toward establishing trust and rapport. Rather than overlooking abused women as "chronic complainers," astute nurses need to be vigilant for subtle clues of abuse.

Learning how to assess for abuse is critical. Some basic assessment guidelines follow.

Screen for Abuse During Every Health Care Visit

Screening for violence takes only a few minutes and can have an enormously positive effect on the outcome for the abused woman. Any woman could be a victim; no single sign marks a woman as an abuse victim, but the following clues may be helpful:

- Injuries: bruises, scars from blunt trauma, or weapon wounds on the face, head, and neck
- Injury sequelae: headaches, hearing loss, joint pain, sinus infections, teeth marks, clumps of hair missing, dental trauma, pelvic pain, breast or genital injuries
- Reported history of injury that is not consistent with the actual presenting problem
- Mental health problems: depression, anxiety, substance abuse, eating disorders, suicidal ideation or suicide attempts
- Frequent health care visits for chronic, stress-related disorders such as chest pain, headaches, back or pelvic pain, insomnia, and gastrointestinal disturbances
- Partner's behavior at the health care visit: appears overly solicitous or overprotective, is unwilling to leave her alone with the health care provider, answers questions for her, and attempts to control the situation (Aggeles, 2007)

Look for the following indicators of abuse:

- Previous history of assault
- Previous injuries inflicted by weapons
- Multiple medical visits for injuries or anxiety symptoms
- History of depression, substance use, or suicide attempts
- Tranquilizer or sedative use
- Sexually transmitted infections or pelvic inflammatory disease
- Bruises to the upper arm, neck and face, abdomen, or breasts
- Comments about emotional or physical abuse of "a friend"
- Hovering behavior of male partner during visit (Aggeles, 2007; Giardino, 2007)

Dorothy, who you met at the beginning of the chapter, has been frequenting the clinic with vague somatic complaints in recent weeks and admits she is sometimes afraid at home. She tells the nurse her partner doesn't want her to work, even though he was only sporadically employed at low-paying jobs. What cues in her assessment might indicate abuse? What physical signs might the nurse observe?

Isolate Patient Immediately From Family

If abuse is detected, immediately isolate the woman to provide privacy and to prevent potential retaliation from the abuser. Asking about abuse in front of the perpetrator may trigger an abusive episode during the interview or at home. Ways to ensure the woman's safety would be to take the victim to an area away from the abuser to ask questions. The assessment can take place anywhere—x-ray area, ultrasound room, elevator, ladies' room, laboratory—that is private and away from the abuser.

If abuse is detected, the nurse can do the following to enhance the nurse–client relationship:

- Educate the woman about the connection between the violence and her symptoms.
- Help the woman acknowledge what has happened to her and begin to deal with the situation.
- Offer her referrals so she can get the help that will allow her to begin to heal.

Dorothy returns to the prenatal clinic a month later with anemia, inadequate weight gain, bruises on her face and neck, and second-trimester bleeding. This time she is accompanied by her partner, who stays close to Dorothy. What questions should the nurse ask to assess the situation? Where is the appropriate location to ask these questions? What legal responsibilities does the nurse have concerning her observations?

Ask Direct or Indirect Questions About Abuse

Questions to screen for abuse should be routine and handled just like any other question. Many nurses feel uncomfortable asking questions of this nature, but broaching the subject is important even if the answer comes later. Just

knowing that someone else knows about the abuse offers a victim some relief.

Ask difficult questions in an empathetic and nonthreatening manner and remain nonjudgmental in all responses and interactions. Choose the type of question that makes you most comfortable. Direct and indirect questions produce the same results. "Does your partner hit you?" or "Have you ever been or are you now in an abusive relationship?" are direct questions. If that approach feels uncomfortable, try indirect questions: "We see many women with injuries or complaints like yours and often they are being abused. Is that what is happening to you?" or "Many women in our community experience abuse from their partners. Is anything like that happening in your life?" With either approach, nurses need to maintain a nonjudgmental acceptance of whatever answer the woman offers.

The SAVE Model is a screening protocol that nurses can use when assessing women for violence (Box 9.2).

BOX 9.2 SAVE Model

SCREEN all of your patients for violence by asking:
- Do you feel safe in your home?
- Do you feel you are in control of your life?
- Have you ever been sexually or physically abused?
- Can you talk about your abuse with me now?

ASK direct questions in a nonjudgmental way:
- Begin by normalizing the topic to the woman.
- Make continuous eye contact with the woman.
- Stay calm; avoid emotional reactions to what she tells you.
- Never blame the woman, even if she blames herself.
- Don't dismiss or minimize what she tells you, even if she does.
- Wait for each answer patiently. Don't rush to the next question.
- Do not use formal, technical, or medical language.
- Use a nonthreatening, accepting approach.

VALIDATE the patient by telling her:
- You believe her story.
- You do not blame her for what happened.
- It is brave of her to tell you this.
- Help is available for her.
- Talking with you is a hopeful sign and a first big step.

EVALUATE, educate, and refer this patient by asking her:
- What type of violence was it?
- Is she now in any danger?
- How is she feeling now?
- Does she know that there are consequences to violence?
- Is she aware of community resources available to help her?

Sources: Dutton, 2007; Du Plat-Jones, 2006; Thackeray et al., 2007.

Assess Immediate Safety

The Danger Assessment Tool helps women and health care providers assess the potential for homicidal behavior in an ongoing abusive relationship. It is based on research that showed several risk factors for abuse-related murders:

- Increased frequency or severity of abuse
- Presence of firearms
- Sexual abuse
- Substance abuse
- Generally violent behavior outside of the home
- Control issues (e.g., daily chores, friends, job, money)
- Physical abuse during pregnancy
- Suicide threats or attempts (victim or abuser)
- Child abuse (Kelly, 2007)

Document and Report Your Findings

If the interview reveals a history of abuse, accurate documentation is critical because this evidence may support the woman's case in court. Documentation must include details about the frequency and severity of abuse; the location, extent, and outcome of injuries; and any treatments or interventions. When documenting, use direct quotes and be very specific: "He choked me." Describe any visible injuries, and use a body map (outline of a woman's body) to show where the injuries are. Obtain photos (with informed consent) or document her refusal if the woman declines photos. Pictures or diagrams can be worth a thousand words. Figure 9.2 shows a sample documentation form for intimate partner violence.

Laws in many states require health care providers to alert the police to any injuries that involve knives, firearms, or other deadly weapons or that present life-threatening emergencies. If assessment reveals suspicion or actual indication of abuse, you can explain to the woman that you are required by law to report it.

Nursing Diagnosis

When violence is suspected or validated, the nurse needs to formulate nursing diagnoses based on the completed assessment. Possible nursing diagnoses related to violence against women might include the following:

- Deficient knowledge related to understanding the cycle of violence and availability of resources
- Fear related to possibility of severe injury to self or children during cycle of violence
- Low self-esteem related to feelings of worthlessness
- Hopelessness related to prolonged exposure to violence
- Compromised individual and family coping related to persistence of victim–abuser relationship

Interventions

If abuse is identified, nurses can undertake interventions that can increase the woman's safety and improve her health. The goal of intervention is to enable the victim to gain control of her life. Provide sensitive, predictable care

INTIMATE PARTNER VIOLENCE DOCUMENTATION FORM

Explain to Client: The majority of what you tell me is confidential and cannot be shared with anyone without your written permission. However, I am required by law to report information pertaining to child or adult abuse and gunshot wounds or life-threatening injuries.

STEP 1–Establish total privacy to ask screening questions. Safety is the first priority. Client must be alone, or if the client has a child with her, the child must not be of verbal age. ONLY complete this form if YOU CAN assure the client's safety, privacy, and confidentiality.

STEP 2–Ask the client screening questions.

"Because abuse is so common, we are now asking all of our female clients:

Are you in a relationship in which you are being hurt or threatened, emotionally or physically?
___Yes ___ No

Do you feel unsafe at home?"
___Yes ___ No

If both screening questions are NO in STEP 2, and you are not concerned that the client may be a victim, sign and date the form in the signature block directly below. Provide information and resources as appropriate.

Signature _____ **Title** _____ **Date** _____

If both screening answers are NO and you are concerned that the client may be a victim, go to STEP 5. If the client answers YES to either question, proceed to STEP 3 below. Sign and date the signature block on the back of the form after completing STEP 6.

STEP 3–Assess the abuse and safety of the client and any children.

Say to client: "From the answers you have just given me, I am worried for you."

"Has the relationship gotten worse, or is it getting scarier?" ___Yes ___ No

"Does your partner ever watch you closely, follow you, or stalk you?" ___Yes ___ No

Ask the following question in clinic settings only. Do not ask in home settings:

"If your partner is here with you today, are you afraid to leave with him/her?" ___Yes ___ No

"Is there anything else you want to tell me?" _____
_____
_____
_____

Name: _____
ID No: _____
Date of Birth: _____

DH 3202, 2/03
Stock Number: 5744-000-3202-2

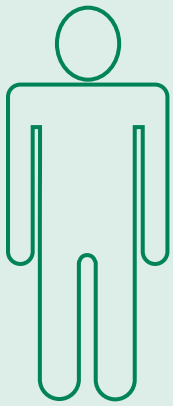
FIGURE 9.2 Intimate partner violence documentation form. (Florida Department of Health) *(continued)*

"Are there children in the home?" ___Yes ___ No

If the answer to the question above is "yes," say to client: "I'm concerned for your safety and the safety of your children. You and your children deserve to be at home without feeling afraid."

"Have there been threats of abuse or direct abuse of the children?" ___Yes ___ No

STEP 4–Assess client's physical injuries and health conditions, past and present.



Observations/Comments/Interventions:

_____
_____
_____
_____
_____
_____
_____
_____
_____
_____

STEP 5–If both screening answers are NO, and you ARE CONCERNED that the client may be a victim:

a. Say to the client: "All of us know of someone at some time in our lives who is abused. So, I am providing you with information in the event you or a friend may need it in the future."

b. Document under comments in Step 6.

STEP 6–Information, referrals or reports made

Yes	No	
___	___	1. Client given domestic violence information including safety planning
___	___	2. Reviewed domestic violence information including safety planning
___	___	3. State Abuse Hotline (1-800-96-ABUSE) and State Domestic Violence Hotline number (1-800-500-1119) given to the client
___	___	4. Client called hotline during visit
___	___	5. Client seen by advocate during visit
___	___	6. Report made. If yes, to whom: _____

Comments

FIGURE 9.2 (continued) Intimate partner violence documentation form. (Florida Department of Health)

in an accepting setting. Offer step-by-step explanations of procedures. Provide educational materials about violence. Allow the victim to actively participate in her care and have control over all health care decisions. Pace your nursing interventions and allow the woman to take the lead. Communicate support through a nonjudgmental attitude. Carefully document assessment findings and nursing interventions.

Depending on when in the cycle of violence the nurse encounters the abused woman, goals may fall into three groups:

- Primary prevention: aimed at breaking the abuse cycle through community educational initiatives by nurses, physicians, law enforcement, teachers, and clergy
- Secondary prevention: focuses on dealing with victims and abusers in early stages, with the goal of preventing progression of abuse
- Tertiary prevention: activities are geared toward helping severely abused women and children recover and become productive members of society and rehabilitating abusers to stop the cycle of violence. These activities are typically long term and expensive.

A tool developed by Holtz and Furniss (1993)—the ABCDES—provides a framework for providing sensitive nursing interventions to abused women (Box 9.3).

Specific nursing interventions for the abused woman include educating her about community services, providing emotional support, and offering a safety plan.

BOX 9.3 The ABCDES of Caring for Abused Women

- **A** is reassuring the woman that she is not alone. The isolation by her abuser keeps her from knowing that others are in the same situation and that health care providers can help her.
- **B** is expressing the belief that violence against women is not acceptable in any situation and that it is not her fault.
- **C** is confidentiality, since the woman might believe that if the abuse is reported, the abuser will retaliate.
- **D** is documentation, which includes the following:
  1. A clear quoted statement about the abuse
  2. Accurate descriptions of injuries and the history of them
  3. Photos of the injuries (with the woman's consent)
- **E** is education about the cycle of violence and that it will escalate.
- **S** is safety, the most important aspect of the intervention, to ensure that the woman has resources and a plan of action to carry out when she decides to leave.

Educate the Woman About Community Services

A wide range of support services are available to meet the needs of victims of violence. Nurses should be prepared to help the woman take advantage of these opportunities. Services will vary by community but might include psychological counseling, legal advice, social services, crisis services, support groups, hotlines, housing, vocational training, and other community-based referrals.

Give the woman information about shelters or services even if she initially rejects it. Give the woman the National Domestic Violence hotline number: (800) 799-7233. Since 1992, guidelines from the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) have required emergency departments to maintain lists of community referral agencies that deal with the victims of intimate partner violence (JCAHO, 2007).

Provide Emotional Support

Providing reassurance and support to a victim of abuse is key if the violence is to end. Nurses in all clinical settings can help victims to feel a sense of personal power and provide them with a safe and supportive environment. Appropriate action can help victims to express their thoughts and feelings in constructive ways, manage stress, and move on with their lives. Appropriate interventions are:

- Strengthen the woman's sense of control over her life by:
  - Teaching coping strategies to manage her stress
  - Assisting with activities of daily living to improve her lifestyle
  - Allowing her to make as many decisions as she can
  - Educating her about the symptoms of post-traumatic stress disorder and their basis
- Encourage the woman to establish realistic goals for herself by:
  - Teaching problem-solving skills
  - Encouraging social activities to connect with other people
- Provide support and allow the woman to grieve for her losses by:
  - Listening to and clarifying her reactions to the traumatic event
  - Discussing shock, disbelief, anger, depression, and acceptance
- Explain to the woman that:
  - Abuse is never OK. She didn't ask for it and she doesn't deserve it.
  - She is not alone and help is available.
  - Abuse is a crime and she is a victim.
  - Alcohol, drugs, money problems, depression, or jealousy does not cause violence, but these things can give the abuser an excuse for losing control and abusing her.
  - The actions of the abuser are not her fault.
  - Her history of abuse is believed.
  - Making a decision to leave an abusive relationship can be very hard and takes time.

Offer a Safety Plan

The choice to leave must rest with the victim. Nurses cannot choose a life for the victim; they can only offer choices. Leaving is a process, not an event. Victims may try to leave their abusers as many as seven or eight times before succeeding. Frequently, the final attempt to leave may result in the death of the victim. Women planning to leave an abusive relationship should have a safety plan, if possible (Teaching Guidelines 9.1).

Sexual Violence

Sexual violence is both a public health problem and a human rights violation. More than once every 3 minutes, 78 times an hour, 1,871 times a day, girls and women in America are raped (Medicine Net, 2007). Rape has been reported against females from age 6 months to 93 years, but it still remains one of the most underreported violent crimes in the United States. Estimates suggest that, somewhere in the United States, a woman is sexually assaulted every 2.5 minutes (RAINN, 2007). The National Center for Prevention and Control of Sexual Assault estimates that one out of three women will be sexually assaulted sometime in her life, and two thirds of these assaults will not be reported (CDC, 2007b). Over the course of their lives, women may experience more than one type of violence.

Sexual violence can have a variety of devastating short- and long-term effects. Women can experience psychological, physical, and cognitive symptoms that affect them daily. They can include chronic pelvic pain, headaches, backache, sexually transmitted infections, pregnancy, anxiety, denial, fear, withdrawal, sleep disturbances, guilt, nervousness, phobias, substance abuse, depression, sexual dysfunction, and post-traumatic stress disorder (CDC, 2007b). A traumatic experience not only damages a woman's sense of safety in the world, but it can also reduce her self-esteem and her ability to continue her education, to earn money and be productive, to have children and, if she has children, to nurture and protect them (Macy et al., 2007).

▶ ***Take*** *NOTE!*

Sexual violence has been called a "tragedy of youth." More than half of all rapes (54%) of women occur before age 18 (Medicine Net, 2007).

Assailants, like their victims, come from all walks of life and all ethnic backgrounds; there is no typical profile. More than half are under 25, and the majority are married and leading "normal" sex lives. Why do men rape? No theory provides a satisfactory explanation. So few assailants are caught and convicted that a clear profile remains elusive. What is known is that many assailants have trouble dealing with the stresses of daily life. Such men become angry and experience feelings of powerlessness. They commit a sexual assault as an expression of power and control (Macy et al., 2007).

Sexual violence is a broad term that can be used to describe sexual abuse, incest, rape, female genital mutilation, and human trafficking.

Sexual Abuse

Sexual abuse occurs when a woman is forced to have sexual contact of any kind (vaginal, oral, or anal) without her consent. Marriage does not constitute a tacit agreement for a spouse to inflict one's demands on the other without permission. Childhood sexual abuse is any type of sexual exploitation that involves a child younger than 18 years old; it might include disrobing, nudity, masturbation, fondling, digital penetration, and intercourse (Alekseeva, 2007).

Childhood sexual abuse has a lifelong impact on its survivors. Women who were sexually abused during childhood are at a heightened risk for repeat abuse. This is because the early abuse lowers their self-esteem and their ability to protect themselves and set firm boundaries. Childhood sexual abuse is a trauma that influences the way victims form relationships, deal with adversity, cope with daily problems, relate to their children and peers, protect their health, and live. Studies have shown that the more victimization a woman experiences, the more likely it is she will be re-victimized (Kristensen & Lau, 2007).

TEACHING GUIDELINES 9.1

Safety Plan for Leaving an Abusive Relationship

- When leaving an abusive relationship, take the following items:
  - Driver's license or photo ID
  - Social security number or green card/work permit
  - Birth certificates for you and your children
  - Phone numbers for social services or women's shelter
  - The deed or lease to your home or apartment
  - Any court papers or orders
  - A change of clothing for you and your children
  - Pay stubs, checkbook, credit cards, and cash
  - Insurance cards (Du Plat-Jones, 2006; Dutton, 2007)
  - If you need to leave a domestic violence situation immediately, turn to authorities for assistance in gathering this material.
- Develop a "game plan" for leaving and rehearse it.
- Don't use phone cards—they leave a trail to follow.

EVIDENCE-BASED PRACTICE 9.2
Cognitive-Behavioral Interventions for Children Who Have Been Sexually Abused

Despite different perceptions as to what constitutes child sexual abuse, there is a consensus among clinicians and researchers that this is a substantial social problem that affects large numbers of children and young people worldwide. The effects of sexual abuse manifest themselves in a wide range of symptoms, including fear, anxiety, post-traumatic stress disorder and behavior problems such as externalizing or internalizing, or inappropriate sexual behaviors. Child sexual abuse is associated with an increased risk of psychological problems in adulthood. Knowing what is most likely to benefit children already traumatized by these events is important.

● Study
The aim of this review was to assess the efficacy of cognitive-behavioral therapy (CBT) in addressing the immediate and longer-term sequelae of sexual abuse in children. Ten studies comprising 847 children were identified that met the inclusion criteria.

▲ Findings
The evidence suggests that CBT may have a positive impact on the sequelae of child sexual abuse, but most results were statistically nonsignificant.

● Nursing Implications
The review confirms CBT's potential for addressing the adverse consequences of child sexual abuse but highlights the tenuousness of the evidence base and the need for more carefully conducted and better reported trials.

Macdonald, G. M., Higgins, J. P. T., & Ramchandani, P. (2006). Cognitive-behavioral interventions for children who have been sexually abused. *Cochrane Database of Systematic Reviews* 2006, Issue 4. Art. No.: CD001930. DOI: 10.1002/14651858.CD001930.pub2.

Incest

Childhood sexual abuse involves any kind of sexual experience between a child and another person that violates the social taboos of family roles; children cannot yet understand these activities and cannot give informed consent (Alekseeva, 2007). **Incest** is any type of sexual exploitation between blood relatives or surrogate relatives before the victim reaches 18 years of age. Such sexual abuse is not only a crime but also a symptom of acute and irreversible family dysfunction. Survivors of incest are often tricked, coerced, or manipulated. All adults appear to be powerful to children. Perpetrators might threaten victims so that they are afraid to disclose the abuse or might tell them the abuse is their fault. Often these threats serve to silence victims.

Incestual relationships in the home endanger not only the child's intellectual and moral development, but also the health of the child. Many children don't ask for help because they don't want to expose their "secret." For this reason, just the tip of the iceberg is statistically visible—serious injuries, internal damage, sexually transmitted infections, or pregnancy. Incest can have serious long-term effects on its victims, which may include eating disorders, sexual problems in their adult life, post-traumatic stress disorder, intense guilt and shame, low self-esteem, depression, and self-destructive behavior (NCVC, 2007).

Whether an incest victim endured an isolated incident of abuse or ongoing assaults over an extended period, recovery can be painful and difficult. The recovery process begins with admission of abuse and the recognition that help and services are needed. Resources for incest victims include books, self-help groups, workshops, therapy programs, and possibly legal remedies. In addition to listening to and believing incest victims, nurses need to search for ways to prevent future generations from enduring such abuse and from continuing the cycle of abuse in their own family and relationships.

▶ *Consider* THIS!

At 53 years old, I stood and looked at myself in the mirror. The image staring back at me was one of a frightened, middle-aged, cowardly woman hiding her past. I had been sexually abused by my father for many years as a child and never told anyone. My mother knew of the abuse but felt helpless to make it stop. I married right out of high school to escape and felt I lived a "happy normal life" with my husband and three children. My children have left home and live away, and my husband recently died of a sudden heart attack. I am now experiencing dreams and thoughts about my past abuse and feeling afraid again.

Thoughts: This woman suppressed her abusive past for most of her life and now her painful experience has surfaced. What can be done to reach out to her at this point? Did her health care providers miss the "red flags" that are common to women with a history of childhood sexual abuse all those years?

▶ **Take** NOTE!

Childhood sexual abuse is a trauma that can affect every aspect of the victim's life.

Rape

Rape is an expression of violence, not a sexual act. It is not an act of lust or an overzealous release of passion: it is a violent, aggressive assault on the victim's body and integrity. Rape is a legal rather than a medical term. It denotes penile penetration of the vagina, mouth, or rectum of the female or male without consent. It may or may not include the use of a weapon. **Statutory rape** is sexual activity between an adult and a person under the age of 18 and is considered to have occurred even if the underage person was willing (Kandakai & Smith, 2007). Nine out of every 10 rape victims are female (Alexander et al., 2007). Enforcement of laws, education, and community empowerment are all needed to prevent rape.

Many people believe that rape usually occurs on a dark night when a stranger assaults a provocatively dressed, promiscuous woman. They believe that rapists are sex-starved people seeking sexual gratification. Such myths and the facts are presented in Table 9.2.

Acquaintance Rape

In **acquaintance rape**, someone is forced to have sex by a person he or she knows. Rape by a coworker, a teacher, a husband's friend, or a boss is considered acquaintance rape. **Date rape**, an assault that occurs within a dating relationship or marriage without consent of one of the participants, is a form of acquaintance rape. Acquaintance and date rapes commonly occur on college campuses. One in four college women has been raped—that is, has been forced, physically or verbally, actively or implicitly, to engage in sexual activity (Elliott, 2008).

These forms of rape are physically and emotionally devastating for the victims. Research has indicated that the survivors of acquaintance rape report similar levels of depression, anxiety, complications in subsequent relationships, and difficulty attaining pre-rape levels of sexual satisfaction to what survivors of stranger rape report. Acquaintance rape remains a controversial topic because there is lack of agreement on the definition of consent (Sampson, 2007).

Although acquaintance rape and date rape do not always involve drugs, a rapist might use alcohol or other drugs to sedate his victim. In 1996 the federal government passed a law making it a felony to give an unsuspecting person a "date rape drug" with the intent of raping him or her. Even with penalties of large fines and up to 20 years in prison, the use of date rape drugs is growing (U.S. DHHS, 2007).

Date rape drugs are also known as "club drugs" because they are often used at dance clubs, fraternity parties, and all-night raves. The most common is Rohypnol (also known as roofies, forget pills, and the drop drug). It comes in the form of a liquid or pill that quickly dissolves in liquid with no odor, taste, or color. This drug is 10 times as strong as diazepam (Valium) and produces memory loss for up to 8 hours. Gamma hydroxybutyrate (GHB; called liquid ecstasy or easy lay) produces euphoria, an out-of-body high, sleepiness, increased sex drive, and memory loss. It comes in a white powder or liquid and may cause unconsciousness, depression, and coma.

TABLE 9.2 COMMON MYTHS AND FACTS ABOUT RAPE

Myths	Facts
Women who are raped get over it quickly.	It can take several years to recover emotionally and physically from rape.
Most rape victims tell someone about it.	The majority of women never tell anyone about it. In fact, almost two thirds of victims never report it to the police.
Once the rape is over, a survivor can again feel safe in her life.	The victim feels vulnerable, betrayed, and insecure afterwards.
If a woman does not want to be raped, it cannot happen.	A woman can be forced and overpowered by most men.
Women who feel guilty after having sex then say they were raped.	Few women falsely cry "rape." It is very traumatizing to be a victim.
Victims should report the violence to the police and judicial system.	Only 1% of rapists are arrested and convicted.
Women blame themselves for the rape, believing they did something to provoke the rape.	Women should never blame themselves for being the victim of someone else's violence.
Women who wear tight, short clothes are "asking for it."	No victim invites sexual assault, and what she wears is irrelevant.
Women have rape fantasies and want to be raped.	Reality and fantasy are different.
Medication can help women forget about the rape.	Dreams have nothing to do with the brutal violation of rape.
	Initially medication can help, but counseling is needed.

Sources: CDC, 2007b; Dutton, 2007; Medicine Net, 2007.

TEACHING GUIDELINES 9.2

Protecting Yourself Against Date Rape Drugs

- Avoid parties where alcohol is being served.
- Never leave a drink of any kind unattended.
- Don't accept a drink from someone else. Accept drinks from a bartender or in a closed container only.
- Don't drink from a punch bowl or a keg.
- If you think someone drugged you, call 911.

The third date rape drug, ketamine (known as Special K, vitamin K, or super acid), acts on the central nervous system to separate perception and sensation. Combining ketamine with other drugs can be fatal.

Date rape drugs can be very dangerous, and there are a variety of ways that women can protect themselves (Teaching Guidelines 9.2).

Rape Recovery

Rape survivors take a long time to heal from their traumatic experience. Some women never heal and never get professional counseling, but most can cope. Rape is viewed as a situational crisis that the survivor is unprepared to handle because it is an unforeseen event. Survivors typically go through four phases of recovery following rape (Table 9.3).

A significant proportion of women who are raped also experience symptoms of **post-traumatic stress disorder** (PTSD). PTSD develops when an event outside the range of normal human experience occurs that produces marked distress in the person. Symptoms of PTSD are divided into three groups:

- Intrusion (re-experiencing the trauma, including nightmares, flashbacks, recurrent thoughts)
- Avoidance (avoiding trauma-related stimuli, social withdrawal, emotional numbing)
- Hyperarousal (increased emotional arousal, exaggerated startle response, irritability)

Nursing Management

Research has found that rape survivors undergo a profound and complex trauma. The survivor should be provided with a safe and comfortable environment for a forensic examination. Nursing care of the rape survivor should focus on providing supporting care, collecting and documenting evidence, assessing for sexually transmitted infections, preventing pregnancy, and assessing for PTSD. Once initial treatment and evidence collection are completed, follow-up care should include counseling, medical treatment, and crisis intervention. There is mounting evidence that early intervention and immediate counseling speed a rape survivor's recovery. Nursing Care Plan 9.1 highlights a sample plan of care for a victim of rape.

▶ ***Take*** NOTE!

Many rape survivors seek treatment in the hospital emergency room if there are no rape crisis centers available. Unfortunately, many emergency room doctors and nurses have little training in how to treat rape survivors or in collecting evidence. To make matters worse, if they have to wait for hours in public waiting rooms, survivors may leave the hospital, never to receive treatment or supply the evidence needed to arrest and convict their assailants.

Providing Supporting Care

Establishing a therapeutic and trusting relationship will help the survivor describe her experience. Take the woman to a secure, isolated area away from family, friends, and other patients and staff so she can be open and honest when asked about the assault. Provide a change of clothes, access to a shower and toiletries, and a private waiting area for family and friends.

Collecting and Documenting Evidence

The victim should be instructed to bring all clothing, especially undergarments, worn at the time of the assault to the medical facility. The victim should not shower or bathe before presenting for care. Typically a specially trained nurse will collect the evidence from the victim.

TABLE 9.3 FOUR PHASES OF RAPE RECOVERY

Phase	Survivor's Response
Acute phase (disorganization)	Shock, fear, disbelief, anger, shame, guilt, feelings of uncleanliness; insomnia, nightmares, and sobbing
Outward adjustment phase (denial)	Appears outwardly composed and returns to work or school; refuses to discuss the assault and denies need for counseling
Reorganization	Denial and suppression don't work, and the survivor attempts to make life adjustments by moving or changing jobs and uses emotional distancing to cope.
Integration and recovery	Survivor begins to feel safe and starts to trust others. She may become an advocate for other rape victims.

Nursing Care Plan 9.1

OVERVIEW OF THE WOMAN WHO IS A VICTIM OF RAPE

Lucia, a 20-year-old college junior, was admitted to the emergency room after police found her when a passerby called 911 to report an assault. She stated, "I think I was raped a few hours ago while I was walking home through the park." Assessment reveals the following: numerous cuts and bruises of varying sizes on her face, arms, and legs; lip swollen and cut; right eye swollen and bruised; jacket and shirt ripped and bloodied; hair matted with grass and debris; vital signs within acceptable parameters; client tearful, clutching her clothing, and trembling; perineal bruising and tearing.

NURSING DIAGNOSIS: Rape-trauma syndrome related to report of recent sexual assault

Outcome Identification and Evaluation

Client will demonstrate adequate coping skills related to effects of rape as evidenced by her ability to discuss the event, verbalize her feelings and fears, and exhibit appropriate actions to return to her pre-crisis level of functioning.

Interventions: Promoting Adequate Coping Skills

- Stay with the client *to promote feelings of safety.*
- Explain the procedures to be completed based on facility's policy *to help alleviate client's fear of the unknown.*
- Assist with physical examination for specimen collection *to obtain evidence for legal proceedings.*
- Administer prophylactic medication as ordered *to prevent pregnancy and sexually transmitted infections.*
- Provide care to wounds as ordered *to prevent infection.*
- Assist client with hygiene measures as necessary *to promote self-esteem.*
- Allow client to describe the events as much as possible *to encourage ventilation of feelings about the incident;* engage in active listening and offer nonjudgmental support *to facilitate coping and demonstrate understanding of the client's situation and feelings.*
- Help the client identify positive coping skills and personal strengths used in the past *to aid in effective decision making.*
- Assist client in developing additional coping strategies and teach client relaxation techniques *to help deal with the current crisis and anxiety.*
- Contact the rape counselor in the facility *to help the client deal with the crisis.*
- Arrange for follow-up visit with rape counselor *to provide continued care and to promote continuity of care.*
- Encourage the client to contact a close friend, partner, or family member to accompany her home *to provide support.*
- Provide the client with the telephone number of a counseling service or community support groups *to help her cope and obtain ongoing support.*
- Provide written instructions related to follow-up appointments, care, and testing *to ensure adequate understanding.*

Assessing for Sexually Transmitted Infections

As part of the assessment, a pelvic examination will be done to collect vaginal secretions to rule out any sexually transmitted infections. This examination is very emotionally stressful for most women and should be carried out very gently and sensitively.

Preventing Pregnancy

An essential element in the care of rape survivors involves offering them pregnancy prevention. After unprotected intercourse, including rape, pregnancy can be prevented by using emergency contraceptive pills, sometimes called postcoital contraception. Emergency contraceptive pills involve high doses of the same oral contraceptives that millions of women take every day. The emergency regimen consists of two doses: the first dose is taken within 72 hours of the unprotected intercourse and the second dose is taken 12 hours after the first dose or sooner. Emergency contraception works by preventing ovulation, fertilization, or implantation. It does not disrupt an established pregnancy and should not be confused with mifepristone (RU-486), a drug approved by the Food and Drug Administration for abortion in the first 49 days of gestation. Emergency contraception is most effective if the first dose is taken within 12 hours of the rape; it becomes less effective with every 12 hours of delay thereafter.

Assessing for PTSD

Nurses can begin to assess the extent to which a survivor is suffering from PTSD by asking the following questions:

- To assess the presence of intrusive thoughts:
  - Do upsetting thoughts and nightmares of the trauma bother you?

- Do you feel as though you are actually reliving the trauma?
- Does it upset you to be exposed to anything that reminds you of that event?

- To assess the presence of avoidance reactions:
  - Do you find yourself trying to avoid thinking about the trauma?
  - Do you stay away from situations that remind you of the event?
  - Do you have trouble recalling exactly what happened?
  - Do you feel numb emotionally?
- To assess the presence of physical symptoms:
  - Are you having trouble sleeping?
  - Have you felt irritable or experienced outbursts of anger?
  - Do you have heart palpitations and sweating?
  - Do you have muscle aches and pains all over? (Kiump, 2006)

Female Genital Mutilation

Female genital mutilation, also known as female circumcision, is a cultural practice carried out predominantly in countries of southern Africa and in some areas of the Middle East and Asia. The World Health Organization (WHO) defines female genital mutilation as all procedures involving the partial or total removal or other injury to the female genital organs, whether for cultural or other nontherapeutic purposes (WHO, 2007). More than 140 million girls are estimated to have undergone female genital mutilation and another 2 million are at risk annually, approximately 6,000 daily (WHO, 2007).

This issue has drawn increasing global attention over the past several years. Nongovernmental organizations such as Amnesty International are conducting research and campaign work on the practice. The U.S. government has taken steps to criminalize the practice in America and now considers asylum applications in light of mutilation practices in the country of origin (WHO, 2007). WHO is fighting tirelessly to eradicate this practice through advocacy, policy development, research, and training for health care providers (Zaidi et al., 2007). In fact, WHO, the United Nations Population Fund, and the United Nations Children's Fund have issued a joint plea for the eradication of the practice, saying it would be a major step forward in the promotion of human rights worldwide (WHO, 2007).

▶ ***Take*** NOTE!

From a Western perspective, female genital mutilation is hard to comprehend. Because it is not talked about openly in communities that practice it, women who have undergone it accept it without question and assume it is done to all girls (Wakabi 2007).

Background

Reasons for performing the ritual reflect the ideology and cultural values of each community that practices it. Some consider it a rite of passage into womanhood; others use it as a means of preserving virginity until marriage. In cultures where it is practiced, it is an important part of culturally defined gender identity. In any case, all the reasons are cultural and traditional and are not rooted in any religious texts (RAINBO, 2007). Female genital mutilation causes injury to women and does not benefit them.

Female genital mutilation is usually performed when the girl is between 4 and 10 years old, an age when she cannot give informed consent for a procedure with lifetime health consequences (WHO, 2007). In its mildest form, the clitoris is partially or totally removed. In the most extreme form, called infibulation, the clitoris, labia minora, labia majora, and the urethral and vaginal openings are cut away. The vagina is then stitched or held together, leaving a small opening for menstruation and urination. Cutting and restitching may be necessary to permit the woman to have sexual intercourse and bear children. Box 9.4 lists types of female genital mutilation procedures.

Untrained village practitioners, using no form of anesthesia, generally perform the operation. Cutting instruments may include broken glass, knives, tin lids, scissors, unspecialized razors, or other crude instruments. In addition to causing intense pain, the procedure carries with it a number of health risks, including:

- Pelvic infections
- Hemorrhage
- HIV infection
- Damage to the urethra, vagina, and anus
- Recurrent vaginitis
- Urinary tract infections
- Incontinence
- Post-traumatic stress disorder
- Panic attacks

BOX 9.4 Four Major Types of Female Genital Mutilation Procedures

Type I: Excision of the prepuce with or without excision of part or all of the clitoris
Type II: Excision of the clitoris and part or all of the labia minora
Type III (Infibulation): Excision of all or part of the external genitalia and stitching/narrowing of the vaginal opening
Type IV: Pricking, piercing, or incision of the clitoris or labia
- Stretching of the clitoris and/or labia
- Cauterizing by burning the clitoris and surrounding tissues
- Scraping or cutting the vaginal orifice
- Introduction of a corrosive substance into the vagina
- Placing herbs into the vagina to narrow it

Sources: WHO, 2007; Keleher & Franklin, 2008.

- Keloid formation
- Dermoid cysts
- Vulvar abscesses
- Dysmenorrhea
- Dyspareunia
- Psychosomatic illnesses
- Depression
- Feelings of betrayal
- Bitterness and anger towards family members who allowed it
- Increased morbidity and mortality during childbirth (WHO, 2007)

Nursing Management

Because of increasing migration, nurses throughout the world are increasingly exposed to women who have suffered these procedures and thus need to know about its impact on women's reproductive health. Helping women who have had one of these procedures requires good communication skills and often an interpreter, since many may not speak English. Nurses have the opportunity to educate patients by providing accurate information and positive health care experiences. Make sure that you are comfortable with your own feelings about this practice before dealing with patients. Some guidelines are as follows:

- Let the client know you are concerned and interested and want to help.
- Speak clearly and slowly, using simple, accurate terms.
- Use the term or name for this practice the recipient uses, not "female genital mutilation."
- Use pictures and diagrams to help the woman understand what you are saying.
- Be patient in allowing the client to answer questions.
- Repeat back your understanding of the client's statements.
- Always look and talk directly to the client, not the interpreter.
- Place no judgment on the cultural practice.
- Encourage the client to express herself freely.
- Maintain strict confidentiality.
- Provide culturally competent care to all women.

Human Trafficking

A girl who was just 14 years old was held captive in a tiny trailer room, where she was forced to have sex with as many as 30 men a day. On her night stand was a teddy bear that reminded her of her childhood in Mexico.

This scenario describes **human trafficking**, the enslavement of immigrants for profit in America. Human trafficking is both a global problem and a domestic problem. The United States is a major receiver of trafficked persons. Human trafficking is a modern form of slavery that affects nearly 1 million people worldwide and approximately 20,000 persons in the United States annually (U.S. Department of State, 2007). Women and children are the primary victims of human trafficking, many in the sex trade as described above and others through forced-labor domestic servitude.

Trafficking persons is hugely profitable: one estimate places global profits at approximately $32 billion annually. Among illegal enterprises, trafficking is second only to drug dealing and is tied with the illegal arms industry in its ability to generate dollars (Jones et al., 2007).

The United States is a profitable destination country for traffickers, and these profits contribute to the development of organized criminal enterprises worldwide. According to findings of the Victims of Trafficking and Violence Protection Act of 2000:

- Victims are primarily women and children who lack education, employment, and economic opportunities in their own countries.
- Traffickers promise victims employment as nannies, maids, dancers, factory workers, sales clerks, or models in the United States.
- Traffickers transport the victims from their counties to unfamiliar destinations away from their support systems.
- Once they are here, traffickers coerce them, using rape, torture, starvation, imprisonment, threats, or physical force, into prostitution, pornography, sex trade, forced labor, or involuntary servitude.

These victims are exposed to serious and numerous health risks, such as rape, torture, HIV/AIDS, sexually transmitted infections, cervical cancer, violence, hazardous work environments, poor nutrition, and drug and alcohol addiction (Hodge & Lietz, 2007). Health care is one of the most pressing needs of these victims, and there isn't any comprehensive care available for undocumented immigrants. As a nurse it is important to be alert for trafficking victims in any setting and to recognize cues (Box 9.5).

Human trafficking is a violation of human rights. If you suspect a trafficking situation, notify local law enforcement and a regional social service organization that has experience in dealing with trafficking victims. It is imperative to reach out to these victims and stop the cycle of abuse by following through on your suspicions.

Summary

The causes of violence against women are complex. Many women will experience some type of violence in their lives, and it can have a debilitating affect on their health and future relationships. Violence frequently leaves a "legacy of pain" to future generations. Nurses can empower women and encourage them to move forward and take control of their lives. When women live in peace and security and free from violence, they have an enormous potential to contribute to their own communities and to the

BOX 9.5 Identifying Victims of Human Trafficking

Cues

Look beneath the surface and ask yourself: Is this person. . . .

- A female or a child in poor health?
- Foreign-born and doesn't speak English?
- Lacking immigration documents?
- Giving an inconsistent explanation of injury?
- Reluctant to give any information about self, injury, home, or work?
- Fearful of authority figure or "sponsor" if present? ("Sponsor" might not leave victim alone with health care provider.)
- Living with the employer?

Sample questions to ask the potential victim of human trafficking:

- Can you leave your job or situation if you wish?
- Can you come and go as you please?
- Have you been threatened if you try to leave?
- Has anyone threatened your family with harm if you leave?
- What are your working and living conditions?
- Do you have to ask permission to go to the bathroom, eat, or sleep?
- Is there a lock on your door so you cannot get out?
- What brought you to the United States? Are your plans the same now?
- Are you free to leave your current work or home situation?
- Who has your immigration papers? Why don't you have them?
- Are you paid for the work you do?
- Are there times you feel afraid?
- How can your situation be changed?

national and global society. Violence against women is not normal, legal, or acceptable and it should never be tolerated or justified. It can and must be stopped by the entire world community.

Key Concepts

- Violence against women is a major public health and social problem because it violates a woman's very being and causes numerous mental and physical health sequelae.
- Every woman has the potential to become a victim of violence.
- Several *Healthy People 2010* objectives focus on reducing the rate of physical assaults and the number of rapes and attempted rapes.
- Abuse may be mental, physical, or sexual in nature or a combination.
- The cycle of violence includes three phases: tension-building, acute battering, and honeymoon.
- Many women experience post-traumatic stress disorder (PTSD) after being sexually assaulted. PTSD can inhibit a survivor from adapting or coping in a healthy manner.
- Pregnancy can precipitate violence toward the woman to start or escalate.
- The nurse's role in dealing with survivors of violence is to establish rapport; open up lines of communication; apply the nursing process to assess and screen all patients in all settings; and implement and intervene as appropriate.

Chapter Worksheet

Multiple Choice Questions

1. The primary goal of intervention in working with abused women is to:
   a. Set up an appointment with a mental health counselor for the victim
   b. Convince them to set up a safety plan to use when they leave
   c. Help them to develop courage and financial support to leave the abuser
   d. Empower them and improve their self-esteem to regain control of their lives
2. The first phase of the abuse cycle is characterized by:
   a. The woman provokes the abuser to bring about battering
   b. Tension-building and verbal or minor battery
   c. A honeymoon period that lulls the victim into forgetting
   d. An acute episode of physical battering
3. Women recovering from abusive relationships need to learn ways to improve their:
   a. Cooking skills and provide more nutritious meals for their children
   b. Creativity so as to improve their decorating skills within the home
   c. Communication and negotiation skills to increase their assertiveness
   d. Personal appearance by losing weight and exercising more
4. Which of the following statements might empower abuse victims to take action?
   a. "You deserve better than this."
   b. "Your children deserve to grow up in a two-parent family."
   c. "Try to figure out what you do to trigger his abuse and stop it."
   d. "Give your partner more time to come to his senses about this."

Critical Thinking Exercise

1. Mrs. Boggs has three children under the age of 5 and is 6 months pregnant with her fourth child. She has made repeated unscheduled visits to your clinic with vague somatic complaints regarding the children as well as herself, but has missed several scheduled prenatal appointments. On occasion she has worn sunglasses to cover bruises around her eyes. As a nurse you sense there is something else bothering her, but she doesn't seem to want to discuss it with you. She appears sad and the children cling to her.
   a. Outline your conversation when you broach the subject of abuse with Mrs. Boggs.
   b. What is your role as a nurse in caring for a family in which you suspect abuse?
   c. What ethical/legal considerations are important in planning care for this family?

Study Activities

1. Visit the BellaOnline website for victims of violence (www.bellaonline.com). Discuss what you discovered on this site and your reactions to it.
2. Research the statistics about violence against women in your state. Are law enforcement and community interventions reducing the incidence of sexual assault and intimate partner violence?
3. Attend a dorm orientation at a local college to hear about measures in place to protect women's safety on campus. Find out the number of sexual assaults reported and what strategies the college uses to reduce this number.
4. Volunteer to spend a weekend evening at the local sheriff's department 911 hotline desk to observe the number and nature of calls received reporting domestic violence. Interview the dispatch operator about the frequency and trends of these calls.
5. Identify three community resources that could be useful to a victim of violence. Identify their sources of funding and the services they provide.

UNIT THREE

Pregnancy

This page intentionally left blank.

CHAPTER 10

Fetal Development and Genetics

KEY TERMS

allele
blastocyst
embryonic stage
fertilization
fetal stage
genes
genetic counseling
genetics
genome
genotype
heterozygous
homozygous
karyotype
mosaicism
monosomies
morula
mutation
phenotype
placenta
polyploidy
preembryonic stage
trisomies
trophoblast
umbilical cord
zona pellucida
zygote

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Describe the process of fertilization, implantation, and cell differentiation.
2. Explain the functions of the placenta, umbilical cord, and amniotic fluid.
3. Outline normal fetal development from conception through birth.
4. Compare the various inheritance patterns, including nontraditional patterns of inheritance.
5. Give examples of ethical and legal issues surrounding genetic testing.
6. Explain the role of the nurse in genetic counseling and genetic-related activities.

Robert and Kate Shafer have just received the good news that Kate's pregnancy test was positive. It had been a long and anxious 3 years of trying to start a family. Although both were elated about the prospect of becoming parents, they were concerned about the possibility of a genetic problem because Kate was 38 years old. What might be their first step in looking into their genetic concern? As a nurse, what might raise concerns for you?

Wow

Being a nurse without awe is like food without spice. Nurses only have to witness the miracle of life to find their lost awe.

Human reproduction is one of the most intimate spheres of an individual's life. For conception to occur, a healthy ovum from the woman is released from the ovary, passes into an open fallopian tube, and starts its journey downward. Sperm from the male is deposited into the vagina and swims approximately 7 inches to meet the ovum at the outermost portion of the fallopian tube, the area where fertilization takes place (Gilbert, 2007). When one spermatozoon penetrates the ovum's thick outer membrane, pregnancy begins. All this activity takes place within a 5-hour time span.

Nurses caring for the childbearing family need to have a basic understanding of conception and prenatal development so they can identify problems or variations and can initiate appropriate interventions should any problems occur. This chapter presents an overview of fetal development, beginning with conception. It also discusses hereditary influences on fetal development and the nurse's role in genetic counseling.

Fetal Development

Fetal development during pregnancy is measured in number of weeks after fertilization. The duration of pregnancy is about 40 weeks from the time of fertilization. This equates to 9 calendar months or approximately 266 to 280 calendar days. The three stages of fetal development during pregnancy are:

1. **Preembryonic stage**: fertilization through the second week
2. **Embryonic stage**: end of the second week through the eighth week
3. **Fetal stage**: end of the eighth week until birth

Fetal circulation is a significant aspect of fetal development that spans all three stages.

Preembryonic Stage

The preembryonic stage begins with **fertilization**, also called *conception.* Fertilization is the union of ovum and sperm, which is the starting point of pregnancy. Fertilization typically occurs around 2 weeks after the last normal menstrual period in a 28-day cycle (Dillon, 2007). Fertilization requires a timely interaction between the release of the mature ovum at ovulation and the ejaculation of enough healthy, mobile sperm to survive the hostile vaginal environment through which they must travel to meet the ovum. All things considered, the act of conception is difficult at best. To say merely that it occurs when the sperm unites with the ovum is overly simple because this union requires an intricate interplay of hormonal preparation and overcoming an overwhelming number of natural barriers. A human being is truly an amazing outcome of this elaborate process.

Prior to fertilization, the ovum and the spermatozoon undergo the process of meiosis. The primary oocyte completes its first meiotic division before ovulation. The secondary oocyte begins its second meiotic division just before ovulation. Primary and secondary spermatocytes undergo meiotic division while still in the testes (Fig. 10.1).

Although more than 200 million sperm/mL are contained in the ejaculated semen, only one is able to enter the ovum to fertilize it. All others are blocked by the clear protein layer called the **zona pellucida**. The zona pellucida disappears in about 5 days. Once the sperm reaches the plasma membrane, the ovum resumes meiosis and forms a nucleus with half the number of chromosomes (23). When the nucleus from the ovum and the nucleus of the sperm make contact, they lose their respective nuclear membranes and combine their maternal and paternal chromosomes. Because each nucleus contains a haploid number of chromosomes (23), this union restores the diploid number (46). The resulting **zygote** begins the process of a new life. The genetic information from both ovum and sperm establishes the unique physical characteristics of the individual. Sex determination is also determined at fertilization and depends on whether the ovum is fertilized by a Y-bearing sperm or an X-bearing sperm. An XX zygote will become a female and an XY zygote will become a male (Fig. 10.2).

Fertilization takes place in the outer third of the ampulla of the fallopian tube. When the ovum is fertilized by the sperm (now called a zygote), a great deal of activity immediately takes place. Mitosis, or *cleavage,* occurs as the zygote is slowly transported into the uterine cavity by tubal muscular movements (Fig. 10.3). After a series of four cleavages, the 16 cells appear as a solid ball of cells or **morula**, meaning "little mulberry." The morula reaches the uterine cavity about 72 hours after fertilization (Johnson, 2007).

With additional cell division, the morula divides into specialized cells that will later form fetal structures. Within the morula, an off-center, fluid-filled space appears, transforming it into a hollow ball of cells called a **blastocyst** (Fig. 10.4). The inner surface of the blastocyst will form the embryo and amnion. The outer layer of cells surrounding the blastocyst cavity is called a **trophoblast**. Eventually, the trophoblast develops into one of the embryonic membranes, the chorion, and helps to form the placenta.

At this time, the developing blastocyst needs more food and oxygen to keep growing. The trophoblast attaches itself to the surface of the endometrium for further nourishment. Normally, implantation occurs in the upper uterus (fundus), where a rich blood supply is available. This area also contains strong muscular fibers, which clamp down on blood vessels after the placenta separates from the inner wall of the uterus. Additionally, the lining is thickest here so the placenta cannot attach so strongly that it remains attached after birth (Alvero & Schlaff, 2006). Figure 10.5 shows the process of fertilization and implantation.

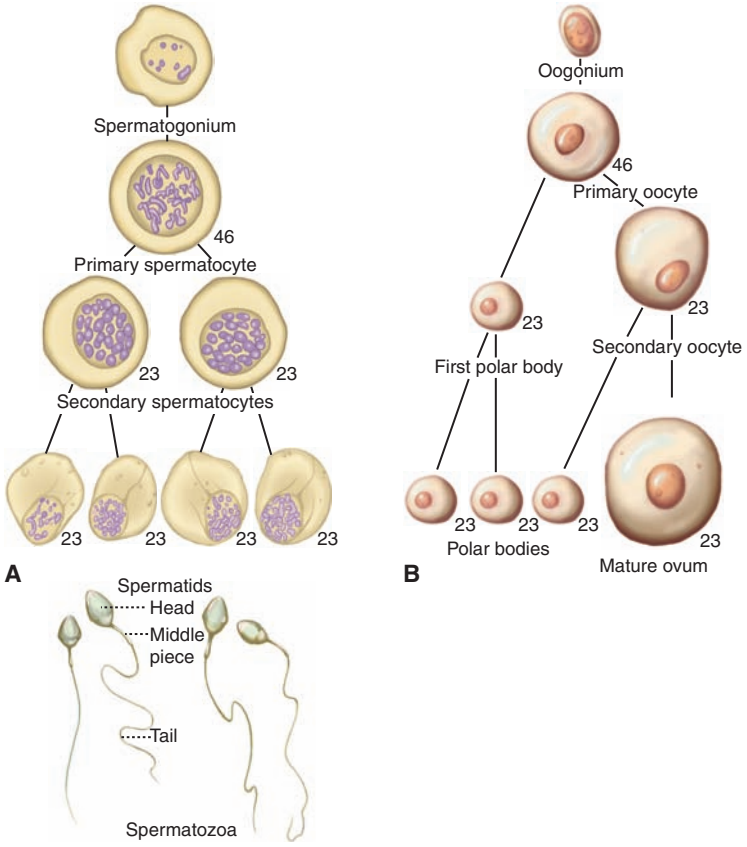

FIGURE 10.1 The formation of gametes by the process of meiosis is known as gametogenesis. (**A**) Spermatogenesis. One spermatogonium gives rise to four spermatozoa. (**B**) Oogenesis. From each oogonium, one mature ovum and three abortive cells are produced. The chromosomes are reduced to one-half the number characteristic for the general body cells of the species. In humans, the number in the body cells is 46, and that in the mature spermatozoon and secondary oocyte is 23.

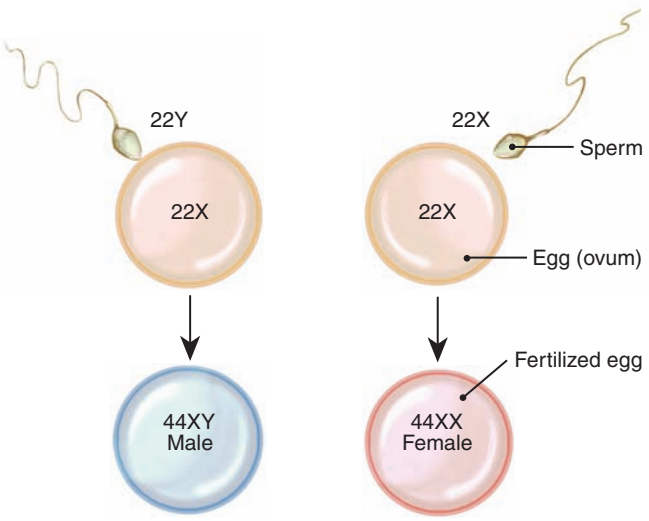

FIGURE 10.2 Inheritance of gender. Each ovum contains 22 autosomes and an X chromosome. Each spermatozoon (sperm) contains 22 autosomes and either an X chromosome or a Y chromosome. The gender of the zygote is determined at the time of fertilization by the combination of the sex chromosomes of the sperm (either X or Y) and the ovum (X).

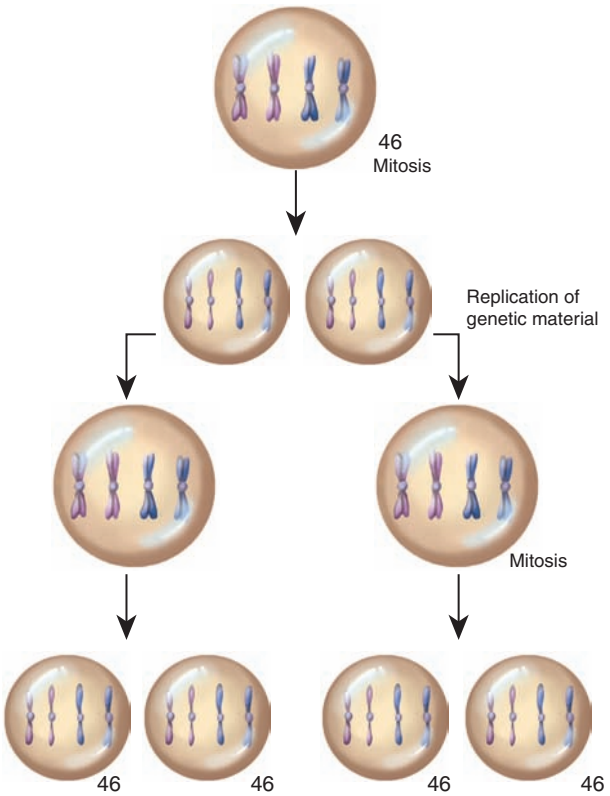

FIGURE 10.3 Mitosis of the stoma cells.

FIGURE 10.4 Blastocyst.

Concurrent with the development of the trophoblast and implantation, further differentiation of the inner cell mass occurs. Some of the cells become the embryo itself, and others give rise to the membranes that surround and protect it. The three embryonic layers of cells formed are:

1. Ectoderm—forms the central nervous system, special senses, skin, and glands
2. Mesoderm—forms the skeletal, urinary, circulatory, and reproductive organs
3. Endoderm—forms the respiratory system, liver, pancreas, and digestive system

These three layers are formed at the same time as the embryonic membranes, and all tissues, organs, and organ systems develop from these three primary germ cell layers (Dillon, 2007). Box 10.1 summarizes preembryonic development.

Despite the intense and dramatic activities going on internally to create a human life, many women are unaware that pregnancy has begun. Several weeks will pass before even one of the presumptive signs of pregnancy—missing the first menstrual period—will take place.

BOX 10.1 Summary of Preembryonic Development

- Fertilization takes place in ampulla of the fallopian tube.
- Union of sperm and ovum forms a *zygote* (46 chromosomes).
- Cleavage cell division continues to form a *morula* (mass of 16 cells).
- The inner cell mass is called *blastocyst,* which forms the embryo and amnion.
- The outer cell mass is called *trophoblast,* which forms the placenta and chorion.
- Implantation occurs 7 to 10 days after conception in the endometrium.

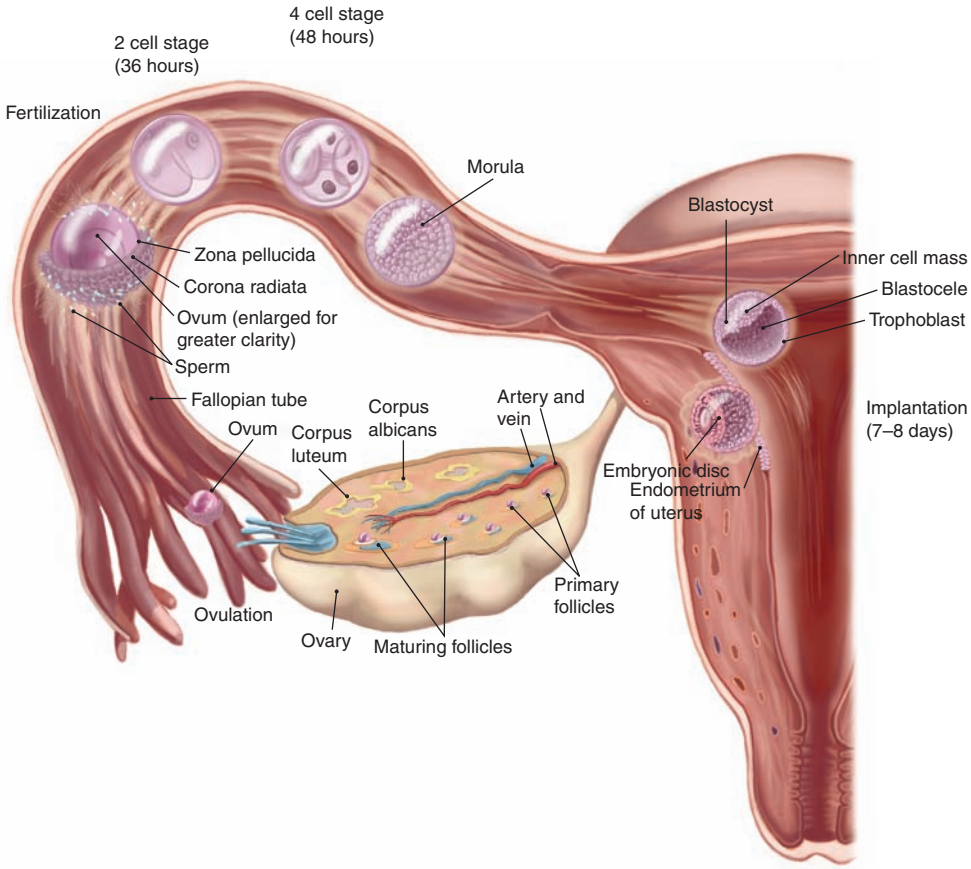

FIGURE 10.5 Fertilization and tubal transport of the zygote. From fertilization to implantation, the zygote travels through the fallopian tube, experiencing rapid mitotic division (cleavage). During the journey toward the uterus the zygote evolves through several stages, including morula and blastocyst.

Embryonic Stage

The embryonic stage of development begins at day 15 after conception and continues through week 8. Basic structures of all major body organs and the main external features are completed during this time period. Table 10.1 and Figure 10.6 summarize embryonic development.

The embryonic membranes (Fig. 10.7) begin to form around the time of implantation. The chorion consists of trophoblast cells and a mesodermal lining. It has finger-like projections called *chorionic villi* on its surface. The amnion originates from the ectoderm germ layer during the early stages of embryonic development. It is a thin protective membrane that contains amniotic fluid. As the embryo grows, the amnion expands until it touches the chorion. These two fetal membranes form the fluid-filled amniotic sac, or bag of waters, that protects the floating embryo (Creatsas, Chrousos, & Mastorakos, 2007).

Amniotic fluid surrounds the embryo and increases in volume as the pregnancy progresses, reaching approximately a liter at term. Amniotic fluid is derived from two sources: fluid transported from the maternal blood across the amnion and fetal urine. Its volume changes constantly as the fetus swallows and voids. Sufficient amounts of amniotic fluid help maintain a constant body temperature for the fetus, permit symmetric growth and development, cushion the fetus from trauma, allow the **umbilical cord** to be relatively free from compression, and promote fetal movement to enhance musculoskeletal development. Amniotic fluid is composed of 98% water and 2% organic matter. It is slightly alkaline and contains albumin, urea, uric acid, creatinine, bilirubin, lecithin,

TABLE 10.1 EMBRYONIC AND FETAL DEVELOPMENT

Week 3
Beginning development of brain, spinal cord, and heart
Beginning development of the gastrointestinal tract
Neural tube forms, which later becomes the spinal cord
Leg and arm buds appear and grow out from body

Week 4
Brain differentiates
Limb buds grow and develop more

4 weeks

Week 5
Heart now beats at a regular rhythm
Beginning structures of eyes and ears
Some cranial nerves are visible
Muscles innervated

Week 6
Beginning formation of lungs
Fetal circulation established
Liver produces RBCs
Further development of the brain
Primitive skeleton forms
Central nervous system forms
Brain waves detectable

Week 7
Straightening of trunk
Nipples and hair follicles form
Elbows and toes visible
Arms and legs move
Diaphragm formed
Mouth with lips and early tooth buds

Week 8
Rotation of intestines
Facial features continue to develop
Heart development complete
Resembles a human being
(Ratner, 2002)

8 weeks

Weeks 9–12
Sexual differentiation continues
Buds for all 20 temporary teeth laid down
Digestive system shows activity
Head comprises nearly half the fetus size
Face and neck are well formed
Urogenital tract completes development
Red blood cells are produced in the liver
Urine begins to be produced and excreted
Fetal gender can be determined by week 12
Limbs are long and thin; digits are well formed

12 weeks

(continued)

TABLE 10.1 EMBRYONIC AND FETAL DEVELOPMENT (continued)

Weeks 13–16
A fine hair develops on the head called lanugo
Fetal skin is almost transparent
Bones become harder
Fetus makes active movement
Sucking motions are made with the mouth
Amniotic fluid is swallowed
Fingernails and toenails present
Weight quadruples
Fetal movement (also know as quickening) detected by mother

16 weeks

Weeks 17–20
Rapid brain growth occurs
Fetal heart tones can be heard with stethoscope
Kidneys continue to secret urine into amniotic fluid
Vernix caseosa, a white greasy film, covers the fetus
Eyebrows and head hair appear
Brown fat deposited to help maintain temperature
Nails are present on both fingers and toes
Muscles are well developed

20 weeks

Weeks 21–24
Eyebrows and eyelashes are well formed
Fetus has a hand grasp and startle reflex
Alveoli forming in lungs
Skin is translucent and red
Lungs begin to produce surfactant

25 weeks

Weeks 25–28
Fetus reaches a length of 15 inches
Rapid brain development
Eyelids open and close
Nervous system controls some functions
Fingerprints are set
Blood formation shifts from spleen to bone marrow
Fetus usually assumes head-down position

28 weeks

Weeks 29–32
Rapid increase in the amount of body fat
Increased central nervous system control over body functions
Rhythmic breathing movements occur
Lungs are not fully mature
Fetus stores iron, calcium, and phosphorus

32 weeks

Weeks 33–38
Testes are in scrotum of male fetus
Lanugo begins to disappear
Increase in body fat
Fingernails reach the end of fingertips
Small breast buds are present on both sexes
Mother supplies fetus with antibodies against disease
Fetus is considered full term at 38 weeks
Fetus fills uterus (Bailey, 2003)

37 weeks

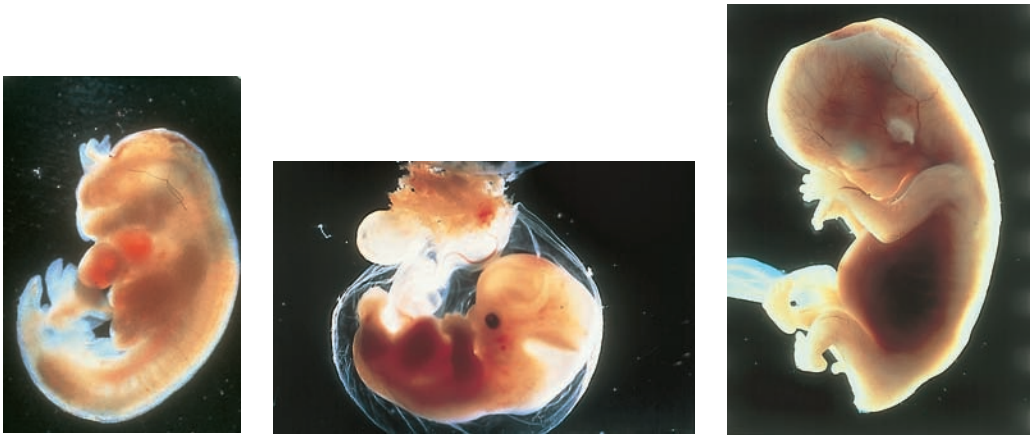

FIGURE 10.6 Embryonic development. (**A**) 4-week embryo. (**B**) 5-week embryo. (**C**) 6-week embryo.

sphingomyelin, epithelial cells, vernix, and fine hair called lanugo (Johnson, 2007).

The volume of amniotic fluid is important in determining fetal well-being. It gradually fluctuates throughout the pregnancy. Alterations in amniotic fluid volume can be associated with problems in the fetus. Too little amniotic fluid (<500 mL at term), termed *oligohydramnios*, is associated with uteroplacental insufficiency and fetal renal abnormalities. Too much amniotic fluid (>2,000 mL at term), termed *hydramnios*, is associated with maternal diabetes, neural tube defects, chromosomal deviations, and malformations of the central nervous system and/or gastrointestinal tract that prevent normal swallowing of amniotic fluid by the fetus (Gilbert, 2007).

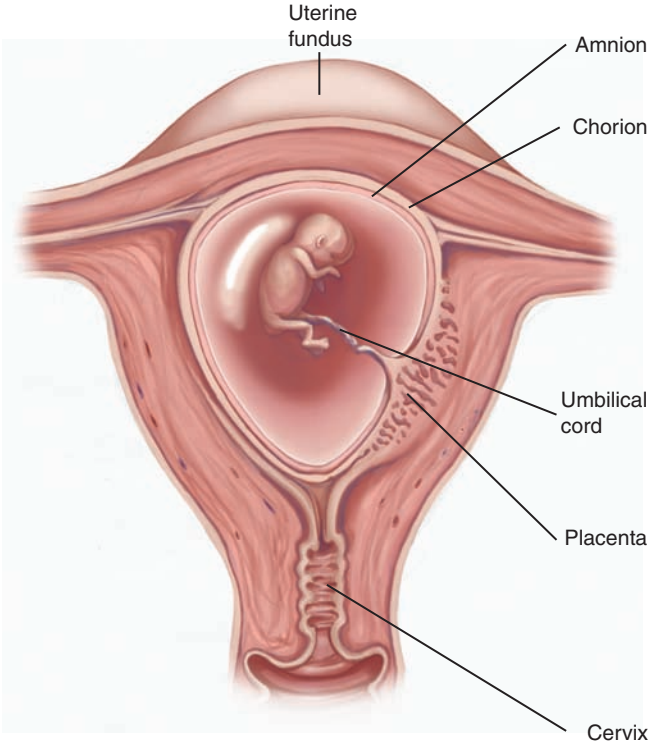

FIGURE 10.7 The embryo is floating in amniotic fluid, surrounded by the protective fetal membranes (amnion and chorion).

While the placenta is developing (end of the second week), the umbilical cord is also formed from the amnion. It is the lifeline from the mother to the growing embryo. It contains one large vein and two small arteries. Wharton's jelly (a specialized connective tissue) surrounds these three blood vessels in the umbilical cord to prevent compression, which would cut off fetal blood and nutrient supply. At term, the average umbilical cord is 22 inches long and about an inch wide (Johnson, 2007).

The precursor cells of the placenta—the trophoblasts—first appear 4 days after fertilization as the outer layer of cells of the blastocyst. These early blastocyst trophoblasts differentiate into all the cells that form the **placenta**. When fully developed, the placenta serves as the interface between the mother and the developing fetus. As early as 3 days after conception, the trophoblasts make human chorionic gonadotropin (hCG), a hormone that ensures that the endometrium will be receptive to the implanting embryo. During the next few weeks the placenta begins to make hormones that control the basic physiology of the mother in such a way that the fetus is supplied with the nutrients and oxygen needed for growth. The placenta also protects the fetus from immune attack by the mother, removes waste products from the fetus, induces the mother to bring more food to the placenta, and, near the time of delivery, produces hormones that ready fetal organs for life outside the uterus (Johnson, 2007).

At no time during pregnancy does the mother's blood mix with fetal blood because there is no direct contact between their bloods; layers of fetal tissue always separate the maternal blood and the fetal blood. These fetal tissues are called the *placental barrier*. Materials can be interchanged only through diffusion. The maternal uterine arteries deliver the nutrients to the placenta, which in turn provides nutrients to the developing fetus; the mother's

uterine veins carry fetal waste products away. The structure of the placenta is usually completed by week 12.

The placenta is not only a transfer organ but a factory as well. It produces several hormones necessary for normal pregnancy:

- hCG—preserves the corpus luteum and its progesterone production so that the endometrial lining of the uterus is maintained; this is the basis for pregnancy tests
- Human placental lactogen (hPL)—modulates fetal and maternal metabolism, participates in the development of maternal breasts for lactation, and decreases maternal insulin sensitivity to increase its availability for fetal nutrition
- Estrogen (estriol)—causes enlargement of a woman's breasts, uterus, and external genitalia; stimulates myometrial contractility
- Progesterone (progestin)—maintains the endometrium, decreases the contractility of the uterus, stimulates maternal metabolism and breast development, provides nourishment for the early conceptus
- Relaxin—acts synergistically with progesterone to maintain pregnancy, causes relaxation of the pelvic ligaments, softens the cervix in preparation for birth (Alvero & Schlaff, 2006)

The placenta acts as a pass-through between the mother and fetus, not a barrier. Almost everything the mother ingests (food, alcohol, drugs) passes through to the developing conceptus. This is why it is so important to advise pregnant women not to use drugs, alcohol, and tobacco, because they can be harmful to the conceptus.

During the embryonic stage, the conceptus grows rapidly as all organs and structures are forming. During this critical period of differentiation the growing embryo is most susceptible to damage from external sources, including teratogens (substances that cause birth defects, such as alcohol and drugs), infections (such as rubella or cytomegalovirus), radiation, and nutritional deficiencies.

Fetal Stage

The average pregnancy lasts 280 days from the first day of the last menstrual period. The fetal stage is the time from the end of the eighth week until birth. It is the longest period of prenatal development. During this stage, the conceptus is mature enough to be called a fetus. Although all major systems are present in their basic form, dramatic growth and refinement of all organ systems take place during the fetal period (see Table 10.1). Figure 10.8 depicts a 12- to 15-week-old fetus.

Fetal Circulation

The circulation through the fetus during uterine life differs from that of a child or an adult. Fetal circulation involves the circulation of blood from the placenta to and through the fetus, and back to the placenta. A properly functioning fetal circulation system is essential to sustain the fetus. Before it develops, nutrients and oxygen diffuse through the

FIGURE 10.8 Fetal development: 12- to 15-week fetus.

extraembryonic coelom and the yolk sac from the placenta. As the embryo grows, its nutrient needs increase and the amount of tissue easily reached by diffusion increases. Thus, the circulation must develop quickly and accurately (Blackburn, 2007).

The circulatory system of the fetus functions much differently from that of a newborn. The most significant difference is that oxygen is received from the placenta during fetal life and via the lungs after birth. In addition, the fetal liver does not perform the metabolic functions that it will after birth because the mother's body performs these functions. Three shunts also are present during fetal life:

1. Ductus venosus—connects the umbilical vein to the inferior vena cava
2. Ductus arteriosus—connects the main pulmonary artery to the aorta
3. Foramen ovale—anatomic opening between the right and left atrium

▶ *Take* NOTE!

Fetal circulation functions to carry highly oxygenated blood to vital areas (e.g., heart, brain) while first shunting it away from less important ones (e.g., lungs, liver). The placenta essentially takes over the functions of the lungs and liver during fetal life. As a result, large volumes of oxygenated blood are not needed.

The oxygenated blood is carried from the placenta to the fetus via the umbilical vein. About half of this blood passes through the hepatic capillaries and the rest flows through the ductus venosus into the inferior vena cava. Blood from the vena cava is mostly deflected through the foramen ovale into the left atrium, then to the left ventricle, into the ascending aorta, and on to the head and upper body. This allows the fetal coronary circulation and the brain to receive the blood with the highest level of oxygenation.

Deoxygenated blood from the superior vena cava flows into the right atrium, the right ventricle, and then the pulmonary artery. Because of high pulmonary vascu-

lar resistance, only a small percentage (5% to 10%) of the blood in the pulmonary artery flows to the lungs; the majority is shunted through the patent ductus arteriosus and then to the descending aorta (Blackburn, 2007). The fetal lungs are essentially nonfunctional because they are filled with fluid, making them resistant to incoming blood flow. They receive only enough blood for proper nourishment. Finally, two umbilical arteries carry the unoxygenated blood from the descending aorta back to the placenta.

At birth, a dramatic change in the fetal circulatory pattern occurs. The foramen ovale, ductus arteriosus, ductus venosus, and umbilical vessels are no longer needed. With the newborn's first breath, the lungs inflate, which leads to an increase in blood flow to the lungs from the right ventricle. This increase raises the pressure in the left atrium, causing a one-way flap on the left side of the foramen ovale, called the septum primum, to press against the opening, creating a functional separation between the two atria. Blood flow to the lungs increases because blood entering the right atrium can no longer bypass the right ventricle. As a result, the right ventricle pumps blood into the pulmonary artery and on to the lungs. The ductus venosus closes with the clamping of the umbilical cord and inhibition of blood flow through the umbilical vein. The ductus arteriosus constricts partly in response to the higher arterial oxygen levels that occur after the first few breaths. This closure prevents blood from the aorta from entering the pulmonary artery (Blackburn, 2007). All of these changes leave the newborn with the typical adult pattern of circulation. Figure 10.9 shows fetal circulation.

Genetics

Genetics is the study of heredity and its variation (Slee, Slee, & Schmidt, 2008). According to the Centers for Disease Control and Prevention (CDC), birth defects and genetic disorders occur in about 3% of all infants born in the United States (CDC, 2007). Traditionally, genetics has been associated with making decisions about childbearing and caring for children with genetic disorders. Recently, genetic and technologic advances are expanding our understanding of how genetic changes affect human diseases such as diabetes, cancer, Alzheimer's disease, and other multifactorial diseases that are prevalent in adults (Dolan, Biermann, & Damus, 2007). Our ability to diagnose genetic conditions is more advanced than our ability to cure or treat the disorders. However, accurate diagnosis has led to improved treatment and outcomes for those affected with these disorders.

▶ ***Take*** NOTE!

Genetic science has the potential to revolutionize health care with regard to national screening programs, predisposition testing, detection of genetic disorders, and pharmacogenetics.

Today, nurses are required to have basic skills and knowledge in genetics, genetic testing, and genetic counseling so they can assume new roles and provide information and support to women, children, and families.

Advances in Genetics

Recent advances in genetic knowledge and technology have affected all areas of health. These advances have increased the number of health interventions that can be undertaken with regard to genetic disorders. For example, genetic diagnosis is now possible before conception and very early in pregnancy (see Evidence-Based Practice). Genetic testing can now identify presymptomatic conditions in children and adults. Gene therapy can be used to replace or repair defective or missing genes with normal ones. Gene therapy has been used for a variety of disorders, including cystic fibrosis, melanoma, diabetes, HIV, and hepatitis (Newman & Bettinger, 2007). The potential exists for creation of increased intelligence and size through genetic intervention. Genetic agents may replace drugs, general surgery may be replaced by gene surgery, and genetic intervention may replace radiation (Erlen, 2006). It may also be used to treat many chronic illnesses. See Evidence-Based Practice.

The Human Genome Project (HGP) was an international 13-year effort to produce a comprehensive sequence of the human genome. It was started in 1990 by the Department of Energy and the National Institutes of Health and was completed in May 2003. It has brought advances to the field of genetics and genetic testing (Jenkins & Calzone, 2007). An individual's **genome** represents his or her genetic blueprint, which determines **genotype** (the gene pairs inherited from parents; the specific genetic makeup) and **phenotype** (observed outward characteristics of an individual) (Edgar, 2004).

A primary goal of the HGP was to translate the findings into new strategies for the prevention, diagnosis, and treatment of genetic diseases and disorders. Two key findings from the project were that all human beings are 99.9% identical at the DNA level, and approximately 30,000 genes make up the human genome (International Human Genome Sequencing Consortium, 2004). More information about the HGP may be accessed at: http://www.ornl.gov/sci/techresources/Human_Genomehome.shtml#index.

Current and potential applications for the HGP to health care include rapid and more specific diagnosis of disease, with hundreds of genetic tests available in research or clinical practice; earlier detection of genetic predisposition to disease; less emphasis on treating the symptoms of a disease and more emphasis on looking at the fundamental causes of the disease; new classes of drugs; avoidance of environmental conditions that may trigger disease; and possible augmentation or replacement of defective genes through gene therapy. This new genetic knowledge and technology, along with the commercialization of this

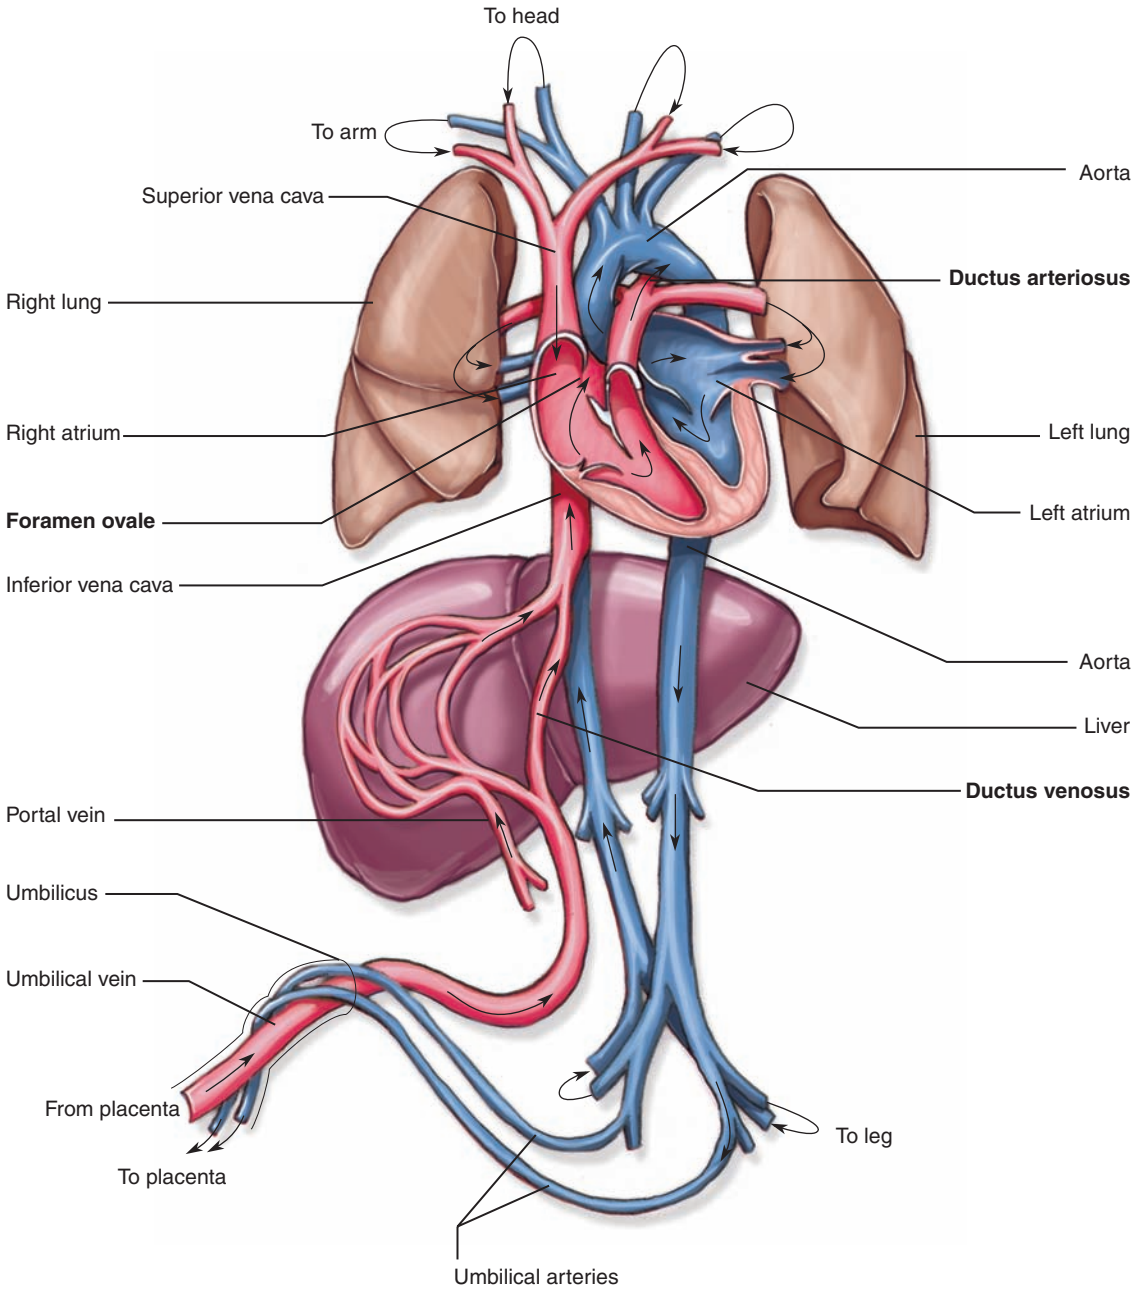

FIGURE 10.9 Fetal circulation. Arrows indicate the path of blood. The umbilical vein carries oxygen-rich blood from the placenta to the liver and through the ductus venosus. From there it is carried to the inferior vena cava to the right atrium of the heart. Some of the blood is shunted through the foramen ovale to the left side of the heart, where it is routed to the brain and upper extremities. The rest of the blood travels down to the right ventricle and through the pulmonary artery. A small portion of the blood travels to the nonfunctioning lungs, while the remaining blood is shunted through the ductus arteriosus into the aorta to supply the rest of the body.

knowledge, will change both professional and parental understanding of genetic disorders.

The potential benefits of these discoveries are vast, but so is the potential for misuse. These advances challenge all health care professionals to consider the many ethical, legal, and social ramifications of genetics in human lives. In the near future, individual risk profiling based on an individual's unique genetic makeup will be used to tailor prevention, treatment, and ongoing management of health conditions. This profiling will raise issues associated with patient privacy and confidentiality related to workplace discrimination and access to health insurance. Issues of autonomy are equally problematic as society considers how to address the injustices that will inevitably surface when

EVIDENCE-BASED PRACTICE 10.1
Preimplantation Genetic Screening and Promoting Pregnancy With Assisted Reproductive Technologies

● Study

Assisted reproductive technologies such as in vitro fertilization (IVF) and intracytoplasmic sperm injection (ICSI) involve the transfer of an embryo to the mother to achieve pregnancy. The physician selects the embryos for transfer based on specific criteria related to their structure and form. These "good-quality" embryos are then implanted in the mother in the hopes of achieving a pregnancy. Unfortunately, many women do not experience a pregnancy. The reasons for these failures are not known. One belief is that the embryos being transferred, although they meet the criteria for structure and form, may have an abnormal number of chromosomes, which affects implantation and the development of a pregnancy. Preimplantation genetic screening (PGS) is a tool being used to identify embryos of good quality with the normal number of chromosomes. Based on the screening, only these embryos are implanted; in theory, this would increase the rate of pregnancy. However, there are questions as to how effective PGS is in improving the rates of pregnancy and live birth.

Two independent authors used predetermined quality criteria to collect and analyze data from numerous databases, registers, and reference lists of articles. The researchers also gathered additional data from other authors as necessary. The researchers selected all relevant randomized controlled trials dealing with IVF or ICSI with and without PGS. The researchers measured the outcome based primarily on the live birth rate.

The researchers reviewed two randomized controlled trials. Both trials involved IVF or ICSI with and without the use of PGS. The group without PGS was considered the control group. The trials also involved women of advanced maternal age (over age 35).

▲ Findings

Compared with the control group, the PGS group did not show significant differences in the live birth rate. There were also no significant differences in the rates for ongoing pregnancy. The researchers noted that these findings are limited by the small number of trials (two trials), the advanced maternal age, and the sample size of the one trial (39 women). Based on this study, the researchers could not find evidence to support routine use of PGS to facilitate pregnancy. They recommended more in-depth randomized trials to evaluate this technology.

■ Nursing Implications

Although the study failed to support the effectiveness of PGS, nurses need to be aware of the emerging technology and techniques associated with genetics so that they can provide women and their families with the most appropriate information about available options and therapies. Nurses can incorporate information from this study in their teaching, anticipatory guidance, and counseling activities related to options so that couple can make the best-informed decision possible.

Twisk, M., Mastenbroek, S., van Wely, M., Heineman, M. J., Van der Veen, F., & Repping, S. (2006). Preimplantation genetic screening for abnormal number of chromosomes (aneuploidies) in in vitro fertilization or intracytoplasmic sperm injection. *Cochrane Database of Systematic Reviews,* Issue 1. Art. No.: CD005291.DOI:10.1002/14651858.CD005291.pub2.

disease risk can be determined years in advance of its occurrence. Nurses will play an important role in developing policies and providing direction and support in this arena, and to do so they will need a basic understanding of genetics, including inheritance and inheritance patterns. (For more information on the ethical, social, and legal issues surrounding human genetic research and advances, go to: http://www.ornl.gov/sci/techresources/Human_Genome/research/elsi.shtml.)

Inheritance

The nucleus within the cell is the controlling factor in all cellular activities because it contains chromosomes, long continuous strands of deoxyribonucleic acid (DNA) that carry genetic information. Each chromosome is made up of **genes**. Genes are individual units of heredity of all traits and are organized into long segments of DNA that occupy a specific location on a chromosome and determine a particular characteristic in an organism.

DNA stores genetic information and encodes the instructions for synthesizing specific proteins needed to maintain life. DNA is double-stranded and takes the form of a double helix. The side pieces of the double helix are made up of a sugar, deoxyribose, and a phosphate, occurring in alternating groups. The cross-connections or rungs of the ladder are attached to the sides and are made up of four nitrogenous bases: adenine, cytosine, thymine, and guanine. The sequence of the base pairs as they form each rung of the ladder is referred to as the genetic code (Fig. 10.10; Wright & Hastie, 2007).

Each gene has a segment of DNA with a specific set of instructions for making proteins needed by body cells for proper functioning. Genes control the types of proteins made and the rate at which they are produced (Dolan, Biermann, & Damus, 2007). Any change in gene structure

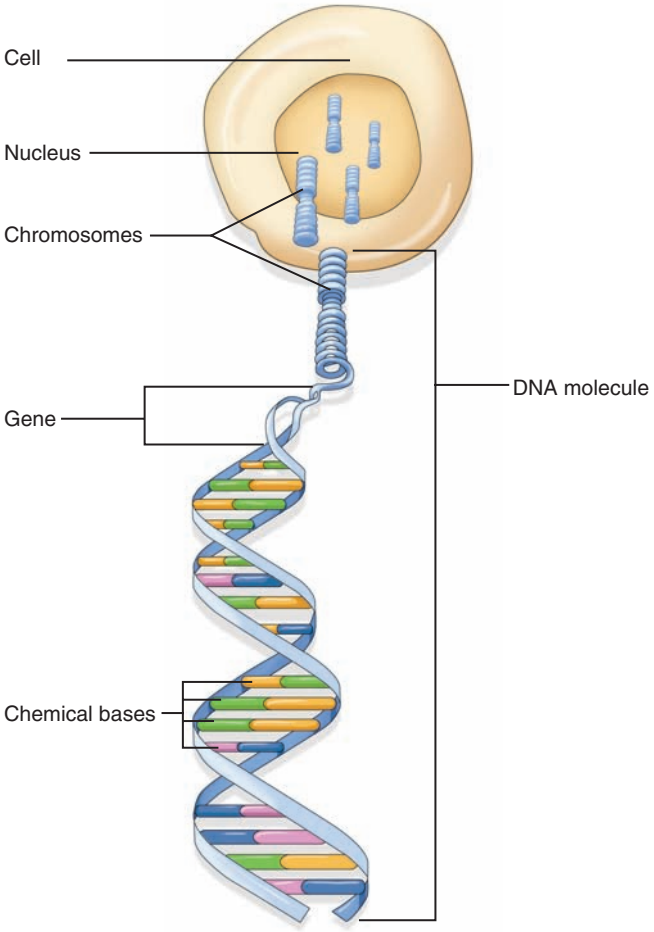

FIGURE 10.10 DNA is made up of four chemical bases. Tightly coiled strands of DNA are packaged in units called chromosomes, housed in the cell's nucleus. Working subunits of DNA are known as genes. (From the National Institute of Health and National Cancer Institute [1995]. *Understanding gene testing* [NIH Pub. No. 96-3905]. Washington, DC: U.S. Department of Human Services.)

or location leads to a **mutation**, which may alter the type and amount of protein produced (Fig. 10.11). Genes never act in isolation; they always interact with other genes and the environment. They are arranged in a specific linear formation along a chromosome.

The genotype, the specific genetic makeup of an individual, usually in the form of DNA, is the internally coded inheritable information. It refers to the particular **allele**, which is one of two or more alternative versions of gene at a given position or locus on a chromosome that imparts the same characteristic of that gene. For instance, each human has a gene that controls height, but there are variations of these genes, which are alleles, in accordance with the specific height for which the gene codes. A gene that controls eye color may have an allele that can produce blue eyes or an allele that produces brown eyes. The genotype, together with environmental variation that influences the individual, determines the phenotype, or the observed, outward characteristics of an individual. A human inherits two genes, one from each parent. Therefore, one allele comes from the mother and one from the father. These alleles may be the same for the characteristic (**homozygous**) or different (**heterozygous**). For example, WW stands for homozygous dominant; ww stands for homozygous recessive. Heterozygous would be indicated as Ww. If the two alleles differ, such as Ww, the dominant one will usually be expressed in the phenotype of the individual.

Human beings typically have 46 chromosomes. This includes 22 pairs of non-sex chromosomes or autosomes and 1 pair of sex chromosomes (two X chromosomes in females, and an X chromosome and a Y chromosome in males). Offspring receive one chromosome of each of the 23 pairs from each parent.

Regulation and expression of the thousands of human genes is very complex and is the result of many intricate interactions within each cell. Alterations in gene structure,

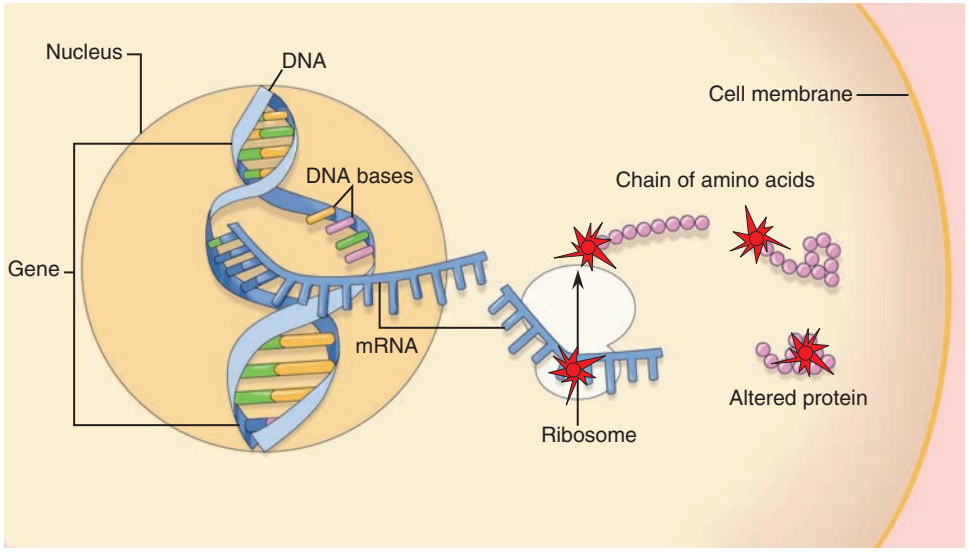

FIGURE 10.11 When a gene contains a mutation, the protein encoded by that gene will be abnormal. Some protein changes are insignificant, while others are disabling. (From the National Institutes of Health and National Cancer Institute. [1995]. *Understanding gene testing* [NIH Pub. No. 96-3905]. Washington, DC: U.S. Department of Human Services.)

function, transcription, translation, and protein synthesis can influence an individual's health (Wright & Hastie, 2007). Gene mutations are a permanent change in the sequence of DNA. Some mutations have no significant effect, whereas others can have a tremendous impact on the health of the individual. Several genetic disorders can result from these mutations, such as cystic fibrosis, sickle-cell disease, phenylketonuria, or hemophilia.

The pictorial analysis of the number, form, and size of an individual's chromosomes is termed the **karyotype**. This analysis commonly uses white blood cells and fetal cells in amniotic fluid. The chromosomes are numbered from the largest to the smallest, 1 to 22, and the sex chromosomes are designated by the letter X or Y. A female karyotype is designated as 46,XX and a male karyotype is designated as 46,XY. Figure 10.12 illustrates an example of a karyotyping pattern.

Patterns of Inheritance

A genetic disorder is a disease caused by an abnormality in an individual's genetic material or genome. Diagnosis of a genetic disorder is usually based on clinical signs and symptoms or on laboratory confirmation of an altered gene associated with the disorder. Accurate diagnosis can be aided by the recognition of the pattern of inheritance within a family. The pattern of inheritance is also vital to understand when teaching and counseling families about the risks in future pregnancies. Some genetic disorders occur in multiple family members, while others may occur in only a single family member. A genetic disorder is caused by completely or partially altered genetic material, while a familial disorder is more common in relatives of the affected individual but may be caused by environmental influences and not genetic alterations. For a more detailed discussion of specific types of genetic disorders, see Chapter 50.

Monogenic Disorders

Patterns of inheritance demonstrate how a genetic disorder can be passed on to offspring. Principles of genetic disease inheritance of single gene disorders are the same principles that govern the inheritance of other traits, such as eye and hair color. These are known as Mendel's laws of inheritance, named for the genetic work of Gregor Mendel, an Austrian naturalist. These patterns occur due to a single gene being defective and are referred to as monogenic or sometimes Mendelian disorders. If the defect occurs on the autosome, the genetic disorder is termed autosomal; if the defect is on the X chromosome, the genetic disorder is termed X-linked. The defect also can be classified as dominant or recessive. Monogenic disorders include autosomal dominant, autosomal recessive, X-linked dominant, and X-linked recessive patterns.

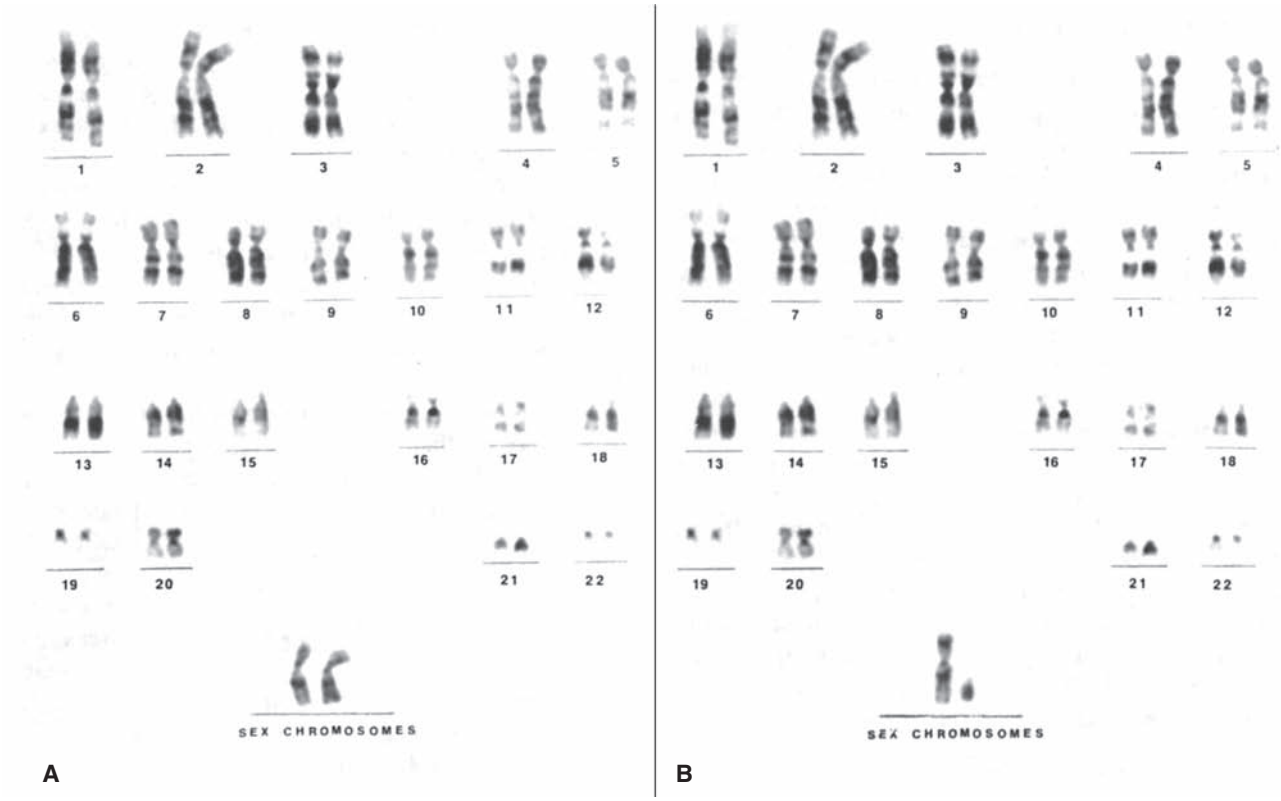

FIGURE 10.12 Karyotype pattern. (**A**) Normal female karyotype. (**B**) Normal male karyotype.

Autosomal Dominant Inheritance Disorders

Autosomal dominant inherited disorders occur when a single gene in the heterozygous state is capable of producing the phenotype. In other words, the abnormal or mutant gene overshadows the normal gene and the individual will demonstrate signs and symptoms of the disorder. The affected person generally has an affected parent, and an affected person has a 50% chance of passing the abnormal gene to each of his or her children (Fig. 10.13). Affected individuals are present in every generation. Males and family members who are phenotypically normal (do not show signs or symptoms of the disorder) do not transmit the condition to their offspring. Females and males are equally affected and a male can pass the disorder on to his son. This male-to-male transmission is important in distinguishing autosomal dominant inheritance from X-linked inheritance. There are varying degrees of presentation among individuals in a family. Therefore, a parent with a mild form could have a child with a more severe form. Common types of genetic disorders that follow the autosomal dominant pattern of inheritance include neurofibromatosis, Huntington's disease, achondroplasia, and polycystic kidney disease.

Autosomal Recessive Inheritance Disorders

Autosomal recessive inherited disorders occur when two copies of the mutant or abnormal gene in the homozygous state are necessary to produce the phenotype. In other words, two abnormal genes are needed for the individual to demonstrate signs and symptoms of the disorder. These disorders are generally less common than autosomal dominant disorders (Behrman et al., 2007). Both parents of the affected person must be heterozygous carriers of the gene (clinically normal but carry the gene), and their offspring have a 25% chance of being homozygous (a 50% chance of getting the mutant gene from each parent and therefore a 25% chance of inheriting two mutant genes). If the child is clinically normal, there is a 50% chance the child is a carrier (Fig. 10.14). Affected individuals are usually present in only one generation of the family. Females and males are equally affected and a male can pass the disorder on to his son. The chance that any two parents will both be carriers of the mutant gene is increased if the couple is consanguineous (having a common ancestor). Common types of genetic disorders that follow the autosomal recessive inheritance pattern include cystic fibrosis, phenylketonuria, Tay-Sachs disease, and sickle-cell disease.

X-linked Inheritance Disorders

X-linked inherited disorders are those associated with altered genes present on the X chromosome. They differ in characteristic from autosomal disorders. If a male inherits an X-linked altered gene, he will express the condition. Since a male has only one X chromosome, all the genes on his X chromosome will be expressed (the Y chromosome carries no normal allele to compensate for the altered gene). Because females inherit two X chromosomes, they can be either heterozygous or homozygous for any allele. Therefore, X-linked disorders in females are expressed similarly to autosomal disorders.

Most X-linked disorders demonstrate a recessive pattern of inheritance. Males are more affected than females. A male has only one X chromosome and all the genes on his X chromosome will be expressed, whereas a female will

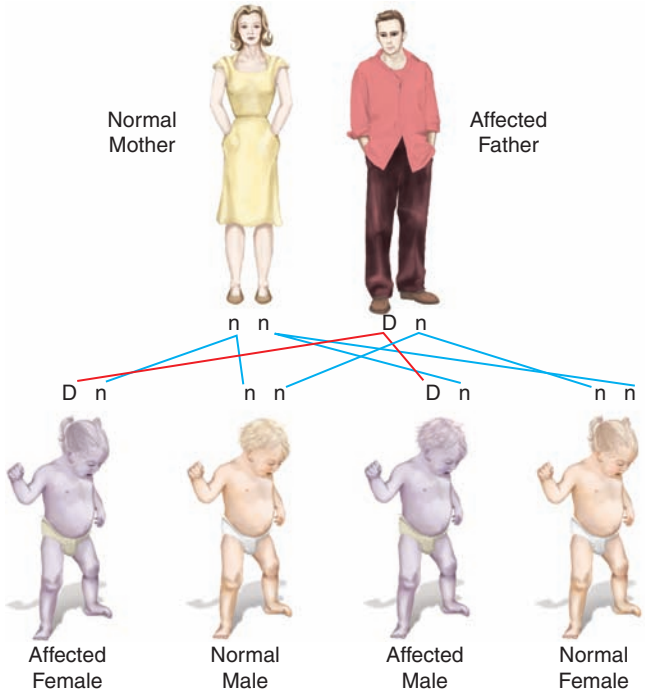

FIGURE 10.13 Autosomal dominant inheritance.

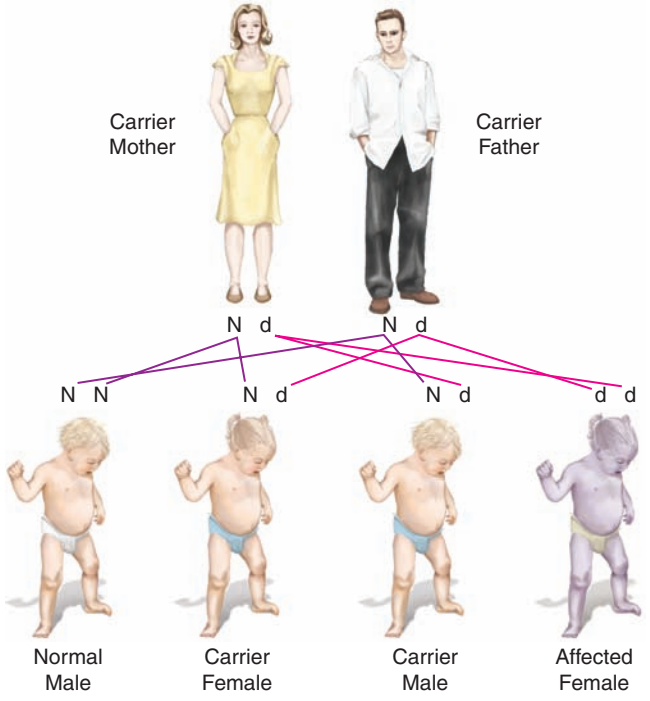

FIGURE 10.14 Autosomal recessive inheritance.

usually need both X chromosomes to carry the disease. There is no male-to-male transmission (since no X chromosome from the male is transmitted to male offspring), but any man who is affected will have carrier daughters. If a woman is a carrier, there is a 50% chance that her sons will be affected and a 50% chance that her daughters will be carriers (Fig. 10.15). Common types of genetic disorders that follow X-linked recessive inheritance patterns include hemophilia, color blindness, and Duchenne muscular dystrophy.

X-linked dominant inheritance is present if heterozygous female carriers demonstrate signs and symptoms of the disorder. All of the daughters and none of the sons of an affected male have the condition, while both male and female offspring of an affected woman have a 50% chance of inheriting and presenting with the condition (Fig. 10.16). X-linked dominant disorders are rare. The most common is hypophosphatemic (vitamin D–resistant) rickets.

Multifactorial Inheritance Disorders

Multifactorial inherited disorders are those disorders thought to be caused by multiple gene (polygenic) and environmental factors. Many of the common congenital malformations, such as cleft lip, cleft palate, spina bifida, pyloric stenosis, clubfoot, congenital hip dysplasia, and cardiac defects, are attributed to multifactorial inheritance. A combination of genes from both parents, along with unknown environmental factors, produces the trait or condition. An individual may inherit a predisposition to a particular anomaly or disease. The anomalies or diseases vary in severity, and often a sex bias is present. For example, pyloric stenosis is seen more often in males, while congenital hip dysplasia is much more likely to occur in females. Multifactorial conditions tend to run in families, but the pattern of inheritance is not as predictable as with single-gene disorders. The chance of recurrence is also less than in single-gene disorders, but the degree of risk is related to the number of genes in common with the affected individual. The closer the degree of relationship, the more genes an individual has in common with the affected family member, resulting in a higher chance the individual's offspring will have a similar defect. In multifactorial inheritance the likelihood that both identical twins will be affected is not 100%, indicating that there are non-genetic factors involved.

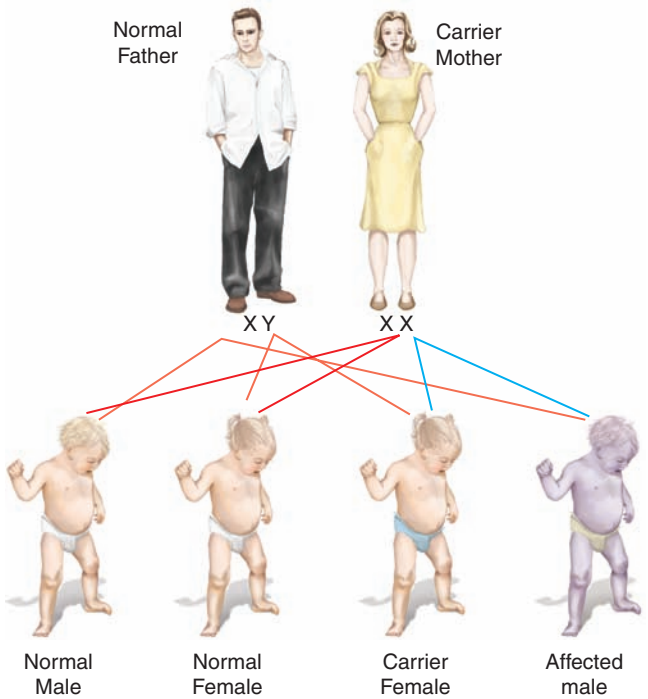

FIGURE 10.15 X-linked recessive inheritance.

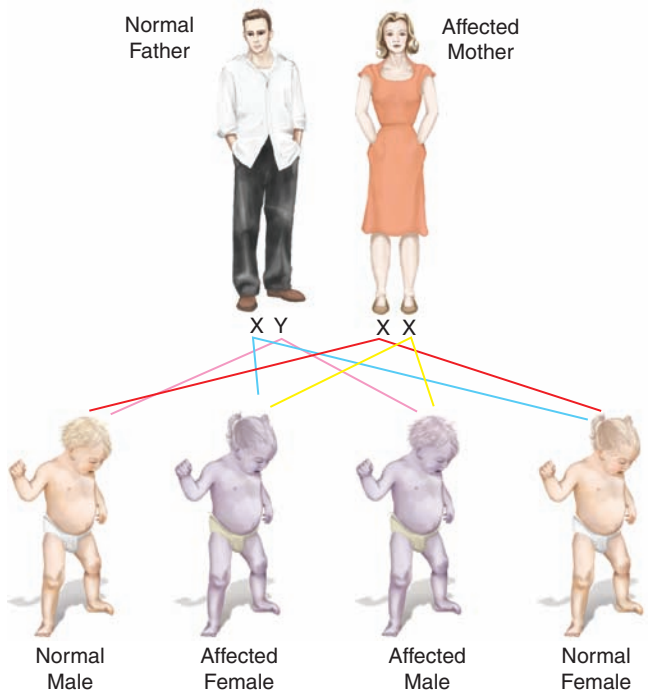

FIGURE 10.16 X-linked dominant inheritance.

Nontraditional Inheritance Patterns

Molecular studies have revealed that some genetic disorders are inherited in ways that do not follow the typical patterns of dominant, recessive, X-linked, or multifactorial inheritance. Examples of nontraditional inheritance patterns include mitochondrial inheritance and genomic imprinting (Box 10.2). As the science of molecular genetics advances and more is learned about inheritance patterns, other nontraditional patterns of inheritance may be discovered or found to be relatively common.

Chromosomal Abnormalities

In some cases of genetic disorders, the abnormality occurs due to problems with the chromosomes. Chromosomal abnormalities do not follow straightforward patterns of

BOX 10.2 Nontraditional Inheritance Patterns

Mitochondrial Inheritance

Certain diseases result from mutations in the mitochondrial DNA. Mitochondria, which are the part of the cell responsible for energy production, are inherited almost exclusively from the mother. Therefore, mitochondrial inheritance is usually passed from the mother to the offspring, regardless of the offspring's sex (differentiating mitochondrial inheritance from X-linked recessive inheritance). These mutations are often deletions and abnormalities of these disorders and are often seen in one or more specific organs, such as the brain, eye, and skeletal muscle. They are often associated with energy deficits in cells with high energy requirements, such as nerve and muscle cells. These disorders tend to be progressive, and the age of onset can vary from infancy to adulthood. There is an extreme amount of variability in symptoms within a family. Examples of disorders that follow mitochondrial inheritance include Kearns-Sayre syndrome, which is a neuromuscular disorder, and Leber's hereditary optic neuropathy, which causes progressive visual impairment.

Genomic Imprinting

Another nontraditional inheritance pattern results from a process called genomic imprinting. Genomic imprinting plays a critical role in fetal growth and development and placental functioning. In genomic imprinting, the expression of a gene is determined by its parental origin. In genomic imprinting both the maternal and paternal alleles are present, but only one is expressed; the other is inactive. Genomic imprinting does not alter the genetic sequence itself but affects the phenotype observed. In these cases the altered genes in a certain region of the genome have very different expressions depending on whether they were inherited from the mother or the father. Several human syndromes are known to be associated with defects in gene imprinting. Disorders that result from a disruption of imprinting usually involve a growth phenotype and include varying degrees of developmental problems. Common examples include Prader-Willi syndrome (a condition resulting in severe hypotonia and hyperphagia leading to obesity and mental retardation), Angelman syndrome (a neurodevelopmental disorder associated with mental retardation, jerky movements, and seizures), and Beckwith-Wiedemann syndrome (characterized by somatic overgrowth, congenital malformations, and a predisposition to embryonic neoplasia).

inheritance. Sperm and egg cells each have 23 unpaired chromosomes. When they unite during pregnancy they form a fertilized egg with 46 chromosomes. Sometimes before pregnancy begins, an error has occurred during the process of cell division, leaving an egg or sperm with too many or too few chromosomes. If this egg or sperm cell joins with a normal egg or sperm cell, the resulting embryo has a chromosomal abnormality. Chromosomal abnormalities can also occur due to an error in the structure of the chromosome. Small pieces of the chromosome may be deleted, duplicated, inverted, misplaced, or exchanged with part of another chromosome. Most chromosomal abnormalities occur due to an error in the egg or sperm. Therefore, the abnormality is present in every cell of the body. However, some abnormalities can happen after fertilization during mitotic cell division and result in **mosaicism**. Mosaicism or mosaic form refers to when the chromosomal abnormalities do not show up in every cell and only some cells or tissues carry the abnormality. In mosaic forms of the disorder, the symptoms are usually less severe than if all the cells were abnormal.

About 1 in 150 live-born infants is born with a chromosomal abnormality (March of Dimes, 2007a). These often cause major defects because they involve added or missing genes. Congenital anomalies and mental retardation are often associated with chromosomal abnormalities. These abnormalities occur on autosomal as well as sex chromosomes and can result from changes in the number of chromosomes or changes in the structure of the chromosomes.

Numerical Abnormalities

Chromosomal abnormalities of number often result due to nondisjunction, or failure of the chromosome pair to separate during cell division, meiosis, or mitosis. Few chromosomal numerical abnormalities are compatible with full-term development and most result in spontaneous abortion. There are some numerical abnormalities that do support development to term because the chromosome on which the abnormality is present carries relatively few genes (such as chromosome 13, 18, 21, or X). Two common abnormalities of chromosome number are monosomies or trisomies. In **monosomies** there is only one copy of a particular chromosome instead of the usual pair (an entire single chromosome is missing). In these cases, all fetuses spontaneously abort in early pregnancy. Survival is seen only in mosaic forms of these disorders. In **trisomies**, there are three of a particular chromosome instead of the usual two (an entire single chromosome is added). The most common trisomies include trisomy 21 (Down syndrome), trisomy 18, and trisomy 13. Figure 10.17 shows the karyotype of a child with Down syndrome. (See Chapter 50 for a detailed discussion of these disorders.) Trisomies may be present in every cell or may present in the mosaic form.

Another type of abnormal chromosome number is **polyploidy**. Polyploidy causes an increase in the number of haploid sets (23) of chromosomes in a cell. Triploidy refers to three whole sets of chromosomes in a single cell (in humans, a total of 69 chromosomes per cell); tetraploidy refers to four whole sets of chromosomes in a

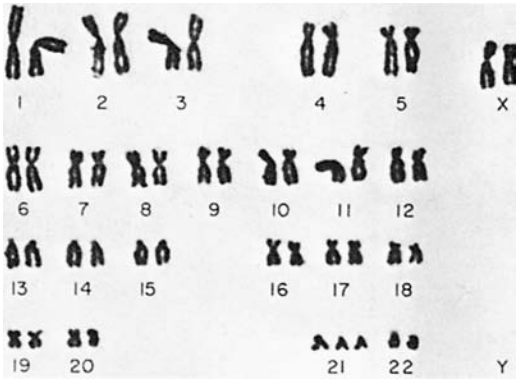

FIGURE 10.17 Karyotype of a child with Down syndrome.

single cell (in humans, a total of 92 chromosomes per cell). Polyploidy usually results in an early spontaneous abortion and is incompatible with life.

Structural Abnormalities

Chromosome abnormalities of structure usually occur when there is a breakage and loss of a portion of one or more chromosomes and during the repair process the broken ends are rejoined incorrectly. Structural abnormalities usually lead to having too much or too little genetic material. Altered chromosome structure can take on several forms. Deletions occur when a portion of the chromosome is missing or deleted, resulting in a loss of that portion of the chromosome. Duplications are seen when a portion of the chromosome is duplicated and an extra chromosomal segment is present. Clinical findings vary depending on how much chromosomal material is involved. Inversions occur when a portion of the chromosome breaks off at two points and is turned upside down and reattached; therefore, the genetic material is inverted. With inversion, there is no loss or gain of chromosomal material and carriers are phenotypically normal, but they do have an increased risk for miscarriage and chromosomally abnormal offspring. Ring chromosomes are seen when a portion of a chromosome has broken off in two places and formed a circle or ring.

The most clinically significant structural abnormality is a translocation. This occurs when a potion of one chromosome is transferred to another chromosome and an abnormal rearrangement is present.

Structural abnormalities can be balanced or unbalanced. Balanced abnormalities involve the rearrangement of genetic material with neither an overall gain nor loss. Individuals who inherit a balanced structural abnormality are usually phenotypically normal but are at a higher risk for miscarriages and having chromosomally abnormal offspring. Examples of structural rearrangements that can be balanced include inversions, translocation, and ring chromosomes. Unbalanced structural abnormalities are similar to numerical abnormalities because genetic material is either gained or lost. Unbalanced structural abnormalities can encompass several genes and result in severe clinical consequences.

Sex Chromosome Abnormalities

Chromosomal abnormalities can also involve sex chromosomes. These cases are usually less severe in their clinical effects than autosomal chromosomal abnormalities. Sex chromosome abnormalities are gender-specific and involve a missing or extra sex chromosome. They affect sexual development and may cause infertility, growth abnormalities, and possibly behavioral and learning problems. Many affected individuals lead essentially normal lives. Examples are Turner syndrome (in females) and Klinefelter's syndrome (in males; see Chapter 50 for a more detailed discussion of these disorders).

Genetic Evaluation and Counseling

Genetic counseling has been defined as "an educational process that seeks to assist affected and/or at risk individuals to understand the nature of a genetic disorder, its transmission, and the options available to them in management and family planning" (Behrman et al., 2004, p. 395). There are a variety of reasons an individual should be referred for genetic counseling. Box 10.3 lists those who may benefit from genetic counseling. In many cases, geneticists and genetic counselors provide information to families regarding genetic diseases. However, an experienced family physician, pediatrician, or nurse who has received special training in genetics may also provide the information.

BOX 10.3 Those Who May Benefit From Genetic Counseling

- Maternal age 35 years or older when the baby is born
- Paternal age 50 years or older
- Previous child, parents, or close relatives with an inherited disease, congenital anomalies, metabolic disorders, developmental disorders, or chromosomal abnormalities
- Consanguinity or incest
- Pregnancy screening abnormality, including alpha-fetoprotein, triple screen, amniocentesis, or ultrasound
- Stillborn with congenital anomalies
- Two or more pregnancy losses
- Teratogen exposure or risk
- Concerns about genetic defects that occur frequently in their ethnic or racial group (for instance, those of African descent are most at risk for having a child with sickle-cell anemia)
- Abnormal newborn screening
- Child born with one or more major malformations in a major organ system
- Child with abnormalities of growth
- Child with developmental delay, mental retardation, blindness, or deafness

A genetic consultation involves evaluation of an individual or a family. Its purposes are to confirm, diagnose, or rule out genetic conditions; to identify medical management issues; to calculate and communicate genetic risks to a family; to discuss ethical and legal issues; and to provide and arrange psychosocial support. Genetic counselors serve as educators and resource persons for other health care providers and the general public.

The ideal time for genetic counseling is before conception. Preconception counseling gives couples the chance to identify and reduce potential pregnancy risks, plan for known risks, and establish early prenatal care. Unfortunately, many woman delay seeking prenatal care until their second or third trimester, after the crucial time of organogenesis. Therefore, it is important that preconception counseling is offered to all women as they seek health care throughout their childbearing years, especially if they are contemplating pregnancy. This requires health care providers to take an active role.

Preconception screening and counseling can raise serious ethical and moral issues for a couple. The results of prenatal genetic testing can lead to the decision to terminate a pregnancy, even if the results are not conclusive but indicate a strong possibility that the child will have an abnormality. The severity of the abnormality may not be known, and some may find the decision to terminate unethical. Another difficult situation that provides an example of the ethical and moral issues surrounding genetic screening and counseling involves disorders that affect only one gender of offspring. A mother may find she is a carrier of a gene for a disorder for which there is no prenatal screening test available. In these cases the couple may decide to terminate any pregnancy where the fetus is the affected sex, even though there is a 50% chance that the child will not inherit the disorder. In these situations, the choice is the couple's and information and support must be provided in a nondirective manner.

Genetic counseling is particularly important if a congenital anomaly or genetic disease has been diagnosed prenatally or if a child is born with a life-threatening congenital anomaly or genetic disease. In these cases families need information urgently so they can make immediate decisions. If a diagnosis with genetic implications is made later in life, if a couple with a family history of a genetic disorder or a previous child with a genetic disorder is planning a family, or if there is suspected teratogen exposure, urgency of information is not such an issue. In these situations, the family needs time to ponder all their options. This may involve several meetings over a longer period of time.

Genetic counseling involves gathering information regarding birth history, past medical history, and current health status as well as a family history of congenital anomalies, mental retardation, genetic diseases, reproductive history, general health, and causes of death. A detailed family history is imperative and in most cases will include the development of a pedigree, which is like a family tree (Fig. 10.18). Information is ideally gathered on three generations, but if the family history is complicated, information from more distant relatives may be needed. Families receiving genetic counseling may benefit from being told in advance that this information will be necessary; they may need to discuss these sensitive, private issues with family members to obtain the needed facts. When necessary, medical records may be requested for family members, especially those who have a genetic disorder, to help ensure accuracy of the information. Sometimes a pedigree may reveal confidential information not known by all family members, such as an adoption, a child conceived through in vitro fertilization, or a husband not being the father of a baby. Therefore, maintaining confidentiality is extremely important. After careful analysis of the data obtained, referral to a genetic counselor when indicated is appropriate.

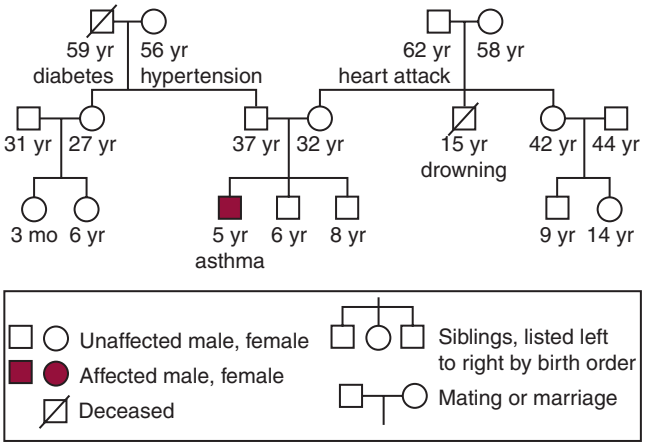

FIGURE 10.18 A pedigree is a diagram made using symbols that demonstrates the links between family members and focuses on medical and health information for each relative.

Medical genetic knowledge has increased dramatically over the past few decades. Not only is it possible to detect specific diseases with genetic mutations, but it is also possible to test for a genetic predisposition to various diseases or conditions and certain physical characteristics. This leads to complex ethical, moral, and social issues. Maintaining client privacy and confidentiality and administering care in a nondiscriminatory manner are essential while maintaining sensitivity to cultural differences. It is essential to respect client autonomy and present information in a nondirective manner.

Nursing Roles and Responsibilities

The nurse is likely to interact with the client in a variety of ways related to genetics—taking a family history, scheduling genetic testing, explaining the purposes of all screening and diagnostic tests, answering questions, and addressing concerns raised by family members. Nurses are often the first health care providers to encounter women with preconception and prenatal issues. Nurses play an important role in beginning the preconception counseling process and referring women and their partners for further genetic testing when indicated.

An accurate and thorough family history is an essential part of preconception counseling. Nurses in any practice setting can obtain a patient's history during the initial encounter. The purpose is to gather patient and family information that may provide clues as to whether the patient has a genetic trait, inherited condition, or inherited predisposition (Erlen, 2006). At a basic level, all nurses should be able to take a family medical history to help identify those at risk for genetic conditions, and then initiate a referral when appropriate. Box 10.4 presents examples of focused assessment questions that can be used. Based on the information gathered during the history, the nurse must decide whether a referral is necessary to a genetic specialist or whether further evaluation is needed. Prenatal testing to assess for genetic risks and defects might be used to identify genetic disorders. These tests are described in Common Laboratory and Diagnostic Tests 10.1.

Remember Robert and Kate Shafer? Based on the information gathered from their genetic history, they were referred to a genetic specialist. What prenatal tests might be ordered to assess their risk for genetic disorders? What would be the nurse's role related to genetic counseling?

BOX 10.4 Focused Health Assessment: Genetic History

What was the cause and age of death for deceased family members?
Does any consanguinity exist between relatives?
Do any serious illnesses or chronic conditions exist? If so, what was the age of onset?
Do any female family members have a history of miscarriages, stillbirths, or diabetes?
Do any female members have a history of alcohol or drug use during pregnancy?
What were the ages of female members during childbearing, especially if older than 35?
Do any family members have mental retardation or developmental delays?
Do any family members have a known or suspected metabolic disorder such as PKU?
Do any family members have an affective disorder such as bipolar disorder?
Have any close relatives been diagnosed with any type of cancer?
What is your ethnic background (explore as related to certain disorders)?
Do any family members have a known or suspected chromosomal disorder?
Do any family members have a progressive neurologic disorder?

Source: Kumar & Burton, 2007.

Nurses working with families involved with genetic counseling typically have certain responsibilities. These include:

- Using interviewing and active listening skills to identify genetic concerns
- Knowing basic genetic terminology and inheritance patterns
- Explaining basic concepts of probability and disorder susceptibility
- Safeguarding the privacy and confidentiality of patients' genetic information
- Providing complete informed consent to facilitate decisions about genetic testing
- Discussing costs of genetic services and the benefits and risks of using health insurance to pay for genetic services, including potential risks of discrimination
- Recognizing and defining ethical, legal, and social issues
- Providing accurate information about the risks and benefits of genetic testing
- Providing culturally appropriate methods to convey genetic information
- Monitoring patients' emotional reactions after receiving genetic analysis
- Providing information on appropriate local support groups
- Knowing their own limitations and making appropriate referrals (Jenkins & Calzone, 2007)

Talking with families who have recently been diagnosed with a genetic disorder or who have had a child born with congenital anomalies is very difficult. Many times the nurse may be the one who has first contact with these parents and will be the one to provide follow-up care.

Genetic disorders are significant, life-changing, and possibly life-threatening situations. The information is highly technical and the field is undergoing significant technologic advances. Nurses need an understanding of who will benefit from genetic counseling and must be able to discuss the role of the genetic counselor with families. The nurse wants to ensure that families at risk are aware that genetic counseling is available before they attempt to have another baby.

Based on the results of their genetic tests, Robert and Kate are placed at moderate risk for having an infant with an autosomal recessive genetic disorder. The couple asks the nurse what all of this means. What information should the nurse provide about concepts of probability and disorder susceptibility for this couple? How can the nurse help this couple to make knowledgeable decisions concerning their reproductive future?

Nurses play an essential role in providing emotional support to the family through this challenging time. This

COMMON LABORATORY AND DIAGNOSTIC TESTS 10.1
PRENATAL TESTS TO ASSESS RISK FOR GENETIC DISORDERS

Test	Description	Indication	Timing
Alpha-fetoprotein	A sample of the woman's blood is drawn to evaluate plasma protein that is produced by the fetal liver, yolk sac, and GI tract, and crosses from the amniotic fluid into the maternal blood.	Increased levels might indicate a neural tube defect, Turner syndrome, tetralogy of Fallot, multiple gestation, omphalocele gastroschisis, or hydrocephaly. Decreased levels might indicate Down syndrome or trisomy 18.	Typically performed between 15 and 18 weeks' gestation
Amniocentesis	Amniotic fluid aspirated from the amniotic sac; safety concerns include infection, pregnancy loss, and fetal needle injuries	To perform chromosome analysis, alpha-fetoprotein, DNA markers, viral studies, karyotyping; and identify inborn errors of metabolism	Usually performed between 15 and 20 weeks' gestation to allow for adequate amniotic fluid volume to accumulate; results take 2 to 4 weeks
Chorionic villus sampling	Removal of small tissue specimen from the fetal portion of the placenta, which reflects the fetal genetic makeup; main complications include severe transverse limb defects and spontaneous pregnancy loss	To detect fetal karyotype, sickle-cell anemia, phenylketonuria, Down syndrome, Duchenne muscular dystrophy, and numerous other genetic disorders	Typically performed between 10 and 12 weeks' gestation, with results available in less than a week
Percutaneous umbilical blood sampling	Insertion of a needle directly into a fetal umbilical vessel under ultrasound guidance; two potential complications: fetal hemorrhage and risk of infection	Used for prenatal diagnosis of inherited blood disorders such as hemophilia A, karyotyping, detection of fetal infection, determination of acid–base status, and assessment and treatment of isoimmunization	Generally performed after 16 weeks' gestation
Fetal nuchal translucency (FNT)	An intravaginal ultrasound that measures fluid collection in the subcutaneous space between the skin and the cervical spine of the fetus	To identify fetal anomalies; abnormal fluid collection can be associated with genetic disorders (trisomies 13, 18, and 21), Turner syndrome, cardiac deformities, and/or physical anomalies. When the FNT is greater than 2.5 mm, the measurement is considered abnormal.	Performed between 10 and 14 weeks' gestation
Level II ultrasound/ fetal scan	Use of high-frequency sound waves to visualize the fetus	Enables evaluation of structural changes to be identified early	Typically performed after 18 weeks' gestation
Triple marker test	Serum screening test using the levels of three maternal serum markers—MSAFP, unconjugated estriol, and hCG—in combination with maternal age to calculate risk	To identify risk for Down syndrome, neural tube defects, and other chromosomal disorders. Elevated hCG combined with lower than normal estriol and MSAFP levels indicate increased risk for Down syndrome or other trisomy condition.	Performed between 16 and 18 weeks' gestation

is especially important with follow-up counseling after the couple or family has been to the genetic specialist.

▶ *Take* NOTE!

Nurses need to be actively engaged with patients and their families and help them consider the facts, values, and context in which they are making decisions. Nurses need to be open and honest with families as they discuss these sensitive and emotionally laden choices.

The nurse is in an ideal position to help families review what has been discussed during the genetic counseling sessions and to answer any additional questions they might have. Referral to appropriate agencies, support groups, and resources, such as a social worker, a chaplain, or an ethicist, is another key role when caring for families with suspected or diagnosed genetic disorders.

▶ *Consider* THIS!

As I waited for the genetic counselor to come into the room, my mind was filled with numerous fears and questions. What does an inconclusive amniocentesis really mean? What if this pregnancy produced an abnormal baby? How would I cope with a special child in my life? If only I had gone to the midwife sooner when I thought I was pregnant, but still in denial. Why did I wait so long to admit this pregnancy and get prenatal care? If only I had started to take my folic acid pills when prescribed. Why didn't I research my family's history to know of any hidden genetic conditions? What about my sister with a Down syndrome child? What must I have been thinking? I guess I could play the "what-if" game forever and never come up with answers. It was too late to do anything about this pregnancy because I was in my last trimester. I started to pray silently when the counselor opened the door. . . .

Thoughts: This woman is reviewing the last several months, looking for answers to her greatest fears. Inconclusive screenings can introduce emotional torment for many women as they wait for validating results. Are these common thoughts and fears for many women facing potential genetic disorders? What supportive interventions might the nurse offer?

Key Concepts

- Fertilization, which takes place in the outer third of the ampulla of the fallopian tube, leads to the formation of a zygote. The zygote undergoes cleavage, eventually implanting in the endometrium about 7 to 10 days after conception.
- Three embryonic layers of cells are formed and include the ectoderm, which forms the central nervous system, special senses, skin, and glands; the mesoderm, which forms the skeletal, urinary, circulatory, and reproductive systems; and the endoderm, which forms the respiratory system, liver, pancreas, and digestive system.
- Amniotic fluid surrounds the embryo and increases in volume as the pregnancy progresses, reaching approximately a liter in volume by term.
- At no time during pregnancy is there any direct connection between the blood of the fetus and the blood of the mother, so there is no mixing of blood.
- A specialized connective tissue known as Wharton's jelly surrounds the three blood vessels in the umbilical cord to prevent compression, which would choke off the supply of blood and nutrients to the growing life inside.
- The placenta protects the fetus from immune attack by the mother, removes waste products from the fetus, induces the mother to bring more food to the placenta, and, near the time of delivery, produces hormones that mature fetal organs in preparation for life outside the uterus.
- The purpose of fetal circulation is to carry highly oxygenated blood to vital areas (heart and brain) while first shunting it away from less vital ones (lungs and liver).
- Humans have 46 paired chromosomes that are found in all cells of the body, except the ovum and sperm cells, which have just 23 chromosomes. Each person has a unique genetic constitution, or genotype.
- Research from the Human Genome Project has provided a better understanding of the genetic contribution to disease.
- Genetic disorders can result from abnormalities in patterns of inheritance or chromosomal abnormalities involving chromosomal number or structure.
- Autosomal dominant inheritance occurs when a single gene in the heterozygous state is capable of producing the phenotype. Autosomal recessive inheritance occurs when two copies of the mutant or abnormal gene in the homozygous state are necessary to produce the phenotype. X-linked inheritance disorders are those associated with altered genes present on the X chromosome. They can be dominant or recessive. Multifactorial inheritance is thought to be caused by multiple genetic and environmental factors.
- In some cases of genetic disorders, a chromosomal abnormality occurs. Chromosomal abnormalities do not follow straightforward patterns of inheritance. These abnormalities occur on autosomal as well as sex chromosomes and can result from changes in the number or structure of the chromosomes.
- Genetic counseling involves evaluation of an individual or a family. Its purpose is to confirm, diagnose, or rule out genetic conditions; identify medical manage-

ment issues; calculate and communicate genetic risks to a family; discuss ethical and legal issues; and assist in providing and arranging psychosocial support.

- Legal, ethical, and social issues can arise related to genetic testing and may include the privacy and confidentiality of genetic information, who should have access to personal genetic information, psychological impact and stigmatization due to individual genetic differences, use of genetic information in reproductive decision making and reproductive rights, and whether testing should be performed if no cure is available.
- Preconception screening and counseling can raise serious ethical and moral issues for a couple. Prenatal genetic testing can lead to the decision to terminate a pregnancy based on the results.
- Nurses play an important role in beginning the preconception counseling process and referring women and their partners for further genetic information when indicated. Many times the nurse is the one who has first contact with these women and will be the one to provide follow-up care.
- Nurses need to have a solid understanding of who will benefit from genetic counseling and be able to discuss the role of the genetic counselor with families, ensuring that families at risk are aware that genetic counseling is available before they attempt to have another baby.
- Nurses play an essential role in providing emotional support and referrals to appropriate agencies, support groups, and resources when caring for families with suspected or diagnosed genetic disorders. Nurses can assist patients with their decision making by referring them to a social worker, a chaplain, or an ethicist.

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. After teaching a group of students about fertilization, the instructor determines that the teaching was successful when the group identifies which as the usual site of fertilization?
   a. Fundus of the uterus
   b. Endometrium of the uterus
   c. Upper portion of fallopian tube
   d. Follicular tissue of the ovary
2. A client comes to the clinic for pregnancy testing. The nurse explains that the test detects the presence of which hormone?
   a. hPL
   b. hCG
   c. FSH
   d. TSH
3. The nurse is counseling a couple, one of whom is affected by an autosomal dominant disorder. They express concerns about the risk of transmitting the disorder. What is the best response by the nurse regarding the risk that their baby may have for the disease?
   a. "You have a one in four (25%) chance."
   b. "The risk is 12.5%, or a one in eight chance."
   c. "The chance is 100%."
   d. "Your risk is 50%, or a one in two chance."
4. What is the first step in determining a couple's risk for a genetic disorder?
   a. Observing the patient and family over time
   b. Conducting extensive psychological testing
   c. Obtaining a thorough family health history
   d. Completing an extensive exclusionary list
5. A nurse is working in a women's health clinic. Genetic counseling would be most appropriate for the woman who:
   a. Just had her first miscarriage at 10 weeks
   b. Is 30 years old and planning to conceive
   c. Has a history that reveals a close relative with Down syndrome
   d. Is 18 weeks pregnant with a normal triple screen result

CRITICAL THINKING EXERCISE

1. Mr. and Mrs. Martin wish to start a family, but they can't agree on something important. Mr. Martin wants his wife to be tested for cystic fibrosis (CF) to see if she is a carrier. Mr. Martin had a brother with CF and watched his parents struggle with the hardship and the expense of caring for him for years, and he doesn't want to experience it in his own life. Mr. Martin has found out he is a CF carrier. Mrs. Martin doesn't want to have the test because she figures that once a baby is in their arms, they will be glad, no matter what.
   a. What information/education should this couple consider before deciding whether to have the test?
   b. How can you assist this couple in their decision-making process?
   c. What is your role in this situation if you don't agree with their decision?

STUDY ACTIVITIES

1. Obtain the video "Miracle of Life," which shows conception and fetal development. What are your impressions? Is the title of this video realistic?
2. Select one of the websites listed above to explore the topic of genetics. Critique the information presented. Was it understandable to a layperson? What specifically did you learn? Share your findings with your classmates during a discussion group.
3. Draw your own family pedigree, identifying inheritance patterns. Share it with your family to validate its accuracy. What did you discover about your family's past health?
4. Select one of the various prenatal screening tests (alpha-fetoprotein, amniocentesis, chorionic villus sampling, or fetal nuchal translucency) and research it in depth. Role-play with another nursing student how you would explain its purpose, the procedure, and potential findings to an expectant couple at risk for a fetal abnormality.

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms used in this chapter.
2. Differentiate between subjective (presumptive), objective (probable), and diagnostic (positive) signs of pregnancy.
3. Explain maternal physiologic changes that occur during pregnancy.
4. Summarize the nutritional needs of the pregnant woman and her fetus.
5. Identify the emotional and psychological changes that occur during pregnancy.

Marva, age 17, appeared at the health department clinic complaining that she had a stomach virus and needed to be seen today. When the nurse asked her additional questions about her illness, Marva reported that she had been sick to her stomach and "beat tired" for days. She had stopped eating to avoid any more nausea and vomiting.

Wow

When a woman discovers that she is pregnant, she must remember to protect and nourish the fetus by making wise choices.

Pregnancy is a normal life event that involves considerable physical and psychological adjustments for the mother. A pregnancy is divided into three **trimesters** of 13 weeks each (Arenson & Drake, 2007). Within each trimester, numerous adaptations take place that facilitate the growth of the fetus. The most obvious are physical changes to accommodate the growing fetus. However, pregnant women also undergo psychological changes as they prepare for parenthood.

Signs and Symptoms of Pregnancy

Traditionally, signs and symptoms of pregnancy have been grouped into the following categories: presumptive, probable, and positive (Box 11.1). The only signs that can determine a pregnancy with 100% accuracy are positive signs.

What additional information is necessary to complete the assessment of Marva, the 17-year-old with nausea and vomiting? What diagnostic tests might be done to confirm the nurse's suspicion that she is pregnant?

Subjective (Presumptive) Signs

Presumptive signs are those signs experienced by the woman herself. The most obvious presumptive sign of pregnancy is the absence of menstruation. Skipping a period is not a reliable sign of pregnancy by itself, but if it is accompanied by consistent nausea, fatigue, breast tenderness, and urinary frequency, pregnancy would seem very likely.

Presumptive changes are the least reliable indicators of pregnancy because any one of them can be caused by conditions other than pregnancy (Walsh, 2007). For example, amenorrhea can be caused by early menopause, endocrine dysfunction, malnutrition, anemia, diabetes mellitus, long-distance running, cancer, or stress. Nausea and vomiting can be caused by gastrointestinal disorders, food poisoning, acute infections, or eating disorders. Fatigue could be caused by anemia, stress, or viral infections. Breast tenderness may result from chronic cystic mastitis, premenstrual changes, or the use of oral contraceptives. Urinary frequency could have a variety of causes other than pregnancy, such as infection, cystocele, structural disorders, pelvic tumors, or emotional tension (Frieden & Chan, 2007).

▶ *Consider* THIS!

Jim and I decided to start our family, so I stopped taking the Pill 3 months ago. One morning when I got out of bed to take the dog out, I felt queasy and lightheaded. I sure hoped I wasn't coming down with the flu. By the end of the week, I was feeling really tired and started taking naps in the afternoon. In addition, I seemed to be going to the bathroom frequently, despite not drinking much fluid. When my breasts started to tingle and ache, I decided to make an appointment with my doctor to see what "illness" I had contracted.

After listening to my list of physical complaints, the office nurse asked me if I might be pregnant. My eyes opened wide: I had somehow missed the link between my symptoms and pregnancy. I started to think about when my last period was, and it had been 2 months ago. The office ran a pregnancy test and much to my surprise it was positive!

Thoughts: Many women stop contraceptives in an attempt to achieve pregnancy but miss the early signs

(continued)

BOX 11.1 Signs and Symptoms of Pregnancy

Presumptive (Time of Occurrence)	Probable (Time of Occurrence)	Positive (Time of Occurrence)
Fatigue (12 wk)	Braxton Hicks contractions (16–28 wk)	Ultrasound verification of embryo or fetus (4–6 wk)
Breast tenderness (3–4 wk)	Positive pregnancy test (4–12 wk)	Fetal movement felt by experienced clinician (20 wk)
Nausea and vomiting (4–14 wk)	Abdominal enlargement (14 wk)	Auscultation of fetal heart tones via Doppler (10–12 wk)
Amenorrhea (4 wk)	Ballottement (16–28 wk)	
Urinary frequency (6–12 wk)	Goodell's sign (5 wk)	
Hyperpigmentation of the skin (16 wk)	Chadwick's sign (6–8 wk)	
Fetal movements (quickening; 16–20 wk)	Hegar's sign (6–12 wk)	
Uterine enlargement (7–12 wk)		
Breast enlargement (6 wk)

Consider THIS! *(continued)*

of pregnancy. This woman was experiencing several signs of early pregnancy—urinary frequency, fatigue, morning nausea, and breast tenderness. What advice can the nurse give this woman to ease these symptoms? What additional education related to her pregnancy would be appropriate at this time?

Objective (Probable) Signs

Probable signs of pregnancy are those that are apparent on physical examination by a health care professional. Common probable signs of pregnancy include softening of the lower uterine segment or isthmus (Hegar's sign), softening of the cervix (Goodell's sign), and a bluish-purple coloration of the vaginal mucosa and cervix (Chadwick's sign). Other probable signs include changes in the shape and size of the uterus, abdominal enlargement, Braxton Hicks contractions, and **ballottement** (the examiner pushes against the woman's cervix during a pelvic examination and feels a rebound from the floating fetus).

Along with these physical signs, pregnancy tests are also considered a probable sign of pregnancy. Several pregnancy tests are available (Table 11.1). The tests vary in sensitivity, specificity, and accuracy and are influenced by the length of gestation, specimen concentration, presence of blood, and the presence of some drugs (Likes & Rittenhouse, 2007).

Human chorionic gonadotropin (hCG) is the earliest biochemical marker for pregnancy, and many pregnancy tests are based on the recognition of hCG or a beta subunit of hCG. hCG levels in normal pregnancy usually double every 48 to 72 hours until they peak approximately 60 to 70 days after fertilization; they then decrease to a plateau at 100 to 130 days of pregnancy (Likes & Rittenhouse, 2007).

Take NOTE!

This elevation of hCG corresponds to the morning sickness period of approximately 6 to 12 weeks during early pregnancy.

Home pregnancy tests are available over the counter and have become quite popular since their introduction in 1975. These tests are very sensitive, cost-effective, and faster than traditional laboratory pregnancy tests. Enzyme-linked immunosorbent assay (ELISA) technology is the basis for most home pregnancy tests.

Although probable signs suggest pregnancy and are more reliable than presumptive signs, they still are not 100% reliable in confirming a pregnancy. For example, uterine tumors, polyps, infection, and pelvic congestion can cause changes to uterine shape, size, and consistency. And although pregnancy tests are used to establish the diagnosis of pregnancy when the physical signs are still inconclusive, they are not completely reliable, because conditions other than pregnancy (e.g., ovarian cancer, choriocarcinoma, hydatidiform mole) can also elevate hCG levels.

Positive Signs

Usually within 2 weeks after a missed period, enough subjective symptoms are present so that a woman can be reasonably sure she is pregnant. However, an experienced health care professional can confirm her suspicions by

TABLE 11.1 SELECTED PREGNANCY TESTS

Type	Specimen	Example	Remarks
Agglutination inhibition tests	Urine	Pregnosticon, Gravindex	If hCG is present in urine, agglutination does not occur, which is positive for pregnancy; reliable 14–21 days after conception; 95% accurate in diagnosing pregnancy
Immunoradiometric assay	Blood serum	Neocept, Pregnosis	Measures ability of blood sample to inhibit the binding of radiolabeled hCG to receptors; reliable 6–8 days after conception; 99% accurate in diagnosing pregnancy
Enzyme-linked immunosorbent assay (ELISA)	Blood serum or urine	Over-the-counter home/office pregnancy tests; precise	Uses an enzyme to bond with hCG in the urine if present; reliable 4 days after implantation; 99% accurate if hCG specific

Sources: Hackley, Kriebs, & Rousseau, 2007; Likes & Rittenhouse, 2007.

identifying positive signs of pregnancy. The positive signs of pregnancy confirm that a fetus is growing in the uterus. Visualizing the fetus by ultrasound, palpating for fetal movements, and hearing a fetal heartbeat are all signs that make the pregnancy a certainty.

Once pregnancy is confirmed, the health care professional will set up a schedule of prenatal visits to assess the woman and her fetus throughout the entire pregnancy. Assessment and education begins at the first visits and continues throughout the pregnancy (see Chapter 12).

Remember Marva, who thought she had a stomach virus? Her pregnancy test was positive. On questioning by the nurse, she acknowledged missing two menstrual periods and being sexually active with her boyfriend without using protection. What is the nurse's role at this point with Marva? What instructions might be given to her while she waits for her first prenatal visit?

Physiologic Adaptations During Pregnancy

Every system of a woman's body changes during pregnancy to accommodate the needs of the growing fetus, and with startling rapidity. The physical changes of pregnancy can be uncomfortable, although every woman reacts uniquely.

Reproductive System Adaptations

Significant changes occur throughout the woman's body during pregnancy to accommodate the growing human being within her. Many have a protective role for maternal homeostasis and are essential to meet the demands of both the mother and the fetus. Many adaptations are reversible after the woman gives birth, but some persist for life.

Uterus

During the first few months of pregnancy, estrogen stimulates uterine growth, and the uterus undergoing a tremendous increase in size, weight, length, width, depth, volume, and overall capacity throughout pregnancy. The weight of the uterus increases from 70 g to about 1100 g at term; its capaxity increases from 10 mL to 5000 mL or more at term (Levano, Cunningham, Alexander, et al., 2007). The uterine walls thin to 1.5 cm or less; from a solid globe, the uterus becomes a hollow vessel.

Uterine growth occurs as a result of both hyperplasia and hypertrophy of the myometrial cells, which do not increase much in number but do increase in size. Blood vessels elongate, enlarge, dilate, and sprout new branches to support and nourish the growing muscle tissue, and the increase in uterine weight is accompanied by a large increase in uterine blood flow necessary to perfuse the uterine muscle and accommodate the growing fetus (Frieden & Chan, 2007).

Uterine contractility is enhanced as well. Spontaneous, irregular, and painless contractions, called **Braxton Hicks contractions**, begin during the first trimester. These contractions continue throughout pregnancy, becoming especially noticeable during the last month, when they function to thin out or efface the cervix before birth (see Chapter 12 for more information).

Changes in the uterus occurring during the first 6 to 8 weeks of gestation produce some of the typical findings, including a positive **Hegar's sign**. This softening and compressibility of the lower uterine segment results in exaggerated uterine anteflexion during the early months of pregnancy, which adds to urinary frequency (Arenson & Drake, 2007).

The uterus remains in the pelvic cavity for the first 3 months of pregnancy, after which it progressively ascends into the abdomen (Fig. 11.1). As the uterus grows, it presses on the urinary bladder and causes the increased frequency of urination experienced during early pregnancy. In addition, the heavy gravid uterus in the last trimester can fall back against the inferior vena cava in the supine position, resulting in vena cava compression, which reduces venous return and decreases cardiac output and blood pressure, with increasing orthostatic stress. This occurs when the woman changes her position from recumbent to sitting to standing. This acute hemodynamic change, termed supine hypotensive syndrome, causes the woman

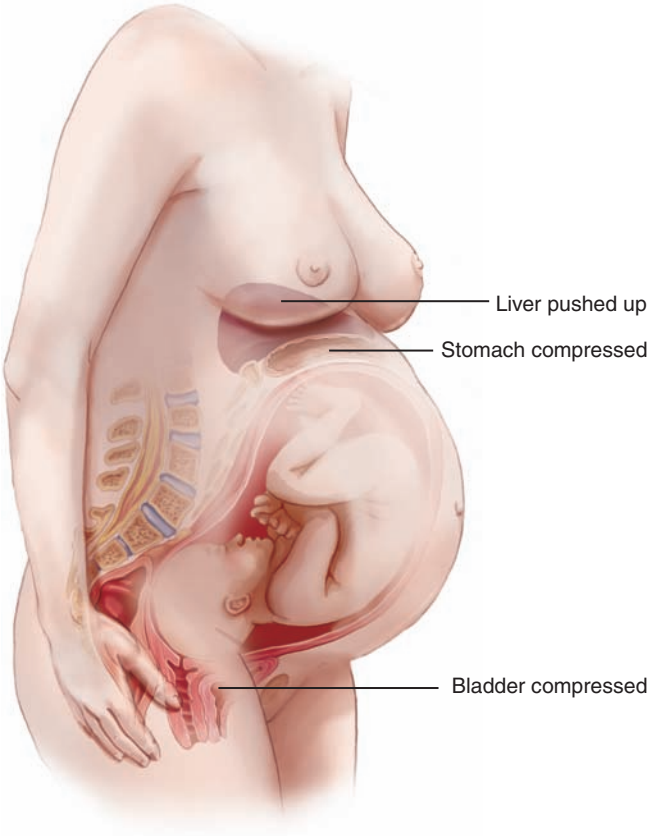

FIGURE 11.1 The growing uterus in the abdomen.

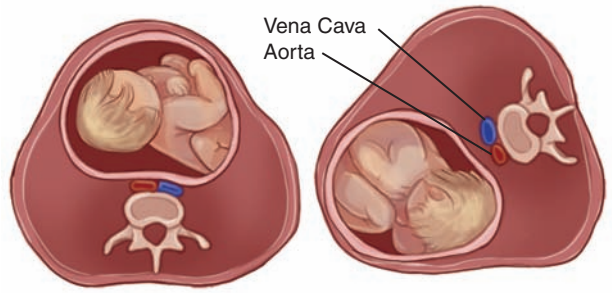

FIGURE 11.2 Supine hypotensive syndrome.

to experience symptoms of weakness, lightheadedness, nausea, dizziness, or syncope (Fig. 11.2). These changes are reversed when the woman is in the left lateral position, which displaces the uterus to the left and off the vena cava.

The uterus, which starts as a pear-shaped organ, becomes ovoid as length increases over width. By 20 weeks' gestation, the fundus, or top of the uterus, is at the level of the umbilicus and measures 20 cm. A monthly measurement of the height of the top of the uterus in centimeters, which corresponds to the number of gestational weeks, is commonly used to date the pregnancy.

▶ ***Take*** *NOTE!*

Fundal height can be typical of gestational weeks between 18 and 32 weeks, but after 36 weeks' gestation, this measurement is no longer reliable because of the beginning of fetal descent.

The fundus reaches its highest level, at the xiphoid process, at approximately 36 weeks. Between 38 to 40 weeks, fundal height drops as the fetus begins to descend and engage into the pelvis. Because it pushes against the diaphragm, many women experience shortness of breath. By 40 weeks, the fetal head begins to descend and engage in the pelvis, which is termed *lightening.* For the woman who is pregnant for the first time, lightening usually occurs approximately 2 weeks before the onset of labor; for the woman who is experiencing her second or subsequent pregnancy, it usually occurs at the onset of labor. Although breathing becomes easier because of this descent, the pressure on the urinary bladder now increases and women experience urinary frequency again.

Cervix

Between weeks 6 and 8 of pregnancy, the cervix begins to soften (**Goodell's sign**) due to vasocongestion. Along with the softening, the endocervical glands increase in size and number and produce more cervical mucus. Under the influence of progesterone, a thick mucus plug is formed that blocks the cervical os and protects the opening from bacterial invasion. At about the same time, increased vascularization of the cervix causes **Chadwick's sign**. Cervical ripening (softening, effacement, and increased distensibility) begins about 4 weeks before birth. Ripening is an inflammatory process and is not dependent on uterine contractions (Blackburn, 2007).

Vagina

During pregnancy, there is increased vascularity because of the influences of estrogen, resulting in pelvic congestion and hypertrophy of the vagina in preparation for the distention needed for birth. The vaginal mucosa thickens, the connective tissue begins to loosen, the smooth muscle begins to hypertrophy, and the vaginal vault begins to lengthen (Frieden & Chan, 2007).

Vaginal secretions become more acidic, white, and thick. Most women experience an increase in a whitish vaginal discharge, called leukorrhea, during pregnancy. This is normal except when it is accompanied by itching and irritation, possibly suggesting *Candida albicans,* a monilial vaginitis, which is a very common occurrence in this glycogen-rich environment (Mashburn, 2006). Monilial vaginitis is a benign fungal condition that is uncomfortable for the woman, but it can be transmitted from an infected mother to her newborn at birth. Neonates develop an oral infection known as thrush, which presents as white patches on the mucous membranes of their mouths. It is self-limiting and is treated with local antifungal agents.

Ovaries

The increased blood supply to the ovaries causes them to enlarge until approximately the 12th to 14th week of gestation. The ovaries are not palpable after that time because the uterus fills the pelvic cavity. Ovulation ceases during pregnancy because of the elevated levels of estrogen and progesterone, which block secretion of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) from the anterior pituitary. The ovaries are very active in hormone production to support the pregnancy until about weeks 6 to 7, when the corpus luteum regresses and the placenta takes over the major production of progesterone.

Breasts

The breasts increase in fullness, become tender, and grow larger throughout pregnancy under the influence of estrogen and progesterone. The breasts become highly vascular, and veins become visible under the skin. The nipples become larger and more erect. Both the nipples and the areola become deeply pigmented, and tubercles of Montgomery (sebaceous glands) become prominent. These sebaceous glands keep the nipples lubricated for breastfeeding.

Changes that occur in the connective tissue of the breasts, along with the tremendous growth, lead to striae (stretch marks) in approximately half of all pregnant women (Graham, 2007). Initially they appear as pink to purple lines on the skin, but they eventually fade to a silver color. Although they become less conspicuous in time, they never completely disappear.

Creamy, yellowish breast fluid called colostrum can be expressed by the third trimester. This fluid provides nourishment for the breastfeeding newborn during the first few days of life (see Chapters 15 and 16 for more information).

Table 11.2 summarizes reproductive system adaptations.

General Body System Adaptations

In addition to changes in the reproductive system, the pregnant woman also experiences changes in virtually every other body system in response to the growing fetus.

Gastrointestinal System

The gastrointestinal (GI) system begins in the oral cavity and ends at the rectum. During pregnancy, the gums become hyperemic, swollen, and friable and tend to bleed easily. This change is influenced by estrogen and increased proliferation of blood vessels and circulation to the mouth. In addition, the saliva produced in the mouth becomes more acidic. Some women complain about excessive salivation, termed ptyalism, which may be caused by the decrease in unconscious swallowing by the woman when nauseated (Cunningham et al., 2005). Dental plaque, calculus, and debris deposits increase during pregnancy and are all associated with gingivitis. Recent studies have linked periodontal disease with preterm birth and low-birthweight risk (Pretorius, Jagatt, & Lamont, 2007).

Smooth muscle relaxation and decreased peristalsis occur related to the influence of progesterone. Elevated progesterone levels cause smooth muscle relaxation, which results in delayed gastric emptying and decreased peristalsis. Transition time of food throughout the GI tract may be so much slower that more water than normal is reabsorbed, leading to bloating and constipation. Constipation can also result from low-fiber food choices, reduced fluid intake, use of iron supplements, decreased activity level, and intestinal displacement secondary to a growing uterus. Constipation, increased venous pressure, and the pressure of the gravid uterus contribute to the formation of hemorrhoids.

The slowed gastric emptying combined with relaxation of the cardiac sphincter allows reflux, which causes heartburn. Acid indigestion or heartburn (pyrosis) seems to be a universal problem for pregnant women. It is caused by regurgitation of the stomach contents into the upper esophagus and may be associated with the generalized relaxation of the entire digestive system. Over-the-counter antacids will usually relieve the symptoms, but they should be taken with the health care provider's knowledge and only as directed.

The emptying time of the gallbladder is prolonged secondary to the smooth muscle relaxation from progesterone. Hypercholesterolemia can follow, increasing the risk of gallstone formation. Other risk factors for

TABLE 11.2 SUMMARY OF REPRODUCTIVE SYSTEM ADAPTATIONS

Reproductive Organ	Adaptations
Uterus	Size increases 20 times that of nonpregnant size. Capacity increases by 2,000 times to accommodate the developing fetus. Weight increases from 2 oz to approximately 2 lb at term. Uterine growth occurs as a result of both hyperplasia and hypertrophy of the myometrial cells. Increased strength and elasticity allow uterus to contract and expel fetus during birth.
Cervix	Increases in mass, water content, and vascularization Changes from a relatively rigid to a soft, distensible structure that allows the fetus to be expelled Under the influence of progesterone, a thick mucus plug is formed, which blocks the cervical os and protects the developing fetus from bacterial invasion.
Vagina	Increased vascularity because of estrogen influences, resulting in pelvic congestion and hypertrophy Increased thickness of mucosa, along with an increase in vaginal secretions to prevent bacterial infections
Ovaries	Increased blood supply to the ovaries causes them to enlarge until approximately the 12th to 14th week of gestation, when the placenta takes over their function. Ovulation ceases during pregnancy because of the elevated levels of estrogen and progesterone.
Breasts	Breast changes begin soon after conception; they increase in size and areolar pigmentation. The tubercles of Montgomery enlarge and become more prominent, and the nipples more erect. The blood vessels become more prominent, and blood flow to the breast doubles.

gallbladder disease include obesity, Hispanic ethnicity, and increasing maternal age (Ko, 2006).

Nausea and vomiting, better known as morning sickness, plagues about 50% to 80% of pregnant women (Lane, 2007). Although it occurs most often in the morning, the nauseated feeling can last all day in some women. The highest incidence of morning sickness is between 6 and 12 weeks. The physiologic basis for morning sickness is still debatable. It has been linked to the high levels of hCG, high levels of circulating estrogens, reduced stomach acidity, and the lowered tone and motility of the digestive tract (Lane, 2007).

Cardiovascular System

Cardiovascular changes occur early during pregnancy to meet the demands of the enlarging uterus and the placenta for more blood and more oxygen. Perhaps the most striking cardiac alteration occurring during pregnancy is the increase in blood volume.

Blood Volume

Blood volume increases by approximately 1,500 mL, or 50% above nonpregnant levels (Cunningham et al., 2005). The increase is made up of 1,000 mL plasma plus 450 mL red blood cells (RBCs). It begins at weeks 10 to 12, peaks at weeks 32 to 34, and decreases slightly at week 40.

▶ ***Take*** NOTE!

The rise in blood volume correlates directly with fetal weight.

This increase in blood volume is needed to provide adequate hydration of fetal and maternal tissues, to supply blood flow to perfuse the enlarging uterus, and to provide a reserve to compensate for blood loss at birth and during postpartum (Martin & Foley, 2006). This increase is also necessary to meet the increased metabolic needs of the mother and to meet the need for increased perfusion of other organs, especially the woman's kidneys, because she is excreting waste products for herself and the fetus.

Cardiac Output and Heart Rate

Cardiac output is the product of stroke volume and heart rate. It increases from 30% to 50% over the nonpregnant rate by the 32nd week of pregnancy and declines to about a 20% increase at 40 weeks' gestation. The increase in cardiac output is associated with an increase in venous return and greater right ventricular output, especially in the left lateral position (Blackburn, 2007). Heart rate increases by 10 to 15 bpm between 14 and 20 weeks of gestation, and this persists to term. There is slight hypertrophy or enlargement of the heart during pregnancy. This is probably to accommodate the increase in blood volume and cardiac output. The heart works harder and pumps more blood to supply the oxygen needs of the fetus as well as those of the mother. Both heart rate and venous return are increased in pregnancy, contributing to the increase in cardiac output seen throughout gestation. A woman with preexisting heart disease may become symptomatic and begin to decompensate during the time the blood volume peaks. Close monitoring is warranted during 28 to 35 weeks' gestation.

Blood Pressure

Blood pressure, especially the diastolic pressure, declines slightly during pregnancy as a result of peripheral vasodilation caused by progesterone. It reaches a low point at midpregnancy and thereafter increases to prepregnant levels until term (Blackburn, 2007). During the first trimester, blood pressure typically remains at the prepregnancy level. During the second trimester, the blood pressure decreases 5 to 10 mmHg and thereafter returns to first-trimester levels (Blackburn, 2007). Any significant rise in blood pressure during pregnancy should be investigated to rule out gestational hypertension.

Blood Components

The number of RBCs also increases throughout pregnancy to a level 25% to 33% higher than nonpregnant values, depending on the amount of iron available. This increase is necessary to transport the additional oxygen required during pregnancy. Although there is an increase in RBCs, there is a greater increase in the plasma volume as a result of hormonal factors and sodium and water retention. Because the plasma increase exceeds the increase of RBC production, normal hemoglobin and hematocrit values decrease. This state of hemodilution is referred to as **physiologic anemia of pregnancy**. Changes in RBC volume are due to increased circulating erythropoietin and accelerated RBC production. The rise in erythropoietin in the last two trimesters is stimulated by progesterone, prolactin, and human placental lactogen (Blackburn, 2007).

Iron requirements during pregnancy increase because of the demands of the growing fetus and the increase in maternal blood volume. The fetal tissues take predominance over the mother's tissues with respect to use of iron stores. With the accelerated production of RBCs, iron is necessary for hemoglobin formation, the oxygen-carrying component of RBCs.

▶ ***Take*** NOTE!

Many women enter pregnancy with insufficient iron stores and thus need supplementation to meet the extra demands of pregnancy.

Both fibrin and plasma fibrinogen levels increase, along with various blood-clotting factors. These factors make pregnancy a hypercoagulable state. These changes, coupled with venous stasis secondary to venous pooling, which occurs during late pregnancy after long periods of standing in the upright position with the pressure exerted by the uterus on the large pelvic veins, contribute to slowed venous return, pooling, and dependent edema. These factors also increase the woman's risk for venous thrombosis (Martin & Foley, 2006).

Respiratory System

The growing uterus and the increased production of the hormone progesterone cause the lungs to function differently during pregnancy. During the pregnancy, the amount of space available to house the lungs decreases as the uterus puts pressure on the diaphragm and causes it to shift upward by 4 cm above its usual position. The growing uterus does change the size and shape of the thoracic cavity, but diaphragmatic excursion increases, chest circumference increases by 2 to 3 in, and the transverse diameter increases by an inch, allowing a larger tidal volume, as evidenced by deeper breathing (Blackburn, 2007). Tidal volume or the volume of air inhaled increases gradually by 30 to 40% (from 500 to 700 mL) as the pregnancy progresses. As a result of these changes, the women's breathing becomes more diaphragmatic than abdominal (Torgersen & Curran, 2006).

A pregnant woman breathes faster and more deeply because she and the fetus need more oxygen. Oxygen consumption increases during pregnancy as airway resistance and lung compliance remain unchanged. Changes in the structures of the respiratory system take place to prepare the body for the enlarging uterus and increased lung volume (Alexander et al., 2007). As muscles and cartilage in the thoracic region relax, the chest broadens, with a conversion from abdominal breathing to thoracic breathing. This leads to a 50% increase in air volume per minute. All these structural alterations are temporary and revert back to their prepregnant state at the end of the pregnancy.

Increased vascularity of the respiratory tract is influenced by increased estrogen levels, leading to congestion. This congestion gives rise to nasal and sinus stuffiness, epistaxis (nosebleed), and changes in the tone and quality of the woman's voice (Martin & Foley, 2006).

Renal/Urinary System

The renal system must handle the effects of increased maternal intravascular and extracellular volume and metabolic waste products as well as excretion of fetal wastes. The predominant structural change in the renal system during pregnancy is dilation of the renal pelvis and uterus. Changes in renal structure occur from hormonal influences of estrogen and progesterone, pressure from an enlarging uterus, and an increase in maternal blood volume. Like the heart, the kidneys work harder throughout the pregnancy. Changes in kidney function occur to accommodate a heavier workload while maintaining a stable electrolyte balance and blood pressure. As more blood flows to the kidneys, the glomerular filtration rate (GFR) increases, leading to an increase in urine flow and volume, substances delivered to the kidneys, and filtration and excretion of water and solutes (Jeyabalan & Lain, 2007).

Anatomically, the kidneys enlarge during pregnancy. Each kidney increases in length and weight as a result of hormonal effects that cause increased tone and decreased motility of the smooth muscle. The renal pelvis becomes dilated. The ureters (especially the right ureter) elongate, widen, and become more curved above the pelvic rim as early as the 10th gestational week (Jeyabalan & Lain, 2007). Progesterone is thought to cause both these changes because of its relaxing influence on smooth muscle.

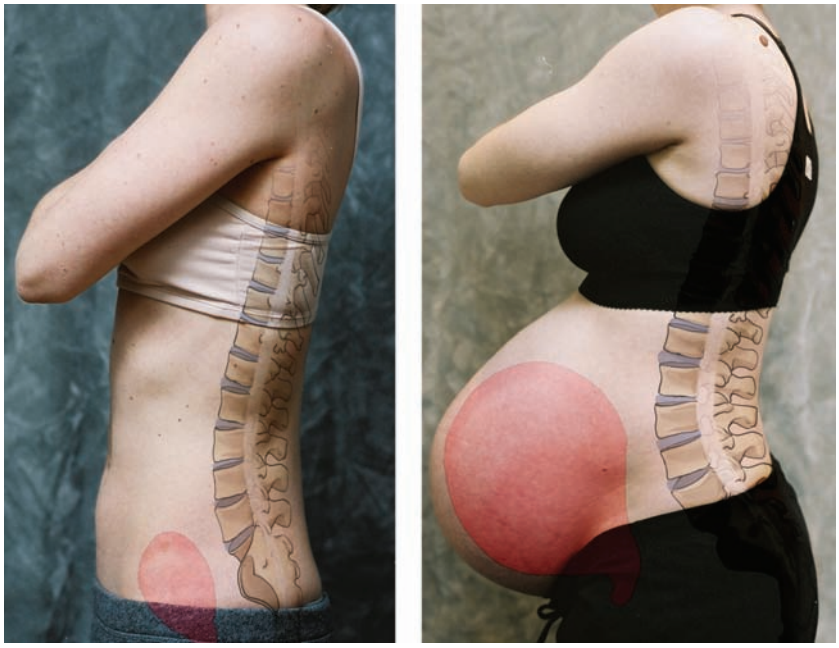
Blood flow to the kidneys increases by 50% to 80% as a result of the increase in cardiac output. This in turn leads to an increase in the GFR by as much as 40% to 60% starting during the second trimester. This elevation continues until birth (Blackburn, 2007).

The activity of the kidneys normally increases when a person lies down and decreases on standing. This difference is amplified during pregnancy, which is one reason a pregnant woman feels the need to urinate frequently while trying to sleep. Late in the pregnancy, the increase in kidney activity is even greater when the woman lies on her side rather than her back. Lying on the side relieves the pressure that the enlarged uterus puts on the vena cava carrying blood from the legs. Subsequently, venous return to the heart increases, leading to increased cardiac output. Increased cardiac output results in increased renal perfusion and glomerular filtration (Fitzgerald & Graziano, 2007).

Musculoskeletal System

Changes in the musculoskeletal system are progressive, resulting from the influence of hormones, fetal growth, and maternal weight gain. Pregnancy is characterized by changes in posture and gait. By the 10th to 12th week of pregnancy, the ligaments that hold the sacroiliac joints and the pubis symphysis in place begin to soften and stretch, and the articulations between the joints widen and become more movable (Frieden & Chan, 2007). The relaxation of the joints peaks by the beginning of the third trimester. The purpose of these changes is to increase the size of the pelvic cavity and to make delivery easier.

The postural changes of pregnancy—an increased swayback and an upper spine extension to compensate for the enlarging abdomen—coupled with the loosening of the sacroiliac joints may result in lower back pain. The woman's center of gravity shifts forward, requiring a realignment of the spinal curvatures. An increase in the normal lumbosacral curve (lordosis) occurs and a compensatory curvature in the cervicodorsal area develops



A. Early pregnancy **B.** Late pregnancy

FIGURE 11.3 Postural changes during (**A**) the first trimester and (**B**) the third trimester.

to assist her in maintaining her balance (Fig. 11.3). In addition, relaxation and increased mobility of joints occur because of the hormones progesterone and relaxin, which lead to the characteristic "waddle gait" that pregnant women demonstrate toward term. Increased weight gain can add to this discomfort by accentuating the lumbar and dorsal curves (Torgersen & Curran, 2006).

Integumentary System

The skin of pregnant women undergoes hyperpigmentation primarily as a result of estrogen, progesterone, and melanocyte-stimulating hormone levels. These changes are mainly seen on the nipples, areola, umbilicus, perineum, and axilla. Although many integumentary changes disappear after giving birth, some only fade. Many pregnant women express concern about stretch marks, skin color changes, and hair loss. Unfortunately, little is known about how to avoid these changes.

Complexion changes are not unusual. The increased pigmentation that occurs on the breasts and genitalia also develops on the face to form the "mask of pregnancy," or facial melasma. It occurs in up to 70% of pregnant women. There is a genetic predisposition toward melasma, which is exacerbated by the sun; it tends to recur in subsequent pregnancies. This blotchy, brownish pigment covers the forehead and cheeks in dark-haired women. Most fade as the hormones subside at the end of the pregnancy, but some may linger. The skin in the middle of the abdomen may develop a pigmented line called **linea nigra**, which extends from the umbilicus to the pubic area (Fig. 11.4).

Striae gravidarum, or stretch marks, are irregular reddish streaks that appear on the abdomen, breasts, and buttocks in about half of pregnant women. Striae are most prominent by 6 to 7 months. They result from reduced connective tissue strength resulting from the elevated adrenal steroid levels and stretching of the structures secondary to growth (Tunzi & Gray, 2007). They are more common in younger women, women with larger infants, and women with higher body mass indices. Nonwhites and women with a history of breast or thigh striae or a family history of striae gravidarum also are at higher risk (Osman et al., 2007).

FIGURE 11.4 Linea nigra.

Vascular changes during pregnancy manifested in the integumentary system include varicosities of the legs, vulva, and perineum. Varicose veins commonly are the result of distention, instability, and poor circulation secondary to prolonged standing or sitting and the heavy gravid uterus placing pressure on the pelvic veins, preventing complete venous return. Interventions to reduce the risk of developing varicosities include:

- Elevating both legs when sitting or lying down
- Avoiding prolonged standing or sitting; changing position frequently
- Resting in the left lateral position
- Walking daily for exercise
- Avoiding tight clothing or knee-high hosiery
- Wearing support hose if varicosities are a preexisting condition to pregnancy

Another skin manifestation, believed to be secondary to vascular changes and high estrogen levels, is the appearance of small blood vessels called vascular spiders. They may appear on the neck, thorax, face, and arms. They are especially obvious in white women and typically disappear after childbirth (Tunzi & Gray, 2007). Palmar erythema is a well-delineated pinkish area on the palmar surface of the hands. This integumentary change is also related to elevated estrogen levels (Tunzi & Gray, 2007).

Some women also notice a decline in hair growth during pregnancy. The hair follicles normally undergo a growing and resting phase. The resting phase is followed by a loss of hair; the hairs are then replaced by new ones. During pregnancy, fewer hair follicles go into the resting phase. After delivery, the body catches up with subsequent hair loss for several months. Nails typically grow faster during pregnancy. Pregnant women may experience increased brittleness and transverse grooves on the nails, but most of these conditions resolve in the postpartum period (Tunzi & Gray, 2007).

Endocrine System

The endocrine system undergoes many changes during pregnancy because hormonal changes are essential in meeting the needs of the growing fetus. Hormonal changes play a major role in controlling the supplies of maternal glucose, amino acids, and lipids to the fetus. Although estrogen and progesterone are the main hormones involved in pregnancy changes, other endocrine glands and hormones also change during pregnancy.

Thyroid Gland

The thyroid gland enlarges slightly and becomes more active during pregnancy as a result of increased vascularity and hyperplasia. Increased gland activity results in an increase in thyroid hormone secretion starting during the first trimester; levels taper off within a few weeks after birth and return to normal limits (Poppe, Velkeniers, & Glinoer, 2007). With an increase in the secretion of thyroid hormones, the basal metabolic rate (BMR; the amount of oxygen consumed by the body over a unit of time in milliliters per minute) progressively increases by 25%, along with heart rate and cardiac output (Blackburn, 2007).

Pituitary Gland

The pituitary gland, also known as the hypophysis, is a small, oval gland about the size of a pea that is connected to the hypothalamus by a stalk called the infundibulum. During pregnancy, the pituitary gland enlarges; it returns to normal size after birth.

The anterior lobe of the pituitary is glandular tissue and produces multiple hormones. The release of these hormones is regulated by releasing and inhibiting hormones produced by the hypothalamus. Some of these anterior pituitary hormones induce other glands to secrete their hormones. The increase in blood levels of the hormones produced by the final target glands (e.g., the ovary or thyroid) inhibits the release of anterior pituitary hormones. Changes in levels of pituitary hormones are discussed in the following paragraphs.

FSH and LH secretion are inhibited during pregnancy, probably as a result of hCG produced by the placenta and corpus luteum, and the increased secretion of prolactin by the anterior pituitary gland. Levels remain decreased until after delivery.

Thyroid-stimulating hormone (TSH) is reduced during the first trimester but usually returns to normal for the remainder of the pregnancy. Decreased TSH is thought to be one of the factors, along with elevated hCG levels, associated with morning sickness, nausea, and vomiting during the first trimester.

Growth hormone (GH) is an anabolic hormone that promotes protein synthesis. It stimulates most body cells to grow in size and divide, facilitating the use of fats for fuel and conserving glucose. During pregnancy, there is a decrease in the number of GH-producing cells and a corresponding decrease in GH blood levels. The action of human placental lactogen (hPL) is thought to decrease the need for and use of GH.

During pregnancy, prolactin is secreted in pulses and increases ten-fold to promote breast development and the lactation process. High levels of progesterone secreted by the placenta inhibit the direct influence of prolactin on the breast during pregnancy, thus suppressing lactation. At birth, as soon as the placenta is expelled and there is a drop in progesterone, lactogenesis can begin (Cunningham et al., 2005).

Melanocyte-stimulating hormone (MSH), another anterior pituitary hormone, increases during pregnancy. For many years, its increase was thought to be responsible for many of the skin changes of pregnancy, particularly changes in skin pigmentation (e.g., darkening of the areola, melasma, and linea nigra). However, currently it is thought that the skin changes are due to estrogen (and possibly progesterone) as well as the increase in MSH.

The two hormones oxytocin and antidiuretic hormone (ADH) released by the posterior pituitary are actually synthesized in the hypothalamus. They migrate along nerve fibers to the posterior pituitary and are stored until stimulated to be released into the general circulation.

Oxytocin is released by the posterior pituitary gland, and its production gradually increases as the fetus matures (Ochedalski et al., 2007). Oxytocin is responsible for uterine contractions, both before and after delivery. The muscle layers of the uterus (myometrium) become more sensitive to oxytocin near term. Toward the end of a term pregnancy, levels of progesterone decline and contractions that were previously suppressed by progesterone begin to occur more frequently and with stronger intensity. This change in the hormonal levels is believed to be one of the initiators of labor.

Oxytocin is responsible for stimulating the uterine contractions that bring about delivery. Contractions lead to cervical thinning and dilation. They also exert pressure, helping the fetus to descend in the pelvis for eventual delivery. After delivery, oxytocin secretion continues, causing the myometrium to contract and helping to constrict the uterine blood vessels, decreasing the amount of vaginal bleeding after delivery.

Oxytocin is also responsible for milk ejection during breastfeeding. Stimulation of the breasts through sucking or touching stimulates the secretion of oxytocin from the posterior pituitary gland. Oxytocin causes contraction of the myoepithelial cells in the lactating mammary gland. With breastfeeding, "after pains" often occur, which signals that oxytocin is being released.

Vasopressin (ADH) functions to inhibit or prevent the formation of urine via vasoconstriction, which results in increased blood pressure. Vasopressin also exhibits an antidiuretic effect and plays an important role in the regulation of water balance (Fitzgerald & Graziano, 2007).

Pancreas

The pancreas is an exocrine organ, supplying digestive enzymes and buffers, and an endocrine organ. The endocrine pancreas consists of the islets of Langerhans, which are groups of cells scattered throughout, each containing four cell types. One of the cell types is the beta cell, which produces insulin. Insulin lowers blood glucose by increasing the rate of glucose uptake and utilization by most body cells. The growing fetus needs significant amounts of glucose, amino acids, and lipids. Even during early pregnancy the fetus makes demands on the maternal glucose stores. Ideally, hormonal changes of pregnancy help meet fetal needs without putting the mother's metabolism out of balance.

A woman's insulin secretion works on a "supply-versus-demand" mode. As the demand to meet the needs of pregnancy increases, more insulin is secreted. Maternal insulin does not cross the placenta, so the fetus must produce his or her own supply to maintain glucose control (Box 11.2 gives information about pregnancy, glucose, and insulin).

BOX 11.2 Pregnancy, Insulin, and Glucose

- During early pregnancy, there is a decrease in maternal glucose levels because of the heavy fetal demand for glucose. The fetus is also drawing amino acids and lipids from the mother, decreasing the mother's ability to synthesize glucose. Maternal glucose is diverted across the placenta to assist the growing embryo/fetus during early pregnancy, and thus levels decline in the mother. As a result, maternal glucose concentrations decline to a level that would be considered "hypoglycemic" in a nonpregnant woman. During early pregnancy there is also a decrease in maternal insulin production and insulin levels.
- The pancreas is responsible for the production of insulin, which facilitates entry of glucose into cells. Although glucose and other nutrients easily cross the placenta to the fetus, insulin does not. Therefore, the fetus must produce its own insulin to facilitate the entry of glucose into its own cells.
- After the first trimester, hPL from the placenta and steroids (cortisol) from the adrenal cortex act against insulin. hPL acts as an antagonist against maternal insulin, and thus more insulin must be secreted to counteract the increasing levels of hPL and cortisol during the last half of pregnancy.
- Prolactin, estrogen, and progesterone are also thought to oppose insulin. As a result, glucose is less likely to enter the mother's cells and is more likely to cross over the placenta to the fetus (Cunningham et al., 2005).

During the first half of pregnancy, much of the maternal glucose is diverted to the growing fetus, and thus the mother's glucose levels are low. hPL and other hormonal antagonists increase during the second half of pregnancy. Therefore, the mother must produce more insulin to overcome the resistance by these hormones.

If the mother has normal beta cells of the islets of Langerhans, there is usually no problem meeting the demands for extra insulin. However, if the woman has inadequate numbers of beta cells, she may be unable to produce enough insulin and will develop glucose intolerance during pregnancy. If the woman has glucose intolerance, she is not able to meet the increasing demands and her blood glucose level increases.

Adrenal Glands

Pregnancy does not cause much change in the size of the adrenal glands themselves, but there are changes in some secretions and activity. One of the key changes is the marked increase in cortisol secretion, which regulates carbohydrate and protein metabolism and is helpful

in times of stress. Although pregnancy is considered a normal condition, it is a time of stress for a woman's body. Cortisol increases in response to increased estrogen levels throughout pregnancy and returns to normal levels within 6 weeks postpartum (Blackburn, 2007).

During the stress of pregnancy, cortisol:

- Helps keep up the level of glucose in the plasma by breaking down noncarbohydrate sources, such as amino and fatty acids, to make glycogen. Glycogen, stored in the liver, is easily broken down to glucose when needed so that glucose is available in times of stress.
- Breaks down proteins to repair tissues and manufacture enzymes
- Has anti-insulin, anti-inflammatory, and antiallergic actions
- Is needed to make the precursors of adrenaline, which the adrenal medulla produces and secretes (Cunningham et al., 2005)

Aldosterone, also secreted by the adrenal glands, is increased during pregnancy. It normally regulates absorption of sodium from the distal tubules of the kidney. During pregnancy, progesterone allows salt to be "wasted" (or lost) in the urine. Aldosterone is produced in increased amounts by the adrenal glands as early as 15 weeks of pregnancy (Jeyabalan & Lain, 2007).

Prostaglandin Secretion During Pregnancy

Prostaglandins are not protein or steroid hormones; they are chemical mediators, or "local" hormones. Although hormones circulate in the blood to influence distant tissues, prostaglandins act locally on adjacent cells. The fetal membranes of the amniotic sac—the amnion and chorion—are both believed to be involved in the production of prostaglandins. Various maternal and fetal tissues, as well as the amniotic fluid itself, are considered to be sources of prostaglandins, but details about their composition and sources are limited. It is widely believed that prostaglandins play a part in softening the cervix and initiating and/or maintaining labor, but the exact mechanism is unclear.

Placental Secretion

The placenta has a feature possessed by no other endocrine organ—the ability to form protein and steroid hormones. Very early during pregnancy, the placenta begins to produce the following hormones:

- hCG
- hPL
- Relaxin
- Progesterone
- Estrogen

Table 11.3 summarizes the role of these hormones.

Immune System

The immune system is made up of organs and specialized cells whose primary purpose is to defend the body from foreign substances (antigens) that may cause tissue injury or disease. The mechanisms of innate and adaptive immunity work cooperatively to prevent, control, and eradicate foreign antigens in the body.

A general enhancement of innate immunity (inflammatory response and phagocytosis) and suppression of adaptive immunity (protective response to a specific foreign antigen) takes place during pregnancy. These immunologic alterations help prevent the mother's immune system from rejecting the fetus (foreign body), increase her risk of developing certain infections such as urinary tract infections, and influence the course of chronic disorders such as autoimmune diseases. Some chronic conditions worsen (diabetes) while others seem to stabilize (asthma) during pregnancy, but this is individualized and not predictable. In general, immune function in pregnant women is similar to immune function in nonpregnant women.

Marva returns for her first prenatal appointment and tells the nurse that her whole body is "out of sorts." She is overwhelmed and feels poorly. Outline the bodily changes Marva can expect each trimester to help her understand the adaptations taking place. What guidance can the nurse give Marva to help her understand the changes of pregnancy?

Table 11.4 summarizes the general body systems adaptations to pregnancy.

Changing Nutritional Needs of Pregnancy

Healthy eating during pregnancy enables optimal gestational weight gain and reduces complications, both of which are associated with positive birth outcomes. During pregnancy, maternal nutritional needs change to meet the demands of the pregnancy. Healthy eating can help ensure that adequate nutrients are available for both mother and fetus.

Nutritional intake during pregnancy has a direct effect on fetal well-being and birth outcome. Inadequate nutritional intake, for example, is associated with preterm birth, low birthweight, and congenital anomalies. Excessive nutritional intake is connected with fetal macrosomia (>4,000 g), leading to a difficult birth, neonatal hypoglycemia, and continued obesity in the mother (Blackburn, 2007).

Since the requirements for so many nutrients increase during pregnancy, pregnant women should take a vitamin and mineral supplement daily. Prenatal vitamins are prescribed routinely as a safeguard against a less-than-optimal diet. In particular, iron and folic acid need to be supplemented because their increased requirements during pregnancy are usually too great to be met through diet alone

TABLE 11.3 PLACENTAL HORMONES

Hormone	Description
hCG	• Responsible for maintaining the maternal corpus luteum, which secretes progesterone and estrogens, with synthesis occurring before implantation • Production by fetal trophoblast cells until the placenta is developed sufficiently to take over that function • Basis for early pregnancy tests because it appears in the maternal bloodstream soon after implantation • Production peaks at 8 weeks and then gradually declines.
hPL (also known as human chorionic somatomammotropin [hCS])	• Preparation of mammary glands for lactation and involved in the process of making glucose available for fetal growth by altering maternal carbohydrate, fat, and protein metabolism • Antagonist of insulin because it decreases tissue sensitivity or alters the ability to use insulin • Increase in the amount of circulating free fatty acids for maternal metabolic needs and decrease in maternal metabolism of glucose to facilitate fetal growth
Relaxin	• Secretion by the placenta as well as the corpus luteum during pregnancy • Thought to act synergistically with progesterone to maintain pregnancy • Increase in flexibility of the pubic symphysis, permitting the pelvis to expand during delivery • Dilation of the cervix, making it easier for the fetus to enter the vaginal canal; thought to suppress the release of oxytocin by the hypothalamus, thus delaying the onset of labor contractions (Blackburn, 2007)
Progesterone	• Often called the "hormone of pregnancy" because of the critical role it plays in supporting the endometrium of the uterus • Supports the endometrium to provide an environment conducive to fetal survival • Produced by the corpus luteum during the first few weeks of pregnancy and then by the placenta until term • Initially, causes thickening of the uterine lining in anticipation of implantation of the fertilized ovum. From then on, it maintains the endometrium, inhibits uterine contractility, and assists in the development of the breasts for lactation (Graham, 2007).
Estrogen	• Promotes enlargement of the genitals, uterus, and breasts, and increases vascularity, causing vasodilatation. • Relaxation of pelvic ligaments and joints (Blackburn, 2007) • Associated with hyperpigmentation, vascular changes in the skin, increased activity of the salivary glands, and hyperemia of the gums and nasal mucous membranes (Tunzi & Gray, 2007) • Aids in developing the ductal system of the breasts in preparation for lactation (Graham, 2007)

(Blackburn, 2007). Iron and folic acid are needed to form new blood cells for the expanded maternal blood volume and to prevent anemia. Folic acid is essential before pregnancy and in the early weeks of pregnancy to prevent neural tube defects in the fetus. For most pregnant women, supplements of 30 mg of ferrous iron and 600 mcg of folic acid per day are recommended by the **dietary reference intakes (DRIs)** (Institute of Medicine [IOM], 2006a, 2006b, 2006c, 2006d, 2006e, 2006f). Women with a previous history of a fetus with a neural tube defect are often prescribed a higher dose.

There is an abundance of conflicting advice about nutrition during pregnancy and what is good or bad to eat. Overall, the following guidelines are helpful:

- Increase your consumption of fruits and vegetables.
- Replace saturated fats with unsaturated ones.
- Avoid hydrogenated or partially hydrogenated fats.
- Use reduced-fat spreads and dairy products instead of full-fat ones.
- Eat at least two servings of fish weekly, with one of them being an oily fish.
- Consume at least 2 quarts of water daily (Arenson & Drake, 2007).

In the months before conception, food choices are key. The foods and vitamins consumed can ensure that the woman and her fetus will have the nutrients that are essential for the very start of pregnancy.

While most women recognize the importance of healthy eating during pregnancy, some find it challenging to achieve. Many women say they have little time and energy to devote to meal planning and preparation. Another barrier to healthy eating is conflicting messages from various sources, resulting in a lack of clear, reliable, and relevant information. Moreover, many women

TABLE 11.4 SUMMARY OF GENERAL BODY SYSTEM ADAPTATIONS

System	Adaptation
Gastrointestinal system	*Mouth and pharynx:* Gums become hyperemic, swollen, and friable and tend to bleed easily. Saliva production increases. *Esophagus:* Decreased lower esophageal sphincter pressure and tone, which increases the risk of developing heartburn *Stomach:* Decreased tone and mobility with delayed gastric emptying time, which increases the risk of gastroesophageal reflux and vomiting. Decreased gastric acidity and histamine output, which improves symptoms of peptic ulcer disease. *Intestines:* Decreased intestinal tone motility with increased transit time, which increases risk of constipation and flatulence *Gallbladder:* Decreased tone and motility, which may increase risk of gallstone formation
Cardiovascular system	*Blood volume:* Marked increase in plasma (50%) and RBCs (25% to 33%) compared to nonpregnant values. Causes hemodilution, which is reflected in a lower hematocrit and hemoglobin. *Cardiac output and heart rate:* CO increases from 30% to 50% over the nonpregnant rate by the 32nd week of pregnancy. The increase in CO is associated with an increase in venous return and greater right ventricular output, especially in the left lateral position. Heart rate increases by 10 to 15 bpm between 14 and 20 weeks of gestation, and this increase persists to term. *Blood pressure:* Diastolic pressure decreases typically 10 to 15 mmHg to reach its lowest point by mid-pregnancy; it then gradually returns to nonpregnant baseline values by term. *Blood components:* The number of RBCs increases throughout pregnancy to a level 25% to 33% higher than nonpregnant values. Both fibrin and plasma fibrinogen levels increase, along with various blood-clotting factors. These factors make pregnancy a hypercoagulable state.
Respiratory system	Enlargement of the uterus shifts the diaphragm up to 4 cm above its usual position. As muscles and cartilage in the thoracic region relax, the chest broadens, with conversion from abdominal breathing to thoracic breathing. This leads to a 50% increase in air volume per minute. Tidal volume, or the volume of air inhaled, increases gradually by 30% to 40% (from 500 to 700 mL) as the pregnancy progresses.
Renal/Urinary system	The renal pelvis becomes dilated. The ureters (especially the right ureter) elongate, widen, and become more curved above the pelvic rim. Bladder tone decreases and bladder capacity doubles by term. GFR increases 40% to 60% during pregnancy. Blood flow to the kidneys increases by 50% to 80% as a result of the increase in cardiac output.
Musculoskeletal system	Distention of the abdomen with growth of the fetus tilts the pelvis forward, shifting the center of gravity. The woman compensates by developing an increased curvature (lordosis) of the spine. Relaxation and increased mobility of joints occur because of the hormones progesterone and relaxin, which lead to the characteristic “waddle gait” that pregnant women demonstrate toward term.
Integumentary system	Hyperpigmentation of the skin is the most common alteration during pregnancy. The most common areas include the areola, genital skin, axilla, inner aspects of the thighs, and linea nigra. Striae gravidarum, or stretch marks, are irregular reddish streaks that may appear on the abdomen, breasts, and buttocks in about half of pregnant women. The skin in the middle of the abdomen may develop a pigmented line called linea nigra, which extends from the umbilicus to the pubic area. Melasma (“mask of pregnancy”) occurs in 45% to 70% of pregnant women. It is characterized by irregular, blotchy areas of pigmentation on the face, most commonly on the cheeks, chin, and nose.
Endocrine system	Controls the integrity and duration of gestation by maintaining the corpus luteum via hCG secretion; production of estrogen, progesterone, hPL, and other hormones and growth factors via the placenta; release of oxytocin (by the posterior pituitary gland), prolactin (by the anterior pituitary), and relaxin (by the ovary, uterus, and placenta).
Immune system	A general enhancement of innate immunity (inflammatory response and phagocytosis) and suppression of adaptive immunity (protective response to a specific foreign antigen) takes place during pregnancy. These immunologic alterations help prevent the mother’s immune system from rejecting the fetus (foreign body), increase her risk of developing certain infections, and influence the course of chronic disorders such as autoimmune diseases.

are eating less in an effort to control their weight, putting them at greater risk of inadequate nutrient intake.

Nutritional Requirements During Pregnancy

Pregnancy is one of the most nutritionally demanding periods of a woman's life. Gestation involves rapid cell division and organ development, and an adequate supply of nutrients is essential to support this tremendous fetal growth.

Most women are usually motivated to eat properly during pregnancy for the sake of the fetus. The Food and Nutrition Board of the National Research Council has made recommendations for nutrient intakes for people living in the United States. The DRIs are more comprehensive than previous nutrient guidelines issued by the board. They have replaced previous recommendations because they are not limited to preventing deficiency diseases; rather, the DRIs incorporate current concepts about the role of nutrients and food components in reducing the risk of chronic disease, developmental disorders, and other related problems. The DRIs can be used to plan and assess diets for healthy people (Dudek, 2006).

These dietary recommendations also include information for women who are pregnant or lactating, because growing fetal and maternal tissues require increased quantities of essential dietary components. For example, the current DRIs suggest an increase in the pregnant woman's intake of protein from 60 to 80 g per day, iron from 18 to 27 g per day, and folate from 400 to 600 mcg per day, along with an increase of 300 calories per day over the recommended intake of 1,800 to 2,200 calories for nonpregnant women (IOM, 2006a, 2006b, 2006c, 2006d, 2006e, 2006f) (Table 11.5).

For a pregnant woman to meet recommended DRIs, it is important for her to eat according to the USDA's Food Guide Pyramid (Fig. 11.5). The 2005 Dietary Guidelines for Americans are the basis for federal nutrition policy. The Food Guide Pyramid provides guidance to help implement these guidelines. A summary of the new guidelines is as follows:

- Eat a variety of food from all food groups using portion control.
- Increase intake of vitamins, minerals, and dietary fiber.
- Lower intake of saturated fats, trans fats, and cholesterol.
- Consume adequate synthetic folic acid from supplements or from fortified foods.
- Increase intake of fruits, vegetables, and whole grains.
- Balance calorie intake with exercise to maintain ideal healthy weight (USDA, 2005).

An eating plan that follows the pyramid should provide sufficient nutrients for a healthy pregnancy. Except

TABLE 11.5 DIETARY RECOMMENDATIONS FOR THE PREGNANT AND LACTATING WOMAN

Nutrient	Nonpregnant Women	Pregnant Woman	Lactating Woman
Calories	2,200	2,500	2,700
Protein	60 g	80 g	80 g
Water/fluids	6–8 glasses daily	8 glasses daily	8 glasses daily
Vitamin A	700 mcg	770 mcg	1,300 mcg
Vitamin C	75 mg	85 mg	120 mg
Vitamin D	5 mcg	5 mcg	5 mcg
Vitamin E	15 mcg	15 mcg	19 mcg
B1 (thiamine)	1.1 mg	1.5 mg	1.5 mg
B2 (riboflavin)	1.1 mg	1.4 mg	1.6 mg
B3 (niacin)	14 mg	18 mg	17 mg
B6 (pyridoxine)	1.3 mg	1.9 mg	2 mg
B12 (cobalamin)	2.4 mcg	2.6 mcg	2.8 mcg
Folate	400 mcg	600 mcg	500 mcg
Calcium	1,000 mg	1,000 mg	1,000 mg
Phosphorus	700 mg	700 mg	700 mg
Iodine	150 mcg	220 mcg	290 mcg
Iron	18 mg	27 mg	9 mg
Magnesium	310 mg	350 mg	310 mg
Zinc	8 mg	11 mg	12 mg

MyPyramid Plan for Moms

Food Group	1st Trimester	2nd and 3rd Trimesters	What counts as 1 cup or 1 ounce?	Remember to...
	Eat this amount from each group daily.*			
Fruits	2 cups	2 cups	1 cup fruit or juice, ½ cup dried fruit	***Focus on fruits***—Eat a variety of fruit.
Vegetables	2½ cups	3 cups	1 cup raw or cooked vegetables or juice, 2 cups raw leafy vegetables	***Vary your* veggies**—Eat more dark green and orange vegetables and cooked dry beans.
Grains	6 ounces	8 ounces	1 slice bread; ½ cup cooked pasta, rice, cereal; 1 ounce ready-to-eat cereal	***Make half your grains whole***—Choose whole instead of refined grains.
Meat and Beans	5½ ounces	6½ ounces	1 ounce lean meat, poultry, fish; 1 egg; ¼ cup cooked dry beans; ½ ounce nuts; 1 tablespoon peanut butter	***Go lean with protein***—Choose low-fat or lean meats and poultry.
Milk	3 cups	3 cups	1 cup milk, 8 ounces yogurt, 1½ ounces cheese, 2 ounces processed cheese	***Get your calcium-rich foods***—Go low-fat or fat-free when you choose milk, yogurt, and cheese.

*These amounts are for an average pregnant woman. You may need more or less than the average. Check with your doctor to make sure you are gaining weight as you should.

FIGURE 11.5 Food Guide Pyramid for pregnancy.

for iron, folic acid, and calcium, most of the nutrients a woman needs during pregnancy can be obtained by making healthy food choices. However, a vitamin and mineral supplement is generally prescribed.

▶ ***Take* NOTE!**

Good food sources of folic acid include dark green vegetables, such as broccoli, romaine lettuce, and spinach; baked beans; black-eyed peas; citrus fruits; peanuts; and liver.

Fish and shellfish are an important part of a healthy diet because they contain high-quality protein, are low in saturated fat, and contain omega-3 fatty acids. However, nearly all fish and shellfish contain traces of mercury and some contain higher levels of mercury that may harm a developing fetus if ingested by pregnant women in large amounts. With this in mind, the FDA and the Environmental Protection Agency (EPA) are advising women who may become pregnant, pregnant women, and nursing mothers to do the following:

- Avoid eating shark, swordfish, king mackerel, and tilefish.
- Eat up to 12 ounces (two average meals) weekly of these fish:
  - Shrimp, canned light tuna, salmon
  - Pollock and catfish
- Check local advisories about the safety of fish caught by family and friends in local lakes, rivers, and coastal areas (Hibbeln et al., 2007)

EVIDENCE-BASED PRACTICE 11.1
Effects of Zinc Supplementation in Pregnancy on Maternal, Fetal, Neonatal, and Infant Outcomes

● Study
It has been suggested that low serum zinc levels may be associated with suboptimal outcomes of pregnancy such as prolonged labor, atonic postpartum hemorrhage, pregnancy-induced hypertension, preterm labor, and post-term pregnancies, although many of these associations have not yet been established.

Many women of childbearing age may have mild to moderate zinc deficiency. Low zinc levels may cause preterm birth or may prolong labor. It is also possible that zinc deficiency may affect infant growth.

A review of 17 trials, involving over 9,000 women and their babies, found that although zinc supplementation has a small effect on reducing preterm births, it does not help to prevent low-birthweight babies. Finding ways to improve women's overall nutritional status, particularly in low-income areas, will do more to improve the health of mothers and babies than giving pregnant women zinc supplements.

▲ Findings
The 14% relative reduction in preterm birth for zinc compared with placebo was primarily in the group of studies involving women of low income, and this has some relevance in areas of high perinatal mortality. There was no convincing evidence that zinc supplementation during pregnancy results in other important benefits. Since the preterm association could well reflect poor nutrition, studies to address ways of improving the overall nutritional status of populations in impoverished areas, rather than focusing on micronutrient and/or zinc supplementation in isolation, should be a priority.

■ Nursing Implications
Nurses can dispel any myths associated with the use of zinc as a preventive measure for preterm births, since research doesn't seem to validate this. Encouraging better nutrition, increasing water consumption, and taking rest periods throughout the day are all associated with longevity of pregnancy. At this point, the exact triggering mechanism for preterm labor is not known.

Mahomed, K., Bhutta, Z., & Middleton, P. (2007). Zinc supplementation for improving pregnancy and infant outcome. *Cochrane Database of Systematic Reviews,* Issue 2. Art. No.: CD000230. DOI: 10.1002/14651858.CD000230.pub3.

Maternal Weight Gain

The amount of weight that a woman gains during pregnancy is not as important as what she eats. A woman can lose extra weight after a pregnancy, but she can never make up for a poor nutritional status during the pregnancy. Currently, the American College of Obstetricians & Gynecologists (2005) recommends a 25- to 35-pound weight gain during pregnancy. Table 11.6 summarizes the distribution of weight gain during pregnancy.

The best way to assess whether a pregnant woman is consuming enough calories is to follow her pattern of weight gain. If she is gaining in a steady, gradual manner, then she is taking in enough calories. However, consuming an adequate amount of calories doesn't guarantee that her nutrients are sufficient. It is critical to evaluate both the quantity and the quality of the foods eaten.

The IOM has issued recommendations for weight gain during pregnancy based on prepregnancy body mass index (BMI; Box 11.3). A woman who is underweight before pregnancy or who has a low maternal weight gain pattern should be monitored carefully because she is at risk of giving birth to a low-birthweight infant (<2,500 g or 5.5 pounds). Frequently these women simply need advice on what to eat to add weight. Encourage the woman to eat snacks that are high in calories such as nuts, peanut butter, milkshakes, cheese, fruit, yogurt, and ice cream. Any woman who has a prepregnancy BMI of less than 19.8 is considered to be high risk and should be referred to a nutritionist. These women are encouraged to gain 28 to 40 pounds during the pregnancy (IOM, 2006a).

Conversely, women who start a pregnancy while overweight (BMI >25 to 29) run the risk of having a high-

TABLE 11.6 NORMAL DISTRIBUTION OF WEIGHT GAIN DURING PREGNANCY

Component	Weight
Fetus	7.5–8.5 pounds
Blood	4 pounds
Uterus	2 pounds
Breasts	1 pound
Placenta and umbilical cord	1.5 pounds
Fat and protein stores	7.5 pounds
Tissue fluids	2.7 pounds
Amniotic fluid	1.8 pounds
Approximate total weight gain	29 pounds

Sources: ACOG, 2005; Blackburn, 2007; Dudek, 2006.

BOX 11.3 Body Mass Index

Body Mass Index (BMI) provides an accurate estimate of total body fat and is considered a good method to assess overweight and obesity in people. BMI is a weight-to-height ratio calculation that can be determined by dividing a woman's weight in kilograms by her height in meters squared. BMI can also be calculated by weight in pounds divided by the height in inches squared, multiplied by 704.5.

The Centers for Disease Control and Prevention (CDC) categorizes BMI as follows:

- Underweight: less than 18.5
- Healthy weight: 18.5 to 24.9
- Overweight: 25 to 29.9
- Obese: 30 or higher (CDC, 2007)

Use this example to calculate BMI:

Mary is 5-foot-5 tall and weighs 150 pounds.

1. Convert weight into kilograms 150 divided by 2.2 lb/kg = 68.18 kg.
2. Convert height into meters:
   a. 5-foot-5 = 65 inches times 2.54 cm/in = 165.1 cm
   b. 165.1 cm/100 cm = 1.65 m
3. Then square the height in meters: 1.65 times 1.65 = 2.72
4. Calculate BMI 68.18 divided by 2.72 = 25

birthweight infant, with resulting cephalopelvic disproportion and, potentially, a surgical birth. Dieting during pregnancy is never recommended, even for women who are obese. Severe restriction of caloric intake is associated with a decrease in birthweight. Because of the expansion of maternal blood volume and the development of fetal and placental tissues, some weight gain is essential for a healthy pregnancy. Women who gain more than the recommended weight during pregnancy and who fail to lose this weight 6 months after giving birth are at much higher risk of being obese nearly a decade later (ACOG, 2005). Women who are overweight when beginning a pregnancy should gain no more than 15 to 25 pounds during the pregnancy, depending on their nutritional status and degree of obesity (ACOG, 2005).

All pregnant women should aim for a steady rate of weight gain throughout pregnancy. During the first trimester, for women whose prepregnant weight is within the normal weight range, weight gain should be about 3.5 to 5 pounds. For underweight women, weight gain should be at least 5 pounds. For overweight women, weight gain should be about 2 pounds. Much of the weight gained during the first trimester is caused by growth of the uterus and expansion of the blood volume.

During the second and third trimesters, the following pattern is recommended. For women whose prepregnant weight is within the normal weight range, weight gain should be about 1 pound per week. For underweight women, weight gain should be slightly more than 1 pound per week. For overweight women, weight gain should be about two thirds of a pound per week (Blackburn, 2007).

Nutrition Promotion

Through education, nurses can play an important role in ensuring adequate nutrition for pregnant women. During the initial prenatal visit, health care providers conduct a thorough assessment of a woman's typical dietary practices and address any conditions that may cause inadequate nutrition, such as nausea and vomiting or lack of access to adequate food. Assess and reinforce dietary information at every prenatal visit to promote good nutrition. A normal pregnancy and a well-balanced diet generally provide most of the recommended nutrients except iron and folate, both of which must be supplemented in the form of prenatal vitamins.

The Food Guide Pyramid, developed in 1992 and revised in 2005 by the U.S. Department of Agriculture, is the typical tool used for nutritional education and is recognized by the general population as the gold standard for healthy eating patterns (Dudek, 2006). Use this well-known tool as a basis for dietary instruction and tailor it to meet each woman's individual needs (Teaching Guidelines 11.1).

Special Nutritional Considerations

Many factors play an important role in shaping a person's food habits, and these factors must be taken into account

TEACHING GUIDELINES 11.1

Teaching to Promote Optimal Nutrition During Pregnancy

- Follow the Food Guide Pyramid and select a variety of foods from each group.
- Gain weight in a gradual and steady manner as follows:
  a. Normal-weight woman—25 to 35 pounds
  b. Underweight woman—28 to 40 pounds
  c. Overweight woman—15 to 25 pounds
  d. Obese woman—15 pounds
- Take your prenatal vitamin/mineral supplementation daily.
- Avoid weight-reduction diets during pregnancy.
- Do not skip meals; eat three meals with one or two snacks daily.
- Limit the intake of sodas and caffeine-rich drinks.
- Avoid the use of diuretics during pregnancy.
- Do not restrict the use of salt unless instructed to do so by your health care provider.
- Engage in reasonable physical activity daily.

if nutritional counseling is to be realistic and appropriate. Nurses need to be aware of these factors to ensure individualized teaching and care.

Cultural Variations and Restrictions

Food is important to every cultural group. It is often part of celebrations and rituals. When working with women from various cultures, the nurse needs to adapt American nutritional guidelines to meet their nutritional needs within their cultural framework. Food choices and variations for different cultures might include the following:

- Bread, cereal, rice and pasta group:
  - Bolello
  - Couscous
  - Hau juan
  - Flaxseed
- Vegetable group:
  - Agave
  - Bok choy
  - Jicama
  - Okra
  - Water chestnuts
- Protein group:
  - Bean paste
  - Blood sausage
  - Legumes
  - Shellfish
- Fruit group:
  - Catabopy
  - Kumquats
  - Plantain
  - Yucca fruit
  - Zapate
- Milk and dairy:
  - Buttermilk
  - Buffalo milk
  - Soybean milk

Lactose Intolerance

The best source of calcium is milk and dairy products, but for women with lactose intolerance, adaptations are necessary. Women with lactose intolerance lack an enzyme (lactase) needed for the breakdown of lactose into its component simple sugars, glucose, and galactose. Without adequate lactase, lactose passes through the small intestine undigested and causes abdominal discomfort, gas, and diarrhea. Lactose intolerance is especially common among women of African, Asian, and Middle Eastern descent (Dudek, 2006).

Additional or substitute sources of calcium may be necessary. These may include peanuts, almonds, sunflower seeds, broccoli, salmon, kale, and molasses (Escott-Stump, 2007). In addition, encourage the woman to drink lactose-free dairy products or calcium-enriched orange juice or soy milk.

Vegetarians

Vegetarian diets are becoming increasing prevalent in the United States. People choose a vegetarian diet for various reasons, including environmental, animal rights, philosophical, religious, and health beliefs (Hughes & Brown, 2006). Vegetarians choose not to eat meat, chicken, and fish. Their diets consist mostly of plant-based foods, such as legumes, vegetables, whole grains, nuts, and seeds. Vegetarians fall into groups defined by the types of foods they eat. Lacto-ovo-vegetarians omit red meat, fish, and poultry but eat eggs, milk, and dairy products, in addition to plant-based foods. Lacto-vegetarians consume milk and dairy products along with plant-based foods; they omit eggs, meat, fish, and poultry. Vegans eliminate all foods from animals, including milk, eggs, and cheese, and eat only plant-based foods (Dudek, 2006).

The concern with any form of vegetarianism, especially during pregnancy, is that the diet may be inadequate in nutrients. Other risks of vegetarian eating patterns during pregnancy may include low gestational weight gain, iron-deficiency anemia, compromised protein utilization, and decreased mineral absorption (Dudek, 2006). A diet can become so restrictive that a woman is not gaining weight or is consistently not eating enough from one or more of the food groups. Generally, the more restrictive the diet, the greater the chance of nutrient deficiencies.

Well-balanced vegetarian diets that include dairy products provide adequate caloric and nutrient intake and do not require special supplementation; however, vegan diets do not include any meat, eggs, or dairy products. Pregnant vegetarians must pay special attention to their intake of protein, iron, calcium, and vitamin B12. Suggestions include:

- For protein: substitute soy foods, beans, lentils, nuts, grains, and seeds.
- For iron: eat a variety of meat alternatives, along with vitamin C-rich foods.
- For calcium: substitute soy, calcium-fortified orange juice, and tofu.
- For vitamin B12: eat fortified soy foods and a B12 supplement.

The woman may also take a multivitamin prenatal supplement (Hughes & Brown, 2006).

Pica

Many women experience unusual food cravings during their pregnancy. Having cravings during pregnancy is perfectly normal. Sometimes, however, women crave substances that have no nutritional value and can even be dangerous to themselves and their fetus. **Pica** is the compulsive ingestion of nonfood substances. Pica is derived from the Latin term for magpie, a bird that is known to consume a variety of nonfood substances. Unlike the bird, however, pregnant women who develop a pica habit typically have one or two specific cravings.

The exact cause of pica is not known. Many theories have been advanced to explain it, but none has been proven scientifically. The incidence of pica is difficult to determine, since it is underreported. It is more common in the United States among African-American women compared to other ethnicities, but the practice of pica is not limited to any one geographic area, race, creed, or culture. In the United States, pica is also common in women from rural areas and women with a family history of it (Mikkelsen, Andersen, & Olsen, 2007)

The three main substances consumed by women with pica are soil or clay (geophagia), ice (pagophagia), and laundry starch (amylophagia). Nutritional implications include:

- Soil: replaces nutritive sources and causes iron-deficiency anemia
- Clay: produces constipation; can contain toxic substances and cause parasitic infection
- Ice: can cause iron-deficiency anemia, tooth fractures, freezer burn injuries
- Laundry starch: replaces iron-rich foods, leads to iron deficiencies, and replaces protein metabolism, thus depriving the fetus of amino acids needed for proper development (Blackburn, 2007)

Clinical manifestations of anemia often precede the identification of pica because it is rarely addressed by the health care provider and the woman does not usually volunteer such information (Cunningham et al., 2005). Secrecy surrounding this habit makes research and diagnosis difficult because some women fail to view their behavior as anything unusual, harmful, or worth reporting. Because of the clinical implications, pica should be discussed with all pregnant women as a preventive measure. The topic can be part of a general discussion of cravings, and the nurse should stress the harmful effects outlined above.

Suspect pica when the woman exhibits anemia although her dietary intake is appropriate. Ask about her usual dietary intake, and include questions about the ingestion of nonfood substances. Consider the potential negative outcomes for the pregnant woman and her fetus, and take appropriate action.

Psychosocial Adaptations During Pregnancy

WATCH & LEARN

Pregnancy is a unique time in a woman's life. It is a time of dramatic alterations in her body and her appearance, as well as a time of change in her social status. All these changes occur simultaneously. Concurrent with the physiologic changes within her body systems are psychosocial changes within the mother and family members as they face significant role and lifestyle changes.

Maternal Emotional Responses

Motherhood, perhaps more than any role in society, has acquired a special significance for women. Women are taught they should find fulfillment and satisfaction in the role of the "ever-bountiful, ever-giving, self-sacrificing mother" (Thies & Travers, 2006). With such high expectations, many pregnant women experience various emotions throughout their pregnancy. The woman's approach to these emotions is influenced by her emotional makeup, her sociologic and cultural background, her acceptance or rejection of the pregnancy, whether the pregnancy was planned, if the father is known, and her support network (Alexander et al., 2007).

Despite the wide-ranging emotions associated with the pregnancy, many women experience similar responses. These responses commonly include ambivalence, introversion, acceptance, mood swings, and changes in body image.

Ambivalence

The realization of a pregnancy can lead to fluctuating responses, possibly at the opposite ends of the spectrum. For example, regardless of whether the pregnancy was planned, the woman may feel proud and excited at her achievement while at the same time fearful and anxious of the implications. The reactions are influenced by several factors, including the way the woman was raised, her current family situation, the quality of the relationship with the expectant father, and her hopes for the future. Some women express concern over the timing of the pregnancy, wishing that goals and life objectives had been met before becoming pregnant. Other women may question how a newborn or infant will affect their career or their relationships with friends and family. These feelings can cause conflict and confusion about the pregnancy.

Ambivalence, or having conflicting feelings at the same time, is a universal feeling and is considered normal when preparing for a lifestyle change and new role. Pregnant women commonly experience ambivalence during the first trimester. Usually ambivalence evolves into acceptance by the second trimester, when fetal movement is felt. The woman's personality, her ability to adapt to changing circumstances, and the reactions of her partner will affect her adjustment to being pregnant and her acceptance of impending motherhood.

Introversion

Introversion, or focusing on oneself, is common during the early part of pregnancy. The woman may withdraw and become increasingly preoccupied with herself and her fetus. As a result, her participation with the outside world may be less, and she will appear passive to her family and friends.

This introspective behavior is a normal psychological adaptation to motherhood for most women. Intro-

version seems to heighten during the first and third trimesters, when the woman's focus is on behaviors that will ensure a safe and health pregnancy outcome. Couples need to be aware of this behavior and should be informed about measures to maintain and support the focus on the family.

Acceptance

During the second trimester, the physical changes of the growing fetus with an enlarging abdomen and fetal movement bring reality and validity to the pregnancy. There are many tangible signs that someone separate from herself is present. The pregnant woman feels fetal movement and may hear the heartbeat. She may see the fetal image on an ultrasound screen and feel distinct parts, recognizing independent sleep and wake patterns. She becomes able to identify the fetus as a separate individual and accepts this.

Many women will verbalize positive feelings about the pregnancy and will conceptualize the fetus. The woman may accept her new body image and talk about the new life within. Generating a discussion about the woman's feelings and offering support and validation at prenatal visits are important.

Mood Swings

Emotional lability is characteristic throughout most pregnancies. One moment a woman can feel great joy, and within a short time she can feel shock and disbelief. Frequently, pregnant women will start to cry without any apparent cause. Some women feel as though they are riding an "emotional roller-coaster." These extremes in emotion can make it difficult for partners and family members to communicate with the pregnant woman without placing blame on themselves for their mood changes. Clear explanations about how common mood swings are during pregnancy are essential.

Change in Body Image

The way in which pregnancy affects a woman's body image varies greatly from person to person. Some women feel as if they have never been more beautiful, whereas others spend their pregnancy feeling overweight and uncomfortable. For some women pregnancy is a relief from worrying about weight, whereas for others it only exacerbates their fears of weight gain. Changes in body image are normal but can be very stressful for the pregnant woman. Offering a thorough explanation and initiating discussion of the expected bodily changes may help the family to cope with them.

Maternal Role Tasks

Reva Rubin (1984) identified maternal tasks that a woman must accomplish to incorporate the maternal role into her personality. Accomplishing these tasks helps the expectant mother to develop her self-concept as a mother and to form a mutually gratifying relationship with her infant. These tasks are listed in Box 11.4.

BOX 11.4 Maternal Role Tasks

- **Ensuring safe passage throughout pregnancy and birth**
  - Primary focus of the woman's attention
  - First trimester: woman focuses on herself, not on the fetus
  - Second trimester: woman develops attachment of great value to her fetus
  - Third trimester: woman has concern for herself and her fetus as a unit
  - Participation in positive self-care activities related to diet, exercise, and overall well-being
- **Seeking acceptance of infant by others**
  - First trimester: acceptance of pregnancy by herself and others
  - Second trimester: family needs to relate to the fetus as member
  - Third trimester: unconditional acceptance without rejection
- **Seeking acceptance of self in maternal role to infant ("binding in")**
  - First trimester: mother accepts idea of pregnancy, but not of infant
  - Second trimester: with sensation of fetal movement (quickening), mother acknowledges fetus as a separate entity within her
  - Third trimester: mother longs to hold infant and becomes tired of being pregnant
- **Learning to give of oneself**
  - First trimester: identifies what must be given up to assume new role
  - Second trimester: identifies with infant, learns how to delay own desires
  - Third trimester: questions her ability to become a good mother to infant (Rubin, 1984)

Pregnancy and Sexuality

The way a pregnant woman feels and experiences her body during pregnancy can affect her sexuality. The woman's changing shape, emotional status, fetal activity, changes in breast size, pressure on the bladder, and other discomforts of pregnancy result in increased physical and emotional demands. These can produce stress on the sexual relationship between the pregnant woman and her partner. As the changes of pregnancy ensue, many partners become confused, anxious, and fearful of how the relationship may be affected.

Sexual desire of pregnant women may change throughout the pregnancy. During the first trimester, the woman may be less interested in sex because of

fatigue, nausea, and fear of disturbing the early embryonic development. During the second trimester, her interest may increase because of the stability of the pregnancy. During the third trimester, her enlarging size may produce discomfort during sexual activity (Frieden & Chan, 2007).

A woman's sexual health is intimately linked to her own self-image. Sexual positions to increase comfort as the pregnancy progresses as well as alternative noncoital modes of sexual expression, such as cuddling, caressing, and holding, should be discussed. Giving permission to talk about and then normalizing sexuality can help enhance the sexual experience during pregnancy and, ultimately, the couple's relationship. If avenues of communication are open regarding sexuality during pregnancy, any fears and myths the couple may have can be dispelled.

Pregnancy and the Partner

Nursing care related to childbirth has expanded from a narrow emphasis on the physical health needs of the mother and infant to a broader focus on family-related, social and emotional needs. One prominent feature of this family-centered approach is the recent movement toward promoting the mother–infant bond. To achieve a truly family-centered practice, nursing must make a comparable commitment to understanding and meeting the needs of the partner in the emerging family. Recent studies suggest that the partner's potential contribution to the infant's overall development has been misperceived or devalued and that the partner's ability and willingness to assume a more active role in the infant's care may have been underestimated.

Reactions to pregnancy and to the psychological and physical changes by the woman's partner vary greatly. Some enjoy the role of being the nurturer, whereas others experience alienation and may seek comfort or companionship elsewhere. Some expectant fathers may view pregnancy as proof of their masculinity and assume the dominant role, whereas others see their role as minimal, leaving the pregnancy up to the woman entirely. Each expectant partner reacts uniquely.

Emotionally and psychologically, expectant partners may undergo less visible changes than women, but most of these changes remain unexpressed and unappreciated (Thies & Travers, 2006). Expectant partners also experience a multitude of adjustments and concerns. Physically, they may gain weight around the middle and experience nausea and other GI disturbances—what is termed couvade syndrome, a sympathetic response to their partner's pregnancy. They also experience ambivalence during early pregnancy, with extremes of emotions (e.g., pride and joy versus an overwhelming sense of impending responsibility).

During the second trimester of pregnancy, partners go through acceptance of their role of breadwinner, caretaker, and support person. They come to accept the reality of the fetus when movement is felt, and they experience confusion when dealing with the woman's mood swings and introspection. During the third trimester, the expectant partner prepares for the reality of this new role and negotiates what the role will be during the labor and birthing process. Many express concern about being the primary support person during labor and birth and worry how they will react when faced with their loved one in pain. Expectant partners share many of the same anxieties as their pregnant partners. However, it is uncommon for them to reveal these anxieties to the pregnant partner or health care professionals. Often, how the expectant partner responds during the third trimester depends on the state of the marriage or partnership. When the marriage or partnership is struggling, the impending increase in responsibility toward the end of pregnancy acts to drive the expectant partner further away. Often it manifests as working late, staying out late with friends, or beginning new or superficial relationships. In the stable marriage or partnership, the expectant partner who may have been struggling to find his or her place in the pregnancy now finds concrete tasks to do—for example, painting the nursery, assembling the car seat, attending Lamaze classes, and so on.

Pregnancy and Siblings

A sibling's reaction to pregnancy is age-dependent. Some children might express excitement and anticipation, whereas others might have negative reactions. A young toddler might regress in toilet training or ask to drink from a bottle again. An older school-aged child may ignore the new addition to the family and engage in outside activities to avoid the new member. The introduction of an infant into the family is often the beginning of sibling rivalry, which results from the child's fear of change in the security of the relationship with his or her parents (Thies & Travers, 2006). Preparation of the siblings for the anticipated birth is imperative and must be designed according to the age and life experiences of the sibling at home. Constant reinforcement of love and caring will help to reduce the older child's fear of change and worry about being replaced by the new family member.

If possible, parents should include siblings in preparation for the birth of the new baby to help them feel as if they have an important role to play (Fig. 11.6). Parents must also continue to focus on the older sibling after the birth to reduce regressive or aggressive behavior toward the newborn.

Key Concepts

- Pregnancy is a normal life event that involves considerable physical, psychosocial, emotional, and relationship adjustments.
- The signs and symptoms of pregnancy have been grouped into those that are subjective (presumptive)

FIGURE 11.6 Parents preparing sibling for the birth of a new baby.

and experienced by the woman herself, those that are objective (probable) and observed by the health care professional, and those that are the positive, beyond-the-shadow-of-a-doubt signs.

- Physiologically, almost every system of a woman's body changes during pregnancy with startling rapidity to accommodate the needs of the growing fetus. A majority of the changes are influenced by hormonal changes.
- The placenta is a unique kind of endocrine gland; it has a feature possessed by no other endocrine organ—the ability to form protein and steroid hormones.
- Occurring in conjunction with the physiologic changes in the woman's body systems are psychosocial changes occurring within the mother and family members as they face significant role and lifestyle changes.
- Commonly experienced emotional responses to pregnancy in the woman include ambivalence, introversion, acceptance, mood swings, and changes in body image.
- Reactions of expectant partners to pregnancy and to the physical and psychological changes in the woman vary greatly.
- A sibling's reaction to pregnancy is age dependent. The introduction of a new infant to the family is often the beginning of sibling rivalry, which results from the established child's fear of change in security of their relationships with their parents. Therefore, preparation of the siblings for the anticipated birth is imperative.

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. What factors would change during a pregnancy if the hormone progesterone were reduced or withdrawn?
   a. The woman's gums would become red and swollen and would bleed easily.
   b. The uterus would contract more and peristalsis would increase.
   c. Morning sickness would increase and would be prolonged.
   d. It would inhibit the secretion of prolactin by the pituitary gland.
2. Which of the following is a presumptive sign or symptom of pregnancy?
   a. Restlessness
   b. Elevated mood
   c. Urinary frequency
   d. Low backache
3. When obtaining a blood test for pregnancy, which hormone would the nurse expect the test to measure?
   a. hCG
   b. hPL
   c. FSH
   d. LH
4. During pregnancy, which of the following should the expectant mother reduce or avoid?
   a. Raw meat or uncooked shellfish
   b. Fresh, washed fruits and vegetables
   c. Whole grains
   d. Protein and iron from meat sources
5. A feeling expressed by most women upon learning they are pregnant is:
   a. Acceptance
   b. Depression
   c. Jealousy
   d. Ambivalence
6. Reva Rubin identified four major tasks that the pregnant woman undertakes to form a mutually gratifying relationship with her infant. What is "binding in"?
   a. Ensuring safe passage through pregnancy, labor, and birth
   b. Seeking acceptance of this infant by others
   c. Seeking acceptance of self as mother to the infant
   d. Learning to give of oneself on behalf of the infant

CRITICAL THINKING EXERCISES

1. When interviewing a woman at her first prenatal visit, the nurse asks about her feelings. The woman replies, "I'm frightened and confused. I don't know whether I want to be pregnant or not. Being pregnant means changing our whole life, and now having somebody to care for all the time. I'm not sure I would be a good mother. Plus I'm a bit afraid of all the changes that would happen to my body. Is this normal? Am I okay?"
   a. How should the nurse answer this question?
   b. What specific information is needed to support the client during this pregnancy?
2. Sally, age 23, is 9 weeks pregnant. At her clinic visit she says, "I'm so tired I can barely make it home from work. Then once I'm home, I don't have the energy to make dinner." She says she is so sick in the morning that she is frequently late to work and spends much of the day in the bathroom. Sally's current lab work is within normal limits.
   a. What explanation can the nurse offer Sally about her discomforts?
   b. What interventions can the nurse offer to Sally?
3. Bringing a new infant into the family affects the siblings. What strategies can a nurse discuss when a mother asks how to deal with this?

STUDY ACTIVITIES

1. Go to your local health department's maternity clinic and interview several women regarding their feelings and the bodily changes that have taken place since they became pregnant. Based on your findings, place them into appropriate trimesters of their pregnancy.
2. Search the Internet for information about the psychological changes that occur during pregnancy. Share your websites with your clinical group.
3. During pregnancy, the plasma volume increases by 50% but the RBC volume increases by only 25% to 33%. This disproportion is manifested as _____.
4. When a pregnant woman in her third trimester lies on her back and experiences dizziness and lightheadedness, the underlying cause of this is _____.

CHAPTER 12

Nursing Management During Pregnancy

KEY TERMS

alpha-fetoprotein
amniocentesis
biophysical profile
chorionic villus sampling (CVS)
gravida
high-risk pregnancy
linea nigra
natural childbirth
para
perinatal education
preconception care

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms used in this chapter.
2. Identify the information typically collected at the initial prenatal visit.
3. Explain the assessments completed at follow-up prenatal visits.
4. Describe the tests used to assess maternal and fetal well-being, including nursing management for each.
5. Outline appropriate nursing management to promote maternal self-care and to minimize the common discomforts of pregnancy.
6. List the key components of perinatal education.

Linda and her husband, Rob, are eager to start a family within the next year. They are stable in their careers and financially secure. They decide to check out a new nurse-midwife practice associated with the local hospital, and they go for a preconception appointment. They leave their appointment overwhelmed with all the information they were given about having a healthy pregnancy.

Wow

The secret of human touch is simple: showing a sincere liking and interest in people. Nurses need to use touch often.

Pregnancy is a time of many physiologic and psychological changes that can positively or negatively affect the woman, her fetus, and her family. Misconceptions, inadequate information, and unanswered questions about pregnancy, birth, and parenthood are common. The ultimate goal of any pregnancy is the birth of a healthy newborn, and nurses play a major role in helping the pregnant woman and her partner achieve this goal. Ongoing assessment and education are essential.

This chapter describes the nursing management required during pregnancy. It begins with a brief discussion of preconception care and then describes the assessment of the woman at the first prenatal visit and on follow-up visits. The chapter discusses tests commonly used to assess maternal and fetal well-being, including specific nursing management related to each test. The chapter also identifies important strategies to minimize the common discomforts of pregnancy and promote self-care. Lastly, the chapter discusses perinatal education, including childbirth education, birthing options, care provider options, preparation for breastfeeding or bottle feeding, and final preparation for labor and birth.

Preconception Care

Ideally, couples thinking about having a child should schedule a visit with their health care provider for preconception counseling to ensure that they are in the best possible state of health before pregnancy. **Preconception care** is the promotion of the health and well-being of a woman and her partner before pregnancy. The goal of preconception care is to identify any areas such as health problems, lifestyle habits, or social concerns that might unfavorably affect pregnancy (Dunlop, Jack, & Frey, 2007).

Risk Factors for Adverse Pregnancy Outcomes

Preconception care is just as important as prenatal care to reduce adverse pregnancy outcomes such as maternal and infant mortality, preterm births, and low-birthweight infants. Adverse pregnancy outcomes constitute a major public health challenge: 12% of infants are born premature; 8% are born with low birthweight; 3% have major birth defects; and 32% of women suffer pregnancy complications (Centers for Disease Control & Prevention [CDC], 2007b).

Risk factors for these adverse pregnancy outcomes are prevalent among women of reproductive age, as demonstrated by the following statistics:

- 12% of women smoke during pregnancy, contributing to fetal addiction to nicotine.
- 13% consume alcohol during pregnancy, leading to fetal alcohol spectrum disorder.
- 70% of women do not take folic acid supplements, increasing the risk of neural tube defects in the newborn. Taking folic acid reduces the incidence of neural tube defects by two thirds.
- 32% of women starting a pregnancy are obese, which may increase their risk of developing hypertension, diabetes, and thromboembolic disease and may increase the need for cesarean birth.
- 3% take prescription or over-the-counter drugs that are known teratogens (substances harmful to the developing fetus).
- 5% of women have preexisting medical conditions that can negatively affect pregnancy if unmanaged (CDC, 2007b).

All of the factors above pose risks to pregnancy and could be addressed with early interventions if the woman sought preconception health care. Specific recognized risk factors for adverse pregnancy outcomes that fall into one or more of the above categories are listed in Box 12.1.

The period of greatest environmental sensitivity and consequent risk for the developing embryo is between days 17 and 56 after conception. The first prenatal visit, which is usually a month or later after a missed menstrual period, may occur too late to affect reproductive outcomes associated with abnormal organogenesis secondary to poor lifestyle choices. In some cases, such as with unplanned pregnancies, women may delay seeking health care, denying that they are pregnant. Thus, commonly used prevention practices may begin too late to avert the morbidity and mortality associated with congenital anomalies and low birthweight (Atrash et al., 2006). Therefore, it is best that the woman and her partner seek preconception care.

What is the purpose of couples like Linda and Rob going for preconception counseling? What are the goals of preconception care for this couple?

BOX 12.1 Risk Factors for Adverse Pregnancy Outcomes

- Taking retinoic acid (Accutane) to clear cystic acne
- Alcohol use
- Anti-epileptic drugs
- Autoimmune disorders
- Diabetes (preconception)
- Folic acid deficiency
- HIV/AIDS
- Maternal phenylketonuria (PKU)
- Rubella seronegativity
- Obesity
- STI
- Smoking (CDC, 2006)
- Underweight

Sources: CDC (2008); NIH (2008); March of Dimes (2008).

Nursing Management

Preconception care involves obtaining a complete health history and physical examination of the woman and her partner. Key areas include:

- Immunization status of the woman
- Underlying medical conditions, such as cardiovascular and respiratory problems or genetic disorders
- Reproductive health data, such as pelvic examinations, use of contraceptives, and sexually transmitted infections (STIs)
- Sexuality and sexual practices, such as safer-sex practices and body image issues
- Nutrition history and present status
- Lifestyle practices, including occupation and recreational activities
- Psychosocial issues such as levels of stress, exposure to abuse and violence
- Medication and drug use, including use of tobacco, alcohol, over-the-counter and prescription medications, and illicit drugs
- Support system, including family, friends, and community (Fig. 12.1 gives a sample preconception screening tool)

This information provides a foundation for planning health-promotion activities and education. For example, to have a positive impact on the pregnancy:

- Ensure that the woman's immunizations are up to date.
- Take a thorough history of both partners to identify any medical or genetic conditions that need treatment or a referral to specialists.
- Identify history of STIs and high-risk sexual practices so they can be modified.
- Complete a dietary history combined with nutritional counseling.
- Gather information regarding exercise and lifestyle practices to encourage daily exercise for well-being and weight maintenance.
- Stress the importance of taking folic acid to prevent neural tube defects.
- Urge the woman to achieve optimal weight before a pregnancy.
- Identify work environment and any needed changes to promote health.
- Address substance use issues, including smoking and drugs.
- Identify victims of violence and assist them to get help.
- Manage chronic conditions such as diabetes and asthma.
- Educate the couple about environmental hazards, including metals and herbs.
- Offer genetic counseling to identify carriers.
- Suggest the availability of support systems, if needed (Graham, 2006).

Nurses can act as advocates and educators, creating healthy, supportive communities for women and their partners in the childbearing phases of their lives. It is important to enter into a collaborative partnership with the woman and her partner, enabling them to examine their own health and its influence on the health of their future baby. Provide information to allow the woman and her partner to make an informed decision about having a baby, but keep in mind that this decision rests solely with the couple.

▶ *Take* NOTE!

"Preconception care should be integrated into the women's health care continuum to achieve high levels of lifetime wellness for all women" (Dunlop, Jack, & Frey, 2007).

Linda and Rob decide to change several aspects of their lifestyle and nutritional habits before conceiving a baby, based on advice from the nurse-midwife. They both want to lose weight, stop smoking, and increase their intake of fruits and vegetables. How will these lifestyle and dietary changes benefit Linda's future pregnancy? What other areas might need to be brought up to date to prepare for a future pregnancy?

The First Prenatal Visit

Once a pregnancy is suspected and, in some cases, tentatively confirmed by a home pregnancy test, the woman should seek prenatal care to promote a healthy outcome. Although the most opportune window (preconception) for improving pregnancy outcomes may be missed, appropriate nursing management starting at conception and continuing throughout the pregnancy can have a positive impact on the health of pregnant women and their unborn children.

The assessment process begins at this initial prenatal visit and continues throughout the pregnancy. The initial visit is an ideal time to screen for factors that might place the woman and her fetus at risk for problems such as preterm delivery. The initial visit also is an optimal time to begin educating the client about changes that will affect her life.

Counseling and education of the pregnant woman and her partner are critical to ensure healthy outcomes for mother and her infant. Pregnant women and their partners frequently have questions, misinformation, or misconceptions about what to eat, weight gain, physical discomforts, drug and alcohol use, sexuality, and the birthing process. The nurse needs to allow time to answer questions and provide anticipatory guidance during the pregnancy and to make appropriate community referrals to meet the needs of these clients. To address these issues and foster the

ARE YOU PLANNING TO GET PREGNANT IN THE NEXT SIX MONTHS? ___ Y ___N

IF YOUR ANSWER TO A QUESTION IS YES, PUT A CHECK MARK ON THE LINE IN FRONT OF THE QUESTION. FILL IN OTHER INFORMATION THAT APPLIES TO YOU.

DIET AND EXERCISE

What do you consider a healthy weight for you?_____
___Do you eat three meals a day?
___Do you follow a special diet (vegetarian, diabetic, other)?
___Which do you drink (__ coffee __ tea __ cola __ milk __ water __ soda/pop other_____)?
___Do you eat raw or undercooked food (meat, other)?
___Do you take folic acid?
___Do you take other vitamins daily (__ multivitamin __ vitamin A __ other)?
___Do you take dietary supplements (__ black cohosh __ pennyroyal __ other)?
___Do you have current/past problems withh eating disorders?
___Do you exercise? Type/frequency:_____

Notes:

MEDICATION /DRUGS

___Are you taking prescribed drugs (Accutane, valproic acid, blood thinners)? List them_____
___Are you taking non-prescribed drugs?
List them:_____
___Are you using birth control pills?
___Do you get injectable contraceptives or shots for birth control?
___Do you use any herbal remedies or alternative medicine?
List:_____

NOTES:

WOMEN'S HEALTH

___Do you have any problems with your menstrual cycle?
___How many times have you been pregnant?
What was/ were the outcomes(s)?_____
___Did you have difficulty getting pregnant last time?
___Have you been treated for infertility?
Have you had surgery on your uterus, cervix, ovaries, or tubes?
___Did you mother take the hormone DES during pregnancy?
Have you ever had HPV, genital warts or chlamydia?
___Have you ever been treated for a sexually transmitted infection (genital herpes, gonorrhea, syphilis, HIV/AIDS, other)? List:_____

NOTES:

HOME ENVIRONMENT

___Do you feel emotionally supported at home?
___Do you have help from relatives or friends if needed?
___Do you feel you have serious money/financial worries?
___Are you in a stable relationship?
___Do you feel safe at home?
___Does anyone threaten or physically hurt you?
___Do you have pets (cats, rodents, exotic animals)? List:_____
___Do have any contact with soil, cat litter, or sandboxes?

Baby preparation (if planning pregnancy):
___Do you have a place for a baby to sleep?
___Do you need any baby items?

NOTES:

LIFESTYLE

___Do you smoke cigarettes or use other tobacco products?
How many cigarettes/packs a day?_____
___Are you exposed to second-hand smoke?
___Do you drink alcohol?
What kind?_____How often?_____How much?_____
___Do you use recreational drugs (cocaine, heroin, ecstasy, meth/ice, other?
List:_____
___Do you see a dentist regularly?
What kind of work do you do?_____
___Do you work or live near possible hazards (chemicals, x-ray or other radiation, lead)? List:_____
___Do you use saunas or hot tubs?

Notes:

MEDICAL/FAMILY HISTORY

Do you have or have you ever had:
___Epilepsy?
___Diabetes?
___Asthma?
___High blood pressure?
___Heart disease?
___Anemia?
___Kidney or bladder disorders?
___Thyroid disease?
___Chickenpox?
___Hepatitis C?
___Digestive problems?
___Depression or other mental health problem?
___Surgeries?
___Lupus?
___Scleroderma?
___Other conditions?
Have you ever been vaccinated for:
___Measles, mumps, rubella?
___Hepatitis B?

overall well-being of pregnant women and their fetuses, specific National Health Goals have been established (see the Healthy People 2010 box).

Comprehensive Health History

During the initial visit, a comprehensive health history is obtained, including age, menstrual history, prior obstetric history, past medical and surgical history, family history, genetic screening, medication or drug use, and history of exposure to infections (STIs) (Frieden & Chan, 2007). Often, using a prenatal history form (Fig. 12.2) is the best way to document the data collected.

The initial health history typically includes questions about three major areas: the reason for seeking care; the client's past medical, surgical, and personal history, including that of the family and her partner; and the client's reproductive history. During the history-taking process, the nurse and client establish the foundation of a trusting relationship and jointly develop a plan of care for the pregnancy. Tailor this plan to the client's lifestyle as much as possible and focus primarily on education for overall wellness during the pregnancy. The ultimate goal is early detection and prevention of any problems that occur during the pregnancy (Frieden & Chan, 2007).

HEALTHY PEOPLE 2010

Objective	Nursing Implications
Increase the proportion of pregnant women who receive early and adequate prenatal care: • Increase the number of women receiving maternal prenatal care beginning in the first trimester of pregnancy from a baseline of 83% to 90% of live births. • Increase the number of women receiving early and adequate prenatal care from a baseline of 74% to 90% of live births.	Will contribute to reduced rates of perinatal illness, disability, and death by helping to identify possible risk factors and implementing measures to lessen these factors that contribute to poor outcomes
Increase the proportion of pregnant women who attend a series of prepared childbirth classes.	Will contribute to a more pleasant birthing experience because women will be prepared for what they will face; also help in reducing pain and anxiety
Increase abstinence from alcohol, cigarettes, and illicit drugs among pregnant women.	Will help to reduce the wide-ranging effects, such as spontaneous abortion, low birthweight, and preterm birth, associated with prenatal substance use

Source: U.S. Department of Health & Human Services, 2000.

Reason for Seeking Care

The woman commonly comes for prenatal care based on the suspicion that she is pregnant. She may report that she has missed her menstrual period or has had a positive result on a home pregnancy test. Ask the woman for the date of her last menstrual period (LMP). Also ask about any presumptive or probable signs of pregnancy that she might be experiencing. Typically a urine or blood test to check for evidence of human chorionic gonadotropin (hCG) is done to confirm the pregnancy.

Past History

Ask about the woman's past medical and surgical history. This information is important because conditions that the woman experienced in the past (e.g., urinary tract infections) may recur or be exacerbated during pregnancy. Also, chronic illnesses, such as diabetes or heart disease, can increase the risk for complications during pregnancy for the woman and her fetus. Ask about any history of allergies to medications, foods, or environmental substances. Ask about any mental health problems, such as depression or anxiety. Gather similar information about the woman's family and her partner.

The woman's personal history also is important. Ask about her occupation, possible exposure to teratogens, exercise and activity level, recreational patterns (including the use of substances such as alcohol, tobacco, and drugs), use of alternative and complementary therapies, sleep patterns, nutritional habits, and general lifestyle. Each of these may have an impact on the outcome of the pregnancy. For example, if the woman smokes during pregnancy, nicotine in the cigarettes causes vasoconstriction in the mother, leading to reduced placental perfusion. As a result, the newborn may be small for gestational age. The newborn will also go through nicotine withdrawal soon after birth. In addition, no safe level of alcohol ingestion in pregnancy has been determined. Many fetuses exposed to heavy alcohol levels during pregnancy develop fetal alcohol syndrome, a collection of deformities and disabilities.

Reproductive History

The woman's reproductive history includes a menstrual, obstetric, and gynecologic history. Typically, this history begins with a description of the woman's menstrual cycle, including her age at menarche, number of days in her cycle, typical flow characteristics, and any discomfort experienced. The use of contraception also is important, including when the woman last used any contraception.

Ask the woman the date of her LMP to determine the estimated or expected date of birth (EDB) or delivery (EDD). Several methods may be used to estimate the date of birth. Nagele's rule can be used to establish the EDD or EDB. Using this rule, subtract 3 months and then add 7 days to the first day of the LMP. Then correct the year by adding 1 to it. This date has a margin of error of plus or minus 2 weeks. For instance, if a woman reports that her LMP was Oct. 14, 2007, you would subtract 3 months

FIGURE 12.2 (continued)

(July) and add 7 days (21), then add 1 year (2008). The woman's EDD or EDB is July 21, 2008.

Because of the normal variations in women's menstrual cycles, differences in the normal length of gestation between ethnic groups, and errors in dating methods, there is no such thing as an exact due date. In general, a birth 2 weeks before or 2 weeks after the EDD or EDB is considered normal. Nagele's rule is less accurate if the woman's menstrual cycles are irregular, if the woman conceives while breastfeeding or before her regular menstrual cycle is established, if she is ovulating although she is amenorrheic, or after she discontinues oral contraceptives (Hackley, Kriebs, & Rousseau, 2007).

A gestational or birth calculator or wheel can also be used to calculate the due date (Fig. 12.3). Some practitioners use ultrasound to more accurately determine the gestational age and date the pregnancy.

Typically, an obstetric history provides information about the woman's past pregnancies, including any problems encountered during the pregnancy, labor, delivery, and afterward. Such information can provide clues to problems that might develop in the current pregnancy. Some common terms used to describe and document an obstetric history include:

- Gravid: the state of being pregnant
- **Gravida**: a pregnant woman; gravida I (primigravida) during the first pregnancy, gravida II (secundigravida) during the second pregnancy, and so on
- **Para**: The number of pregnancies that a woman has, regardless of whether the newborn is born alive or dead. Thus, a primipara is a woman who has given birth once after a pregnancy of at least 20 weeks, commonly referred to as a "primip" in clinical practice. A multipara is a woman who has had two or more pregnancies resulting in viable offspring, commonly referred to as a "multip." Nullipara (para 0) is a woman who has not produced a viable offspring.

Other systems may be used to document a woman's obstetric history. These systems often break down the category of para more specifically (Box 12.2).

Information about the woman's gynecologic history is important. Ask about any reproductive tract surgeries the woman has undergone. For example, surgery on the uterus may affect its ability to contract effectively during labor. A history of tubal pregnancy increases the woman's risk for another tubal pregnancy. Also ask about safe-sex practices and any history of STIs.

Physical Examination

The next step in the assessment process is the physical examination, which detects any physical problems that may affect the pregnancy outcome. The initial physical examination provides the baseline for evaluating changes during future visits.

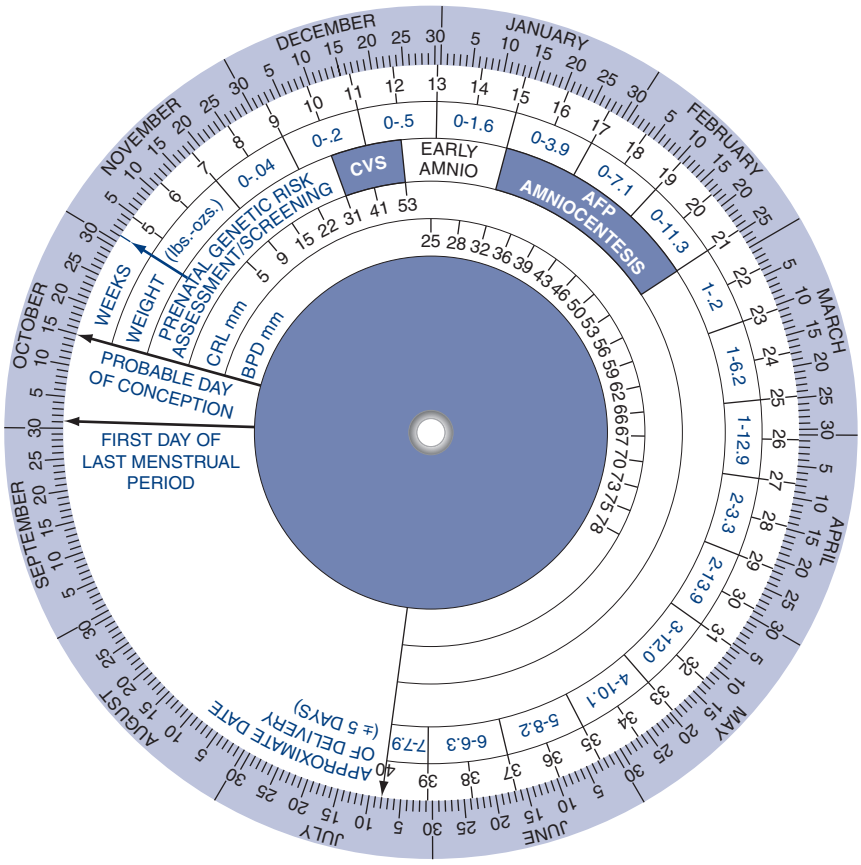

FIGURE 12.3 EDB using a birth wheel. The first day of the woman's last normal menstrual period was October 1. Using the birth wheel, her EDB would be approximately July 8 of the following year. (Used with permission. Copyright March of Dimes, 2007.)

BOX 12.2 Obstetric History Terms

GTPAL or TPAL
G = gravida, T = term births, P = preterm births,
A = abortions, L = living children
G—the current pregnancy
T—the number of pregnancies ending >37 weeks' gestation, at term
P—the number of preterm pregnancies ending >20 weeks or viability but before completion of 37 weeks
A—the number of pregnancies ending before 20 weeks or viability
L—the number of children currently living
Consider this example:
Mary Johnson is pregnant for the fourth time. She had one abortion at 8 weeks' gestation. She has a daughter who was born at 40 weeks' gestation and a son born at 34 weeks. Mary's obstetric history would be documented as follows:
Using the gravida/para method: gravida 4, para 2
Using the TPAL method: 1112 (T = 1 [daughter born at 40 weeks]; P = 1 [son born at 34 weeks], A = 1 [abortion at 8 weeks]; L = 2 [two living children])

Preparation

Instruct the client to undress and put on a gown. Also ask her to empty her bladder and, in doing so, to collect a urine specimen. Typically this specimen is a clean-catch urine specimen that is sent to the laboratory for a urinalysis to detect a possible urinary tract infection.

Begin the physical examination by obtaining vital signs, including blood pressure, respiratory rate, temperature, and pulse. Also measure the client's height and weight. Abnormalities such as an elevated blood pressure may suggest pregestational hypertension, requiring further evaluation. Abnormalities in pulse rate and respiration require further investigation for possible cardiac or respiratory disease. If the woman weighs less than 100 pounds or more than 200 pounds or there has been a sudden weight gain, report these findings to the primary care provider; medical treatment or nutritional counseling may be necessary.

Head-to-Toe Assessment

A complete head-to-toe assessment is usually performed by the health care professional. Every body system is assessed. Some of the major areas are discussed here. Throughout the assessment, be sure to drape the client appropriately to ensure privacy and prevent chilling.

Head and Neck

Assess the head and neck area for any previous injuries and sequelae. Evaluate for any limitations in range of motion. Palpate for any enlarged lymph nodes or swelling. Note any edema of the nasal mucosa or hypertrophy of gingival tissue in the mouth; these are typical responses to increased estrogen levels in pregnancy. Palpate the thyroid gland for enlargement. Slight enlargement is normal, but marked enlargement may indicate hyperthyroidism, requiring further investigation.

Chest

Auscultate heart sounds, noting any abnormalities. A soft systolic murmur caused by the increase in blood volume may be noted. Anticipate an increase in heart rate by 10 to 15 beats per minute (starting between 14 and 20 weeks of pregnancy) secondary to increases in cardiac output and blood volume. The body adapts to the increase in blood volume with peripheral dilatation to maintain blood pressure. Progesterone causes peripheral dilatation.

Auscultate the chest for breath sounds, which should be clear. Also note symmetry of chest movement and thoracic breathing patterns. Estrogen promotes relaxation of the ligaments and joints of the ribs, with a resulting increase in the anteroposterior chest diameter. Expect a slight increase in respiratory rate to accommodate the increase in tidal volume and oxygen consumption.

Inspect and palpate the breasts. Increases in estrogen and progesterone and blood supply make the breasts feel full and more nodular, with increased sensitivity to touch. Blood vessels become more visible and there is an increase in breast size. Striae gravidarum (stretch marks) may be visible in women with large breasts. Darker pigmentation of the nipple and areola is present, along with enlargement of Montgomery's glands.

▶ *Take* NOTE!

Use this opportunity to reinforce and teach breast self-examination.

Abdomen

The appearance of the abdomen depends on the number of weeks of gestation. The abdomen enlarges progressively as the fetus grows. Palpate the abdomen, which should be rounded and nontender. A decrease in muscle tone may be noted due to the influence of progesterone. Inspection also may reveal striae gravidarum (stretch marks) and linea nigra, depending on the duration of the pregnancy.

Typically, the height of the fundus is measured when the uterus arises out of the pelvis to evaluate fetal growth. At 12 weeks' gestation the fundus can be palpated at the symphysis pubis. At 16 weeks' gestation the fundus is midway between the symphysis and the umbilicus. At 20 weeks the fundus can be palpated at the umbilicus and measures approximately 20 cm from the symphysis pubis. By 36 weeks the fundus is just below the ensiform cartilage and measures approximately 36 cm. The uterus maintains a globular/ovoid shape throughout pregnancy (Frieden & Chan, 2007).

Extremities

Inspect and palpate both legs for dependent edema, pulses, and varicose veins. If edema is present in early pregnancy, further evaluation may be needed to rule out gestational hypertension. Ask the woman if she has any pain in her calf that increases when she ambulates. This might indicate a deep vein thrombosis (DVT). High levels of estrogen during pregnancy place women at higher risk for DVT.

Pelvic Examination

The pelvic examination provides information about the internal and external reproductive organs. In addition, it aids in assessing some of the presumptive and probable signs of pregnancy and allows for determination of pelvic adequacy. During the pelvic examination, remain in the examining room to assist the health care provider with any specimen collection, fixation, and labeling. Also provide comfort and emotional support for the woman, who might be anxious. Throughout the examination, explain what is happening and why, and answer any questions as necessary.

External Genitalia

After the client is placed in the lithotomy position and draped appropriately, the external genitalia are inspected visually. They should be free from lesions, discharge, hematomas, varicosities, and inflammation upon inspection. A culture for STIs may be collected at this time.

Internal Genitalia

Next, the internal genitalia are examined via a speculum. The cervix should be smooth, long, thick, and closed. Because of increased pelvic congestion, the cervix will be softened (Goodell's sign), the uterine isthmus will be softened (Hegar's sign), and there will be a bluish coloration of the cervix and vaginal mucosa (Chadwick's sign).

The uterus typically is pear-shaped and mobile, with a smooth surface. It will undergo cell hypertrophy and hyperplasia so that it enlarges throughout the pregnancy to accommodate the growing fetus.

During the pelvic examination, a Papanicolaou (Pap) smear may be obtained. Additional cultures, such as for gonorrhea and chlamydia screening and group B streptococcus screening, also may be obtained. Ensure that all specimens obtained are labeled correctly and sent to the laboratory for evaluation. A rectal examination is done last to assess for lesions, masses, prolapse, or hemorrhoids.

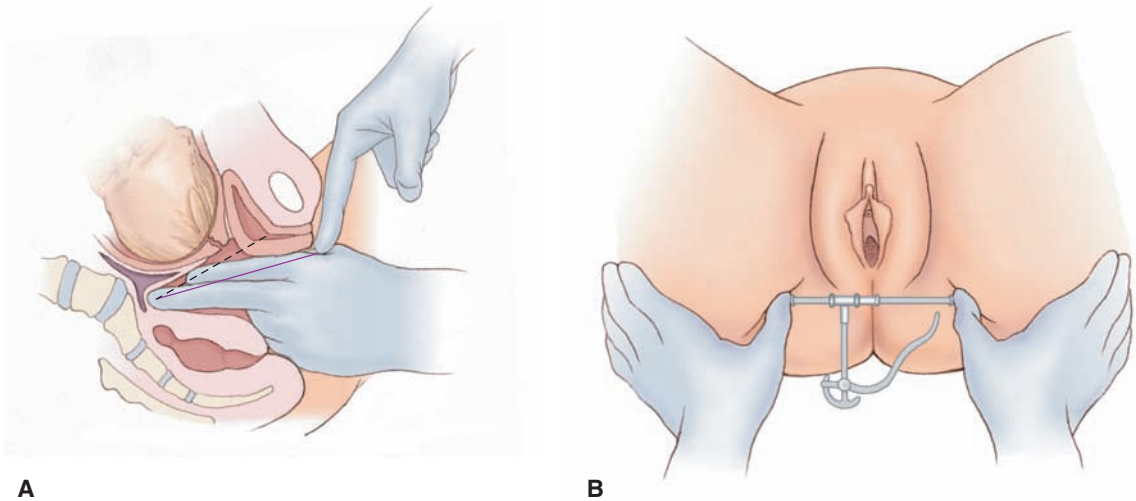
Once the examination of the internal genitalia is completed and the speculum is removed, a bimanual examination is performed to estimate the size of the uterus to confirm dates and to palpate the ovaries. The ovaries should be small and nontender, without masses. At the conclusion of the bimanual examination, the health care professional reinserts the index finger into the vagina and the middle finger into the rectum to assess the strength and regularity of the posterior vaginal wall.

Pelvic Size, Shape, and Measurements

The size and shape of the women's pelvis can affect her ability to deliver vaginally. Pelvic shape is typically classified as one of four types: gynecoid, android, anthropoid, and platypelloid. Refer to Chapter 13 for an in-depth discussion of pelvic size and shape.

Taking internal pelvic measurements determines the actual diameters of the inlet and outlet through which the fetus will pass. This is extremely important if the woman has never given birth vaginally. Taking pelvic measurements is unnecessary for the woman who has given birth vaginally before (unless she has experienced some type of trauma to the area) because vaginal delivery demonstrates that the pelvis is adequate for the passage of the fetus.

Three measurements are assessed: diagonal conjugate, true conjugate, and ischial tuberosity (Fig. 12.4). The diagonal conjugate is the distance between the anterior surface of the sacral prominence and the anterior surface



A B

FIGURE 12.4 Pelvic measurements. (**A**) Diagonal conjugate (solid line) and true conjugate (dotted line). (**B**) Ischial tuberosity diameter.

of the inferior margin of the symphysis pubis (Frieden & Chan, 2007). This measurement, usually 12.5 cm or greater, represents the anteroposterior diameter of the pelvic inlet. The diagonal conjugate is the most useful measurement for estimating pelvic size because a misfit with the fetal head occurs if it is too small.

The true conjugate, also called the obstetric conjugate, is the measurement from the anterior surface of the sacral prominence to the posterior surface of the inferior margin of the symphysis pubis. This diameter cannot be measured directly; rather, it is estimated by subtracting 1 to 2 cm from the diagonal conjugate measurement. The average true conjugate diameter is at least 11.5 cm (Cunningham et al., 2005). This measurement is important because it is the smallest front-to-back diameter through which the fetal head must pass when moving through the pelvic inlet.

The ischial tuberosity diameter is the transverse diameter of the pelvic outlet. This measurement is made outside the pelvis at the lowest aspect of the ischial tuberosities. A diameter of 10.5 cm or more is considered adequate for passage of the fetal head (Blackburn, 2007).

Laboratory Tests

A series of tests are generally ordered during the initial visit so that baseline data can be obtained, allowing for early detection and prompt intervention if any problems occur. Tests that are generally conducted for all pregnant women include urinalysis and blood studies. The urine is analyzed for albumin, glucose, ketones, and bacteria casts. Blood studies usually include a complete blood count (hemoglobin, hematocrit, red and white blood cell counts, and platelets), blood typing and Rh factor, a rubella titer, hepatitis B surface antibody antigen, HIV, VDRL, and RPR tests, and cervical smears to detect STIs (Common Laboratory and Diagnostic Tests 12.1). In addition, most offices and clinics have ultrasound equipment available to validate an intrauterine pregnancy and assess early fetal growth.

The need for additional laboratory studies is determined by a woman's history, physical examination findings, current health status, and risk factors identified in the initial interview. Additional tests can be offered, but ultimately the woman and her partner make the decision about undergoing them. Educate the client and her partner about the tests, including the rationale. In addition, support the client and her partner in their decision-making process, regardless of whether you agree with the couple's decision. The couple's decisions about their health care are based on the ethical principle of autonomy, which allows an individual the right to make decisions about his or her own body.

COMMON LABORATORY AND DIAGNOSTIC TESTS 12.1

Test	Explanation
Complete blood cell count (CBC)	Evaluates hemoglobin (12–14 g) and hematocrit (42% +/– 5) levels and red blood cell count (4.2–5.4 million/mm^3) to detect presence of anemia; identifies WBC (5,000–10,000/mm^3), which if elevated may indicate an infection; determines platelet count (150,000–450,000 cubic mL) to assess clotting ability
Blood typing	Determines woman's blood type and Rh status to rule out any blood incompatibility issues early; Rh-negative mother would likely receive RhoGAM (at 28 weeks) if she is Rh sensitive via indirect Coombs test
Rubella titer	Detects antibodies for the virus that causes German measles; if titer is 1:8 or less, the woman is not immune, requires immunization after birth, and is advised to avoid people with undiagnosed rashes
Hepatitis B	Determines if mother has hepatitis B by detecting presence of hepatitis antibody surface antigen (HbsAg) in her blood
HIV testing	Detects HIV antibodies and if positive requires more specific testing, counseling, and treatment during pregnancy with antiretroviral medications to prevent transmission to fetus
STI screening: Venereal Disease Research Laboratory (VDRL) or rapid plasma reagin (RPR) serologic tests	Detects STIs (such as syphilis, herpes, HPV, gonorrhea) so that treatment can be initiated early to prevent transmission to fetus
Cervical smears	Detects abnormalities such as cervical cancer (Pap test) or infections such as gonorrhea, chlamydia, or group B streptococcus so that treatment can be initiated if positive

Remember Linda and Rob, the couple who want to start a family? Ten months after the preconception appointment, Linda calls to make a first prenatal appointment. What key areas will be addressed at this first prenatal visit? What interventions might be suggested for Linda to implement in order to ensure a healthy newborn?

Follow-Up Visits

Continuous prenatal care is important for a successful pregnancy outcome. The recommended follow-up visit schedule for a healthy pregnant woman is as follows:

- Every 4 weeks up to 28 weeks (7 months)
- Every 2 weeks from 29 to 36 weeks
- Every week from 37 weeks to birth

At each subsequent prenatal visit the following assessments are completed:

- Weight and blood pressure, which are compared to baseline values
- Urine testing for protein, glucose, ketones, and nitrites
- Fundal height measurement to assess fetal growth
- Assessment for quickening/fetal movement to determine fetal well-being
- Assessment of fetal heart rate (should be 110 to 160 bpm)

At each follow-up visit, answer questions, provide anticipatory guidance and education, review nutritional guidelines, and evaluate the client for compliance with prenatal vitamin therapy. Throughout the pregnancy, encourage the woman's partner to participate if possible.

Fundal Height Measurement

Fundal height is the distance (in cm) measured with a tape measure from the top of the pubic bone to the top of the uterus (fundus) with the client lying on her back with her knees slightly flexed (Fig. 12.5). Measurement in this way is termed the McDonald's method. Fundal height typically increases as the pregnancy progresses; it reflects fetal growth and provides a gross estimate of the duration of the pregnancy.

FIGURE 12.5 Fundal height measurement.

Between 12 and 14 weeks' gestation, the fundus can be palpated above the symphysis pubis. The fundus reaches the level of the umbilicus at approximately 20 weeks and measures 20 cm. Fundal measurement should approximately equal the number of weeks of gestation until week 36. For example, a fundal height of 24 cm suggests a fetus at 24 weeks' gestation. After 36 weeks, the fundal height then drops due to lightening and may no longer correspond with the week of gestation.

It is expected that the fundal height will increase progressively throughout the pregnancy, reflecting fetal growth. However, if the growth curve flattens or stays stable, it may indicate the presence of intrauterine growth restriction (IUGR). If the fundal height measurement is greater than 4 cm from the estimated gestational age, further evaluation is warranted if a multifetal gestation has not been diagnosed or hydramnios has not been ruled out (Dillon, 2007).

Fetal Movement Determination

Fetal movement is usually perceived by the client between 16 and 20 weeks' gestation. Perceived fetal movement is most often related to trunk and limb motion and rollovers, or flips (Arenson & Drake, 2007). Fetal movement is a gross indicator of fetal well-being. Decreased fetal movement may indicate asphyxia and IUGR. If compromised, the fetus decreases its oxygen requirements by decreasing activity (Mangesi & Hofmeyr, 2007). A decrease in fetal movement may be related to other factors as well, such as maternal use of central nervous system depressants, fetal sleep cycles, hydrocephalus, bilateral renal agenesis, and bilateral hip dislocation (Arenson & Drake, 2007).

Two suggested techniques for determining fetal movement, also called fetal movement counts, are the Cardiff technique and the Sadovsky technique (Box 12.3). Fetal movement is a noninvasive method of screening and can be easily taught to all pregnant women. Both techniques require client participation.

Instruct the client about how to count fetal movements, the reasons for doing so, and the significance of decreased fetal movements. Urge the client to perform the counts in a relaxed environment and a comfortable position, such as semi-Fowler's or side-lying. Provide the client with detailed information concerning fetal movement counts and stress the need for consistency in monitoring (at approximately the same time each day) and the importance of informing the health care provider promptly of any reduced movements. Providing clients with "fetal kick count" charts to record movement helps promote compliance. There is no established number of fetal movements that indicates fetal well-being, but instruct the

BOX 12.3 Techniques for Fetal Movement Counts

Maternal perception of fetal movements or counting fetal movements is an inexpensive, noninvasive method of assessing fetal well-being. Several different techniques, two of which are described below, can be used. Scientific evidence has not shown that one technique is better than another. However, the amount of time required for the client to complete the count varies. Additionally, because counts are highly subjective on the mother's part, consistency is essential when performing fetal movement counts. Fetal movement counts should be done at approximately the same time each day, and further testing should be initiated within 12 hours of a client's perception of decreased activity (Mangesti & Hofmeyr, 2007).

Cardiff Technique

The woman lies or sits and concentrates on fetal movements until she records 10 movements. She must record the length of time during which the 10 movements occurred. She is instructed to notify her health care provider if she doesn't feel at least 10 movements within 1 hour. Further follow-up testing is indicated.

Sadovsky Technique

The woman lies down on her left side for 1 hour after meals and concentrates on fetal movement. Four movements should be felt within 1 hour. If four movements have not been felt within 1 hour, then the woman should monitor movement for a second hour. If after 2 hours four movements haven't been felt, the client should contact her health care provider.

Nursing Procedure 12.1

MEASURING FETAL HEART RATE

Purpose: To assess fetal well-being

1. Assist the woman onto the examining table and have her lie down.
2. Cover her with a sheet to ensure privacy, and then expose her abdomen.
3. Palpate the abdomen to determine the fetal lie, position, and presentation.
4. Locate the back of the fetus (the ideal position to hear the heart rate).
5. Apply lubricant gel to abdomen in the area where the back has been located.
6. Turn on the handheld Doppler device and place it on the spot over the fetal back.
7. Listen for the sound of the amplified heart rate, moving the device slightly from side to side as necessary to obtain the loudest sound. Assess the woman's pulse rate and compare it to the amplified sound. If the rates appear the same, reposition the Doppler device.
8. Once the fetal heart rate has been identified, count the number of beats in 1 minute and record the results.
9. Remove the Doppler device and wipe off any remaining gel from the woman's abdomen and the device.
10. Record the heart rate on the woman's medical record.
11. Provide information to the woman regarding fetal well-being based on findings.

woman to report a count of less than three fetal movements within an hour. Further investigation with a nonstress test or biophysical profile is usually warranted (Mangesi & Hofmeyr, 2007).

Fetal Heart Rate Measurement

Fetal heart rate measurement is integral to fetal surveillance throughout the pregnancy. Auscultating the fetal heart rate with a handheld Doppler at each prenatal visit helps confirm that the intrauterine environment is still supportive to the growing fetus. The purpose of assessing fetal heart rate is to determine rate and rhythm. Nursing Procedure 12.1 lists the steps in measuring fetal heart rate.

Follow-Up Visit Intervals and Assessments

Up to 28 weeks' gestation, follow-up visits involve assessment of the client's blood pressure and weight. The urine is tested for protein and glucose. Fundal height and fetal heart rate are assessed at every office visit. Between weeks 24 and 28, a blood glucose level is obtained using a 50-g glucose load followed by a 1-hour plasma glucose determination. If the result is more than 140 mg/dL, further testing, such as a 3-hour 100-g glucose tolerance test, is warranted to determine whether gestational diabetes is present.

During this time, review the common discomforts of pregnancy, evaluate any client complaints, and answer questions. Reinforce the importance of good nutrition and use of prenatal vitamins, along with daily exercise.

Between 29 and 36 weeks' gestation, all the assessments of previous visits are completed, along with assessment for edema. Special attention is focused on the presence and location of edema during the last trimester. Pregnant women commonly experience dependent edema of the lower extremities from constriction of blood vessels secondary to the heavy gravid uterus. Periorbital

edema around the eyes, edema of the hands, and pretibial edema are abnormal and could be signs of gestational hypertension. Inspecting and palpating both extremities, listening for complaints of tight rings on fingers, and observing for swelling around the eyes are important assessments. Abnormal findings in any of these areas need to be reported.

If the mother is Rh negative, her antibody titer is re-evaluated. RhoGAM is given if indicated. The client also is evaluated for risk of preterm labor. At each visit, ask if she is experiencing any common signs or symptoms of preterm labor (e.g., uterine contractions, dull backache, feeling of pressure in the pelvic area or thighs, increased vaginal discharge, menstrual-like cramps, vaginal bleeding). A pelvic examination is performed to assess the cervix for position, consistency, length, and dilation. If the woman has had a previous preterm birth, she is at risk for another and close monitoring is warranted.

Counsel the woman about choosing a health care provider for the newborn, if she has not selected one yet. Along with completion of a breast assessment, discuss the choice of breastfeeding versus bottle-feeding. Reinforce the importance of daily fetal movement monitoring as an indicator of fetal well-being. Re-evaluate hemoglobin and hematocrit levels to assess for anemia.

Between 37 and 40 weeks' gestation, the same assessments are done as for the previous weeks. In addition, screening for group B streptococcus, gonorrhea, and chlamydia is done. Fetal presentation and position (via Leopold's maneuvers) are assessed. Review the signs and symptoms of labor and forward a copy of the prenatal record to the hospital labor department for future reference. Review the client's desire for family planning after birth as well as her decision to breastfeed or bottle-feed. Remind the client that an infant car seat is required by law and must be used to drive the newborn home from the hospital or birthing center.

Teaching About the Danger Signs of Pregnancy

It is important to educate the client about danger signs during pregnancy that require further evaluation. Explain that she should contact her health care provider immediately if she experiences any of the following:

- During the first trimester: spotting or bleeding (miscarriage), painful urination (infection), severe persistent vomiting (hyperemesis gravidarum), fever higher than 100°F (infection), and lower abdominal pain with dizziness and accompanied by shoulder pain (ruptured ectopic pregnancy)
- During the second trimester: regular uterine contractions (preterm labor); pain in calf, often increased with foot flexion (blood clot in deep vein); sudden gush or leakage of fluid from vagina (premature rupture of membranes); and absence of fetal movement for more than 24 hours (possible fetal distress or demise)
- During the third trimester: sudden weight gain; periorbital or facial edema, severe upper abdominal pain, or headache with visual changes (pregnancy-induced hypertension); and a decrease in fetal daily movement for more than 24 hours (possible demise). Any of the previous warning signs and symptoms can also be present in this last trimester (March of Dimes, 2008c).

One of the warning signs that should be emphasized is early contractions, which can lead to preterm birth. All pregnant women need to be able to recognize early signs of contractions to prevent preterm labor, which is a major public health problem in the United States. Approximately 12% of all live births—or one out of eight babies—is born too soon (March of Dimes, 2008c). These preterm infants (born at less than 37 weeks' gestation) can suffer lifelong health consequences such as mental retardation, chronic lung disease, cerebral palsy, seizure disorders, and blindness, among other problems (March of Dimes, 2008c). Preterm labor can happen to any pregnant women at any time. In many cases it can be stopped with medications if it is recognized early, before significant cervical dilation has taken place. If the woman experiences menstrual-like cramps occurring every 10 minutes accompanied by a low, dull backache, she should stop what she is doing and lie down on her left side for 1 hour and drink two or three glasses of water. If the symptoms worsen or don't subside after 1 hour, she should contact her health care provider.

Assessment of Fetal Well-Being

During the antepartum period, several tests are performed routinely to monitor fetal well-being and to detect possible problems. When a high-risk pregnancy is identified, additional antepartum testing can be initiated to promote positive maternal, fetal, and neonatal outcomes. **High-risk pregnancies** include those that are complicated by maternal or fetal conditions (coincidental with or unique to pregnancy) that jeopardize the health status of the mother and put the fetus at risk for uteroplacental insufficiency, hypoxia, and death (Gilbert, 2007). However, additional antepartum fetal testing should take place only when the results obtained will guide future care, whether it is reassurance, more frequent testing, admission to the hospital, or the need for immediate delivery (Gilbert, 2007).

Ultrasonography

Since its introduction in the late 1950s, ultrasonography has become a very useful diagnostic tool in obstetrics. Real-time scanners can produce a continuous picture of the fetus on a monitor screen. A transducer that emits high-frequency sound waves is placed on the mother's abdomen and moved to visualize the fetus (Fig. 12.6). The fetal

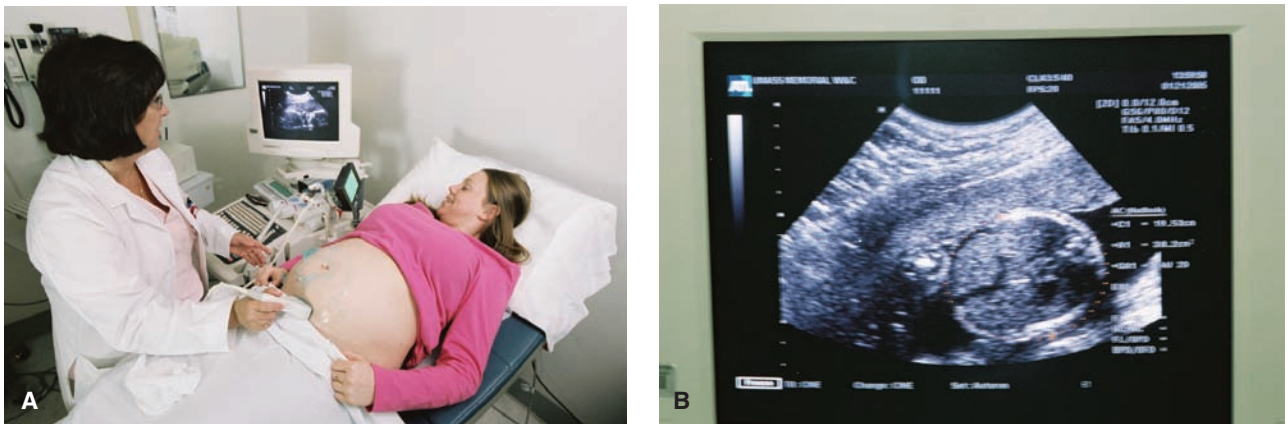

FIGURE 12.6 Ultrasound. (**A**) Ultrasound device being applied to client's abdomen. (**B**) View of monitor.

heartbeat and any malformations in the fetus can be assessed and measurements can be made accurately from the picture on the monitor screen.

Ultrasound, which is noninvasive, is considered a safe, accurate, and cost-effective tool. It provides important information about fetal activity, growth, and gestational age, assesses fetal well-being, and determines the need for invasive intrauterine tests (Valley & Fly, 2006).

There are no hard-and-fast rules as to the number of ultrasounds a woman should have during her pregnancy. An ultrasound usually is performed in the first trimester to confirm pregnancy, exclude ectopic or molar pregnancies, and confirm cardiac pulsation. A second scan may be performed at about 18 to 20 weeks to look for congenital malformations, exclude multifetal pregnancies, and verify dates and growth. A third scan may be done at around 34 weeks to evaluate fetal size, assess fetal growth, and verify placental position (Valley & Fly, 2006). An ultrasound is used to confirm placental location during amniocentesis and to provide visualization during chorionic villus sampling. An ultrasound is also ordered whenever an abnormality is suspected based on clinical grounds.

Nursing management during the ultrasound focuses on educating the woman about the ultrasound test and reassuring her that she will not experience any sensation from the sound waves during the test. No special client preparation is needed before performing the ultrasound, although in early pregnancy the woman may need to have a full bladder. Inform her that she may experience some discomfort from the pressure on the full bladder during the scan, but it will last only a short time. Tell the client that the conducting gel used on the abdomen during the scan may feel cold initially.

Doppler Flow Studies

Doppler flow studies can be used to measure the velocity of blood flow via ultrasound. Doppler flow studies can detect fetal compromise in high-risk pregnancies. The test is noninvasive and has no contraindications. The color images produced help to identify abnormalities in diastolic flow within the umbilical vessels. The velocity of the fetal red blood cells can be determined by measuring the change in the frequency of the sound wave reflected off the cells. Thus, Doppler flow studies can detect the movement of red blood cells in vessels (Gilbert, 2007). In pregnancies complicated by hypertension or IUGR, diastolic blood flow may be absent or even reversed (Gilbert, 2007). Doppler flow studies also can be used to evaluate the blood flow through other fetal blood vessels, such as the aorta and those in the brain. Research continues to determine the indications for Doppler flow studies to improve pregnancy outcomes. Nursing management of the woman undergoing Doppler flow studies is similar to that described for an ultrasound.

Alpha-Fetoprotein Analysis

Alpha-fetoprotein (AFP) is a substance produced by the fetal liver between weeks 13 and 20 of gestation. About 30 years ago, elevated levels of maternal serum AFP or amniotic fluid AFP were first linked to the occurrence of fetal neural tube defects. This biomarker screening test is now recommended for all pregnant women (Alexander et al., 2007; ACOG, 2007a).

AFP is present in amniotic fluid in low concentrations between 10 and 14 weeks of gestation and can be detected in maternal serum beginning approximately at 12 to 14 weeks of gestation (Gilbert, 2007). If there is a developmental defect, such as failure of the neural tube to close, more AFP escapes into amniotic fluid from the fetus. AFP then enters the maternal circulation by crossing the placenta, and the level in maternal serum can be measured. The optimal time for AFP screening is 16 to 18 weeks of gestation (ACOG, 2007a). Correct information about gestational dating, maternal weight, race, number of fetuses, and insulin dependency is necessary to ensure the accuracy of this screening test. If incorrect maternal information is submitted or the blood specimen is not drawn during the appropriate time frame, false-positive results

may occur, increasing the woman's anxiety. Subsequently, further testing might be ordered based on an inaccurate interpretation, resulting in additional financial and emotional costs to the woman.

A variety of situations can lead to elevation of maternal serum AFP, including open neural tube defect, underestimation of gestational age, the presence of multiple fetuses, gastrointestinal defects, low birthweight, oligohydramnios, and decreased maternal weight (Frieden & Chan, 2007). Lower-than-expected maternal serum AFP levels are seen when fetal gestational age is overestimated or in cases of fetal death, hydatidiform mole, increased maternal weight, maternal type I diabetes, and fetal trisomy 21 (Down syndrome) or trisomy 18 (Edward's syndrome) (Gilbert, 2007).

Measurement of maternal serum AFP is minimally invasive, requiring only a venipuncture for a blood sample. It detects approximately 80% of all open neural tube defects and open abdominal wall defects in early pregnancy (Dashe et al., 2006). AFP has now been combined with other biomarker screening tests to determine the risk of neural tube defects and Down syndrome.

Nursing management for AFP testing consists of preparing the woman for this screening test by gathering accurate information about the date of her LMP, weight, race, and gestational dating. Accurately determining the window of 16 to 18 weeks' gestation will help to ensure that the test results are correct. Also explain that the test involves obtaining a blood specimen.

Marker Screening Tests

Two additional blood screening tests may be used to determine the risk of open neural tube defects and Down syndrome: the triple-marker screen and the addition of a fourth marker, inhibin A, which is used to enhance the accuracy of screening for Down syndrome in women younger than 35 years of age. Low inhibin A levels indicate the possibility of Down syndrome (Frieden & Chan, 2007). These tests combine three or four procedures to enhance the ability to make a diagnosis. These biomarkers are merely screening tests and identify women who need further definitive procedures (i.e., amniocentesis and genetic counseling) to make a diagnosis of neural tube defects (anencephaly, spina bifida, and encephalocele) or Down syndrome in the fetus. Most screening tests are performed between 15 to 22 weeks of gestation (16 to 18 weeks is ideal) (Blackburn, 2007).

The triple-marker screening or triple screening test is performed at 16 to 18 weeks of gestation. It uses the levels of three maternal serum markers (AFP, unconjugated estriol, and hCG), in combination with maternal age, to calculate risk (Frieden & Chan, 2007). With this screening, low maternal serum AFP and unconjugated estriol levels and a high hCG level suggests the possibility of Down syndrome. Elevated levels of maternal serum AFP are associated with open neural tube defects, ventral wall defects, some renal abnormalities, multiple gestation, certain skin disorders, fetal demise, and placental abnormality. The addition of the other two markers enhances the detection rate, from 25% using AFP alone to approximately 69% using all three (Frieden & Chan, 2007).

The screening test using four maternal markers (i.e., quadruple-marker screening) is also used to screen for Down syndrome. It uses maternal age at term and the concentration of four biomarkers in maternal serum: AFP, unconjugated estriol, hCG, and inhibin A. This test is done at 14 to 22 weeks of pregnancy and is reported to detect 85% of trisomy 21 cases; the triple screen was reported to detect only 69% (Hackley, Kriebs, & Rousseau, 2007). AFP and inhibin A levels are decreased in infants with trisomy 21 (Down syndrome).

Nursing management related to marker screening tests consists primarily of providing education about the tests. Prenatal screening has become standard in prenatal care. However, for many couples it remains confusing, emotionally charged, and filled with uncertain risks. Offer a thorough explanation of the test, reinforcing the information given by the health care professional. Provide couples with a description of the risks and benefits of performing these screens, emphasizing that these tests are for screening purposes only. Remind the couple that a definitive diagnosis is not made without further tests such as an amniocentesis. Answer any questions about these prenatal screening tests and respect the couple's decision if they choose not to have them done. Many couples may choose not to know because they would not consider having an abortion regardless of the test results.

Nuchal Translucency Screening

Nuchal translucency screening (ultrasound) is also done in the first trimester between 11 and 14 weeks. This allows for earlier detection and diagnosis of some fetal chromosomal and structural abnormalities. Ultrasound is used to identify an increase in nuchal translucency, which is due to the subcutaneous accumulation of fluid behind the fetal neck. Increased nuchal translucency is associated with chromosomal abnormalities such as trisomy 21, 18, and 13. Infants with trisomies tend to have more collagen and elastic connective tissue, allowing for accumulation (Caughey et al., 2007).

Amniocentesis

Amniocentesis involves a transabdominal puncture of the amniotic sac to obtain a sample of amniotic fluid for analysis. The fluid contains fetal cells that are examined to detect chromosomal abnormalities and several hereditary metabolic defects in the fetus before birth. In addition, amniocentesis is used to confirm a fetal abnormality when other screening tests detect a possible problem.

Amniocentesis is performed in the second trimester, usually between weeks 16 and 18. It can be done as early as week 14 or as late as week 20 (Singh & Singh, 2007). Over 40 different chromosomal abnormalities, inborn errors of metabolism, and neural tube defects can be diagnosed with amniocentesis. It can replace a genetic probability with a diagnostic certainty, allowing the woman and her partner to make an informed decision about the option of therapeutic abortion.

Amniocentesis can be performed in any of the three trimesters of pregnancy. An early amniocentesis (performed between weeks 11 and 14) is done to detect genetic anomalies. However, early amniocentesis has been associated with a high risk of spontaneous miscarriage and postprocedural amniotic fluid leakage compared with transabdominal chorionic villus screening (Singh & Singh, 2007). ACOG (2004) has issued a position statement on first-trimester screening methods, recommending chorionic villus sampling and nuchal translucency to detect Down syndrome rather than amniocentesis because of the increased risks associated with the early procedure. However, early screening and diagnosis can provide the couple with time to make decisions about the pregnancy outcome.

In the second trimester the procedure is performed between 15 and 20 weeks to detect chromosomal abnormalities, evaluate the fetal condition when the woman is sensitized to the Rh-positive blood, diagnose intrauterine infections, and investigate amniotic fluid AFP when the maternal serum AFP level is elevated (Gilbert, 2007).

In the third trimester amniocentesis is most commonly indicated to determine fetal lung maturity after the 35th week of gestation via analysis of lecithin-to-sphingomyelin ratios (L/S ratio) and to evaluate the fetal condition with Rh isoimmunization. Table 12.1 lists amniotic fluid analysis findings and their implications.

The second trimester is the most common time to have an amniocentesis for any prenatal diagnosis since it carries such high risk if done earlier. By week 14 to 16 of gestation, there is sufficient amniotic fluid for sampling yet enough time for a safe abortion, if desired. Amniocentesis is offered to women who are 35 years of age or older, women who have a child with a neural tube defect, and women with elevated maternal serum AFP levels. It also

TABLE 12.1 AMNIOTIC FLUID ANALYSIS AND IMPLICATIONS

Test Component	Normal Findings	Fetal Implications of Abnormal Findings
Color	Clear with white flecks of vernix caseosa in a mature fetus	Blood of maternal origin is usually harmless. "Port wine" fluid may indicate abruptio placentae. Fetal blood may indicate damage to the fetal, placental, or umbilical cord vessels.
Bilirubin	Absent at term	High levels indicate hemolytic disease of the neonate in isoimmunized pregnancy.
Meconium	Absent (except in breech presentation)	Presence indicates fetal hypotension or distress.
Creatinine	More than 2 mg/dL in a mature fetus	Decrease may indicate immature fetus (less than 37 weeks).
Lecithin–sphingomyelin ratio (L/S ratio)	More than 2 generally indicates fetal pulmonary maturity.	A ratio of less than 2 indicates pulmonary immaturity and subsequent respiratory distress syndrome.
Phosphatidylglycerol	Present	Absence indicates pulmonary immaturity.
Glucose	Less than 45 mg/dL	Excessive increases at term or near term indicate hypertrophied fetal pancreas and subsequent neonatal hypoglycemia.
Alpha-fetoprotein	Variable, depending on gestation age and laboratory technique; highest concentration (about 18.5 µg/mL) occurs at 13 to 14 weeks	Inappropriate increases indicate neural tube defects such as spina bifida or anencephaly, impending fetal death, congenital nephrosis, or contamination of fetal blood.
Bacteria	Absent	Presence indicates chorioamnionitis.
Chromosomes	Normal karyotype	Abnormal karyotype may indicate fetal sex and chromosome disorders.
Acetylcholinesterase	Absent	Presence may indicate neural tube defects, exomphalos, or other serious malformations.

Sources: Blackburn, 2007; Dillon, 2007; Frieden & Chang, 2007.

may be used to detect chromosomal aberrations when a parent has a chromosomal abnormality or is a carrier for a metabolic disease (Cunningham et al., 2005).

Procedure

Amniocentesis is performed after an ultrasound examination identifies an adequate pocket of amniotic fluid free of fetal parts, the umbilical cord, or the placenta (Fig. 12.7). The health care provider inserts a long pudendal or spinal needle, a 22-gauge, 5-inch needle, into the amniotic cavity and aspirates amniotic fluid, which is placed in an amber or foil-covered test tube to protect it from light. When the desired amount of fluid has been withdrawn, the needle is removed and slight pressure is applied to the site. If there is no evidence of bleeding, a sterile bandage is applied to the needle site. The specimens are then sent to the laboratory immediately for the cytologist to evaluate.

Examining a sample of fetal cells directly produces a definitive diagnosis rather than a "best guess" diagnosis based on indirect screening tests. It is an invaluable diagnostic tool, but the risks include spontaneous abortion (1 in 200), maternal or fetal infection, fetal-maternal hemorrhage, leakage of amniotic fluid, and maternal discomfort after the procedure. The test results may take up to 3 weeks.

Nursing Management

When preparing the woman for an amniocentesis, explain the procedure and encourage her to empty her bladder just before the procedure to avoid the risk of bladder puncture.

FIGURE 12.7 Technique for amniocentesis: Inserting needle.

Inform her that a 20-minute electronic fetal monitoring strip usually is obtained to evaluate fetal well-being and obtain a baseline to compare after the procedure is completed. Obtain and record maternal vital signs.

After the procedure, assist the woman to a position of comfort and administer RhoGAM intramuscularly if the woman is Rh negative to prevent potential sensitization to fetal blood. Assess maternal vital signs and fetal heart rate every 15 minutes for an hour after the procedure. Observe the puncture site for bleeding or drainage. Instruct the client to rest after returning home and remind her to report fever, leaking amniotic fluid, vaginal bleeding, or uterine contractions or any changes in fetal activity (increased or decreased) to the health care provider.

When the test results come back, be available to offer support, especially if a fetal abnormality is found. Also prepare the woman and her partner for the need for genetic counseling. Trained genetic counselors can provide accurate medical information and help couples to interpret the results of the amniocentesis so they can make the decisions that are right for them as a family.

Chorionic Villus Sampling

Chorionic villus sampling (CVS) is a procedure for obtaining a sample of the chorionic villi for prenatal evaluation of chromosomal disorders, enzyme deficiencies, and fetal gender determination and to identify sex-linked disorders such as hemophilia, sickle cell anemia, and Tay-Sachs disease (Blackburn, 2007). Chorionic villi are finger-like projections that cover the embryo and anchor it to the uterine lining before the placenta is developed. Because they are of embryonic origin, sampling provides information about the developing fetus. CVS can be used to detect numerous genetic disorders, with the exception of neural tube defects (Jenkins et al., 2007).

There has been an impetus to develop earlier prenatal diagnostic procedures so that couples can make an early decision to terminate the pregnancy if an anomaly is confirmed. Early prenatal diagnosis by CVS was proposed as an alternative to routine amniocentesis, which carries fewer risks if done later in the pregnancy. In addition, results of CVS testing are available sooner than those of amniocentesis, usually within 48 hours.

Procedure

CVS is generally performed 10 to 13 weeks after the LMP. Earlier, chorionic villi may not be sufficiently developed for adequate tissue sampling and the risk of limb defects is increased (Kenner & Lott, 2007). First, an ultrasound is done to confirm gestational age and viability. Then, under continuous ultrasound guidance, CVS is performed using either a transcervical or transabdominal approach. With the transcervical approach, the woman is placed in the lithotomy position and a sterile catheter is introduced

through the cervix and inserted in the placenta, where a sample of chorionic villi is aspirated. This approach requires the client to have a full bladder to push the uterus and placenta into a position that is more accessible to the catheter. A full bladder also helps in better visualization of the structures. With the transabdominal approach, an 18-gauge spinal needle is inserted through the abdominal wall into the placental tissue and a sample of chorionic villi is aspirated. Regardless of the approach used, the sample is sent to the cytogenetics laboratory for analysis.

Potential complications of CVS include mild vaginal bleeding and cramping, spontaneous abortion, limb abnormalities, rupture of membranes, infection, chorioamnionitis, and fetal-maternal hemorrhage (Blackburn, 2007). The pregnancy loss rate is approximately 1.3%, which is somewhat higher than with traditional amniocentesis (Walling, 2007). In addition, women who are Rh negative should receive immune globulin (RhoGAM) to avoid isoimmunization (Gilbert, 2007).

Nursing Management

Explain to the woman that the procedure will last about 15 minutes. An ultrasound will be done first to locate the embryo, and a baseline set of vital signs will be taken before starting. Make sure she is informed of the risks related to the procedure, including their incidence.

If a transabdominal CVS procedure is planned, advise her to fill her bladder by drinking increased amounts of water. Inform her that a needle will be inserted through her abdominal wall and samples will be collected. Once the samples are collected, the needle will be withdrawn and the samples will be sent to the genetics laboratory for evaluation.

For transcervical CVS, inform the women that a speculum will be placed into the vagina under ultrasound guidance. Then the vagina is cleaned and a small catheter is inserted through the cervix. The samples obtained through the catheter are then sent to the laboratory.

After either procedure, assist the woman to a position of comfort and clean any excess lubricant or secretions from the area. Instruct her about signs to watch for and report, such as fever, cramping, and vaginal bleeding. Urge her not to engage in any strenuous activity for the next 48 hours. Assess the fetal heart rate for changes and administer RhoGAM to an unsensitized Rh-negative woman after the procedure.

Percutaneous Umbilical Blood Sampling

Percutaneous umbilical blood sampling (PUBS) permits the collection of a blood specimen directly from the fetal circulation (Fig. 12.8). This test allows for rapid chromosomal analysis to achieve a timely diagnosis. It is done specifically for women at risk for genetic anomalies and those with potential blood disorders, such as blood incompatibility or hemoglobinopathies.

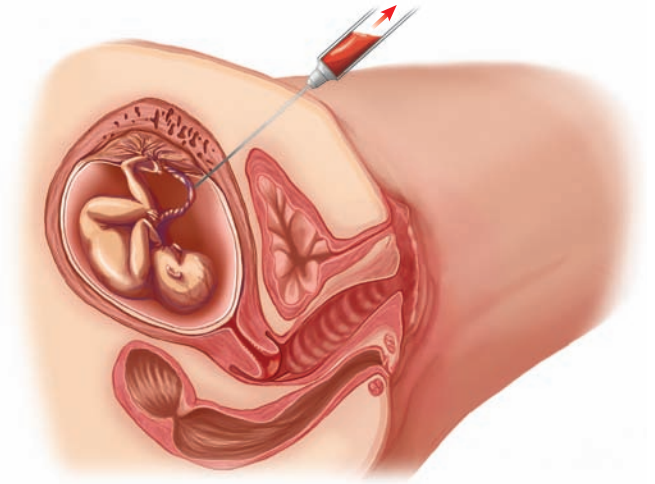

FIGURE 12.8 Collecting blood sample for PUBS.

Procedure

Under continuous ultrasound guidance, a fine needle is inserted through the mother's abdomen and uterine wall into an umbilical cord vessel. Specimens can be evaluated for coagulation studies, blood group typing, complete blood count, karyotyping, and blood gas analysis (Singh & Singh, 2008). Fetal infection, Rh incompatibility, and fetal acid–base status can be determined. The blood sample is usually drawn late in the second trimester to assist in medical management, but PUBS can be done anytime after 16 weeks of gestation.

Although the information gained from this procedure is valuable and can be life-saving for many fetuses, PUBS is not without risks. Potential complications include leakage of blood from the puncture site, cord laceration, cord hematomas, transient fetal bradycardia, infection, thromboembolism in the umbilical cord, preterm labor, infection, and premature rupture of membranes (Blackburn, 2007).

Nursing Management

Explain the procedure thoroughly to the woman. Position her properly on the examination table and help clean the area for needle insertion. Monitor vital signs and fetal heart rate throughout the procedure. At the conclusion of the procedure, closely monitor the mother and fetus for changes. Assess fetal heart rate continuously and perform external fetal monitoring for up to 2 hours before the woman is discharged from the outpatient area. A repeat ultrasound is usually done within an hour after the procedure to rule out bleeding or hematoma formation.

Prior to discharge, instruct the woman to report signs of infection, an increase in contractions, or a change in fetal

activity level from normal. Reinforce the need to count fetal movements, and review the technique so she can assess them when she is discharged home.

Nonstress Test

The nonstress test (NST) is an indirect measurement of uteroplacental function. Unlike the fetal movement counting done by the mother alone, this procedure requires specialized equipment and trained personnel. The basis for the nonstress test is that the normal fetus produces characteristic fetal heart rate patterns in response to fetal movements. In the healthy fetus there is an acceleration of the fetal heart rate with fetal movement. Currently, an NST is recommended twice weekly (after 28 weeks of gestation) for clients with diabetes and other high-risk conditions, such as IUGR, preeclampsia, postterm pregnancy, renal disease, and multifetal pregnancies (Cunningham et al., 2005).

NST is a noninvasive test that requires no initiation of contractions. It is quick to perform and there are no known side effects. However, it is not as sensitive to fetal oxygen reserves as the contraction stress test, and there is a high false-positive rate (Gilbert, 2007).

Procedure

Before the procedure the client eats a meal to stimulate fetal activity. Then she is placed in the left lateral recumbent position to avoid supine hypotension syndrome. An external electronic fetal monitoring device is applied to her abdomen. The device consists of two belts, each with a sensor. One of the sensors records uterine activity; the second sensor records fetal heart rate. The client is handed an "event marker" with a button that she pushes every time she perceives fetal movement. When the button is pushed, the fetal monitor strip is marked to identify that fetal movement has occurred. The procedure usually lasts 20 to 30 minutes.

Nursing Management

Prior to the NST, explain the testing procedure and have the woman empty her bladder. Position her in a semi-Fowler's position and apply the two external monitor belts. Document the date and time the test is started, patient information, the reason for the test, and the maternal vital signs. Obtain a baseline fetal monitor strip over 15 to 30 minutes.

During the test, observe for signs of fetal activity with a concurrent acceleration of the fetal heart rate. Interpret the NST as reactive or nonreactive. A "reactive" NST includes at least two fetal heart rate accelerations from the baseline of at least 15 bpm for at least 15 seconds within the 20-minute recording period. If the test does not meet these criteria after 40 minutes, it is considered nonreactive. A "nonreactive" NST is characterized by the absence of two fetal heart rate accelerations using the 15-by-15 criterion in a 20-minute time frame. A nonreactive test has been correlated with a higher incidence of fetal distress during labor, fetal mortality, and IUGR. Additional testing, such as a contraction stress test or biophysical profile, should be considered (Frieden & Chan, 2007).

After the NST procedure, assist the woman off the table, provide her with fluids, and allow her to use the restroom. Typically the results are discussed with the woman at this time by the health care provider. Provide teaching about signs and symptoms to report. If serial NSTs are being done, schedule the next testing session.

Contraction Stress Test

Because blood flow to the uterus and placenta is slowed during uterine contractions, the contraction stress test (CST), formerly called the oxytocin-challenge test, is a diagnostic procedure performed to determine the fetal heart rate response under stress, such as during contractions. The goal of the test is to achieve three uterine contractions in a 10-minute period. This can occur spontaneously with the aid of nipple stimulation, which causes the release of endogenous oxytocin, or through the use of an oxytocin infusion. Its use has been indicated in pregnancies in which placental insufficiency is suspected—preeclampsia, IUGR, diabetes mellitus, postterm pregnancy, a previous stillbirth—or when an irregularity of the fetal heart rate has been observed. However, the CST has given way to the biophysical profile and has limited use today (Blackburn, 2007).

Biophysical Profile

A **biophysical profile** uses a real-time ultrasound to allow assessment of various parameters of fetal well-being: fetal tone, breathing, motion, and amniotic fluid volume. These four parameters, together with the NST, constitute the biophysical profile. Each parameter is controlled by a different structure in the fetal brain: fetal tone by the cortex; fetal movements by the cortex and motor nuclei; fetal breathing movements by the centers close to the fourth ventricle; and the NST by the posterior hypothalamus and medulla. The amniotic fluid is the result of fetal urine volume. Not all facilities perform an NST unless other parameters of the profile are abnormal (Gilbert, 2007). The biophysical profile is based on the concept that a fetus that experiences hypoxia loses certain behavioral parameters in the reverse order in which they were acquired during fetal development (normal order of development: tone at 8 weeks; movement at 9 weeks; breathing at 20 weeks; and fetal heart rate reactivity at 24 weeks).

Scoring and Interpretation

The biophysical profile is a scored test with five components, each worth 2 points if present. A total score of 10 is

possible if the NST is used. Thirty minutes are allotted for testing, although fewer than 10 minutes are usually needed. The following criteria must be met to obtain a score of 2; anything less is scored as 0 (Gilbert, 2007):

- Body movements: three or more discrete limb or trunk movements
- Fetal tone: one or more instances of full extension and flexion of a limb or trunk
- Fetal breathing: one or more fetal breathing movements of more than 30 seconds
- Amniotic fluid volume: one or more pockets of fluid measuring 2 cm
- NST: normal NST = 2 points; abnormal NST = 0 points

Interpretation of the biophysical profile score can be complicated, depending on several fetal and maternal variables. Because it is indicated as a result of a nonreassuring finding from previous fetal surveillance tests, this test can be used to quantify the interpretation, and intervention can be initiated if appropriate. One of the important factors is the amniotic fluid volume, taken in conjunction with the results of the NST. Amniotic fluid is largely composed of fetal urine. As placental function decreases, perfusion of fetal organs, such as kidneys, decreases, and this can lead to a reduction of amniotic fluid. If oligohydramnios or decreased amniotic fluid is present, the potential exists for antepartum or intrapartum fetal compromise (Gearhart & Sehdev, 2007).

Overall, a score of 8 to 10 is considered normal if the amniotic fluid volume is adequate. A score of 6 or below is suspicious, possibly indicating a compromised fetus; further investigation of fetal well-being is needed.

Because the biophysical profile is an ultrasonographic assessment of fetal behavior, it requires more extensive equipment and more highly trained personnel than other testing modalities. The cost is much greater than with less sophisticated tests. It permits conservative therapy and prevents premature or unnecessary intervention. There are fewer false-positive results than with the NST alone or CST (Gearhart & Sehdev, 2007).

Nursing Management

Nursing management focuses primarily on offering the client support and answering her questions. Expect to complete the NST before scheduling the biophysical profile, and explain why further testing might be needed. Tell the woman that the ultrasound will be done in the diagnostic imaging department.

Nursing Management for the Common Discomforts of Pregnancy

Most women experience common discomforts during pregnancy and ask a nurse's advice about ways to minimize them. However, other women will not bring up their concerns unless asked. Therefore, the nurse needs to address the common discomforts that occur in each trimester at each prenatal visit and provide realistic measures to help the client deal with them (Teaching Guidelines 12.1). Nursing Care Plan 12.1 applies the nursing process to the care of a woman experiencing some discomforts of pregnancy.

First-Trimester Discomforts

During the first 3 months of pregnancy, the woman's body is undergoing numerous changes. Some women experience many discomforts, but others have few. These discomforts are caused by the changes taking place within the body and pass as the pregnancy progresses.

Urinary Frequency or Incontinence

Urinary frequency or incontinence is common in the first trimester because the growing uterus compresses the bladder. This also is a common complaint during the third trimester, especially when the fetal head settles into the pelvis. However, the discomfort tends to improve in the second trimester, when the uterus becomes an abdominal organ and moves away from the bladder region.

After infection and gestational diabetes have been ruled out as causative factors of increased urinary frequency, suggest that the woman decrease her fluid intake 2 to 3 hours before bedtime and limit her intake of caffeinated beverages. Increased voiding is normal, but encourage the client to report any pain or burning during urination. Also explain that increased urinary frequency may subside as she enters her second trimester, only to recur in the third trimester. Teach the client to perform Kegel exercises throughout the day to help strengthen perineal muscle tone, thereby enhancing urinary control and decreasing the possibility of incontinence.

Fatigue

Fatigue plagues all pregnant women, primarily in the first and third trimesters (the highest energy levels typically occur during the second trimester), even if they get their normal amount of sleep at night. First-trimester fatigue most often is related to the many physical changes (e.g., increased oxygen consumption, increased levels of progesterone and relaxin, increased metabolic demands) and psychosocial changes (e.g., mood swings, multiple role demands) of pregnancy. Third-trimester fatigue can be caused by sleep disturbances from increased weight (many women cannot find a comfortable sleeping position due to the enlarging abdomen), physical discomforts such as heartburn, and insomnia due to mood swings, multiple role anxiety, and a decrease in exercise (Trupin, 2006).

Once anemia, infection, and blood dyscrasias have been ruled out as contributing to the client's fatigue, advise

TEACHING GUIDELINES 12.1

Teaching to Manage the Discomforts of Pregnancy

Urinary Frequency or Incontinence

- Try Kegel exercises to increase control over leakage.
- Empty your bladder when you first feel a full sensation.
- Avoid caffeinated drinks, which stimulate voiding.
- Reduce your fluid intake after dinner to reduce nighttime urination.

Fatigue

- Attempt to get a full night's sleep, without interruptions.
- Eat a healthy balanced diet.
- Schedule a nap in the early afternoon daily.
- When you are feeling tired, rest.

Nausea and Vomiting

- Avoid an empty stomach at all times.
- Munch on dry crackers/toast in bed before arising.
- Eat several small meals throughout the day.
- Drink fluids between meals rather than with meals.
- Avoid greasy, fried foods or ones with a strong odor, such as cabbage or Brussels sprouts.

Backache

- Avoid standing or sitting in one position for long periods.
- Apply heating pad (low setting) to the small of your back.
- Support your lower back with pillows when sitting.
- Stand with your shoulders back to maintain correct posture.

Leg Cramps

- Elevate legs above heart level frequently throughout the day.
- If you get a cramp, straighten both legs and flex your feet toward your body.
- Ask your health care provider about taking additional calcium supplements, which may reduce leg spasms.

Varicosities

- Walk daily to improve circulation to extremities.
- Elevate both legs above heart level while resting.
- Avoid standing in one position for long periods of time.
- Don't wear constrictive stockings and socks.
- Don't cross the legs when sitting for long periods.
- Wear support stockings to promote better circulation.

Hemorrhoids

- Establish a regular time for daily bowel elimination.
- Prevent straining by drinking plenty of fluids and eating fiber-rich foods and exercising daily.
- Use warm sitz baths and cool witch hazel compresses for comfort.

Constipation

- Increase your intake of foods high in fiber and drink at least eight 8-ounce glasses of fluid daily.
- Exercise each day (brisk walking) to promote movement through the intestine.
- Reduce the amount of cheese consumed.

Heartburn/Indigestion

- Avoid spicy or greasy foods and eat small frequent meals.
- Sleep on several pillows so that your head is elevated.
- Stop smoking and avoid caffeinated drinks to reduce stimulation.
- Avoid lying down for at least 2 hours after meals.
- Try drinking sips of water to reduce burning sensation.
- Take antacids sparingly if burning sensation is severe.

Braxton Hicks Contractions

- Keep in mind that these contractions are a normal sensation.
- Try changing your position or engaging in mild exercise to help reduce the sensation.
- Drink more fluids if possible.

her to arrange work, childcare, and other demands in her life to permit additional rest periods. Work with the client to devise a realistic schedule for rest. Using pillows for support in the side-lying position relieves pressure on major blood vessels that supply oxygen and nutrients to the fetus when resting (Fig. 12.9). Also recommend the use of relaxation techniques, providing instructions as necessary, and suggest she increase her daily exercise level.

Nausea and Vomiting

Nausea and vomiting are common discomforts during the first trimester: at least 50% of women experience nausea during pregnancy (Hackley, Kriebs, & Rousseau, 2007). The physiologic changes that cause nausea and vomiting are unknown, but research suggests that unusually high levels of estrogen, progesterone, and hCG and a vitamin B6 deficiency may be contributing factors. Symp-

Nursing Care Plan 12.1

OVERVIEW OF THE WOMAN EXPERIENCING COMMON DISCOMFORTS OF PREGNANCY

Alicia, a 32-year-old, G1 P0, at 10 weeks' gestation, comes to the clinic for a visit. During the interview she tells you, "I'm running to the bathroom to urinate it seems like all the time, and I'm so nauseous that I'm having trouble eating." She denies any burning or pain on urination. Vital signs are within acceptable limits.

NURSING DIAGNOSIS: Impaired urinary elimination related to frequency secondary to physiologic changes of pregnancy

Outcome Identification and Evaluation

Client will report a decrease in urinary complaints, as evidenced by a decrease in the number of times she uses the bathroom to void, reports that she feels her bladder is empty after voiding, and use of Kegel exercises.

Interventions: Promoting Normal Urinary Elimination Patterns

- Assess client's usual bladder elimination patterns to establish a baseline for comparison.
- Obtain a urine specimen for analysis to rule out infection or glucosuria.
- Review with client the physiologic basis for the increased frequency during pregnancy; inform client that frequency should abate during the second trimester and that it most likely will return during her third trimester. This will promote understanding of the problem.
- Encourage the client to empty her bladder when first feeling a sensation of fullness to minimize risk of urinary retention.
- Suggest client avoid caffeinated drinks, which can stimulate the need to void.
- Encourage client to drink adequate amounts of fluid throughout the day; however, have client reduce her fluid intake before bedtime to reduce nighttime urination.
- Urge client to keep perineal area clean and dry to prevent irritation and excoriation from any leakage.
- Instruct client in Kegel exercises to increase perineal muscle tone and control over leakage.
- Teach client about the signs and symptoms of urinary tract infection and urge her to report them should they occur to ensure early detection and prompt intervention.

NURSING DIAGNOSIS: Imbalanced nutrition, less than body requirements, related to nausea and vomiting

Outcome Identification and Evaluation

Client will ingest adequate amounts of nutrients for maternal and fetal well-being as evidenced by acceptable weight gain pattern and statements indicating an increase in food intake with a decrease in the number of episodes of nausea and vomiting.

Interventions: Promoting Adequate Nutrition

- Obtain weight and compare to baseline to determine effects of nausea and vomiting on nutritional intake.
- Review client's typical dietary intake over 24 hours to determine nutritional intake and patterns so that suggestions can be individualized.
- Encourage client to eat five or six small frequent meals throughout the day to prevent her stomach from becoming empty.
- Suggest that she munch on dry crackers, toast, cereal, or cheese or drink a small amount of lemonade before arising to minimize nausea.
- Encourage client to arise slowly from bed in the morning and avoid sudden movements to reduce stimulation of the vomiting center.
- Advise client to drink fluids between meals rather than with meals to avoid overdistention of the abdomen and subsequent increase in abdominal pressure.
- Encourage her to increase her intake of foods high in vitamin B6 such as meat, poultry, bananas, fish, green leafy vegetables, peanuts, raisins, walnuts, and whole grains, as tolerated, to ensure adequate nutrient intake.
- Advise the client to avoid greasy, fried, or highly spiced foods and to avoid strong odors, including foods such as cabbage, to minimize gastrointestinal upset.
- Encourage the client to avoid wearing tight or restricting clothes to minimize pressure on the expanding abdomen.
- Arrange for consultation with nutritionist as necessary to assist with diet planning.

FIGURE 12.9 Using pillows for support in the side-lying position.

toms generally last until the second trimester and are generally associated with a positive pregnancy outcome (Cunningham et al., 2005).

To help alleviate nausea and vomiting, advise the woman to eat small, frequent meals (five or six a day) to prevent her stomach from becoming completely empty. Other helpful suggestions include eating dry crackers, Cheerios, lemonade, or cheese before getting out of bed in the morning and increasing her intake of foods high in vitamin B6, such as meat, poultry, bananas, fish, green leafy vegetables, peanuts, raisins, walnuts, and whole grains, or making sure she is receiving enough vitamin B6 by taking her prescribed prenatal vitamins. Other helpful tips to deal with nausea and vomiting include:

- Get out of bed in the morning very slowly.
- Avoid sudden movements.
- Open a window to remove odors of food being cooked.
- Limit intake of fluids or soups during meals (drink them between meals).
- Avoid fried foods and foods cooked with grease, oils, or fatty meats, for they tend to upset the stomach.
- Avoid highly seasoned foods such as those cooked with garlic, onions, peppers, and chili.
- Drink a small amount of caffeine-free carbonated beverage (ginger ale) if nauseated.
- Avoid strong smells.
- Avoid wearing tight or restricting clothes, which might place increased pressure on the expanding abdomen.
- Avoid stress (Lane, 2007).

Breast Tenderness

Due to increased estrogen and progesterone levels, which cause the fat layer of breasts to thicken and the number of milk ducts and glands to increase during the first trimester, many women experience breast tenderness. Offering a thorough explanation to the woman about the reasons for the breast discomfort is important. Wearing a larger bra with good support can help alleviate this discomfort. Advise her to wear a supportive bra, even while sleeping. As her breasts increase in size, advise her to change her bra size to ensure adequate support.

Constipation

Increasing levels of progesterone during pregnancy lead to decreased contractility of the gastrointestinal tract, slowed movement of substances through the colon, and a resulting increase in water absorption. All of these factors lead to constipation. Lack of exercise or too little fiber or fluids in the diet can also promote constipation. In addition, the large bowel is mechanically compressed by the enlarging uterus, adding to this discomfort. The iron and calcium in prenatal vitamins can also contribute to constipation during the first and third trimesters.

Explain how pregnancy exacerbates the symptoms of constipation and offer the following suggestions:

- Eat fresh or dried fruit daily.
- Eat more raw fruits and vegetables, including their skins.
- Eat whole-grain cereals and breads such as raisin bran or bran flakes.
- Participate in physical activity every day.
- Eat meals at regular intervals.
- Establish a time of day to defecate, and elevate your feet on a stool to avoid straining.
- Drink six to eight glasses of water daily.
- Decrease your intake of refined carbohydrates.
- Drink warm fluids on arising to stimulate bowel motility.
- Decrease your consumption of sugary sodas.
- Avoid eating large amounts of cheese.

If the suggestions above are ineffective, suggest that the woman use a bulk-forming laxative such as Metamucil.

Nasal Stuffiness, Bleeding Gums, Epistaxis

Increased levels of estrogen cause edema of the mucous membranes of the nasal and oral cavities. Advise the woman to drink extra water for hydration of the mucous membranes or to use a cool mist humidifier in her bedroom at night. If she needs to blow her nose to relieve nasal stuffiness, advise her to blow gently, one nostril at a time. Advise her to avoid the use of nasal decongestants and sprays.

If a nosebleed occurs, advise the woman to loosen the clothing around her neck, sit with her head tilted forward, pinch her nostrils with her thumb and forefinger for 10 to 15 minutes, and apply an ice pack to the bridge of her nose.

If the woman has bleeding gums, encourage her to practice good oral hygiene by using a soft toothbrush and flossing daily. Warm saline mouthwashes can relieve discomfort. If the gum problem persists, instruct her to see her dentist.

Cravings

Desires for certain foods and beverages are likely to begin during the first trimester but do not appear to reflect any

physiologic need. Foods with a high sodium or sugar content often are the ones craved. At times, some women crave non-food substances such as clay, cornstarch, laundry detergent, baking soda, soap, paint chips, dirt, ice, or wax. This craving for non-food substances, termed pica, may indicate a severe dietary deficiency of minerals or vitamins, or it may have cultural roots (Lynch, 2007). Pica is discussed in Chapter 11.

Leukorrhea

Increased vaginal discharge begins during the first trimester and continues throughout pregnancy. The physiologic changes behind leukorrhea arise from the high levels of estrogen, which cause increased vascularity and hypertrophy of cervical glands as well as vaginal cells (Cunningham et al., 2005). The result is progressive vaginal secretions throughout pregnancy.

Advise the woman to keep the perineal area clean and dry, washing the area with mild soap and water during her daily shower. Also recommend that she avoid wearing pantyhose and other tight-fitting nylon clothes that prevent air from circulating to the genital area. Encourage the use of cotton underwear and suggest wearing a nightgown rather than pajamas to allow for increased airflow. Also instruct the woman to avoid douching and tampon use.

Second-Trimester Discomforts

A sense of well-being typically characterizes the second trimester for most women. By this time, the fatigue, nausea, and vomiting have subsided and the uncomfortable changes of the third trimester are a few months away. Not every woman experiences the same discomforts during this time, so nursing assessments and interventions must be individualized.

Backache

Backache, experienced by many women during the second trimester, is due to a shift in the center of gravity caused by the enlarging uterus. Muscle strain results. In addition, a high level of circulating progesterone softens cartilage and loosens joints, thus increasing discomfort. Upper back pain also can be caused by increased breast size (ACOG, 2007b).

After exploring other reasons that might cause backache, such as uterine contractions, urinary tract infection, ulcers, or musculoskeletal back disorders, the following instructions may be helpful:

- Maintain correct posture, with head up and shoulders back.
- Wear low-heeled shoes with good arch support.
- When standing for long periods, place one foot on a stool or box.
- Use good body mechanics when lifting objects.
- When sitting, use foot supports and pillows behind the back.
- Try pelvic tilt or rocking exercises to strengthen the back (ACOG, 2007b).

The pelvic tilt or pelvic rock is used to alleviate pressure on the lower back during pregnancy by stretching the lower back muscles. It can be done sitting, standing, or on all fours. To do it on all fours, the hands are positioned directly under the shoulders and the knees under the hips. The back should be in a neutral position with the head and neck aligned with the straight back. The woman then presses up with the lower back and holds this position for a few seconds, then relaxes to a neutral position. This action of pressing upward is repeated frequently throughout the day to prevent a sore back (ACOG, 2007b). See Evidence-Based Practice 12.1.

Leg Cramps

Leg cramps occur primarily in the second and third trimesters and could be related to the pressure of the gravid uterus on pelvic nerves and blood vessels (Arenson & Drake, 2007). Diet can also be a contributing factor if the woman is not consuming enough of certain minerals, such as calcium and magnesium. The sudden stretching of leg muscles may also play a role in causing leg cramps (Trupin, 2006).

Encourage the woman to gently stretch the muscle by dorsiflexing the foot up toward the body. Wrapping a warm, moist towel around the leg muscle can also help the muscle to relax. Advise the client to avoid stretching her legs, pointing her toes, and walking excessively. Stress the importance of wearing low-heeled shoes and support hose and arising slowly from a sitting position. If the leg cramps are due to deficiencies in minerals, the condition can be remedied by eating more foods rich in these nutrients. Also instruct the woman on calf-stretching exercises: have her stand 3 feet from the wall and lean toward it, resting her lower arms against it, while keeping her heels on the floor. This may help reduce cramping if it is done before going to bed.

Elevating the legs throughout the day will help relieve pressure and minimize strain. Wearing support hose and avoiding curling the toes may help to relieve leg discomfort. Also instruct the client to avoid standing in one spot for a prolonged period or crossing her legs. If she must stand for prolonged periods, suggest that she change her position at least every 2 hours by walking or sitting to reduce the risk of leg cramps. Encourage her to drink eight 8-ounce glasses of fluid throughout the day to ensure adequate hydration.

Varicosities of the Vulva and Legs

Varicosities of the vulva and legs are associated with the increased venous stasis caused by the pressure of the gravid uterus on pelvic vessels and the vasodilation resulting from increased progesterone levels. Progesterone relaxes the vein walls, making it difficult for blood to return to the heart from the extremities; pooling can result. Genetic predispo-

EVIDENCE-BASED PRACTICE 12.1
Interventions for Preventing and Treating Pelvic and Back Pain in Pregnancy

● Study
More than two thirds of pregnant women experience back pain and almost one fifth experience pelvic pain. The pain increases with advancing pregnancy and interferes with work, daily activities, and sleep. Many women experience back or pelvic pain during pregnancy. This pain generally increases as pregnancy advances and it interferes with daily activities (like carrying, cleaning, sitting, and walking), can prevent women from going to work, and sometimes disturbs sleep. Suggestions to help manage the pain are varied and include special pregnancy exercises, frequent rest, hot and cold compresses, a supportive belt, massage, acupuncture, chiropractic, aromatherapy, relaxation, herbs, yoga, and Reiki. Sometimes drugs like acetaminophen have also been suggested. No studies were found dealing with the prevention of back and pelvic pain.

For treatment, the review of trials found eight studies, involving 1,305 participants, that examined the effects of various pregnancy-specific exercises, physiotherapy programs, acupuncture, and using special pillows added to usual prenatal care. They were compared to usual pregnancy care or other treatments. The quality of the studies was not the best, and so the findings should be treated with caution.

▲ Findings
The review found that specifically tailored strengthening exercises, sitting pelvic tilt exercise programs, and water gymnastics all reported beneficial effects. In addition, acupuncture seemed more effective than physiotherapy. Adverse effects, when reported, appeared minor and transient. More research is needed on this widespread problem of pregnancy.

■ Nursing Implications
Nurses can apply these findings to help pregnant women cope with and actively participate in their therapy to relieve their pelvic and back discomfort. The nurse should offer a thorough explanation of the reasons for the discomfort and then proceed to outline the effective therapies. In addition, the nurse can provide instruction and demonstrate how to go through each exercise.

Source: Pennick, V. E., & Young, G. (2007). Interventions for preventing and treating pelvic and back pain in pregnancy. *Cochrane Database of Systematic Reviews* 2007, Issue 2. Art. No.: CD001139. DOI: 10.1002/14651858.CD001139.pub2.

sition, inactivity, obesity, and poor muscle tone are contributing factors.

Encourage the client to wear support hose and teach her how to apply them properly. Advise her to elevate her legs above her heart while lying on her back for 10 minutes before she gets out of bed in the morning, thus promoting venous return before she applies the hose. Instruct the client to avoid crossing her legs and avoid wearing knee-high stockings. They cause constriction of leg vessels and muscles and contribute to venous stasis. Also encourage the client to elevate both legs above the level of the heart for 5 to 10 minutes at least twice a day (Fig. 12.10); to wear low-heeled shoes; and to avoid long periods of standing or sitting, frequently changing her position. If the client has vulvar varicosities, suggest she apply ice packs to the area when she is lying down. See Evidence-Based Practice 12.2.

Hemorrhoids
Hemorrhoids are varicosities of the rectum and may be external (outside the anal sphincter) or internal (above the sphincter) (ACOG, 2007d). They occur as a result of progesterone-induced vasodilation and from pressure of the enlarged uterus on the lower intestine and rectum. Hemorrhoids are more common in women with constipation, poor fluid intake or poor dietary habits, smokers, or those with a previous history of hemorrhoids (Arenson & Drake, 2007).

Instruct the client in measures to prevent constipation, including increasing fiber intake and drinking at least 2 liters of fluid per day. Recommend the use of topical anesthetics (e.g., Preparation H, Anusol, witch hazel compresses) to reduce pain, itching, and swelling, if permitted by the health care provider. Teach the client about local comfort measures such as warm sitz baths, witch hazel compresses, or cold compresses. To minimize her risk of straining while defecating, suggest that she elevate her feet on a stool. Also encourage her to avoid prolonged sitting or standing (ACOG, 2007d).

Flatulence With Bloating
The physiologic changes that result in constipation (reduced gastrointestinal motility and dilation secondary to progesterone's influence) may also result in increased flatulence. As the enlarging uterus compresses the bowel, it delays the passage of food through the intestines, thus allowing more time for gas to be formed by bacteria in

FIGURE 12.10 Woman elevating her legs while working.

the colon. The woman usually reports increased passage of rectal gas, abdominal bloating, or belching. Instruct the woman to avoid gas-forming foods, such as beans, cabbage, and onions, as well as foods that have a high content of white sugar. Adding more fiber to the diet, increasing fluid intake, and increasing physical exercise are also helpful in reducing flatus. In addition, reducing the swallowing of air when chewing gum or smoking will reduce gas build-up. Reducing the intake of carbonated beverages and cheese and eating mints can also help reduce flatulence during pregnancy (Trupin, 2006).

Third-Trimester Discomforts

As women enter their third trimester, many experience a return of the first-trimester discomforts of fatigue, urinary frequency, leukorrhea, and constipation. These discomforts are secondary to the ever-enlarging uterus compressing adjacent structures, increasing hormone

EVIDENCE-BASED PRACTICE 12.2
Interventions for Varicose Veins and Leg Edema in Pregnancy

● Study

Pregnancy is presumed to be a major contributory factor in the increased incidence of varicose veins in women, which can in turn lead to venous insufficiency and leg edema. The most common symptom of varicose veins and edema is substantial pain, as well as night cramps, numbness, and tingling; also, the legs may feel heavy and achy and the veins may be unsightly.

Varicose veins, sometimes called varicosity, occur when a valve in the blood vessel walls weakens and the blood stagnates. This leads to problems with the circulation in the veins and to edema or swelling. The vein then becomes distended and its walls stretch and sag, allowing the vein to swell into a tiny balloon near the surface of the skin. The veins in the legs are most commonly affected as they are working against gravity, but the vulva (vaginal opening) or rectum, resulting in hemorrhoids (piles), can be affected too.

Treatment of varicose veins is usually divided into three main groups: surgery, pharmacological, and non-pharmacological treatments. Treatment for leg edema mostly involves symptom reduction rather than cure and uses pharmacological and non-pharmacological approaches.

The review identified three trials involving 159 women. Although the drug rutoside seemed to be effective in reducing symptoms, the study was too small to be able to say this with real confidence. Similarly, with compression stockings and reflexology, there were insufficient data to be able to assess benefits and harms, but they looked promising. More research is needed.

▲ Findings

Rutoside appears to relieve the symptoms of varicose veins in late pregnancy. However, this finding is based on one small study (69 women), and there are not enough data presented in the study to assess its safety in pregnancy. It therefore cannot be routinely recommended. Reflexology appears to improve symptoms for women with leg edema, but again this is based on one small study (43 women). External compression stockings do not appear to have any advantages in reducing edema.

■ Nursing Implications

Nurses can use this evidence to instruct women about varicose veins and outline the various therapies available to treat them. It is not clear that any of the therapies are totally successful in relieving the discomfort associated with varicose veins, based on this analysis, but comfort therapies can be covered to help with the discomfort. Maintaining an ideal weight gain throughout the pregnancy will also help reduce the risk of varicose vein formation.

Source: Bamigboye, A. A., & Smyth, R. (2007). Interventions for varicose veins and leg edema in pregnancy. *Cochrane Database of Systematic Reviews* 2007, Issue 1. Art. No.: CD001066. DOI: 10.1002/14651858.CD001066.pub2.

levels, and the metabolic demands of the fetus. In addition to these discomforts, many women experience shortness of breath, heartburn and indigestion, swelling, and Braxton Hicks contractions.

Shortness of Breath and Dyspnea

The increasing growth of the uterus prevents complete lung expansion late in pregnancy. As the uterus enlarges upward, the expansion of the diaphragm is limited. Dyspnea can occur when the woman lies on her back and the pressure of the gravid uterus against the vena cava reduces venous return to the heart (Arenson & Drake, 2007).

Explain to the woman that dyspnea is normal and will improve when the fetus drops into the pelvis (lightening). Instruct her to adjust her body position to allow for maximum expansion of the chest and to avoid large meals, which increase abdominal pressure. Raising the head of the bed on blocks or placing pillows behind her back is helpful too. In addition, stress that lying on her side will displace the uterus off the vena cava and improve her breathing. Advise the woman to avoid exercise that precipitates dyspnea, to rest after exercise, and to avoid overheating in warm climates. If she still smokes, encourage her to stop.

Heartburn and Indigestion

Heartburn and indigestion result when high progesterone levels cause relaxation of the cardiac sphincter, allowing food and digestive juices to flow backward from the stomach into the esophagus. Irritation of the esophageal lining occurs, causing the burning sensation known as heartburn. It occurs in up to 70% of women at some point during pregnancy, with an increased frequency seen in the third trimester (Blackburn, 2007). The pain may radiate to the neck and throat. It worsens when the woman lies down, bends over after eating, or wears tight clothes. Indigestion (vague abdominal discomfort after meals) results from eating too much or too fast; from eating when tense, tired, or emotionally upset; from eating food that is too fatty or spicy; and from eating heavy food or food that has been badly cooked or processed (Trupin, 2006). In addition, the stomach is displaced upward and compressed by the large uterus in the third trimester, thus limiting the stomach's capacity to empty quickly. Food sits, causing heartburn and indigestion.

Review the client's usual dietary intake and suggest that she limit or avoid gas-producing or fatty foods and large meals. Encourage the client to maintain proper posture and remain in the sitting position for 1 to 3 hours after eating to prevent reflux of gastric acids into the esophagus by gravity. Urge the client to eat slowly, chewing her food thoroughly to prevent excessive swallowing of air, which can lead to increased gastric pressure. Instruct the client to avoid highly spiced foods, chocolate, coffee, alcohol, sodas, and spearmint or peppermint. These items stimulate the release of gastric digestive acids, which may cause reflux into the esophagus. Avoid late-night or large meals and gum chewing.

Dependent Edema

Swelling is the result of increased capillary permeability caused by elevated hormone levels and increased blood volume. Sodium and water are retained and thirst increases. Edema occurs most often in dependent areas such as the legs and feet throughout the day due to gravity; it improves after a night's sleep. Warm weather or prolonged standing or sitting may increase edema. Generalized edema, appearing in the face, hands, and feet, can signal preeclampsia if accompanied by dizziness, blurred vision, headaches, upper quadrant pain, or nausea (Trupin, 2006). This edema should be reported to the health care provider.

Appropriate suggestions to minimize dependent edema include:

- Elevate your feet and legs above the level of the heart.
- Wear support hose when standing or sitting for long periods.
- Change position frequently throughout the day.
- Walk at a sensible pace to help contract leg muscles to promote venous return.
- When taking a long car ride, stop to walk around every 2 hours.
- When standing, rock from the ball of the foot to the toes to stimulate circulation.
- Lie on your left side to keep the gravid uterus off the vena cava to return blood to the heart.
- Avoid foods high in sodium, such as lunch meats, potato chips, and bacon.
- Avoid wearing knee-high stockings.
- Drink six to eight glasses of water daily to replace fluids lost through perspiration.
- Avoid high intake of sugar and fats, because they cause water retention.

Braxton Hicks Contractions

Braxton Hicks contractions are irregular, painless contractions that occur without cervical dilation. Typically they intensify in the third trimester in preparation for labor. In reality, they have been present since early in the pregnancy but may have gone unnoticed. They are thought to increase the tone of uterine muscles for labor purposes (ACOG, 2007e).

Reassure the client that these contractions are normal. Instruct the client in how to differentiate between Braxton Hicks and labor contractions. Explain that true labor contractions usually grow longer, stronger, and closer together and occur at regular intervals. Walking usually strengthens true labor contractions, whereas Braxton Hicks contractions tend to decrease in intensity and taper off. Advise the client to keep herself well hydrated and to rest in a side-lying position to help relieve the discomfort. Suggest that she use breathing techniques such as Lamaze techniques to ease the discomfort.

▶ *Consider* THIS!

One has to wonder sometimes why women go through what they do. During my first pregnancy I was sick for the first 2 months. I would experience waves of nausea from the moment I got out of bed until midmorning. Needless to say, I wasn't the happiest camper around. After the third month, my life seemed to settle down and I was beginning to think that being pregnant wasn't too bad after all. For the moment, I was fooled. Then, during my last 2 months, another wave of discomfort struck—heartburn and constipation—a double whammy! I now feared eating anything that might trigger acid indigestion and also might remain in my body too long. I literally had to become the "fiber queen" to combat these two challenges. Needless to say, my "suffering" was well worth our bright-eyed baby girl in the end.

Thoughts: Despite the various discomforts associated with pregnancy, most women wouldn't change their end result. Do most women experience these discomforts? What suggestions could be made to reduce them?

Nursing Management to Promote Self-Care

Pregnancy is considered a time of health, not illness. Health promotion and maintenance activities are key to promoting an optimal outcome for the woman and her fetus.

Pregnant women commonly have many questions about the changes occurring during pregnancy, how these changes affect their usual routine, such as working, traveling, exercising, or engaging in sexual activity, how the changes influence their typical self-care activities, such as bathing, perineal care, or dental care, and whether these changes are signs of a problem.

▶ *Take* NOTE!

Women may have heard stories about or been told by others what to do and what not to do during pregnancy, leading to many misconceptions and much misinformation.

Nurses can play a major role in providing anticipatory guidance and teaching to foster the woman's responsibility for self-care, helping to clarify misconceptions and correct any misinformation. Educating the client to identify threats to safety posed by her lifestyle or environment and proposing ways to modify them to avoid a negative outcome are important. Counseling should also include healthy ways to prepare food, advice to avoid medications unless they are prescribed for her, and advice on identifying teratogens within her environment or at work and how to reduce her risk from exposure. The pregnant client can better care for herself and the fetus if her concerns are anticipated and identified by the nurse and are incorporated into teaching sessions at each prenatal visit.

Personal Hygiene

Hygiene is a necessity for the maintenance of good health. Cleansing the skin removes dirt, bacteria, sweat, dead skin cells, and body secretions. Counsel women to wash their hands frequently throughout the day to lower the bacterial count on their hands and under their fingernails. During pregnancy a woman's sebaceous (sweat) glands become more active under the influence of hormones, and sweating is more profuse. This increase may make it necessary to use a stronger deodorant and shower more frequently. The cervical and vaginal glands also produce more secretions during pregnancy. Frequent showering helps to keep the area dry and promotes better hygiene. Encourage the use of cotton underwear to allow greater air circulation. Taking a tub bath in early pregnancy is permitted, but closer to term, when the woman's center of gravity shifts, it is safer to shower to prevent the risk of slipping.

Hot Tubs and Saunas

Caution pregnant women to avoid using hot tubs, saunas, whirlpools, and tanning beds during pregnancy. The heat may cause fetal tachycardia as well as raise the maternal temperature. Exposure to bacteria in hot tubs that have not been cleaned sufficiently is another reason to avoid them during pregnancy.

Perineal Care

The glands in the cervical and vaginal areas become more active during pregnancy secondary to hormonal influences. This increase in activity will produce more vaginal secretions, especially in the last trimester. Advise pregnant women to shower frequently and wear all-cotton underwear to minimize the effects of these secretions. Caution pregnant women not to douche, because douching can increase the risk of infection, and not to wear panty liners, which block air circulation and promote moisture. Explain that they should also avoid perfumed soaps, lotions, perineal sprays, and harsh laundry detergents to help prevent irritation and potential infection.

Dental Care

Research has established that the elevated levels of estrogen and progesterone during pregnancy cause women to be more sensitive to the effects of bacterial dental plaque, which can cause gingivitis, an oral infection character-

ized by swollen and bleeding gums (Hackley, Kriebs, & Rousseau, 2007). Brushing and flossing teeth twice daily will help reduce bacteria in the mouth. Advise the woman to visit her dentist early in the pregnancy to address any dental caries and have a thorough cleaning to prevent possible infection later in the pregnancy. Advise her to avoid exposure to x-rays by informing the hygienist of the pregnancy. If x-rays are necessary, the abdomen should be shielded with a lead apron.

Researchers are exploring a link between prematurity and periodontitis, an oral infection that spreads beyond the gum tissues to invade the supporting structures of the teeth. Periodontitis is characterized by bleeding gums, loss of tooth attachment, loss of supporting bone, and bad breath due to pus formation. Unfortunately, because this infection is chronic and often painless, women frequently don't realize they have it. Additional guidelines that the nurse should stress regarding maintaining dental health include:

- Seek professional dental care during the first trimester for assessment and care.
- Obtain treatment for dental pain and infection promptly during pregnancy.
- Brush twice daily for 2 minutes, especially before bed, with fluoridated toothpaste and rinse well. Use a soft-bristled toothbrush and be sure to brush at the gum line to remove food debris and plaque to keep gums healthy.
- Eat healthy foods, especially those high in vitamins A, C, and D and calcium.
- Avoid sugary snacks.
- Chew sugar-free gum for 10 minutes after a meal if brushing isn't possible.
- After vomiting, rinse your mouth immediately with baking soda (¼ teaspoon) and warm water (1 cup) to neutralize the acid (Hackley, Kriebs, & Rousseau, 2007).

Breast Care

Since the breasts enlarge significantly and become heavier throughout pregnancy, stress the need to wear a firm, supportive bra with wide straps to balance the weight of the breasts. Instruct the woman to anticipate buying a larger-sized bra about halfway through her pregnancy because of the increasing size of the breasts. Advise her to avoid using soap on the nipple area because it can be very drying. Encourage her to rinse the nipple area with plain water while bathing to keep it clean. The Montgomery glands secrete a lubricating substance that keeps the nipples moist and discourages growth of bacteria, so there is no need to use alcohol or other antiseptics on the nipples.

If the mother has chosen to breastfeed, nipple preparation is unnecessary unless her nipples are inverted and do not become erect when stimulated. Breast shells can be worn during the last 2 months to address this issue (Alexander et al., 2007).

Around week 16 of pregnancy, colostrum secretion begins, which the woman may notice as moisture in her bra. Advise the woman to place breast pads or a cotton cloth in her bra and change them frequently to prevent build-up, which may lead to excoriation.

Clothing

Many contemporary clothes are loose-fitting and layered, so the woman may not need to buy an entirely new wardrobe to accommodate her pregnancy. Some pregnant women may continue to wear tight clothes. Point out that loose clothing will be more comfortable for the client and her expanding waistline.

Advise pregnant women to avoid wearing constricting clothes and girdles that compress the growing abdomen. Urge the woman to avoid knee-high hose, which might impede lower-extremity circulation and increase the risk of developing deep vein thrombosis. Low-heeled shoes will minimize pelvic tilt and possible backache. Wearing layered clothing may be more comfortable, especially toward term, when the woman may feel overheated.

Exercise

Exercise is well tolerated by a healthy woman during pregnancy. It promotes a feeling of well-being, improves circulation, helps reduce constipation, bloating, and swelling, increases energy level, improves posture, helps sleep, promotes relaxation and rest, and relieves the lower back discomfort that often arises as the pregnancy progresses (ACOG, 2007h). However, the duration and difficulty of exercise should be modified throughout pregnancy because of a decrease in performance efficiency with gestational age. Some women continue to push themselves to maintain their prior level of exercise, but most find that as their shape changes and their abdominal area enlarges, they must modify their exercise routines. Modification also helps to reduce the risk of injury caused by laxity of the joints and connective tissue due to the hormonal effects (ACOG, 2007h).

Exercise during pregnancy is contraindicated in women with preterm labor, poor weight gain, anemia, facial and hand edema, pain, hypertension, threatened abortion, dizziness, shortness of breath, incompetent cervix, multiple gestation, decreased fetal activity, cardiac disease, and palpitations (Trupin, 2006).

ACOG has stated that healthy pregnant women can perform the same activity recommended for the general population: 30 minutes or more of moderate exercise every day (ACOG, 2007h; Fig. 12.11). It is believed that pregnancy is a unique time for behavior modification and that healthy behaviors maintained or adopted during

FIGURE 12.11 Exercising during pregnancy.

pregnancy may improve the woman's health for the rest of her life. The excess weight gained in pregnancy, which some women never lose, is a major public health problem (Trupin, 2006). Exercise helps the woman avoid gaining excess weight during pregnancy.

Exercise during pregnancy helps return a woman's body to good health after the baby is born. The long-term benefits of exercise that begin in early pregnancy include improved posture, weight control, and improved muscle tone; exercise also aids in the prevention of osteoporosis after menopause and assists in keeping the birthweight of the fetus within the normal range (Perkins et al., 2007). Teaching Guidelines 12.2 highlights recommendations for exercise during pregnancy.

Sleep and Rest

Getting enough sleep helps a person feel better and promotes optimal performance levels during the day. The body releases its greatest concentration of growth hormone during sleep, helping the body to repair damaged tissue and grow. Also, with the increased metabolic demands during pregnancy, fatigue is a constant challenge to many pregnant women, especially during the first and third trimesters.

The following tips can help promote adequate sleep:

- Stay on a regular schedule by going to bed and waking up at the same times.
- Eat regular meals at regular times to keep external body cues consistent.
- Take time to unwind and relax before bedtime.
- Establish a bedtime routine or pattern and follow it.
- Create a proper sleep environment by reducing the light and lowering the room temperature.

TEACHING GUIDELINES 12.2

Teaching to Promote Exercise During Pregnancy

- Consume liquids before, during, and after exercising.
- Exercise three or four times each week, not sporadically.
- Engage in brisk walking, swimming, biking, or low-impact aerobics; these are considered ideal activities.
- Avoid getting overheated during exercise.
- Reduce the intensity of workouts in late pregnancy.
- Avoid jerky, bouncy, or high-impact movements.
- Avoid lying flat (supine) after the fourth month because of hypotensive effect.
- Use pelvic tilt and pelvic rocking to relieve backache.
- Start with 5 to 10 minutes of stretching exercises.
- Rise slowly following an exercise session to avoid dizziness.
- Avoid activities such as skiing, surfing, scuba diving, and ice hockey.
- Never exercise to the point of exhaustion.

Sources: ACOG (2007b); AAFP (2008); APA (2008).

- Go to bed when you feel tired; if sleep doesn't occur, read a book until you are sleepy.
- Reduce caffeine intake later in the day.
- Limit fluid intake after dinner to minimize trips to the bathroom.
- Exercise daily to improve circulation and well-being.
- Use a modified Sims position to improve circulation in the lower extremities.
- Avoid lying on your back after the fourth month, which may compromise circulation to the uterus.
- Avoid sharply bending your knees, which promotes venous stasis below the knees.
- Keep anxieties and worries out of the bedroom. Set aside a specific area in the home or time of day for them.

Sexual Activity and Sexuality

Pregnancy is characterized by intense biological, psychological, and social changes. These changes have direct and indirect, conscious and unconscious effects on a woman's sexuality. The woman experiences dramatic alterations in her physiology, her appearance, and her body, as well as her relationships. A woman's sexual responses during pregnancy vary widely. Common symptoms such as fatigue, nausea, vomiting, breast soreness, and urinary frequency may reduce her desire for sexual intimacy. However, many women report enhanced sexual desire due to increasing levels of estrogen.

▶ *Take* NOTE!

Fluctuations in sexual desire are normal and a highly individualized response throughout pregnancy.

The physical and emotional adjustments of pregnancy can cause changes in body image, fatigue, mood swings, and sexual activity. The woman's changing shape, emotional status, fetal activity, changes in breast size, pressure on the bladder, and other common discomforts of pregnancy result in increased physical and emotional demands. These can produce stress on the sexual relationship of the pregnant woman and her partner. However, most women adjust well to the alterations and experience a satisfying sexual relationship (ACOG, 2007c).

Often pregnant women ask whether sexual intercourse is allowed during pregnancy or whether there are specific times when they should refrain from having sex. This is a good opportunity to educate clients about sexual behavior during pregnancy and also to ask about their expectations and individual experience related to sexuality and possible changes. It is also a good time for nurses to address the impact of the changes associated with pregnancy on sexual desire and behavior. For example, some women experience increased sexual desire while others experience less. Couples may enjoy sexual activity more because there is no fear of pregnancy and no need to disrupt spontaneity by using birth control. An increase in pelvic congestion and lubrication secondary to estrogen influence may heighten orgasm for many women. Some women have a decrease in desire because of a negative body image, fear of harming the fetus by engaging in intercourse, and fatigue, nausea, and vomiting (Trupin, 2006). A couple may need assistance to adjust to the various changes brought about by pregnancy.

Reassure the women and her partner that sexual activity is permissible during pregnancy unless there is a history of any of the following:

- Vaginal bleeding
- Placenta previa
- Risk of preterm labor
- Multiple gestation
- Incompetent cervix
- Premature rupture of membranes
- Presence of infection (Trupin, 2006)

Inform the couple that the fetus will not be injured by intercourse. Suggest that alternative positions may be more comfortable (e.g., woman on top, side-lying), especially during the later stages of pregnancy.

Many women feel a particular need for closeness during pregnancy, and the woman should communicate this need to her partner (Thies & Travers, 2006). Emphasize to the couple that closeness and cuddling need not culminate in intercourse, and that other forms of sexual expression, such as mutual masturbation, foot massage, holding hands, kissing, and hugging can be very satisfying (Thies & Travers, 2006).

Women will experience a myriad of symptoms, feelings, and physical sensations during their pregnancy. Having a satisfying sexual relationship during pregnancy is certainly possible, but it requires honest communication between partners to determine what works best for them, and a good relationship with their health care provider to ensure safety (March of Dimes, 2007a).

Employment

For the most part, women can continue working until delivery if they have no complications during their pregnancy and the workplace does not present any special hazards (ACOG, 2007a). Hazardous occupations include health care workers, daycare providers, laboratory technicians, chemists, painters, hairstylists, veterinary workers, and carpenters (ACOG, 2007a). Jobs requiring strenuous work such as heavy lifting, climbing, carrying heavy objects, and standing for prolonged periods place a pregnant woman at risk if modifications are not instituted.

Assess for environmental and occupational factors that place a pregnant women and her fetus at risk for

injury. Interview the woman about her employment environment. Ask about possible exposure to teratogens (substances with the potential to alter the fetus permanently in form or function) and the physical demands of employment: Is she exposed to temperature extremes? Does she need to stand for prolonged periods in a fixed position? A description of the work environment is important in providing anticipatory guidance to the woman. Stress the importance of taking rest periods throughout the day, because constant physically intensive workloads increase the likelihood of low birthweight and preterm labor and birth (Cunningham et al., 2005).

Due to the numerous physiologic and psychosocial changes that women experience during their pregnancies, the employer may need to make special accommodations to reduce the pregnant woman's risk of hazardous exposures and heavy workloads. The employer may need to provide adequate coverage so that the woman can take rest breaks; remove the woman from any areas where she might be exposed to toxic substances; and avoid work assignments that require heavy lifting, hard physical labor, continuous standing, or constant moving. Some recommendations for working while pregnant are given in Teaching Guidelines 12.3.

Travel

Pregnancy does not curtail a woman's ability to travel in a car or in a plane. However, women should follow a few safety guidelines to minimize risk to themselves and their fetuses. According to ACOG, pregnant women can travel safely throughout their pregnancy, although the second trimester is perhaps the best time to travel because there is the least chance of complications (ACOG, 2007f). Pregnant women considering international travel should evaluate the problems that could occur during the journey as well as the quality of medical care available at the destination.

▶ ***Take*** NOTE!

In general, pregnant women with serious underlying illnesses should not travel to developing countries (CDC, 2007c).

Advise pregnant women to be aware of the potential for injuries and trauma related to traveling, and teach women ways to prevent these from occurring. Teaching Guidelines 12.4 offers tips for safe travel on planes and to foreign areas.

When traveling by car, the major risk is a car accident. The impact and momentum can lead to traumatic separation of the placenta from the wall of the uterus. Shock and massive hemorrhage might result (Trupin, 2006). Tips that nurses can offer to promote safety during ground travel include:

- Always wear a three-point seat belt, no matter how short the trip, to prevent ejection or serious injury from collision.
- Apply a nonpadded shoulder strap properly; it should cross between the breasts and over the upper abdomen, above the uterus (Fig. 12.12).
- If no seat belts are available (buses or vans), ride in the back seat of the vehicle.
- Use a lap belt that crosses over the pelvis below the uterus.
- Deactivate the airbag if possible. If you can't, move the seat as far back from the dashboard as possible to minimize impact on the abdomen.
- Avoid using a cellular phone while driving to prevent distraction.
- Avoid driving when very fatigued in the first and third trimesters.
- Avoid late-night driving, when visibility might be compromised.
- Direct a tilting steering wheel away from the abdomen (Hackley, Kriebs, & Rousseau, 2007).

Immunizations and Medications

Ideally, clients should receive all childhood immunizations before conception to protect the fetus from any risk of congenital anomalies. If the client comes for a preconception visit, discuss immunizations such as measles, mumps, and rubella (MMR), hepatitis B, and diphtheria/tetanus (every 10 years); administer them at this time if needed.

TEACHING GUIDELINES 12.3

Teaching for the Pregnant Working Woman

- Plan to take two 10- to 15-minute breaks within an 8-hour workday.
- Be sure there is a place available for you to rest, preferably in the side-lying position, with a restroom readily available.
- Avoid jobs that require strenuous workloads; if this is not possible, then request a modification of work duties (lighter tasks) to reduce your workload.
- Change your position from standing to sitting or vice versa at least every 2 hours.
- Ensure that you are allowed time off without penalty, if necessary, to ensure a healthy outcome for you and your fetus.
- Make sure the work environment is free of toxic substances.
- Ensure the work environment is smoke-free so passive smoking isn't a concern.
- Minimize heavy lifting if associated with bending.

TEACHING GUIDELINES 12.4

Teaching to Promote Safe Travel on Planes and in Foreign Countries

- Bring along a copy of the prenatal record if your travel will be prolonged in case there is a medical emergency away from home.
- When traveling abroad, carry a foreign dictionary that includes words or phrases for the most common pregnancy emergencies.
- Travel with at least one companion at all times for personal safety.
- Check with your health care provider before receiving any immunizations necessary for foreign travel; some may be harmful to the fetus.
- When in a foreign country, avoid fresh fruit, vegetables, and local water.
- Avoid any milk that is not pasteurized.
- Eat only meat that is well cooked to avoid exposure to toxoplasmosis.
- Request an aisle seat and walk about the airplane every 2 hours.
- While sitting on long flights, practice calf-tensing exercises to improve circulation to the lower extremities.
- Be aware of typical problems encountered by pregnant travelers, such as fatigue, heartburn, indigestion, constipation, vaginal discharge, leg cramps, urinary frequency, and hemorrhoids.
- Always wear support hose while flying to prevent the development of blood clots.
- Drink plenty of water to keep well hydrated throughout the flight.

Sources: ACOG (2007f); APA (2008).

The risk to a developing fetus from vaccination of the mother during pregnancy is primarily theoretical. Routine immunizations are not usually indicated during pregnancy. However, no evidence exists of risk from vaccinating pregnant women with inactivated virus or bacterial vaccines or toxoids. A number of other vaccines have not been adequately studied, and thus theoretical risks of vaccination must be weighed against the risks of the disease to mother and fetus (Hackley, Kriebs, & Rousseau, 2007).

▶ *Take* NOTE!

Advise pregnant women to avoid live virus vaccines (MMR and varicella) and to avoid becoming pregnant within 1 month of having received one of these vaccines because of the theoretical risk of transmission to the fetus (CDC, 2007a).

FIGURE 12.12 Proper application of a seat belt during pregnancy.

CDC guidelines for vaccine administration are highlighted in Box 12.4.

It is best for pregnant women not to take any medications. At the very least, encourage them to discuss with the health care provider their current medications and any herbal remedies they take so that they can learn about any potential risks should they continue to take them during pregnancy. Generally, if the woman is taking medicine for seizures, high blood pressure, asthma, or depression,

BOX 12.4 CDC Guidelines for Vaccine Administration During Pregnancy

Vaccines That Should be Considered If Otherwise Indicated

- Hepatitis B
- Influenza (inactivated)
- Tetanus/diphtheria
- Meningococcal
- Rabies

Vaccines Contraindicated During Pregnancy

- Influenza (live, attenuated vaccine)
- Measles
- Mumps
- Rubella
- Varicella

Sources: CDC (2007a); March of Dimes (2008); Future Medicine (2007).

the benefits of continuing the medicine during pregnancy outweigh the risks to the fetus. The safety profile of some medications may change according to the gestational age of the fetus (Trupin, 2006).

The Food and Drug Administration has developed a system of ranking drugs that appears on the labels and in the package inserts. These risk categories are summarized in Box 12.5. Always advise women to check with the health care provider for guidance.

A common concern of many pregnant women involves the use of over-the-counter medications and herbal agents. Many women consider these products benign simply because they are available without a prescription (Cragan et al., 2006). While herbal medications are commonly thought of as "natural" alternatives to other medicines, they can be just as potent as some prescription medications. A major concern about herbal medicine is the lack of consistent potency in the active ingredients in any given batch of product, making it difficult to know the exact strength by reading the label. Also, many herbs contain chemicals that cross the placenta and may cause harm to the fetus.

BOX 12.5 FDA Pregnancy Risk Classification of Drugs

- Category A: These drugs have been tested and found safe during pregnancy. Examples: folic acid, vitamin B6, and thyroid medicine.
- Category B: These drugs have been used frequently during pregnancy and do not appear to cause major birth defects or other fetal problems. Examples: antibiotics, acetaminophen (Tylenol), aspartame (artificial sweetener), famotidine (Pepcid), prednisone (cortisone), insulin, and ibuprofen.
- Category C: These drugs are more likely to cause problems and safety studies have not been completed. Examples: prochlorperazine (Compazine), fluconazole (Diflucan), ciprofloxacin (Cipro), and some antidepressants.
- Category D: These drugs have clear health risks for the fetus. Examples: alcohol, lithium (treats bipolar disorders), phenytoin (Dilantin); all chemotherapeutic agents used to treat cancer.
- Category X: These drugs have been shown to cause birth defects and should never be taken during pregnancy. Examples: Accutane (treats cystic acne), androgens (treat endometriosis), Coumadin (prevents blood clots), antithyroid medications for overactive thyroid; radiation therapy (cancer treatment), Tegison or Soriatane (treats psoriasis), streptomycin (treats tuberculosis); thalidomide (treats insomnia), diethylstilbestrol (DES) (treats menstrual disorders), and organic mercury from contaminated food.

Sources: Trupin (2006); USDHHS (2007).

Nurses are often asked about the safety of over-the-counter medicines and herbal agents. Unfortunately, many drugs have not been evaluated in controlled studies, and it is difficult to make general recommendations for these products. Therefore, encourage pregnant women to check with their health care provider before taking anything. Questions about the use of over-the-counter and herbal products are part of the initial prenatal interview.

Nursing Management to Prepare the Woman and Her Partner for Labor, Birth, and Parenthood

Childbirth today is a very different experience from childbirth in previous generations. In the past, women were literally "put to sleep" with anesthetics, and they woke up with a baby. Most women never remembered the details and had a passive role in childbirth as the physician delivered the newborn. In the 1950s, consumers began to insist on taking a more active role in their health care, and couples desired to be together during the extraordinary event of childbirth. Beginning in the 1970s, the father or significant other support person remained with the mother throughout labor and birth (Lleras, 2007).

Childbirth education began because women demanded to become more involved in their birthing experience rather than simply turning control over to a health care provider. Nurses played a pivotal role in bringing about this change by providing information and supporting clients and their families, fostering a more active role in preparing for the upcoming birth.

Traditional childbirth education classes focused on developing and practicing techniques for use in managing pain and facilitating the progress of labor. Recently, the focus of this education has broadened: it now encompasses not only preparation for childbirth, but also preparation for breastfeeding, infant care, transition to new parenting roles, relationship skills, family health promotion, and sexuality (Risica & Phipps, 2007). The term used to describe this broad range of topics is **perinatal education**. Subjects commonly addressed in perinatal education include:

- Anatomy and physiology of reproduction
- Fetal growth and development
- Prenatal maternal exercise
- Physiologic and emotional changes during pregnancy
- Sex during pregnancy
- Infant growth and development
- Nutrition and healthy eating habits during pregnancy
- Teratogens and their impact on the fetus
- Signs and symptoms of labor
- Preparation for labor and birth (for parents, siblings, and other family members)
- Options for birth
- Infant nutrition, including preparation for breastfeeding
- Infant care, including safety, CPR, and first aid
- Family planning (March of Dimes, 2007b)

Childbirth Education Classes

Childbirth education classes teach pregnant women and their support person about pregnancy, birth, and parenting. The classes are offered in local communities or online and are usually taught by certified childbirth educators.

Most childbirth classes support the concept of **natural childbirth** (a birth without pain-relieving medications) so that the woman can be in control throughout the experience as much as possible. The classes differ in their approach to specific comfort techniques and breathing patterns. The three most common childbirth methods are the Lamaze (psychoprophylactic) method, the Bradley (partner-coached childbirth) method, and the Dick-Read (natural childbirth) method.

Lamaze Method

Lamaze is a psychoprophylactic ("mind prevention") method of preparing for labor and birth that promotes the use of specific breathing and relaxation techniques. Dr. Fernand Lamaze, a French obstetrician, popularized this method of childbirth preparation in the 1960s. Lamaze believed that conquering fear through knowledge and support was important. He also believed women needed to alter the perception of suffering during childbirth. This perception change would come about by learning conditioned reflexes that, instead of signaling pain, would signal the work of producing a child, and thus would carry the woman through labor awake, aware, and in control of her own body (Leonard, 2007). Lamaze felt strongly that all women have the right to deliver their babies with minimal or no medication while maintaining their dignity, minimizing their pain, maximizing their self-esteem, and enjoying the miracle of birth.

Lamaze classes include information on toning exercises, relaxation exercises and techniques, and breathing methods for labor. The breathing techniques are used in labor to enhance relaxation and to reduce the woman's perception of pain. The goal is for women to become aware of their own comfortable rate of breathing in order to maintain relaxation and adequate oxygenation of the fetus. Breathing techniques are an effective attention-focusing strategy to reduce pain.

Paced breathing involves breathing techniques used to decrease stress responses and therefore decrease pain. This type of breathing implies self-regulation by the woman. The woman starts off by taking a cleansing breath at the onset and end of each contraction. This cleansing breath symbolizes freeing her mind from worries and concerns. This breath enhances oxygenation and puts the woman in a relaxed state.

Slow-paced breathing is associated with relaxation and should be half the normal breathing rate (six to nine breaths per minute). This type of breathing is the most relaxed pattern and is recommended throughout labor. Abdominal or chest breathing may be used. It is generally best to breathe in through the nose and breathe out either through the nose or mouth, whichever is more comfortable for the woman.

Modified-paced breathing can be used for increased work or stress during labor to increase alertness or focus attention or when slow-paced breathing is no longer effective in keeping the woman relaxed. The woman's respiratory rate increases, but it does not exceed twice her normal rate. Modified-paced breathing is a quiet upper chest breath that is increased or decreased according to the intensity of the contraction. The inhalation and the exhalation are equal. This breathing technique should be practiced during pregnancy for optimal use during labor.

Patterned-paced breathing is similar to modified-paced breathing but with a rhythmic pattern. It uses a variety of patterns, with an emphasis on the exhalation breath at regular intervals. Different patterns can be used, such as 4/1, 6/1, 4/1. A 4/1 rhythm is four upper chest breaths followed by an exhalation (a sighing out of air, like blowing out a candle). Random patterns can be chosen for use as long as the basic principles of rate and relaxation are met.

Couples practice these breathing patterns typically during the last few months of the pregnancy until they feel comfortable using them. Focal points (visual fixation on a designated object), effleurage (light abdominal massage), massage, and imagery (journey of the mind to a relaxing place) are also added to aid in relaxation. From the nurse's perspective, encourage the woman to breathe at a level of comfort that allows her to cope. Always remain quiet during the woman's periods of imagery and focal point visualization to avoid breaking her concentration.

Bradley Method (Partner-Coached)

The Bradley method uses various exercises and slow, controlled abdominal breathing to accomplish relaxation. Dr. Robert Bradley, a Denver-based obstetrician, advocated a completely unmedicated labor and birth experience. The Bradley method emphasizes the pleasurable sensations of childbirth, teaching women to concentrate on these sensations while "turning on" to their own bodies (Leonard, 2007). In 1965, he wrote *Husband-Coached Childbirth*, which advocated the active participation of the husband as labor coach.

A woman is conditioned to work in harmony with her body using breath control and deep abdominopelvic breathing to promote general body relaxation during labor. This method stresses that childbirth is a joyful, natural process and emphasizes the partner's involvement during pregnancy, labor, birth, and the early newborn period. Thus, the training techniques are directed toward the coach, not the mother. The coach is educated in massage/comfort techniques to use on the mother throughout the labor and birth process.

Dick-Read Method

In 1944 Grantly Dick-Read, a British obstetrician, wrote *Childbirth Without Fear.* He believed that the attitude of a woman toward her birthing process had a considerable influence on the ease of her labor, and he believed that fear is the primary pain-producing agent in an otherwise normal labor. He felt that fear builds a state of tension, creating an antagonistic effect on the laboring muscles of the uterus, which results in pain. Pain causes more fear, which further increases the tension, and the vicious cycle of "fear–tension–pain" is established (Leonard, 2007). Dick-Read sought to interrupt the circular pattern of fear, tension, and pain during the labor and birthing process. He promoted the belief that the degree of fear could be diminished with increased understanding of the normal physiologic response to labor (Alexander et al., 2007).

Dick-Read believed that prenatal instruction was essential for pain relief and that emotional factors during labor interfered with the normal labor progression. The woman achieves relaxation and reduces pain by arming herself with the knowledge of normal childbirth and using abdominal breathing during contractions.

Nursing Management and Childbirth Education

Childbirth education is less about methods than about mastery. The overall aim of any of the methods is to promote an internal locus of control that will enable each woman to yield her body to the process of birth. As the woman gains success and tangible benefits from the exercises she is taught, she begins to reframe her beliefs and gains practical knowledge, and the impetus will be there for her to engage in the conscious use of the techniques (Fig. 12.13). Nurses play a key role in supporting and encouraging each couple's use of the techniques taught in childbirth education classes.

Every woman's labor is unique, and it is important for nurses not to generalize or stereotype women. The most effective support a nurse can offer couples using prepared childbirth methods is encouragement and presence. These nursing measures must be adapted to each individual throughout the labor process. Offering encouraging phrases such as "great job" or "you can do it" helps to reinforce their efforts and at the same time empowers them to continue. Using eye-to-eye contact to engage the woman's total attention is important if she appears overwhelmed or appears to lose control during the transition phase of labor.

Nurses play a significant role in enhancing the couple's relationship by respecting the involvement of the partner and demonstrating concern for his needs throughout labor. Offering to stay with the woman to give him a break periodically allows him to meet his needs while at the same time still actively participating. Offer anticipatory guidance to the couple and assist during critical times in labor. Demonstrate many of the coping techniques to the partner and praise their successful use, which increases self-esteem. Focus on their strengths and the positive elements of the labor experience. Congratulating the couple for a job well done is paramount.

Throughout the labor experience, demonstrate personal warmth and project a friendly attitude. Frequently, a nurse's touch may help to prevent a crisis by reassuring the mother that she is doing fine.

Options for Birth Settings and Care Providers

From the moment a woman discovers she is pregnant, numerous decisions await her—where the infant will be born, what birth setting is best, and who will assist with the birth. The great majority of women are well and healthy and can consider the full range of birth settings—hospital, birth center, or home setting—and care providers. They should be given information about each to ensure the most informed decision.

FIGURE 12.13 A couple practicing the techniques taught in a childbirth education class.

Birth Settings

Hospitals are the most common site for birth in the United States. If the woman has a serious medical condition or is at high risk for developing one, she will probably need to plan to give birth in a hospital setting under the care of an obstetrician. Giving birth in a hospital is advantageous for several reasons. Hospitals are best equipped to diagnose and treat women and newborns with complications; trained personnel are available if necessary; and no transportation is needed if a complication should arise during labor or birth. Disadvantages include the high-tech atmosphere; strict policies and restrictions that might limit who can be with the woman; and the medical model of care.

Within the hospital setting, however, choices do exist regarding birth environments. The conventional delivery room resembles an operating room, where the health care professional delivers the newborn from the woman, who is positioned in stirrups. The woman is then transferred to the recovery area on a stretcher and then again to the postpartum unit. The birthing suite is the other option within the hospital setting. In the birthing suite, the woman and her partner remain in one place for labor, birth, and recovery. The birthing suite is a private room decorated to look as homelike as possible. For example, the bed converts to allow for various birthing positions, and there may be a rocking chair or an easy chair for the woman's partner. Despite the homey atmosphere, the room is still equipped with emergency resuscitative obstetric equipment and electronic fetal monitors in case they are needed quickly (Fig. 12.14A). Such settings provide a more personal childbirth experience in a less formal and intimidating atmosphere compared to the traditional delivery room.

A freestanding birth center (Fig. 12.14B) can be a good choice for a woman who wants more personalized care than in a hospital but does not feel comfortable with a home birth. In contrast to the institutional environment in hospitals, most freestanding birth centers have a homelike atmosphere, and many are, in fact, located in converted homes. Some are located on hospital property and are affiliated with them. Birth centers are designed to provide maternity care to women judged to be at low risk for obstetric complications. Women are allowed and encouraged to give birth in the position most comfortable for them. Care in birth centers is often provided by midwives and is more relaxed, with no routine intravenous lines, fetal monitoring, and restrictive protocols. A disadvantage of the birth center is the need to transport the woman to a hospital quickly if an emergency arises, because emergency equipment is not readily available. In a research study comparing homelike to conventional institutional settings, the author concluded that there appeared to be some benefits from homelike settings for childbirth, although increased support from caregivers may be more important (Walsh, 2007).

Most women who choose a home birth believe that birth is a natural process that requires little medical intervention (Mayor, 2007). Home births can be safe if there are qualified, experienced attendants and an emergency transfer system in place in case of serious complications. Many women choose the home setting out of a strong desire to control their child's birth and to give birth surrounded by family members. Most home birth caregivers are midwives who have provided continuous care to the woman throughout the pregnancy. Disadvantages include the need to transport the woman to the hospital during or after labor if a problem arises, and the limited pain management available in the home setting.

Care Providers

While most women in the United States still receive pregnancy care from an obstetrician, an increasing number are choosing a midwife for their care. The difference is a matter of degrees. Obstetricians must finish a 4-year residency in obstetrics and gynecology in addition to medical school. Certified nurse-midwives complete 1 to 2 years of graduate work in midwifery following nursing school. Obstetricians can handle high-risk pregnancies and delivery emergencies; can administer or order pain-relief

FIGURE 12.14 (**A**) Birthing suite. (**B**) Birthing center.

drugs; and are assisted by a support staff in the hospital setting. Midwives work in hospitals, birthing centers, and home settings to deliver care. They believe in the normalcy of birth and tolerate wide variations of what is considered normal during labor, which leads to fewer interventions applied during the childbirth process (Knowlton, 2007). They are not able to handle high-risk births and some birth emergencies.

In addition to the woman's primary health care professional, some women hire a doula to be with them during the childbearing process. Doula is a Greek word that means "woman's servant." A doula is a laywoman trained to provide women and their families with encouragement, emotional and physical support, and information through late pregnancy, labor, birth, and postpartum. Doulas provide the woman with continuous support throughout labor but do not perform any clinical procedures.

Preparation for Breastfeeding or Bottle-Feeding

Pregnant women are faced with a decision about which method of feeding to choose. Educate the pregnant client about the advantages and disadvantages of each method, allowing the woman and her partner to make an informed decision about the best method for their situation. Providing the client and her partner with this information will increase the likelihood of a successful experience regardless of the method of feeding chosen.

Breastfeeding

Substantial scientific evidence exists documenting the health benefits of breastfeeding for newborns. Human milk provides an ideal balance of nutrients for newborns (ACOG, 2006). Breastfeeding is advantageous for the following reasons:

- Human milk is digestible and economical and requires no preparation.
- Bonding between mother and child is promoted.
- Cost is less than purchasing formula.
- Ovulation is suppressed (however, this is not a reliable birth control method).
- The risk of ovarian cancer and the incidence of premenopausal breast cancer are reduced for the woman.
- Extra calories are used, which promotes weight loss gradually without dieting.
- Oxytocin is released to promote more rapid uterine involution with less bleeding.
- Sucking helps to develop the muscles in the infant's jaw.
- Absorption of lactose and minerals in the newborn is improved.
- The immunologic properties of breast milk help prevent infections in the baby.
- The composition of breast milk adapts to meet the infant's changing needs.
- Constipation in the baby is not a problem with adequate intake.
- Food allergies are less likely to develop in the breastfed baby.
- The incidence of otitis media and upper respiratory infections in the infant is reduced.
- Breastfed babies are less likely to be overfed, thus reducing the risk of adult obesity.
- Breastfed newborns are less prone to vomiting (ACOG, 2006).

One could say that lactation and breastfeeding are so natural that they should just happen on their own accord, but this is not the case. Learning to breastfeed takes practice, requires support from the partner, and requires dedication and patience on the part of the mother; it may be necessary to work closely with a lactation consultant to be successful and comfortable in doing it.

Breastfeeding also has disadvantages. These include breast discomfort, sore nipples, mastitis, engorgement, milk stasis, vaginal dryness, and decreased libido (Blackburn, 2007). Some mothers feel it is inconvenient or embarrassing, limits other activities, limits partner involvement, increases their dependency by being tied to the infant all the time, and restricts their use of alcohol or drugs. Nurses can help mothers to cope with their fear of dependency and feelings of obligation by emphasizing the positive aspects of breastfeeding and encouraging bonding experiences.

Nipple preparation is not necessary during the prenatal period unless the nipples are inverted and do not become erect when stimulated. Assess for this by placing the forefinger and thumb above and below the areola and compressing behind the nipple. If it flattens or inverts, advise the client to wear breast shields during the last 2 months of pregnancy. Breast shields exert a continuous pressure around the areola, pushing the nipple through a central opening in the inner shield (ACOG, 2006). The shields are worn inside the bra. Initially the shields are worn for 1 hour, and then the woman progressively increases the wearing time up to 8 hours daily. The client maintains this schedule until after delivery, and then she wears the shield 24 hours a day until the infant latches on easily (ACOG, 2006). In addition, suggest that the woman wear a supportive nursing bra 24 hours a day.

Encourage the woman to attend a breastfeeding support group (e.g., La Leche League), provide her with sources of information about infant feeding, and suggest that she read a good reference book about lactation. All of these activities will help in her decision-making process and will be invaluable to her should she choose to breastfeed her newborn.

Bottle Feeding

Bottle-feeding an infant isn't just a matter of "open, pour, and feed." Parents need information on types of

formulas, preparation and storage of formula, equipment, and feeding positions. It is recommended that normal full-term infants receive conventional cow's milk-based formula; the physician should direct this choice. If the infant has a reaction (diarrhea, vomiting, abdominal pain, excessive gas) to the first formula, another formula should be tried. Sometimes a soy-based formula is substituted. In terms of preparation of formula and its use, the following guidelines should be stressed:

- Obtain adequate equipment (six 4-ounce bottles, eight 8-ounce bottles, and nipples).
- Consistency is important. Stay with a nipple that is comfortable to the infant.
- Frequently assess nipples for any loose pieces of rubber at the opening.
- Correct formula preparation is critical to the health and development of the infant. Formula is available in three forms: ready-to-feed, concentrate, and powder.
- Read the formula label thoroughly before mixing.
- Correct formula dilution is important to avoid fluid imbalances. For ready-to-use, use as is without dilution. For concentrated formulas, dilute with equal parts of water. For powdered formulas, mix one scoop of powder with 2 ounces of water.
- If the water supply is safe, sterilization is not necessary.
- Bottles and nipples should be washed in hot, sudsy water using a bottle brush.
- Formula should be served at room temperature.
- If the water supply is questionable, water should be boiled for 5 minutes before use.
- Formula should not be heated in a microwave oven, because it is heated unevenly.
- Formula can be prepared 24 hours ahead of time and stored in the refrigerator.

Teach the woman and other caretakers to feed the infant in a semi-upright position using the cradle hold in the arms. This position allows for face-to-face contact between the infant and caretaker. Advise the caretaker to hold the bottle so that the nipple is kept full of formula to prevent excessive air swallowing. Instruct the caretaker to feed the infant every 3 to 4 hours and adapt the feeding times to the infant's needs. Frequent burping of the infant (every ounce) helps prevent gas from building up in the stomach. Caution the caretaker not to prop the bottle; propping the bottle can cause choking (Lawson, 2007).

Bottle-feeding should mirror breastfeeding as closely as possible. While nutrition is important, so are the emotional and interactive components of feeding. Encourage the caretaker to cuddle the infant closely and position the infant so that his or her head is in a comfortable position. Also encourage communication with the infant during feedings.

▶ *Take* NOTE!

Warn the caretaker about the danger of putting the infant to bed with a bottle; this can lead to "baby bottle tooth decay" because sugars in the formula stay in contact with the infant's developing teeth for prolonged periods.

Final Preparation for Labor and Birth

The nurse has played a supportive/education role for the couple throughout the pregnancy and now needs to assist in preparing them for their "big event" by making sure they have made informed decisions and completed the following checklist:

- Attended childbirth preparation classes and practiced breathing techniques
- Selected a birth setting and made arrangements there
- Know what to expect during labor and birth
- Toured the birthing facility
- Packed a suitcase to take to the birthing facility when labor starts
- Made arrangements to have siblings and/or pets taken care of during labor
- Have been instructed on signs and symptoms of labor and what to do
- Know what to do if membranes rupture prior to going into labor
- Know how to reach their health care professional when labor starts
- Communicated their needs and desires concerning pain management
- Discussed the possibility of a cesarean birth if complications occur
- Discussed possible names for the newborn
- Selected a feeding method (bottle or breast) with which they feel comfortable
- Made a decision regarding circumcision if they have a boy
- Purchased an infant safety seat in which to bring their newborn home
- Decided on a pediatrician
- Have items needed to prepare for the newborn's homecoming:
  - Infant clothes in several sizes
  - Nursing bras
  - Infant crib with spaces between the slats that are $2\frac{3}{8}$ inches or less apart
  - Diapers (cloth or disposable)
  - Feeding supplies (bottles and nipples if bottle-feeding)
  - Infant thermometer
- Selected a family planning method to use after the birth

At each prenatal visit the nurse has had the opportunity to discuss and reinforce the importance of being prepared for the birth of the child with the parents. It is

now up to the parents to use the nurse's guidance and put it into action to be ready for their upcoming "big event."

Key Concepts

- Preconception care is the promotion of the health and well-being of a woman and her partner before pregnancy. The goal of preconception care is to identify any areas such as health problems, lifestyle habits, or social concerns that might unfavorably affect pregnancy.
- A thorough history and physical examination is performed on the initial prenatal visit.
- A primary aspect of nursing management during the antepartum period is counseling and educating the pregnant women and her partner to promote healthy outcomes for all involved.
- Nagele's rule can be used to establish the estimated date of birth. Using this rule, subtract 3 months, add 7 days to the first day of the last normal menstrual period, then correct the year by adding 1 to it. This date is within plus or minus 2 weeks (margin of error).
- Pelvic shape is typically classified as one of four types: gynecoid, android, anthropoid, and platypelloid. The gynecoid type is the typical female pelvis and offers the best shape for a vaginal delivery.
- Continuous prenatal care is important for a successful outcome. The recommended schedule is every 4 weeks up to 28 weeks (7 months); every 2 weeks from 29 to 36 weeks; and every week from 37 weeks to birth.
- The height of the fundus is measured when the uterus arises out of the pelvis to evaluate fetal growth.
- The fundus reaches the level of the umbilicus at approximately 20 weeks and measures 20 cm. Fundal measurement should approximately equal the number of weeks of gestation until week 36.
- At each visit the woman is asked whether she is having any common signs or symptoms of preterm labor, which might include uterine contractions, dull backache, pressure in the pelvic area or thighs, increased vaginal discharge, menstrual-like cramps, and vaginal bleeding.
- Prenatal screening has become standard in prenatal care to detect neural tube defects and genetic abnormalities.
- The nurse should address common discomforts that occur in each trimester matter-of-factly at all prenatal visits and should provide realistic measures to help the client deal with them effectively.
- The pregnant client can better care for herself and the fetus if her concerns are anticipated by the nurse and incorporated into guidance sessions at each prenatal visit.
- Iron and folic acid need to be supplemented because their increased requirements during pregnancy are usually too great to be met through diet alone.
- The American College of Obstetricians and Gynecologists recommends a 25- to 35-pound weight gain during pregnancy.
- For a pregnant woman to meet recommended dietary reference intakes (DRIs), it is important for her to eat according to the USDA's Food Guide Pyramid.
- Throughout pregnancy, a well-balanced diet is critical for a healthy baby.
- Perinatal education has broadened its focus to include preparation for pregnancy and family adaptation to the new parenting roles. Childbirth education began because of increasing pressure from consumers who wanted to become more involved in their birthing experience.
- Three common childbirth education methods are Lamaze (psychoprophylactic), Bradley (partner-coached childbirth), and Dick-Read (natural childbirth).
- The great majority of women in the United States are well and healthy and can consider the full range of birth settings: hospital, birth center, or home setting.
- All pregnant women need to be able to recognize early signs of contractions to prevent preterm labor.

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. Which of the following biophysical profile findings indicate poor oxygenation to the fetus?
   a. Two pockets of amniotic fluid
   b. Well-flexed arms and legs
   c. Nonreactive fetal heart rate
   d. Fetal breathing movements noted
2. The nurse teaches the pregnant client how to perform Kegel exercises as a way to accomplish which of the following?
   a. Prevent perineal lacerations
   b. Stimulate postdates labor
   c. Increase pelvic muscle tone
   d. Lose pregnancy weight quickly
3. During a clinic visit, a pregnant client at 30 weeks' gestation tells the nurse, "I've had some mild cramps that are pretty irregular. What does this mean?" The cramps are probably:
   a. the beginning of labor in the very early stages
   b. an ominous finding indicating that the client is about to have a miscarriage
   c. related to overhydration in the client
   d. Braxton Hicks contractions, which occur throughout pregnancy
4. The nurse teaches a pregnant woman about exercise and activity, including activities not recommended during pregnancy. The nurse determines that the teaching was effective when the pregnant woman states that which of the following activities is not recommended during pregnancy?
   a. Swimming
   b. Walking
   c. Scuba diving
   d. Bike riding
5. A pregnant client's last normal menstrual period was on August 10. Using Nagele's rule, the nurse calculates that her estimated date of birth (EDB) will be which of the following?
   a. June 23
   b. July 10
   c. July 30
   d. May 17

CRITICAL THINKING EXERCISES

1. Mary Jones comes to the Women's Health Center, where you work as a nurse. She is in her first trimester of pregnancy and tells you her main complaints are nausea and fatigue, to the point that she wants to sleep most of the time and eats one meal daily. She appears pale and tired. Her mucous membranes are pale. She reports that she gets 8 to 9 hours of sleep each night but still can't seem to stay awake and alert at work. She tells you she knows that she is not eating as she should, but she isn't hungry. Her hemoglobin and hematocrit are low.
   a. What subjective and objective data do you have to make your assessment?
   b. What is your impression of this woman?
   c. What nursing interventions would be appropriate for this client?
   d. How will you evaluate the effectiveness of your interventions?
2. Monica, a 16-year-old African-American high school student, is here for her first prenatal visit. Her last normal menstrual period was 2 months ago, and she states she has been "sick ever since." She is 5 feet, 6 inches tall and weighs 110 pounds. In completing her dietary assessment, the nurse asks about her intake of milk and dairy products. Monica reports that she doesn't like "that stuff" and doesn't want to put on too much weight because it "might ruin my figure."
   a. In addition to the routine obstetric assessments, which additional ones might be warranted for this teenager?
   b. What dietary instruction should be provided to this teenager based on her history?
   c. What follow-up monitoring should be included in subsequent prenatal visits?
3. Maria, a 27-year-old Hispanic woman in her last trimester of pregnancy (34 weeks), complains to the clinic nurse that she is constipated and feels miserable most of the time. She reports that she has started taking laxatives, but mostly they don't help her. When questioned about her dietary habits, she replies that she eats beans and rice and drinks tea with most meals. She says she has tried to limit her fluid intake so she doesn't have to go to the bathroom so much because she doesn't

want to miss any of her daytime soap operas on television.

a. What additional information would the nurse need to assess her complaint?

b. What interventions would be appropriate for Maria?

c. What adaptations will Maria need to make to alleviate her constipation?

STUDY ACTIVITIES

1. Visit a freestanding birth center and compare it to a traditional hospital setting in terms of restrictions, type of pain management available, and costs.
2. Arrange to shadow a nurse-midwife for a day to see her role in working with the childbearing family.
3. Select two of the websites supplied at the end of this chapter and note their target audience, the validity of information offered, and their appeal to expectant couples. Present your findings.
4. Request permission to attend a childbirth education class in your local area and help a woman without a partner practice the paced breathing exercises. Present the information you learned and think about how you can apply it while taking care of a woman during labor.
5. A laywoman with a specialized education and experience in assisting women during labor is a _____.

lightening
molding
position
presentation
station

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Outline premonitory signs of labor.
2. Compare and contrast true versus false labor.
3. Categorize the critical factors affecting labor and birth.
4. Analyze the cardinal movements of labor.
5. Identify the maternal and fetal responses to labor and birth.
6. Classify the stages of labor and the critical events in each stage.
7. Explain the normal physiologic/psychological changes occurring during all four stages of labor.
8. Formulate the concept of pain as it relates to the woman in labor.

Kathy and Chuck have been eagerly awaiting the birth of their first child for what seems to them an eternity. When Kathy finally feels contractions in her abdomen, she and Chuck rush to the birthing center. After the OB nurse completes a complete history and physical assessment, she informs Kathy and her husband that she must have experienced "false labor" and that they should return home until she starts true labor.

Wow

Intense physical and emotional support promotes a positive and memorable birthing experience.

The process of labor and birth involves more than the birth of a newborn. Numerous physiologic and psychological events occur that ultimately result in the birth of a newborn and the creation or expansion of the family.

This chapter describes labor and birth as a process. It addresses initiation of labor, the premonitory signs of labor, including true and false labor, critical factors affecting labor and birth, maternal and fetal response to the laboring process, and the four stages of labor. The chapter also identifies critical factors related to each stage of labor: the "10 P's" of labor.

Initiation of Labor

Labor is a complex, multifaceted interaction between the mother and fetus. It is a series of processes by which the fetus is expelled from the uterus. It is difficult to determine exactly why labor begins and what initiates it. Although several theories have been proposed to explain the onset and maintenance of labor, none of these has been proved scientifically. It is widely believed that labor is influenced by a combination of factors, including uterine stretch, progesterone withdrawal, increased oxytocin sensitivity, and increased release of prostaglandins.

One theory suggests that labor is initiated by a change in the estrogen-to-progesterone ratio. During the last trimester of pregnancy, estrogen levels increase and progesterone levels decrease. This change leads to an increase in the number of myometrium gap junctions. Gap junctions are proteins that connect cell membranes and facilitate coordination of uterine contractions and myometrial stretching (Gilbert, 2007).

Although physiologic evidence for the role of oxytocin in the initiation of labor is inconclusive, the number of oxytocin receptors in the uterus increases at the end of pregnancy. This creates an increased sensitivity to oxytocin. Estrogen, the levels of which are also rising, increases myometrial sensitivity to oxytocin. With the increasing levels of oxytocin in the maternal blood in conjunction with fetal production, initiation of uterine contractions can occur. Oxytocin also aids in stimulating prostaglandin synthesis through receptors in the decidua. Prostaglandins lead to additional contractions, cervical softening, gap junction induction, and myometrial sensitization, thereby leading to a progressive cervical **dilation** (the opening or enlargement of the external cervical os) (Blackburn, 2007).

Prostaglandins are produced in the decidua and fetal membranes and have a central role in the initiation of labor. Prostaglandin levels increase late during pregnancy secondary to elevated estrogen levels. Prostaglandins stimulate smooth muscle contraction of the uterus. An increase in prostaglandins leads to myometrial contractions and a reduction in cervical resistance. Subsequently, the cervix softens, thins out, and dilates during labor.

Premonitory Signs of Labor

Before the onset of labor, a pregnant woman's body undergoes several changes in preparation for the birth of the newborn. The changes that occur often lead to characteristic signs and symptoms that suggest that labor is near. These premonitory signs and symptoms can vary, and not every woman experiences every one of them.

Cervical Changes

Before labor begins, cervical softening and possible cervical dilation with descent of the presenting part into the pelvis occurs. These changes can occur 1 month to 1 hour before actual labor begins.

As labor approaches, the cervix changes from an elongated structure to a shortened, thinned segment. Cervical collagen fibers undergo enzymatic rearrangement into smaller, more flexible fibers that facilitate water absorption, leading to a softer, more stretchable cervix. These changes occur secondary to the effects of prostaglandins and pressure from Braxton Hicks contractions (Blackburn, 2007).

Lightening

Lightening occurs when the fetal presenting part begins to descend into the maternal pelvis. The uterus lowers and moves into a more anterior position. The shape of the abdomen changes as a result of the change in the uterus. With this descent, the woman usually notes that her breathing is much easier. However, she may complain of increased pelvic pressure, cramping, and low back pain. She may notice an increase in vaginal discharge and more frequent urination. Also, edema of the lower extremities may occur as a result of the increased stasis of pooling blood. In primiparas, lightening can occur 2 weeks or more before labor begins; among multiparas it may not occur until labor (Walsh, 2007).

Increased Energy Level

Some women report a sudden increase in energy before labor. This is sometimes referred to as nesting, because many women will focus this energy toward childbirth preparation by cleaning, cooking, preparing the nursery, and spending extra time with other children in the household. The increased energy level usually occurs 24 to 48 hours before the onset of labor. It is thought to be the result of an increase in epinephrine release caused by a decrease in progesterone (Cheng & Caughey, 2007).

Bloody Show

At the onset of labor, the mucous plug that fills the cervical canal during pregnancy is expelled as a result of cervical softening and increased pressure of the presenting part. These ruptured cervical capillaries release a small

amount of blood that mixes with mucus, resulting in the pink-tinged secretions known as bloody show.

Braxton Hicks Contractions

Braxton Hicks contractions, which the woman may have been experiencing throughout the pregnancy, may become stronger and more frequent. Braxton Hicks contractions are typically felt as a tightening or pulling sensation of the top of the uterus. They occur primarily in the abdomen and groin and gradually spread downward before relaxing. In contrast, true labor contractions are more commonly felt in the lower back. These contractions aid in moving the cervix from a posterior position to an anterior position. They also help in ripening and softening the cervix. However, the contractions are irregular and can be decreased by walking, voiding, eating, increasing fluid intake, or changing position.

Braxton Hicks contractions usually last about 30 seconds but can persist for as long as 2 minutes. As birth draws near and the uterus becomes more sensitive to oxytocin, the frequency and intensity of these contractions increase. However, if the contractions last longer than 30 seconds and occur more often than four to six times an hour, advise the woman to contact her health care provider so that she can be evaluated for possible preterm labor, especially if she is less than 38 weeks pregnant.

▶ *Take* NOTE!

An infant born between 34 and 36 completed weeks of gestation is identified as "late preterm" and experiences many of the same health issues as other preterm birth infants (AWHONN, 2007).

Spontaneous Rupture of Membranes

One in four women will experience spontaneous rupture of the membranes before the onset of labor (Institute of Medicine, 2007). The rupture of membranes can result in either a sudden gush or a steady leakage of amniotic fluid. Although much of the amniotic fluid is lost when the rupture occurs, a continuous supply is produced to ensure protection of the fetus until birth.

After the amniotic sac has ruptured, the barrier to infection is gone and an ascending infection is possible. In addition, there is a danger of cord prolapse if engagement has not occurred with the sudden release of fluid and pressure with rupture. Due to the possibility of these complications, advise women to notify their health care provider and go in for an evaluation.

▶ *Consider* THIS!

I always pictured myself a dignified woman and behaved in ways to demonstrate that, for that was the way I was raised. My mother and grandmother always stressed that you should look good, dress well, and do nothing to embarrass yourself in public. I did a fairly good job of living up to their expectations until I become pregnant. I recall I was overdue according to my dates and was miserable in the summer heat. I decided to go to the store for some ice cream. As I waddled down the grocery aisles, all of a sudden my water broke and came pouring down my legs all over the floor. Not wanting to make a spectacle of myself and remembering what my mother always said about being dignified at all times in public, I quickly reached up onto the grocery shelf and "accidentally" knocked off a large jar of pickles right where my puddle was. As I walked hurriedly away from that mess without my ice cream, I heard on the store loudspeaker, "Clean-up on aisle 13!"

Thoughts: We tend to live by what we are taught, and in this case, this woman needed to save face from her ruptured membranes. Many women experience ruptured membranes before the onset of labor, so it is not out of the ordinary for this to happen in public. What risks can occur when membranes do rupture? What action should this woman take now to minimize these risks? How will the nurse validate this woman's ruptured membranes?

True Versus False Labor

False labor is a condition occurring during the latter weeks of some pregnancies in which irregular uterine contractions are felt, but the cervix is not affected. In contrast, true labor is characterized by contractions occurring at regular intervals that increase in frequency, duration, and intensity. True labor contractions bring about progressive cervical dilation and effacement. Table 13.1 summarizes the differences between true and false labor. False labor, prodromal labor, and Braxton Hicks contractions are all names for contractions that do not contribute in a measurable way toward the goal of birth.

Many women fear being sent home from the hospital with "false labor." All women feel anxious when they feel contractions, but they should be informed that labor could be a long process, especially if it is their first pregnancy. Encourage the woman to think of false labor or "pre-labor signs" as positive, as they are part of the entire labor continuum. With first pregnancies, the cervix can take up to 20 hours to dilate completely (Cunningham et al., 2005).

TABLE 13.1 DIFFERENCES BETWEEN TRUE AND FALSE LABOR

Parameters	True Labor	False Labor
Contraction timing	Regular, becoming closer together, usually 4–6 minutes apart, lasting 30–60 seconds	Irregular, not occurring close together
Contraction strength	Become stronger with time, vaginal pressure is usually felt	Frequently weak, not getting stronger with time or alternating (a strong one followed by weaker ones)
Contraction discomfort	Starts in the back and radiates around toward the front of the abdomen	Usually felt in the front of the abdomen
Any change in activity	Contractions continue no matter what positional change is made	Contractions may stop or slow down with walking or making a position change
Stay or go?	Stay home until contractions are 5 minutes apart, last 45–60 seconds, and are strong enough so that a conversation during one is not possible—then go to the hospital or birthing center.	Drink fluids and walk around to see if there is any change in the intensity of the contractions; if the contractions diminish in intensity after either or both—stay home.

Sources: Arenson & Drake, 2007; Blackburn, 2007; Cunningham et al., 2005.

Remember Kathy and Chuck, the anxious couple who came to the hospital too early? Kathy felt sure she was in labor and is now confused. What explanations and anticipatory guidance should be offered to this couple? What term would describe her earlier contractions?

Factors Affecting the Labor Process

In many references, the critical factors that affect the process of labor and birth are outlined as the "five P's":

1. Passageway (birth canal)
2. Passenger (fetus and placenta)
3. Powers (contractions)
4. Position (maternal)
5. Psychological response

These critical factors are commonly accepted and discussed by health care professionals. However, five additional "P's" can also affect the labor process:

1. Philosophy (low-tech, high-touch)
2. Partners (support caregivers)
3. Patience (natural timing)
4. Patient preparation (childbirth knowledge base)
5. Pain control (comfort measures)

These five additional "P's" are helpful in planning care for the laboring family. These patient-focused factors are an attempt to foster labor that can be managed through the use of high touch, patience, support, knowledge, and pain management.

Passageway

The birth passageway is the route through which the fetus must travel to be born vaginally. The passageway consists of the maternal pelvis and soft tissues. Of the two, however, the maternal bony pelvis is more important because it is relatively unyielding (except for the coccyx). Typically the pelvis is assessed and measured during the first trimester, often at the first visit to the health care provider, to identify any abnormalities that might hinder a successful vaginal birth. As the pregnancy progresses, the hormones relaxin and estrogen cause the connective tissues to become more relaxed and elastic and cause the joints to become more flexible to prepare the mother's pelvis for birth. Additionally, the soft tissues usually yield to the forces of labor.

Bony Pelvis

The maternal bony pelvis can be divided into the true and false portions. The false (or greater) pelvis is composed of the upper flared parts of the two iliac bones with their concavities and the wings of the base of the sacrum. The false pelvis is divided from the true pelvis by an imaginary line drawn from the sacral prominence at the back to the superior aspect of the symphysis pubis at the front of the pelvis. This imaginary line is called the linea terminalis. The false pelvis lies above this imaginary line; the true pelvis lies below it (Fig. 13.1). The true pelvis is the bony passageway through which the fetus must travel. It is made up of three planes: the inlet, the mid-pelvis (cavity), and the outlet.

Pelvic Inlet

The pelvic inlet allows entrance to the true pelvis. It is bounded by the sacral prominence in the back, the ilium on the sides, and the superior aspect of the symphysis pubis in

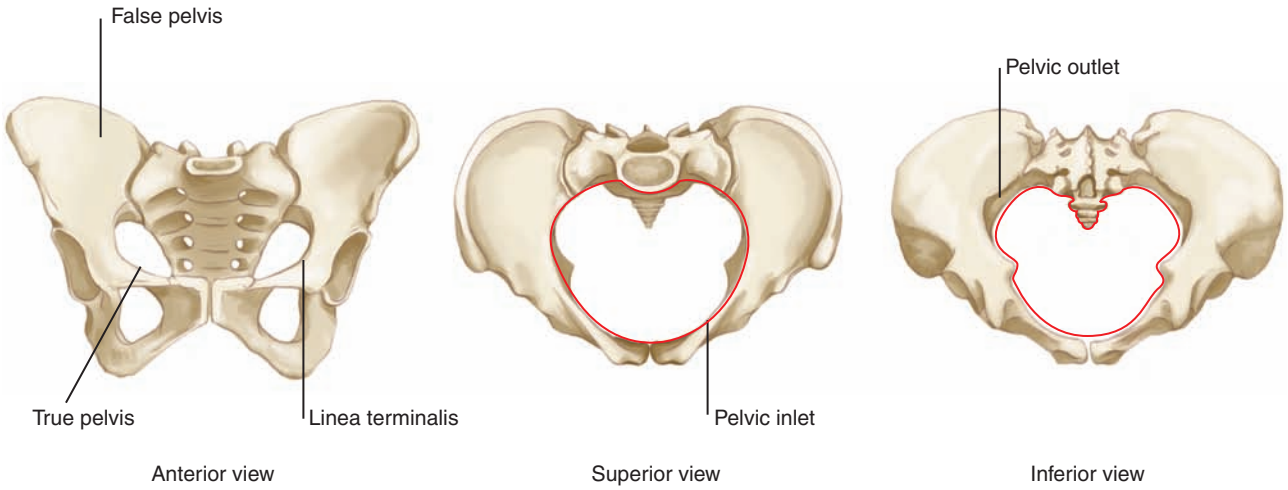

FIGURE 13.1 The bony pelvis.

the front (Edmonds, 2007). The pelvic inlet is wider in the transverse aspect (sideways) than it is from front to back.

Mid-Pelvis

The mid-pelvis (cavity) occupies the space between the inlet and outlet. It is through this snug, curved space that the fetus must travel to reach the outside. As the fetus passes through this small area, its chest is compressed, causing lung fluid and mucus to be expelled. This expulsion removes the space-occupying fluid so that air can enter the lungs with the newborn's first breath.

Pelvic Outlet

The pelvic outlet is bound by the ischial tuberosities, the lower rim of the symphysis pubis, and the tip of the coccyx. In comparison with the pelvic inlet, the outlet is wider from front to back. For the fetus to pass through the pelvis, the outlet must be large enough.

To ensure the adequacy of the pelvic outlet for vaginal birth, the following pelvic measurements are assessed:

- Diagonal conjugate of the inlet (distance between the anterior surface of the sacral prominence and the anterior surface of the inferior margin of the symphysis pubis)
- Transverse or ischial tuberosity diameter of the outlet (distance at the medial and lowest aspect of the ischial tuberosities, at the level of the anus; a known hand span or clenched-fist measurement is generally used to obtain this measurement)
- True or obstetric conjugate (distance estimated from the measurement of the diagonal conjugate; 1.5 cm is subtracted from the diagonal conjugate measurement)

For more information about pelvic measurements, see Chapter 12.

If the diagonal conjugate measures at least 11.5 cm and the true or obstetric conjugate measures 10 cm or more (1.5 cm less than the diagonal conjugate, or about 10 cm), then the pelvis is large enough for a vaginal birth of what would be considered a normal-size newborn.

Pelvic Shape

In addition to size, the shape of a woman's pelvis is a determining factor for a vaginal birth. The pelvis is divided into four main shapes: gynecoid, anthropoid, android, and platypelloid (Fig. 13.2).

The gynecoid pelvis is considered the true female pelvis, occurring in about 50% of all women; it is less common in men (Leonard, 2007). Vaginal birth is most favorable with this type of pelvis because the inlet is round and the outlet is roomy. This shape offers the optimal diameters in all three planes of the pelvis. This type of pelvis allows early and complete fetal internal rotation during labor.

The anthropoid pelvis is common in men and occurs in 20% to 30% of women (Billington & Stevenson, 2007). The pelvic inlet is oval and the sacrum is long, producing a deep pelvis (wider front to back [anterior to posterior] than side to side [transverse]). Vaginal birth is more favorable with this pelvic shape compared to the android or platypelloid shape (Frieden & Chan, 2007).

The android pelvis is considered the male-shaped pelvis and is characterized by a funnel shape. It occurs in approximately 20% of women (Cunningham et al., 2005). The pelvic inlet is heart-shaped and the posterior segments are reduced in all pelvic planes. Descent of the fetal head into the pelvis is slow, and failure of the fetus to rotate is common. The prognosis for labor is poor, subsequently leading to cesarean birth.

The platypelloid or flat pelvis is the least common type of pelvic structure among men and women, with an approximate incidence of 5% (Billington & Stevenson, 2007). The pelvic cavity is shallow but widens at the pelvic outlet, making it difficult for the fetus to descend through

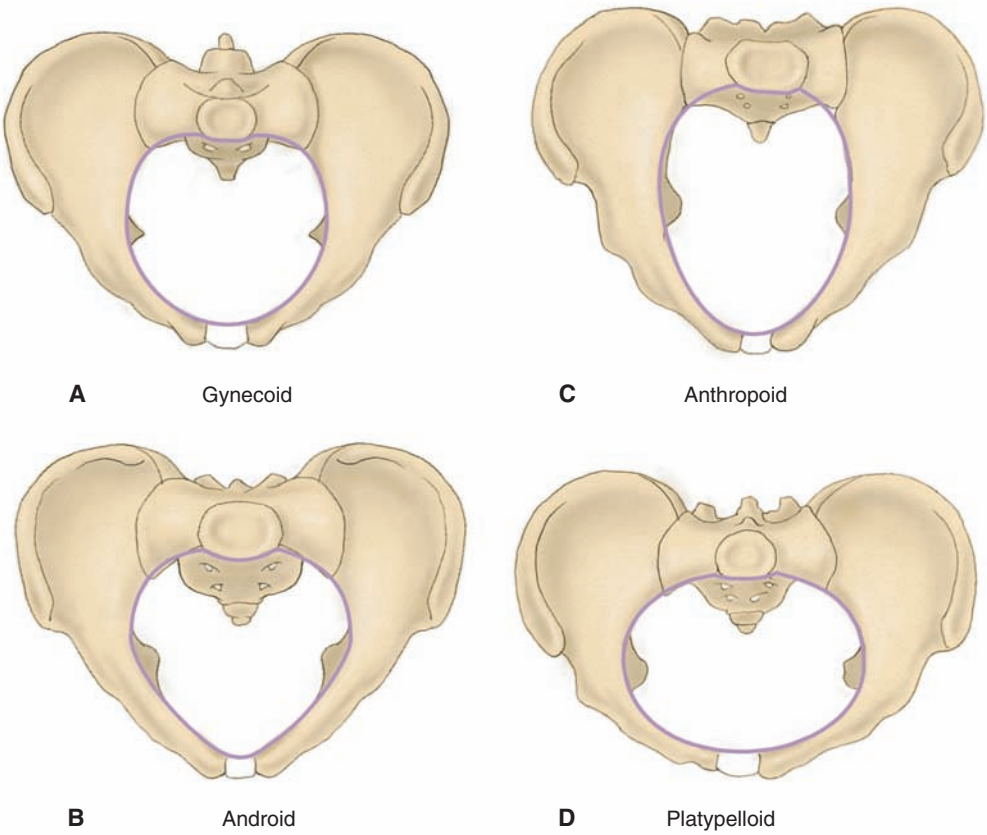

FIGURE 13.2 Pelvic shapes. (**A**) Gynecoid. (**B**) Android. (**C**) Anthropoid. (**D**) Platypelloid.

the mid-pelvis. It is not favorable for a vaginal birth unless the fetal head can pass through the inlet. Women with this type of pelvis usually require cesarean birth.

An important principle is that most pelves are not purely defined but occur in nature as mixed types. Many women have a combination of these four basic pelvis types, with no two pelves being exactly the same. Regardless of the shape, the newborn will be born if size and positioning remain compatible. The narrowest part of the fetus attempts to align itself with the narrowest pelvic dimension (e.g., biparietal to interspinous diameters, which means the fetus generally tends to rotate to the most ample portion of the pelvis).

Soft Tissues

The soft tissues of the passageway consist of the cervix, the pelvic floor muscles, and the vagina. Through **effacement**, the cervix effaces (thins) and dilates (opens) to allow the presenting fetal part to descend into the vagina.

▶ ***Take*** NOTE!

Cervical effacement and dilation is similar to pulling a turtleneck sweater over your head.

The pelvic floor muscles help the fetus to rotate anteriorly as it passes through the birth canal. The soft tissues of the vagina expand to accommodate the fetus during birth.

Passenger

The fetus (with placenta) is the passenger. The fetal head (size and presence of molding), fetal attitude (degree of body flexion), fetal lie (relationship of body parts), fetal presentation (first body part), fetal position (relationship to maternal pelvis), fetal station, and fetal engagement are all important factors that have an impact on the ultimate outcome in the birthing process.

Fetal Head

The fetal head is the largest and least compressible fetal structure, making it an important factor in relation to labor and birth. Considerable variation in the size and diameter of the fetal skull is often seen.

Compared with an adult, the fetal head is large in proportion to the rest of the body, usually about one quarter of the body surface area (Kenner & Lott, 2007). The bones that make up the face and cranial base are fused and essentially fixed. However, the bones that make up the rest of the cranium (two frontal bones, two parietal bones,

and the occipital bone) are not fused; rather, they are soft and pliable, with gaps between the plates of bone. These gaps, which are membranous spaces between the cranial bones, are called sutures, and the intersections of these sutures are called fontanelles. Sutures are important because they allow the cranial bones to overlap in order for the head to adjust in shape (elongate) when pressure is exerted on it by uterine contractions or the maternal bony pelvis. Some diameters shorten whereas others lengthen as the head is molded during the labor and birthing process. This malleability of the fetal skull may decrease fetal skull dimensions by 0.5 to 1 cm (Blackburn, 2007). After birth, the sutures close as the bones grow and the brain reaches its full growth.

The changed (elongated) shape of the fetal skull at birth as a result of overlapping of the cranial bones is known as **molding**. Along with molding, fluid can also collect in the scalp (caput succedaneum) or blood can collect beneath the scalp (cephalohematoma), further distorting the shape and appearance of the fetal head. Caput succedaneum can be described as edema of the scalp at the presenting part. This swelling crosses suture lines and disappears within 3 to 4 days. Cephalhematoma is a collection of blood between the periosteum and the bone. It does not cross suture lines and is generally reabsorbed over the next 4 to 6 weeks (Arenson & Drake, 2007).

▶ ***Take*** NOTE!

Parents may become concerned about the distortion of their newborn's head. However, reassurance that the oblong shape is only temporary is usually all that is needed to reduce their anxiety.

Sutures also play a role in helping to identify the position of the fetal head during a vaginal examination. Figure 13.3 shows a fetal skull. The coronal sutures are located between the frontal and parietal bones and extend transversely on both sides of the anterior fontanelles. The frontal suture is located between the two frontal bones. The lambdoidal sutures are located between the occipital bone and the two parietals, extending transversely on either side of the posterior fontanelles. The sagittal suture is located between the parietal bones and divides the skull into the right and left halves. During a pelvic examination, palpation of these sutures by the examiner reveals the position of the fetal head and the degree of rotation that has occurred.

The anterior and posterior fontanelles are also useful in helping to identify the position of the fetal head, and they allow for molding. In addition, the fontanelles are important when evaluating the newborn. The anterior

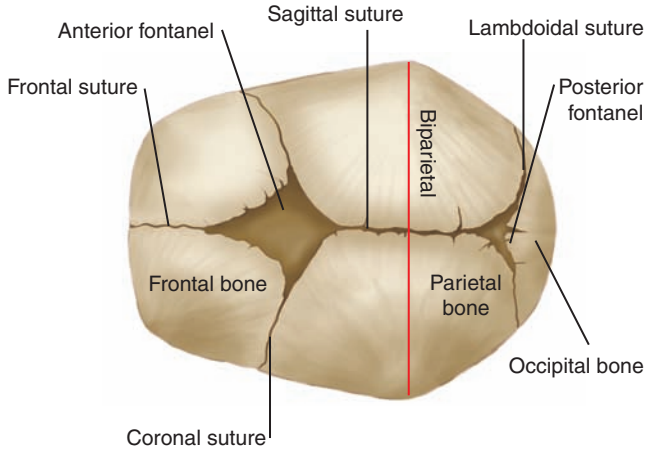

FIGURE 13.3 Fetal skull.

fontanelle is the famous "soft spot" of the newborn's head. It is diamond-shaped and measures about 2 to 3 cm. It remains open for 12 to 18 months after birth to allow for growth of the brain (Edmonds, 2007). The posterior fontanelle corresponds to the anterior one but is located at the back of the fetal head; it is triangular. This one closes within 8 to 12 weeks after birth and measures, on average, 0.5 to 1 cm at its widest diameter (Kenner & Lott, 2007).

The diameter of the fetal skull is an important consideration during the labor and birth process. Fetal skull diameters are measured between the various landmarks of the skull. Diameters include occipitofrontal, occipitomental, suboccipitobregmatic, and biparietal (Fig. 13.4). The two most important diameters that can affect the birth process are the suboccipitobregmatic (approximately 9.5 cm at term) and the biparietal (approximately 9.25 cm at term) diameters. The suboccipitobregmatic diameter, measured from the base of the occiput to the center of the anterior fontanelle, identifies the smallest anteroposterior diameter of the fetal skull. The biparietal diameter measures the largest transverse diameter of the fetal skull: the distance between the two parietal bones. In a cephalic (headfirst) presentation, which occurs in 95% of all term

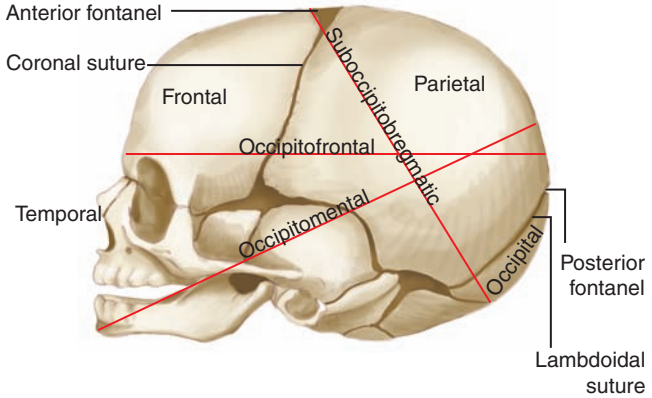

FIGURE 13.4 Fetal skull diameters.

births, if the fetus presents in a flexed position in which the chin is resting on the chest, the optimal or smallest fetal skull dimensions for a vaginal birth are demonstrated. If the fetal head is not fully flexed at birth, the anteroposterior diameter increases. This increase in dimension might prevent the fetal skull from entering the maternal pelvis.

Fetal Attitude

Fetal attitude is another important consideration related to the passenger. Fetal **attitude** refers to the posturing (flexion or extension) of the joints and the relationship of fetal parts to one another. The most common fetal attitude when labor begins is with all joints flexed—the fetal back is rounded, the chin is on the chest, the thighs are flexed on the abdomen, and the legs are flexed at the knees (Fig. 13.5). This normal fetal position is most favorable for vaginal birth, presenting the smallest fetal skull diameters to the pelvis.

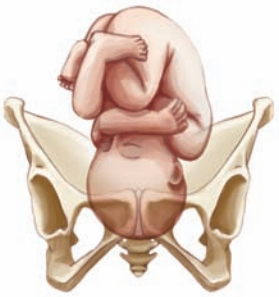
When the fetus presents to the pelvis with abnormal attitudes (no flexion or extension), the diameter can increase the diameter of the presenting part as it passes through the pelvis, increasing the difficulty of birth. An attitude of extension tends to present larger fetal skull diameters, which may make birth difficult.

Fetal Lie

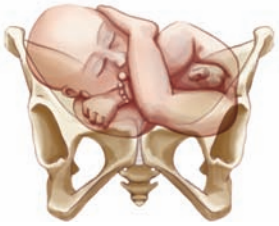
Fetal **lie** refers to the relationship of the long axis (spine) of the fetus to the long axis (spine) of the mother. There are two primary lies: longitudinal (which is the most common) and transverse (Fig. 13.6).

A longitudinal lie occurs when the long axis of the fetus is parallel to that of the mother (fetal spine to maternal spine side-by-side). A transverse lie occurs when the long axis of the fetus is perpendicular to the long axis of the mother (fetus spine lies across the maternal abdomen and crosses her spine). A fetus in a transverse lie position cannot be delivered vaginally (Billington & Stevenson, 2007).

Figure 13.5 Fetal attitude: Full flexion. Note that the smallest diameter presents to the pelvis.



A. Longitudinal lie



B. Transverse lie

Figure 13.6 Fetal lie.

Fetal Presentation

Fetal **presentation** refers to the body part of the fetus that enters the pelvic inlet first (the "presenting part"). This is the fetal part that lies over the inlet of the pelvis or the cervical os. Knowing which fetal part is coming first at birth is critical for planning and initiating appropriate interventions.

The three main fetal presentations are cephalic (head first), breech (pelvis first), and shoulder (scapula first). The majority of term newborns (95%) enter this world in a cephalic presentation; breech presentation accounts for 3% of term births, shoulder presentations for approximately 2% (Edmonds, 2007).

In a cephalic presentation, the presenting part is usually the occiput portion of the fetal head (Fig. 13.7). This presentation is also referred to as a vertex presentation. Variations in a vertex presentation include the military, brow, and face presentations.

Breech presentation occurs when the fetal buttocks or feet enter the maternal pelvis first and the fetal skull enters last. This abnormal presentation poses several challenges at birth. Primarily, the largest part of the fetus (skull) is born last and may become "hung up" or stuck in the pelvis. In addition, the umbilical cord can become compressed between the fetal skull and the maternal pelvis after the fetal chest is born because the head is the last to exit. Moreover, unlike the hard fetal skull, the buttocks are soft and are not as effective as a cervical dilator during labor compared with a cephalic presentation. Finally, there is the possibility of trauma to the head as a result of the lack of opportunity for molding.

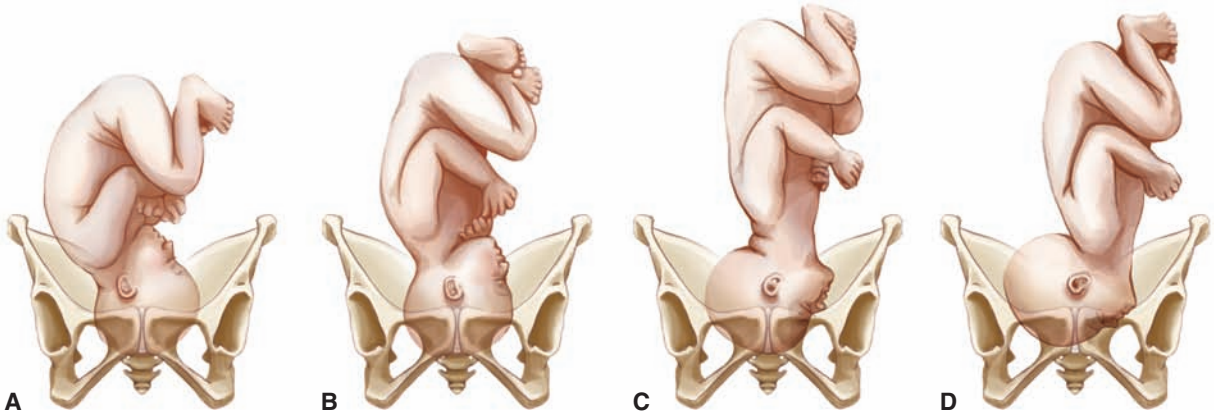


Figure 13.7 Fetal presentation: cephalic presentations. (**A**) Vertex. (**B**) Military. (**C**) Brow. (**D**) Face.

The types of breech presentations are determined by the positioning of the fetal legs (Fig. 13.8). In a frank breech (50% to 70%), the buttocks present first with both legs extended up toward the face. In a full or complete breech (5% to 10%), the fetus sits crossed-legged above the cervix. In a footling or incomplete breech (10% to 30%), one or both legs are presenting. Breech presentations are associated with prematurity, placenta previa, multiparity, uterine abnormalities (fibroids), and some congenital anomalies such as hydrocephaly (Fischer, 2007). A frank breech can result in a vaginal birth, but complete, footling, and incomplete breech presentations generally necessitate a cesarean birth.

A shoulder presentation occurs when the fetal shoulders present first, with the head tucked inside. Odds of a shoulder presentation are one in 1,000 (Cunningham et al., 2005). The fetus is in a transverse lie with the shoulder as the presenting part. Conditions associated with shoulder presentation include placenta previa, multiple gestation, or fetal anomalies. A cesarean birth is typically necessary (Edmonds, 2007).

Fetal Position

Fetal **position** describes the relationship of a given point on the presenting part of the fetus to a designated point of the maternal pelvis (Walsh, 2007). The landmark fetal presenting parts include the occipital bone (O), which designates a vertex presentation; the chin (mentum [M]), which designates a face presentation; the buttocks (sacrum [S]), which designate a breech presentation; and the scapula (acromion process [A]), which designates a shoulder presentation.

In addition, the maternal pelvis is divided into four quadrants: right anterior, left anterior, right posterior, and left posterior. These quadrants designate whether the presenting part is directed toward the front, back, left, or right side of the pelvis. Fetal position is determined first by identifying the presenting part and then the maternal quadrant the presenting part is facing (Fig. 13.9). Position is indicated by a three-letter abbreviation as follows:

- The first letter defines whether the presenting part is tilted toward the left (L) or the right (R) side of the maternal pelvis.

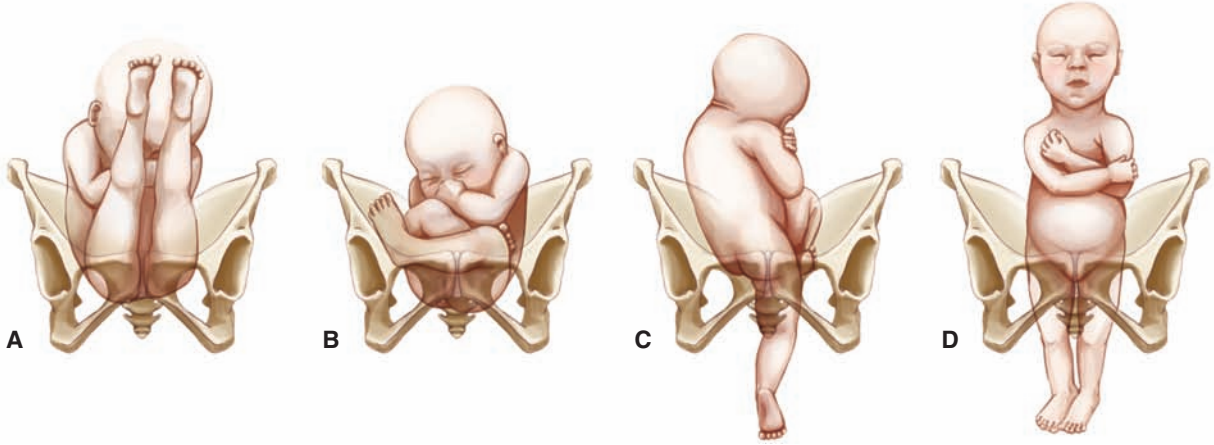

Figure 13.8 Breech presentations. (**A**) Frank breech. (**B**) Complete breech. (**C**) Single footling breech. (**D**) Double footling breech.

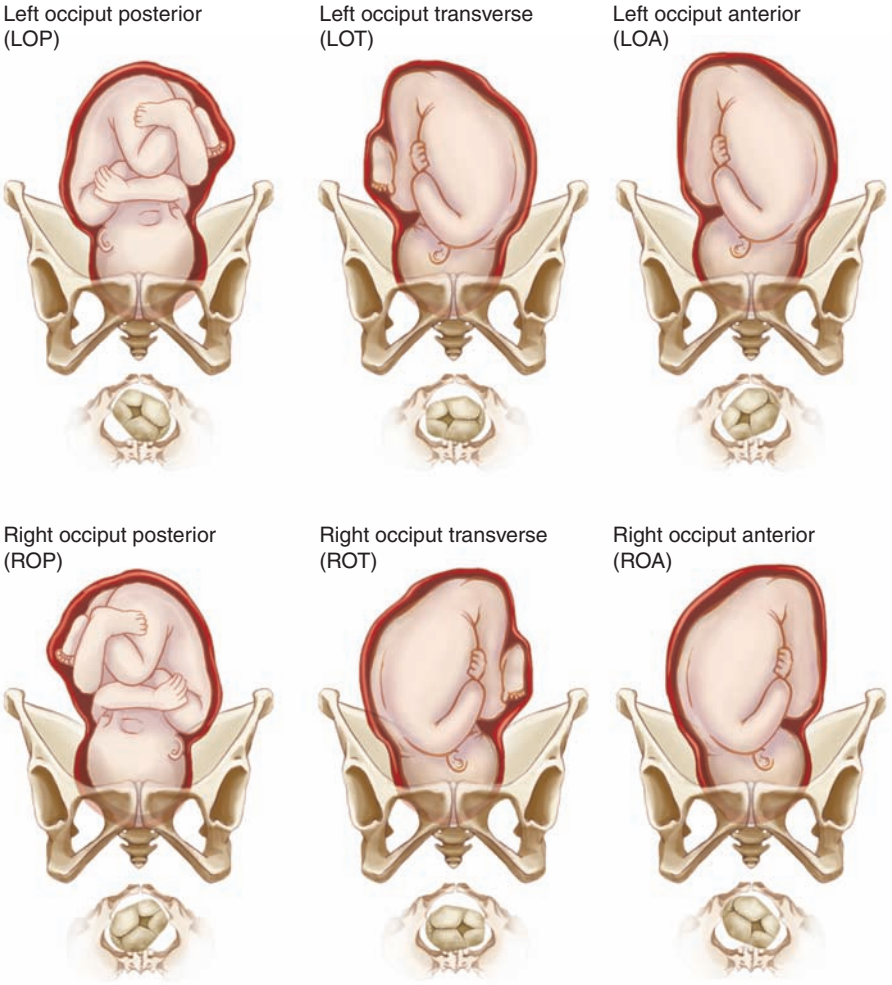

FIGURE 13.9 Examples of fetal positions in a vertex presentation. The lie is longitudinal for each illustration. The attitude is one of flexion. Notice that the view of the top illustration is seen when facing the pregnant woman. The bottom view is that seen with the woman in a dorsal recumbent position.

- The second letter represents the particular presenting part of the fetus: O for occiput, S for sacrum (buttocks), M for mentum (chin), A for acromion process, and D for dorsal (refers to the fetal back) when denoting the fetal position in shoulder presentations (Cheng & Caughey, 2007).
- The third letter defines the location of the presenting part in relation to the anterior (A) portion of the maternal pelvis or the posterior (P) portion of the maternal pelvis. If the presenting part is directed to the side of the maternal pelvis, the fetal presentation is designated as transverse (T).

For example, if the occiput is facing the left anterior quadrant of the pelvis, then the position is termed left occipitoanterior and is recorded as LOA. LOA is the most common (and most favorable) fetal position for birthing today, followed by right occipitoanterior (ROA).

The positioning of the fetus allows the fetal head to contour to the diameters of the maternal pelvis. LOA and ROA are optimal positions for vaginal birth. An occiput posterior position may lead to a long and difficult birth, and other positions may or may not be compatible with vaginal birth.

Fetal Station

Station refers to the relationship of the presenting part to the level of the maternal pelvic ischial spines. Fetal station is measured in centimeters and is referred to as a minus or plus, depending on its location above or below the ischial spines. Typically, the ischial spines are the narrowest part of the pelvis and are the natural measuring point for the birth progress.

Zero (0) station is designated when the presenting part is at the level of the maternal ischial spines. When the presenting part is above the ischial spines, the distance is recorded as minus stations. When the presenting part is below the ischial spines, the distance is recorded as plus stations. For instance, if the presenting part is above the ischial spines by 1 cm, it is documented as being a –1 station; if the presenting part is below the ischial spines by 1 cm, it is documented as being a +1 station. An easy way to understand this concept is to think in terms of meeting the goal, which is the birth. If the fetus is descending downward (past the ischial spines) and moving toward meeting the goal of birth, then the station is positive and the centimeter numbers grow bigger from +1 to +4. If the fetus is not descending past the ischial spines, then the station is negative and the centimeter numbers grow bigger

from –1 to –4. The farther away the presenting part from the outside, the larger the negative number (-4 cm). The closer the presenting part of the fetus is to the outside, the larger the positive number (+4 cm). Figure 13.10 shows stations of presenting part.

Fetal Engagement

Engagement signifies the entrance of the largest diameter of the fetal presenting part (usually the fetal head) into the smallest diameter of the maternal pelvis (Blackburn, 2007). The fetus is said to be "engaged" in the pelvis when the presenting part reaches 0 station. Engagement is determined by pelvic examination.

The largest diameter of the fetal head is the biparietal diameter. It extends from one parietal prominence to the other. It is an important factor in the navigation through the maternal pelvis. Engagement typically occurs in primigravidas 2 weeks before term, whereas multiparas may experience engagement several weeks before the onset of labor or not until labor begins.

▶ ***Take*** *NOTE!*

The term floating *is used when engagement has not occurred, because the presenting part is freely movable above the pelvic inlet.*

Cardinal Movements of Labor

The fetus goes through many positional changes as it travels through the passageway. These positional changes are known as the cardinal movements of labor. They are deliberate, specific, and very precise movements that allow the smallest diameter of the fetal head to pass through a corresponding diameter of the mother's pelvic structure. Although cardinal movements are conceptualized as separate and sequential, the movements are typically concurrent (Fig. 13.11).

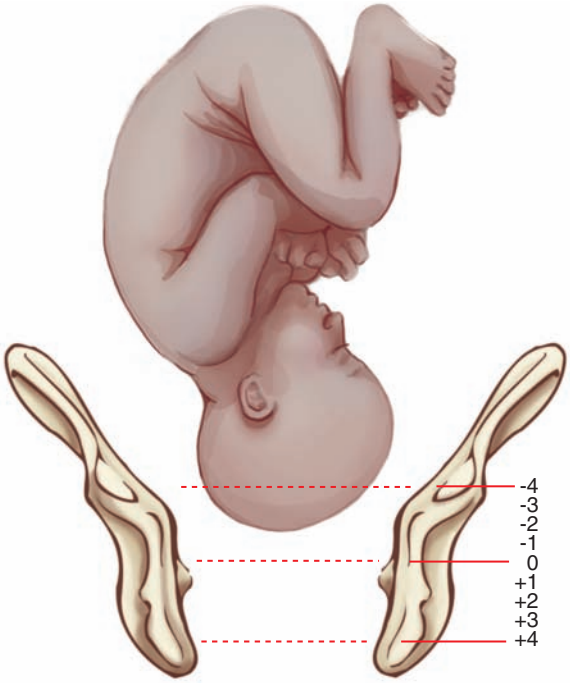

FIGURE 13.10 Fetal stations.

Engagement

Engagement occurs when the greatest transverse diameter of the head in vertex (biparietal diameter) passes through the pelvic inlet (usually 0 station). The head usually enters the pelvis with the sagittal suture aligned in the transverse diameter.

Descent

Descent is the downward movement of the fetal head until it is within the pelvic inlet. Descent occurs intermittently with contractions and is brought about by one or more of the following forces:

- Pressure of the amniotic fluid
- Direct pressure of the fundus on the fetus' buttocks or head (depending on which part is located in the top of the uterus)
- Contractions of the abdominal muscles (second stage)
- Extension and straightening of the fetal body

Descent occurs throughout labor, ending with birth. During this time, the mother experiences discomfort, but she is unable to isolate this particular fetal movement from her overall discomfort.

Flexion

Flexion occurs as the vertex meets resistance from the cervix, the walls of the pelvis, or the pelvic floor. As a result, the chin is brought into contact with the fetal thorax and the presenting diameter is changed from occipitofrontal to suboccipitobregmatic (9.5 cm), which achieves the smallest fetal skull diameter presenting to the maternal pelvic dimensions.

Internal Rotation

After engagement, as the head descends, the lower portion of the head (usually the occiput) meets resistance from one side of the pelvic floor. As a result, the head rotates about 45 degrees anteriorly to the midline under the symphysis. This movement is known as internal rotation. Internal rotation brings the anteroposterior diameter of the head in line with the anteroposterior diameter of the pelvic outlet. It aligns the long axis of the fetal head with the long axis of the maternal pelvis. The widest portion of the maternal pelvis is the anteroposterior diameter, and thus the fetus must rotate to accommodate the pelvis.

Extension

With further descent and full flexion of the head, the nucha (the base of the occiput) becomes impinged under

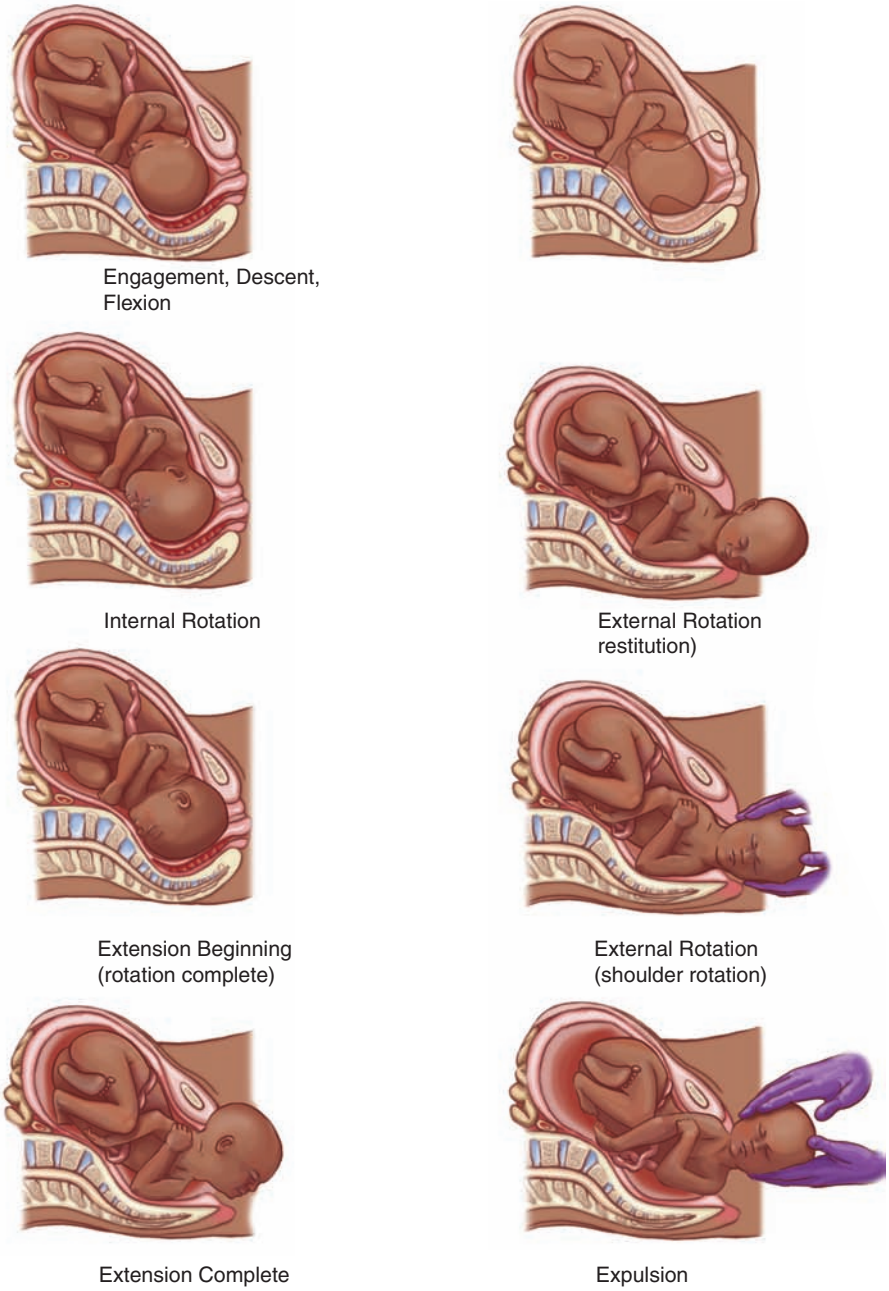

FIGURE 13.11 Cardinal movements of labor.

the symphysis. Resistance from the pelvic floor causes the fetal head to extend so that it can pass under the pubic arch. Extension occurs after internal rotation is complete. The head emerges through extension under the symphysis pubis along with the shoulders. The anterior fontanel, brow, nose, mouth, and chin are born successively.

External Rotation (Restitution)

After the head is born and is free of resistance, it untwists, causing the occiput to move about 45 degrees back to its original left or right position (restitution). The sagittal suture has now resumed its normal right-angle relationship to the transverse (bisacromial) diameter of the shoulders (i.e., the head realigns with the position of the back in the birth canal). External rotation of the fetal head allows the shoulders to rotate internally to fit the maternal pelvis.

Expulsion

Expulsion of the rest of the body occurs more smoothly after the birth of the head and the anterior and posterior shoulders (Cheng & Caughey, 2007).

Powers

The primary stimulus powering labor is uterine contractions. Contractions cause complete dilation and effacement of the cervix during the first stage of labor. The secondary

powers in labor involve the use of intra-abdominal pressure (voluntary muscle contractions) exerted by the woman as she pushes and bears down during the second stage of labor.

Uterine Contractions

Uterine contractions are involuntary and therefore cannot be controlled by the woman experiencing them, regardless of whether they are spontaneous or induced. Uterine contractions are rhythmic and intermittent, with a period of relaxation between contractions. This pause allows the woman and the uterine muscles to rest. In addition, this pause restores blood flow to the uterus and placenta, which is temporarily reduced during each uterine contraction.

Uterine contractions are responsible for thinning and dilating the cervix, and they thrust the presenting part toward the lower uterine segment. With each uterine contraction, the upper segment of the uterus becomes shorter and thicker, whereas the lower passive segment and the cervix become longer, thinner, and more distended. The division between the contractile upper portion (fundus) of the uterus and the lower portion is described as the physiologic retraction ring. Longitudinal traction on the cervix by the fundus as it contracts and retracts leads to cervical effacement and dilation. Uterine contractions cause the upper uterine segment to shorten, making the cervix paper-thin when it becomes fully effaced.

The cervical canal reduces in length from 2 cm to a paper-thin entity and is described in terms of percentages from 0 to 100%. In primigravidas, effacement typically starts before the onset of labor and usually begins before dilation; in multiparas, however, neither effacement nor dilation may start until labor ensues. On clinical examination the following may be assessed:

- Cervical canal 2 cm in length would be described as 0% effaced.
- Cervical canal 1 cm in length would be described as 50% effaced.
- Cervical canal 0 cm in length would be described as 100% effaced.

Dilation is dependent on the pressure of the presenting part and the contraction and retraction of the uterus. The diameter of the cervical os increases from less than 1 cm to approximately 10 cm to allow for birth. When the cervix is fully dilated, it is no longer palpable on vaginal examination. Descriptions may include the following:

- External cervical os closed: 0 cm dilated
- External cervical os half open: 5 cm dilated
- External cervical os fully open: 10 cm dilated

During early labor, uterine contractions are described as mild, they last about 30 seconds, and they occur about every 5 to 7 minutes. As labor progresses, contractions last longer (60 seconds), occur more frequently (2 to 3 minutes apart), and are described as being moderate to high in intensity.

Each contraction has three phases: increment (build-up of the contraction), acme (peak or highest intensity), and decrement (descent or relaxation of the uterine muscle fibers; Fig. 13.12).

Uterine contractions are monitored and assessed according to three parameters: frequency, duration, and intensity.

1. **Frequency** refers to how often the contractions occur and is measured from the increment of one contraction to the increment of the next contraction.
2. **Duration** refers to how long a contraction lasts and is measured from the beginning of the increment to the end of the decrement for the same contraction.
3. **Intensity** refers to the strength of the contraction determined by manual palpation or measured by an internal intrauterine catheter (IUPC). The catheter is positioned in the uterine cavity through the cervix after the membranes have ruptured. It reports intensity by measuring the pressure of the amniotic fluid inside the uterus in millimeters of mercury (Edmonds, 2007).

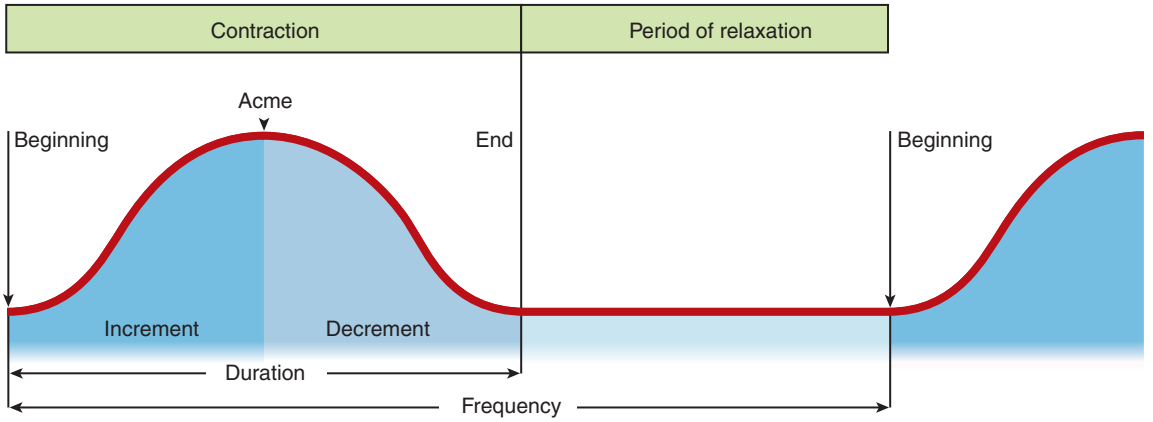

FIGURE 13.12 The three phases of a uterine contraction.

Intra-Abdominal Pressure

Increased intra-abdominal pressure (voluntary muscle contractions) compresses the uterus and adds to the power of the expulsion forces of the uterine contractions (Blackburn, 2007). Coordination of these forces in unison promotes birth of the fetus and expulsion of the fetal membranes and placenta from the uterus. Interference with these forces (such as when a woman is highly sedated or extremely anxious) can compromise the effectiveness of these powers.

Psychological Response

Childbearing can be one of the most life-altering experiences for a woman. The experience of childbirth goes beyond the physiologic aspects: it influences her self-confidence, self-esteem, and view of life, relationships, and children. Her state of mind (psyche) throughout the entire process is critical to bring about a positive outcome for her and her family. Factors promoting a positive birth experience include:

- Clear information about procedures
- Support; not being alone
- Sense of mastery, self-confidence
- Trust in staff caring for her
- Positive reaction to the pregnancy
- Personal control over breathing
- Preparation for the childbirth experience

Having a strong sense of self and meaningful support from others can often help women manage labor well. Feeling safe and secure typically promotes a sense of control and ability to withstand the challenges of the childbearing experience. Anxiety and fear, however, decrease a woman's ability to cope with the discomfort of labor. Maternal catecholamines secreted in response to anxiety and fear can inhibit uterine blood flow and placental perfusion. In contrast, relaxation can augment the natural process of labor (Leonard, 2007). Preparing mentally for childbirth is important so that the woman can work with, rather than against, the natural forces of labor.

Position (Maternal)

Maternal positioning during labor has only recently been the subject of well-controlled research. Scientific evidence has shown that nonmoving, back-lying positions during labor are not healthy (Hanson 2006). However, despite this evidence to the contrary, most women continue to lie flat on their backs during labor. Some of the reasons why this practice continues include the following:

- Belief that laboring women need to conserve their energy and not tire themselves
- Belief that nurses cannot keep track of the whereabouts of ambulating women
- Belief that the supine position facilitates vaginal examinations and external belt adjustment
- Belief that a bed is "where one is supposed to be" in a hospital setting
- Belief that the position is more convenient for the delivering health professional
- Belief that laboring women are "connected to things" that impede movement (Hanson, 2006)

Although many labor and birthing facilities claim that all women are allowed to adopt any position of comfort during their laboring experience, the great majority of women spend their time on their backs during labor and birth.

▶ *Take* NOTE!

If the only furniture provided is a bed, this is what the woman will use. Furnishing rooms with comfortable chairs, beanbags, and other birth props allows a woman to choose from a variety of positions and to be free to move during labor.

Changing positions and moving around during labor and birth offer several benefits. Maternal position can influence pelvic size and contours. Changing position and walking affect the pelvis joints, which may facilitate fetal descent and rotation. Squatting enlarges the pelvic outlet by approximately 25%, whereas a kneeling position removes pressure on the maternal vena cava and helps to rotate the fetus in the posterior position (Terry et al., 2006). The use of any upright or lateral position, compared with supine or lithotomy positions, may:

- Reduce the length of the first stage of labor
- Reduce the duration of the second stage of labor
- Reduce the number of assisted deliveries (vacuum and forceps)
- Reduce episiotomies and perineal tears
- Contribute to fewer abnormal fetal heart rate patterns
- Increase comfort/reduce requests for pain medication
- Enhance a sense of control by the mother
- Alter the shape and size of the pelvis, which assists in descent
- Assist gravity to move the fetus downward (Simkin & Ancheta, 2006)

Using the research available can bring better outcomes, heightened professionalism, and evidence-based practice to childbearing practices (Walsh, 2007).

Philosophy

Not everyone views childbirth in the same way. A philosophical continuum exists that extends from viewing labor as a disease process to a normal process. One philosophy assumes that women cannot manage the birth experience

EVIDENCE-BASED PRACTICE 13.1
Continuous Support for Women During Childbirth

● Study
Historically, women have been attended and supported by other women during labor. However, in recent decades in hospitals worldwide, continuous support during labor has become the exception rather than the rule. Concerns about the consequent dehumanization of the birth experiences have led to calls for a return to continuous support by women for women during labor.

This review of studies included 16 trials, from 11 countries, involving over 13,000 women in a wide range of settings and circumstances. The primary outcome was to assess the effects, on mothers and their babies, of continuous, one-to-one intrapartum support compared with usual care. The secondary outcome was to determine whether the effects of continuous support are influenced by (1) routine practices and policies in the birth environment that may affect a woman's autonomy, freedom of movement, and ability to cope with labor; (2) whether the caregiver is a member of the staff of the institution; and (3) whether the continuous support begins early or later in labor.

▲ Findings
Women who received continuous labor support were more likely to give birth "spontaneously" (vaginally, without vacuum or forceps). They were less likely to use pain medications, were more likely to be satisfied with their experience, and had slightly shorter labors. In general, labor support appeared to be more effective when it was provided by women who were not part of the hospital staff. It also appeared to be more effective when it started early in labor. No adverse effects were identified.

■ Nursing Implications
Knowing the results of this evidence-based study, all nurses should strive to be a real "presence" for all of their laboring couples. Based on the findings, continuous nursing support promotes positive birthing outcomes and fewer technical/surgical interventions. Both maternal and fetal well-being is preserved when nurses are present and involved during the childbirth experience.

Hodnett, E. D., Gates, S., Hofmeyr, G. J., & Sakala, C. (2007). Continuous support for women during childbirth. *Cochrane Database of Systematic Reviews* 2007, 3. Art. No.: CD003766. DOI: 10.1002/14651858.CD003766.pub2.

adequately and therefore need constant expert monitoring and management. The other philosophy assumes that women are capable, reasoning individuals who can actively participate in their birth experience.

The health care system in the United States today appears to be leaning toward the former philosophy, applying technological interventions to most mothers who enter the hospital system. Giving birth in a hospital in the 21st century for many women has become "intervention intensive"—designed to start, continue, and end labor through medical management rather than allowing the normal process of birth to unfold. Advances in medical care have improved the safety for women with high-risk pregnancies. However, the routine use of intravenous therapy, electronic fetal monitoring, augmentation, and epidural anesthesia has not necessarily improved birth outcomes for all women (Leonard, 2007). Perhaps a middle-of-the-road philosophy for intervening when circumstances dictate, along with weighing the risks and benefits before doing so, may be appropriate.

During the 1970s, family-centered maternity care was developed in response to the consumer reaction to the depersonalization of birth. The hope was to shift the philosophy from "technologization" to personalization to humanize childbirth. The term "family-centered birthing" is more appropriate today to denote the low-tech, high-touch approach requested by many childbearing women, who view childbirth as a normal process.

Certified nurse midwives (CNMs) are champions of family-centered birthing, and their participation in the childbirth process is associated with fewer unnecessary interventions when compared to obstetricians. CNMs subscribe to a normal birth process where the woman uses her own instincts and bodily signs during labor. In short, midwives empower women within the birthing environment (Russell, 2007; Steppe, 2007).

No matter what philosophy is held, it is ideal if everyone involved in the particular birth process—from the health care provider to the mother—shares the same philosophy toward the birth process.

Partners

Women desire support and attentive care during labor and birth. Caregivers can convey emotional support by offering their continued presence and words of encouragement. Throughout the world, few women are left to labor totally alone: emotional, physical, or spiritual support during labor is the norm for most cultures (Ballen & Fulcher, 2006). A caring partner can use massage, light touch, acupressure, hand-holding, stroking, and relaxation, can help the woman communicate her wishes to the

staff, and can provide a continuous, reassuring presence, all of which bring some degree of comfort to the laboring woman (Ballen & Fulcher, 2006). Although the presence of the baby's father at the birth provides special emotional support, a partner can be anyone who is present to support the woman throughout the experience.

Worldwide, women usually support other women in childbirth. Hodnett et al. (2003) reported that the continuous presence of a trained female support person (**doula**) reduced the need for medication for pain relief, the use of vacuum or forceps delivery, and the need for cesarean births. Continuous support was also associated with a slight reduction in the length of labor. The doula, who is an experienced labor companion, provides the woman and her partner with emotional and physical support and information throughout the entire labor and birth experience.

A similar study in the United States found that nursing care decreases the likelihood of negative evaluations of the childbirth experience, feelings of tenseness during labor, and finding labor worse than expected. Also reported were less perineal trauma, reduced difficulty in mothering, and reduced likelihood of early cessation of breastfeeding (Ballen & Fulcher, 2006).

Given the many benefits of intrapartum support, laboring women should always have the option to receive partner support, whether from nurses, doulas, significant others, or family. Whoever the support partner is, he or she should provide the mother with continuous presence and hands-on comfort and encouragement.

Patience

The birth process takes time. If more time were allowed for women to labor naturally without intervention, the cesarean birth rate would most likely be reduced (Simkin & Ancheta, 2006). The literature suggests that delaying interventions can give a woman enough time to progress in labor and reduce the need for surgical intervention (American College of Obstetricians and Gynecologists [ACOG], 2007). *Healthy People 2010* has two goals related to cesarean births in the United States:

1. Reduce the rate of cesarean births among low-risk (full-term, singleton, vertex presentation) women having their first child to 15% of live births, from a baseline of 18%.
2. Reduce the rate of cesarean births among women who have had a prior cesarean birth to 63% of live births, from a baseline of 72% (USDHHS, 2000).

We are a long way from achieving these goals, since the current cesarean birth rate in the United States—30%—is the highest since these data first became available from birth certificates in 1989. Cesarean birth is associated with increased morbidity and mortality for both mother and infant, as well as increased inpatient length of stay and health care costs (CDC, 2007).

It is difficult to predict how a labor will progress and therefore equally difficult to determine how long a woman's labor will last. There is no way to estimate the likely strength and frequency of uterine contractions, the extent to which the cervix will soften and dilate, and how much the fetal head will mold to fit the birth canal. We cannot know beforehand whether the complex fetal rotations needed for an efficient labor will take place properly. All of these factors are unknowns when a woman starts labor.

There is a trend in health care, however, to attempt to manipulate the process of labor through medical means such as artificial rupture of membranes and augmentation of labor with oxytocin (Walsh, 2007). The labor induction rate has increased dramatically in the United States since the 1980s (Gulmezoglu, Crowther, & Middleton, 2007).

Approximately one in five women are induced or have labor augmented with uterine-stimulating drugs or artificial rupture of membranes to accelerate their progress (Bricker & Luckas, 2007). An amniotomy (artificial rupture of the fetal membranes) may be performed to augment or induce labor when the membranes have not ruptured spontaneously. Doing so allows the fetal head to have more direct contact with the cervix to dilate it. This procedure is performed with the fetal head at –2 station or lower, with the cervix dilated to at least 3 cm. Synthetic oxytocin (Pitocin) is also used to induce or augment labor by stimulating uterine contractions. It is administered piggybacked into the primary intravenous line with an infusion pump titrated to uterine activity.

There is compelling evidence that elective induction of labor significantly increases the risk of cesarean birth, especially for nulliparous women (Simkin & Ancheta, 2006). The belief is that many cesarean births could be avoided if women were allowed to labor longer and if the natural labor process were allowed to complete the job. The longer wait (using the intervention of patience) usually results in less intervention.

The ACOG attributes the dramatic increase in inductions in part to pressure from women, convenience for physicians, and liability concerns. They recommend a "cautious approach" regarding elective induction until clinical trials can validate a more liberal use of labor inductions (ACOG, 2002). There are medical indications for inducing labor, such as spontaneous rupture of membranes and when labor does not start; a pregnancy more than 42 weeks' gestation; maternal hypertension, diabetes, or lung disease; and a uterine infection (ACOG, 2006).

When the laboring woman feels the urge to bear down, pushing begins. Most women respond extremely well to messages from their body without being directed by the nurse. A more natural, undirected approach allows the woman to wait and bear down when she feels the urge to push. Having patience and letting nature take its course will reduce the incidence of physiologic stress in the mother, resulting in less trauma to her perineal tissue.

Patient Preparation

Basic prenatal education can help women manage their labor process and feel in control of their birthing experience. The literature indicates that if a woman is prepared before the labor and birth experience, the labor is more likely to remain normal or natural (without the need for medical intervention) (Gagnon, 2006). An increasing body of evidence also indicates that the well-prepared woman, with good labor support, is less likely to need analgesia or anesthesia and is unlikely to require cesarean birth (Risica & Phipps, 2006).

Prenatal education teaches the woman about the childbirth experience and increases her sense of control. She is then able to work as an active participant during the labor and birth experience (Brodsky, 2006). The research also suggests that prenatal preparation may affect intrapartum and postpartum psychosocial outcomes. For example, prenatal education covering parenting communication classes had a significant effect on postpartum anxiety and postpartum adjustment. Prenatal education should be viewed as an opportunity to strengthen families by providing anticipatory guidance and improve family members' life skills. In short, prenatal education helps to promote healthy families during the transition to parenthood and beyond (Polomeno, 2006).

▶ *Take* NOTE!

Learning about labor and birth allows women and couples to express their needs and preferences, enhances their confidence, and improves communication between themselves and the staff.

Pain Management

Labor and birth, although a normal physiologic process, can produce significant pain. Pain during labor is a nearly universal experience. Controlling the pain without harm to the fetus or labor process is the major focus of pain management during childbirth.

Pain is a subjective experience involving a complex interaction of physiologic, spiritual, psychosocial, cultural, and environmental influences (Smith et al., 2006). Cultural values and learned behaviors influence perception and response to pain, as do anxiety and fear, both of which tend to heighten the sense of pain (Walsh, 2007). The challenge for care providers is to find the right combination of pain management methods to keep the pain manageable while minimizing the negative effect on the fetus, the normal physiology of labor, maternal–infant bonding, breastfeeding, and a woman's perception of the labor itself (Wood, 2007). Chapter 14 presents a full discussion of pain management during labor and birth.

Physiologic Responses to Labor

Labor is the physiologic process by which the uterus expels the fetus and placenta from the body. During pregnancy, progesterone secreted from the placenta suppresses the spontaneous contractions of a typical uterus, keeping the fetus within the uterus. In addition, the cervix remains firm and noncompliant. At term, however, changes occur in the cervix that make it softer. In addition, uterine contractions become more frequent and regular, signaling the onset of labor.

The labor process involves a series of rhythmic, involuntary, usually quite uncomfortable uterine muscle contractions. They bring about a shortening that causes effacement and dilation of the cervix and a bursting of the fetal membranes. Then, accompanied by both reflex and voluntary contractions of the abdominal muscles (pushing), the uterine contractions result in the birth of the baby (Blackburn, 2007). During labor, the mother and fetus make several physiologic adaptations.

Maternal Responses

As the woman progresses through childbirth, numerous physiologic responses occur that assist her to adapt to the laboring process. The labor process stresses several of the woman's body systems, which react through numerous compensatory mechanisms. Maternal physiologic responses include:

- Heart rate increases by 10 to 20 bpm.
- Cardiac output increases by 10% to 15% during the first stage of labor and by 30% to 50% during the second stage of labor.
- Blood pressure increases by 10 to 30 mm Hg during uterine contractions in all labor stages.
- The white blood cell count increases to 25,000 to 30,000 cells/mm^3, perhaps as a result of tissue trauma.
- Respiratory rate increases and more oxygen is consumed related to the increase in metabolism.
- Gastric motility and food absorption decrease, which may increase the risk of nausea and vomiting during the transition stage of labor.
- Gastric emptying and gastric pH decrease, increasing the risk of vomiting with aspiration.
- Temperature rises slightly, possibly due to an increase in muscle activity.
- Muscular aches/cramps occur as a result of the stressed musculoskeletal system.
- Basal metabolic rate increases and blood glucose levels decrease because of the stress of labor (Blackburn, 2007; Cheng & Caughey, 2007).

A woman's ability to adapt to the stress of labor is influenced by her psychological and physical state. Among the many factors that affect her coping ability are:

- Previous birth experiences and their outcomes
- Current pregnancy experience (planned versus unplanned, discomforts experienced, age, risk status of pregnancy, chronic illness, weight gain)
- Cultural considerations (values and beliefs about health status)
- Support system (presence and support of a valued partner during labor)
- Childbirth preparation (attended childbirth classes and has practiced paced breathing techniques)
- Exercise during pregnancy
- Expectations of the birthing experience
- Anxiety level
- Fear of labor and loss of control
- Fatigue and weariness (Edmonds, 2007)

Fetal Responses

Although the focus during labor may be on assessing the mother's adaptations, several physiologic adaptations occur in the fetus as well. The fetus is experiencing labor along with the mother. If the fetus is healthy, the stress of labor usually has no adverse effects. The nurse needs to be alert to any abnormalities in the fetus' adaptation to labor. Fetal responses to labor include:

- Periodic fetal heart rate accelerations and slight decelerations related to fetal movement, fundal pressure, and uterine contractions
- Decrease in circulation and perfusion to the fetus secondary to uterine contractions (a healthy fetus is able to compensate for this drop)
- Increase in arterial carbon dioxide pressure (PCO_2)
- Decrease in fetal breathing movements throughout labor
- Decrease in fetal oxygen pressure with a decrease in the partial pressure of oxygen (PO_2) (Kenner & Lott, 2007)

▶ *Take* NOTE!

Respiratory changes during labor help to prepare the fetus for extrauterine respiration immediately after birth.

Stages of Labor

Labor is typically divided into four stages: dilation, expulsive, placental, and restorative. Table 13.2 summarizes the major events of each stage.

The first stage is the longest: it begins with the first true contraction and ends with full dilation (opening) of the cervix. Because this stage lasts so long, it is divided into three phases, each corresponding to the progressive dilation of the cervix.

Stage two of labor, or the expulsive stage, begins when the cervix is completely dilated and ends with the birth of the newborn. The expulsive stage can last from minutes to hours.

The third stage, or the placental stage, starts after the newborn is born and ends with the separation and birth of the placenta. Continued uterine contractions typically cause the placenta to be expelled within 5 to 30 minutes.

The fourth stage, or the restorative stage, lasts from 1 to 4 hours after birth. This period is when the mother's body begins to stabilize after the hard work of labor and the loss of the products of conception. The fourth stage is often not recognized as a true stage of labor, but it is a critical period for maternal physiologic transition as well as new family attachment (Arenson & Drake, 2007).

First Stage

During the first stage of labor, the fundamental change underlying the process is progressive dilation of the cervix. Cervical dilation is gauged subjectively by vaginal examination and is expressed in centimeters. The first stage ends when the cervix is dilated to 10 cm in diameter and is large enough to permit the passage of a fetal head of average size. The fetal membranes, or bag of waters, usually rupture during the first stage, but they may have burst earlier or may even remain intact until birth. For the primigravida, the first stage of labor lasts about 12 hours. However, this time can vary widely: for the multiparous woman, it is usually only half that.

During the first stage of labor, women usually perceive the visceral pain of diffuse abdominal cramping and uterine contractions. Pain during the first stage of labor is primarily a result of the dilation of the cervix and lower uterine segment, and the distention (stretching) of these structures during contractions. The first stage is divided into three phases: latent or early phase, active phase, and transition phase.

Latent or Early Phase

The latent or early phase gives rise to the familiar signs and symptoms of labor. This phase begins with the start of regular contractions and ends when rapid cervical dilation begins. Cervical effacement occurs during this phase, and the cervix dilates from 0 to 3 cm.

Contractions usually occur every 5 to 10 minutes, last 30 to 45 seconds, and are described as mild by palpation. Effacement of the cervix is from 0% to 40%. Most women are very talkative during this period, perceiving their contractions to be similar to menstrual cramps. Women may remain at home during this phase, contacting their health care professional about the onset of labor.

For the nulliparous woman, the latent phase typically lasts about 9 hours; in the multiparous woman, it lasts about 6 hours (Cheng & Caughey, 2007). During this phase, women are apprehensive but excited about the start of their labor after their long gestational period.

TABLE 13.2 STAGES AND PHASES OF LABOR

	First Stage	Second Stage	Third Stage	Fourth Stage
Description	From 0–10 cm dilation; consists of three phases	From complete dilation (10 cm) to birth of the newborn; lasts up to 1 hour	Separation and delivery of the placenta	1–4 hours after the birth of the newborn; time of maternal physiologic adjustment
Phases	**Latent phase** (0–3 cm dilation) – Cervical dilation from 0 to 3 cm – Cervical effacement from 0% to 40% – Nullipara, lasts up to 9 hours; multipara, lasts up to 5–6 hours – Contraction frequency every 5–10 minutes – Contraction duration 30–45 seconds – Contraction intensity mild to palpation **Active phase** (4–7 cm dilation) – Cervical dilation from 4 to 7 cm – Cervical effacement from 40% to 80% – Nullipara, lasts up to 6 hours; multipara, lasts up to 4 hours – Contraction frequency every 2–5 minutes – Contraction duration 45–60 seconds – Contraction intensity moderate to palpation **Transition phase** (8–10 cm dilation) – Cervical dilation from 8 to 10 cm – Cervical effacement from 80% to 100% – Nullipara lasts up to 1 hour; multipara, lasts up to 30 minutes – Contraction frequency every 1–2 minutes – Contraction duration 60–90 seconds – Contraction intensity strong by palpation	**Pelvic phase** (period of fetal descent) **Perineal phase** (period of active pushing) – Nullipara, lasts up to 1 hour; multipara, lasts up to 30 minutes – Contraction frequency every 2–3 minutes or less – Contraction duration 60–90 seconds – Contraction intensity strong by palpation – Strong urge to push during the later perineal phase	**Placental separation:** detaching from uterine wall **Placental expulsion:** coming outside the vaginal opening	

Think back to the couple who were sent home from the hospital birthing center. Three days later Kathy awoke with a wet sensation and intense discomfort in her back, spreading around to her abdomen. She decided to go for a walk, but her contractions didn't diminish; instead, they continued to occur every few minutes and grew stronger in intensity. She and Chuck decided to go back to the hospital birthing center. Was there a difference in the location of Kathy's discomfort this time? What changes will the admission nurse find in Kathy if this is true labor?

Active Phase

Cervical dilation begins to occur more rapidly during the active phase. The cervix usually dilates from 4 to 7 cm, with 40% to 80% effacement taking place. This phase can last up to 6 hours for the nulliparous woman and 4.5 hours for the multiparous woman (Simkin & Ancheta, 2006). The fetus descends farther in the pelvis. Contractions become more frequent (every 2 to 5 minutes) and increase in duration (45 to 60 seconds). The woman's discomfort intensifies (moderate to strong by palpation). She becomes more intense and inwardly focused, absorbed in the serious work of her labor. She limits interactions with those in the room. If she and her partner have attended childbirth education classes, she will begin to use the relaxation and paced breathing techniques that they learned to cope with the contractions. The typical dilation rate for the nulliparous woman is 1.2 cm/hour; for the multiparous woman, it is 1.5 cm/hour (Cunningham et al., 2005).

Transition Phase

The transition phase is the last phase of the first stage of labor. During this phase, dilation slows, progressing from 8 to 10 cm, with effacement from 80% to 100%. The transition phase is the most difficult and, fortunately, the shortest phase for the woman, lasting approximately 1 hour in the first birth and perhaps 15 to 30 minutes in successive births (Walsh, 2007). During transition, the contractions are stronger (hard by palpation), more painful, and more frequent (every 1 to 2 minutes), and they last longer (60 to 90 seconds). The average rate of fetal descent is 1 cm/hour in nulliparous women and 2 cm/hour in multiparous women. Pressure on the rectum is great, and there is a strong desire to contract the abdominal muscles and push.

Other maternal features during the transitional phase include nausea and vomiting, trembling extremities, backache, increased apprehension and irritability, restless movement, increased bloody show from the vagina, inability to relax, diaphoresis, feelings of loss of control, and being overwhelmed (the woman may say, "I can't take it any more"). This phase should not last longer than 3 hours for nulliparas and 1 hour for multiparas (Cunningham et al., 2005).

In assessing Kathy, the nurse finds she is 4 cm dilated and 50% effaced with ruptured membranes. In what stage and phase of labor would this assessment finding place Kathy?

Second Stage

The second stage of labor begins with complete cervical dilation (10 cm) and effacement and ends with the birth of the newborn. Although the previous stage of labor primarily involved the thinning and opening of the cervix, this stage involves moving the fetus through the birth canal and out of the body. The cardinal movements of labor occur during the early phase of passive descent in the second stage of labor.

Contractions occur every 2 to 3 minutes, last 60 to 90 seconds, and are described as strong by palpation. The average length of the second stage of labor in a nullipara is approximately 1 hour and less than half that time for the multipara. During this expulsive stage, the mother usually feels more in control and less irritable and agitated. She is focused on the work of pushing. Traditionally, women have been taught to hold their breath to the count of 10, inhale again, push again, and repeat the process several times during a contraction. This sustained, strenuous style of pushing has been shown to lead to hemodynamic changes in the mother and interfere with oxygen exchange between the mother and the fetus. In addition, it is associated with pelvic floor damage: the longer the push, the more damage to the pelvic floor (Hanson, 2006). The newest protocol from the Association of Women's Health and Newborn Nursing (AWHONN) recommends an open-glottis method in which air is released during pushing to prevent the buildup of intrathoracic pressure. Doing so also supports mother's involuntary bearing-down efforts (Roberts, Gonzalez, & Sampselle, 2007).

During the second stage of labor, pushing can either follow the mother's spontaneous urge or be directed by the caregiver. Much debate still exists between spontaneous and directed pushing during the second stage of labor. Although directed pushing is common practice in hospitals, there is evidence to suggest that directed pushing should be avoided. Research seems to support spontaneous pushing—when the woman is allowed to follow her own instincts (Hanson, 2006). Evidence is mounting that the management of the second stage, particularly pushing, is a modifiable risk factor in long-term perinatal outcomes. Valsalva (holding breath) bearing down and supine maternal positions are linked to negative maternal–fetal hemodynamics and outcomes. The adoption of a physiologic, woman-directed approach to bearing down is advocated (Roberts, Gonzalez, & Sampselle, 2007).

Evidence-based practice focuses on a physiologic approach to the second stage of labor. Behaviors demonstrated by laboring women during this time include push-

ing at the onset of the urge to bear down; using their own pattern and technique of bearing down in response to sensations they experience; using open-glottis bearing down with contractions; pushing with variations in strength and duration; pushing down with progressive intensity; and using multiple positions to increase progress and comfort. This approach is in stark contrast to management by arbitrary time limits and the directed bearing-down efforts seen in practice today (Hanson, 2006).

Laboring down (promotion of passive descent) is an alternative strategy for second-stage management in women with epidurals. Using this approach, the fetus descends and is born without coached maternal pushing.

The second stage of labor has two phases (pelvic and perineal) related to the existence and quality of the maternal urge to push and to obstetric conditions related to fetal descent. The early phase of the second stage is called the pelvic phase, because it is during this phase that the fetal head is negotiating the pelvis, rotating, and advancing in descent. The later phase is called the perineal phase, because at this point the fetal head is lower in the pelvis and is distending the perineum. The occurrence of a strong urge to push characterizes the later phase of the second stage and has also been called the phase of active pushing (Roberts, Gonzalez, & Sampselle, 2007).

The later perineal phase occurs when the mother feels a tremendous urge to push as the fetal head is lowered and is distending the perineum. The perineum bulges and there is an increase in bloody show. The fetal head becomes apparent at the vaginal opening but disappears between contractions. When the top of the head no longer regresses between contractions, it is said to have crowned. The fetus rotates as it maneuvers out. The second stage commonly lasts up to 3 hours in a first labor and up to an hour in subsequent ones (Fig. 13.13).

Third Stage

The third stage of labor begins with the birth of the newborn and ends with the separation and birth of the placenta. It consists of two phases: placental separation and placental expulsion.

Placental Separation

After the infant is born, the uterus continues to contract strongly and can now retract, decreasing markedly in size. These contractions cause the placenta to pull away from the uterine wall. The following signs of separation indicate that the placenta is ready to deliver:

- The uterus rises upward.
- The umbilical cord lengthens.
- A sudden trickle of blood is released from the vaginal opening.
- The uterus changes its shape to globular.

Spontaneous birth of the placenta occurs in one of two ways: the fetal side (shiny gray side) presenting first (called Schultz's mechanism or more commonly called "shiny Schultz's") or the maternal side (red raw side) presenting first (termed Duncan's mechanism or "dirty Duncan").

Placental Expulsion

After separation of the placenta from the uterine wall, continued uterine contractions cause the placenta to be expelled within 2 to 30 minutes unless there is gentle external traction to assist. After the placenta is expelled, the uterus is massaged briefly by the attending physician or midwife until it is firm so that uterine blood vessels constrict, minimizing the possibility of hemorrhage. Normal blood loss is approximately 500 mL for a vaginal birth and 1,000 mL for a cesarean birth (Arenson & Drake, 2007).

If the placenta does not spontaneously deliver, the health care professional assists with its removal by manual extraction. On expulsion, the placenta is inspected for its intactness by the health care professional and the nurse to make sure all sections are present. If any piece is still attached to the uterine wall, it places the woman at risk for postpartum hemorrhage because it becomes a space-occupying object that interferes with the ability of the uterus to contract fully and effectively.

Fourth Stage

The fourth stage begins with completion of the expulsion of the placenta and membranes and ends with the initial physiologic adjustment and stabilization of the mother (1 to 4 hours after birth). This stage initiates the postpartum period. The mother usually feels a sense of peace and excitement, is wide awake, and is very talkative initially. The attachment process begins with her inspecting her newborn and desiring to cuddle and breastfeed him or her. The mother's fundus should be firm and well contracted. Typically it is located at the midline between the umbilicus and the symphysis, but it then slowly rises to the level of the umbilicus during the first hour after birth (Walsh, 2007). If the uterus becomes boggy, it is massaged to keep it firm. The lochia (vaginal discharge) is red, mixed with small clots, and of moderate flow. If the woman has had an episiotomy during the second stage of labor, it should be intact, with the edges approximated and clean and no redness or edema present.

The focus during this stage is to monitor the mother closely to prevent hemorrhage, bladder distention, and venous thrombosis. Usually the mother is thirsty and hungry during this time and may request food and drink. Her bladder is hypotonic and thus she has limited sensation to acknowledge a full bladder or to void. Vital signs, the amount and consistency of the vaginal discharge (lochia), and the uterine fundus are usually monitored every 15 minutes for at least 1 hour. The woman will be

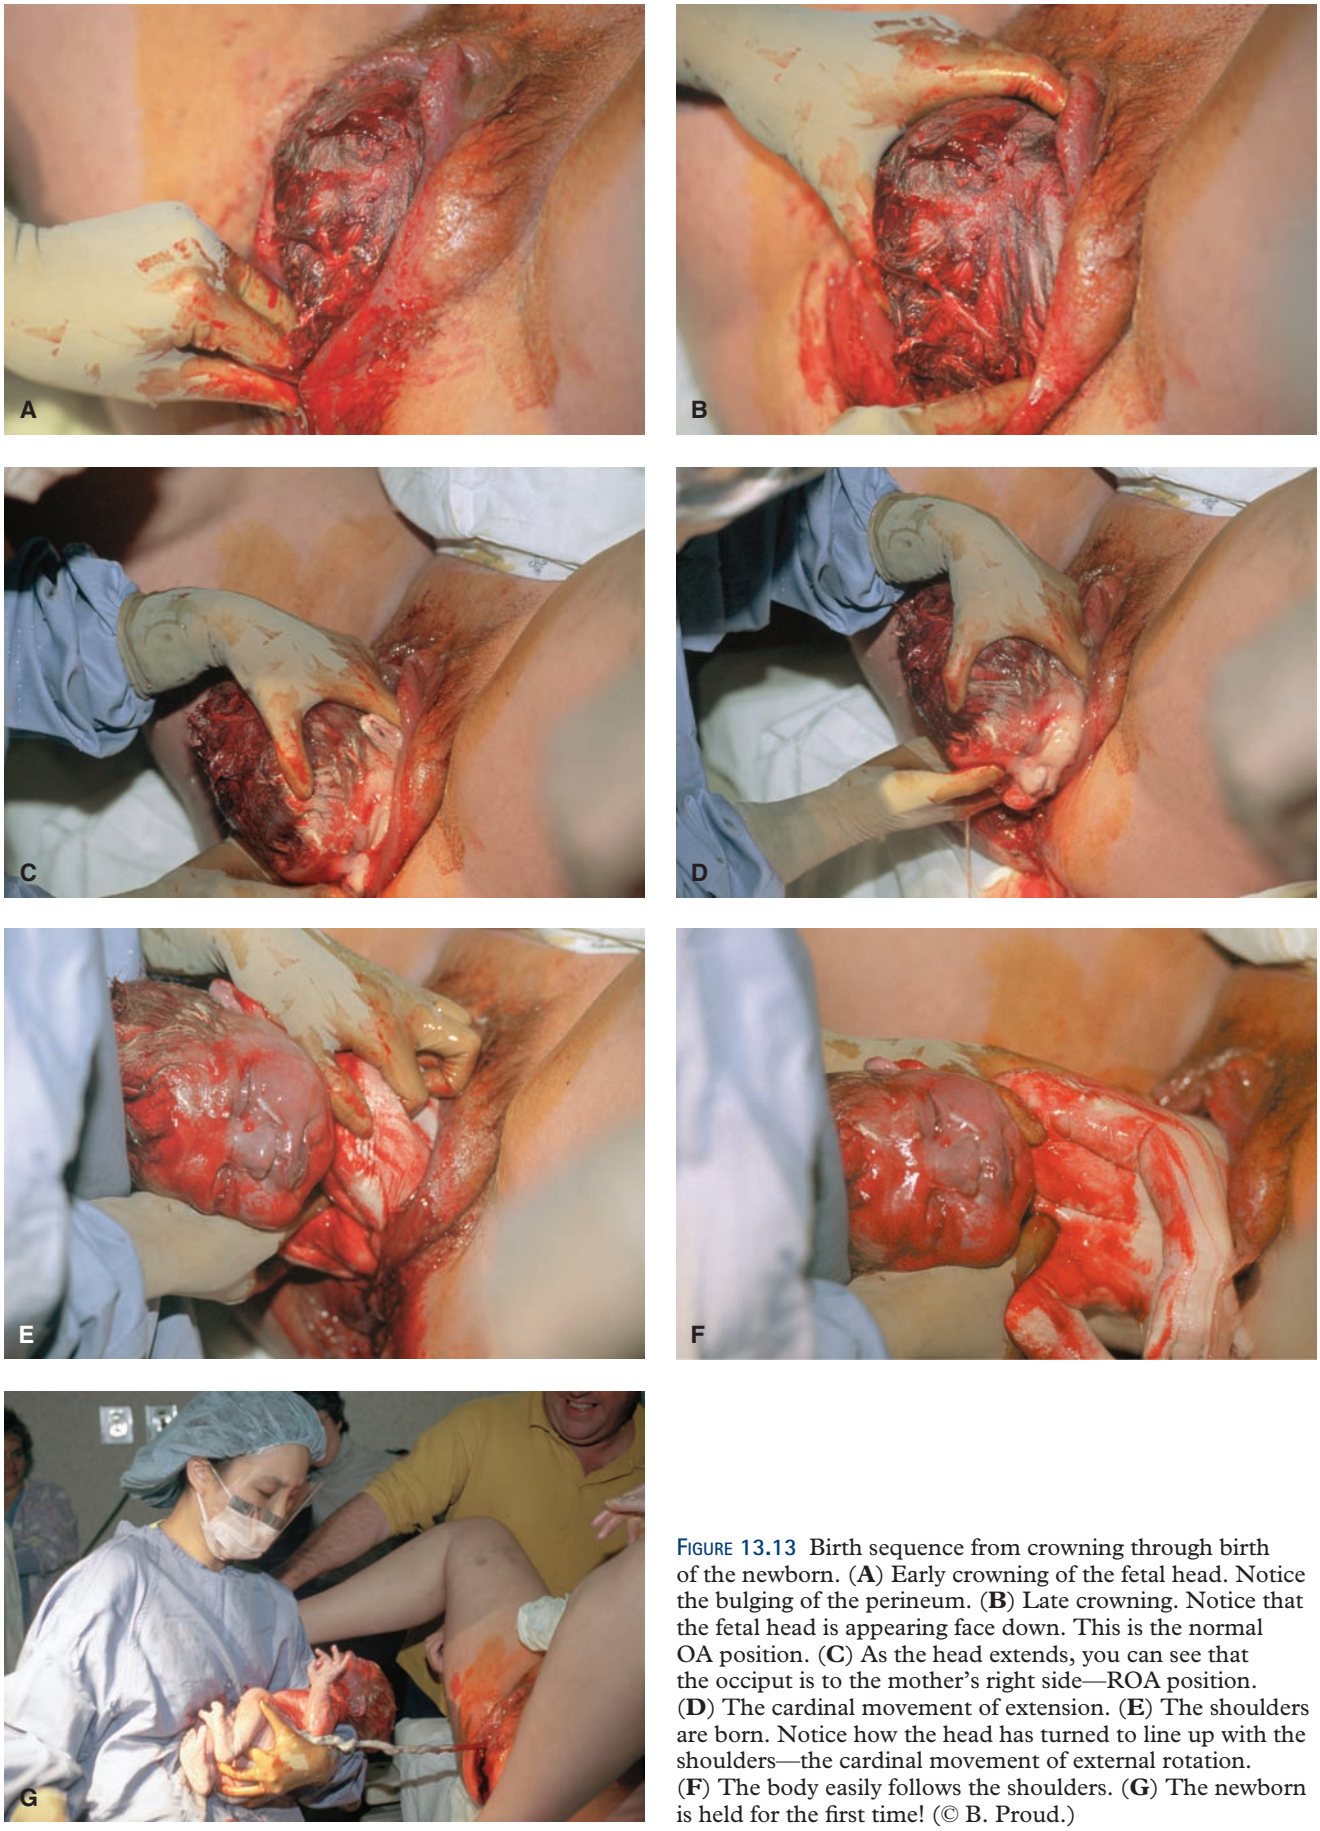

FIGURE 13.13 Birth sequence from crowning through birth of the newborn. (**A**) Early crowning of the fetal head. Notice the bulging of the perineum. (**B**) Late crowning. Notice that the fetal head is appearing face down. This is the normal OA position. (**C**) As the head extends, you can see that the occiput is to the mother's right side—ROA position. (**D**) The cardinal movement of extension. (**E**) The shoulders are born. Notice how the head has turned to line up with the shoulders—the cardinal movement of external rotation. (**F**) The body easily follows the shoulders. (**G**) The newborn is held for the first time! (© B. Proud.)

feeling cramp-like discomfort during this time due to the contracting uterus.

Key Concepts

- Labor is a complex, multifaceted interaction between the mother and fetus. Thus, it is difficult to determine exactly why labor begins and what initiates it.
- Before the onset of labor, a pregnant woman's body undergoes several changes in preparation for the birth of the newborn, often leading to characteristic signs and symptoms that suggest that labor is near. These changes include cervical changes, lightening, increased energy level, bloody show, Braxton Hicks contractions, and spontaneous rupture of membranes.
- False labor is a condition seen during the latter weeks of some pregnancies in which irregular uterine contractions are felt, but the cervix is not affected.
- The critical factors in labor and birth are designated as the 10 P's: passageway (birth canal), passenger (fetus and placenta), powers (contractions), psychological response, maternal position, philosophy (low tech, high touch), partners (support caregivers), patience (natural timing), patient preparation (childbirth knowledge base), and pain control (comfort measures).
- The size and shape of a woman's pelvis are determining factors for a vaginal birth. The female pelvis is classified according to four main groups: anthropoid, android, gynecoid, and platypelloid.
- The labor process is comprised of a series of rhythmic, involuntary, usually quite uncomfortable uterine muscle contractions that bring about a shortening (effacement) and opening (dilation) of the cervix, and a bursting of the fetal membranes. Important parameters of uterine contractions are frequency, duration, and intensity.
- The diameters of the fetal skull vary considerably, with some diameters shortening and others lengthening as the head is molded during the labor and birth process.
- Pain during labor is a nearly universal experience for childbearing women. Having a strong sense of self and meaningful support from others can often help women manage labor well and reduce their sensation of pain.
- Preparing mentally for childbirth is important for women to enable them to work with the natural forces of labor and not against them.
- As the woman experiences and progresses through childbirth, numerous physiologic responses occur that assist her adaptation to the laboring process.
- Labor is typically divided into four stages that are unequal in length.
- During the first stage, the fundamental change underlying the process is progressive dilation of the cervix. It is further divided into three phases: latent phase, active phase, and transition.
- The second stage of labor is from complete cervical dilation (10 cm) and effacement through the birth of the infant.
- The third stage is that of separation and birth of the placenta. It consists of two phases: placental separation and placental expulsion.
- The fourth stage begins after the birth of the placenta and membranes and ends with the initial physiologic adjustment and stabilization of the mother (1–4 hours).

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. When determining the frequency of contractions, the nurse would measure which of the following?
   a. Start of one contraction to the start of the next contraction
   b. Beginning of one contraction to the end of the same contraction
   c. Peak of one contraction to the peak of the next contraction
   d. End of one contraction to the beginning of the next contraction
2. Which fetal lie is most conducive to a spontaneous vaginal birth?
   a. Transverse
   b. Longitudinal
   c. Perpendicular
   d. Oblique
3. Which of the following observations would suggest that placental separation is occurring?
   a. Uterus stops contracting altogether.
   b. Umbilical cord pulsations stop.
   c. Uterine shape changes to globular.
   d. Maternal blood pressure drops.
4. As the nurse is explaining the difference between true versus false labor to her childbirth class, she states that the major difference between them is:
   a. Discomfort level is greater with false labor.
   b. Progressive cervical changes occur in true labor.
   c. There is a feeling of nausea with false labor.
   d. There is more fetal movement with true labor.
5. The shortest but most intense phase of labor is the:
   a. Latent phase
   b. Active phase
   c. Transition phase
   d. Placental expulsion phase
6. A laboring woman is admitted to the labor and birth suite at 6 cm dilation. She would be in which phase of the first stage of labor?
   a. Latent
   b. Active
   c. Transition
   d. Early
7. Which assessment would indicate that a women is in true labor?
   a. Membranes are ruptured and fluid is clear
   b. Presenting part is engaged and not floating
   c. Cervix is 4 cm dilated, 90% effaced
   d. Contractions last 30 seconds, every 5 to 10 minutes

CRITICAL THINKING EXERCISES

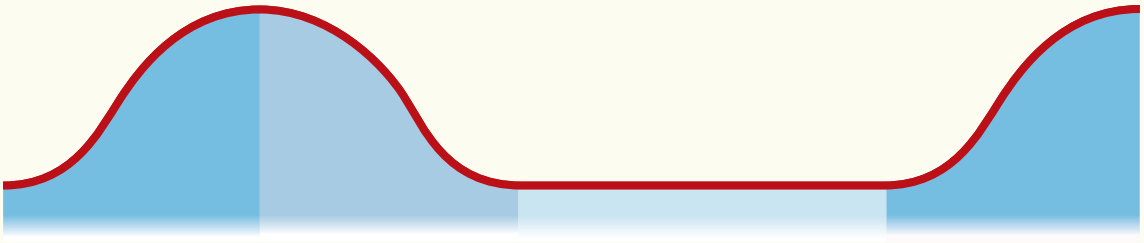
1. Cindy, a 20-year-old primipara, calls the birthing center where you work as a nurse and reports she thinks she is in labor because she feels labor pains. Her due date is this week. The midwives have been giving her prenatal care throughout this pregnancy.
   a. What additional information do you need to respond appropriately?
   b. What suggestions/recommendations would you make to her?
   c. What instructions need to be given to guide her decision making?
   d. What other premonitory signs of labor might the nurse ask about?
   e. What manifestations would be found if Cindy is experiencing true labor?
2. You are assigned to lead a community education class for women in their third trimester of pregnancy to prepare them for their upcoming birth. Prepare an outline of topics that should be addressed.

STUDY ACTIVITIES

1. During clinical post-conference, share with the other nursing students how the critical forces of labor influenced the length of labor and the birthing process for a laboring woman assigned to you.
2. The cardinal movements of labor include which of the following? Select all that apply.
   a. Extension and rotation
   b. Descent and engagement
   c. Presentation and position
   d. Attitude and lie
   e. Flexion and expulsion

3. Interview a woman on the mother–baby unit who has given birth within the past few hours. Ask her to describe her experience and examine psychological factors that may have influenced her laboring process.

4. On the following illustration, identify the parameters of uterine contractions by marking an "X" where the nurse would measure the duration of the contraction.



CHAPTER 14

Nursing Management During Labor and Birth

KEY TERMS

accelerations
artifact
baseline fetal heart rate
baseline variability
crowning
deceleration
electronic fetal monitoring
episiotomy
Leopold's maneuvers
neuraxial analgesia/anesthesia
periodic baseline changes

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms related to the labor and birth process.
2. Discuss the measures used to evaluate maternal status during labor and birth.
3. Explain the advantages and disadvantages of external and internal fetal monitoring, including the appropriate use for each.
4. Choose appropriate nursing interventions to address nonreassuring fetal heart rate patterns.
5. Outline the nurse's role in fetal assessment.
6. Explain the various comfort-promotion and pain-relief strategies used during labor and birth.
7. Summarize the assessment data collected on admission to the perinatal unit.
8. Discuss the ongoing assessments involved in each stage of labor and birth.
9. Explain the nurse's role throughout the labor and birth process.

Sheila is admitted in active labor (5 cm dilated) to the labor and birth suite at term. This is her second pregnancy and she is prepared to avoid pain medications this time so she can be more involved with the birthing process. She has been using modified-paced breathing with success thus far.

Wow

Wise nurses are not always silent, but they know when to be during the miracle of birth.

The laboring and birthing process is a life-changing event for many women. Nurses need to be respectful, available, encouraging, supportive, and professional in dealing with all women. Nursing management for labor and birth involves assessment, comfort measures, emotional support, information and instruction, advocacy, and support for the partner (Sauls, 2007).

The health of mothers and their infants is of critical importance, both as a reflection of the current health status of a large segment of our population and as a predictor of the health of the next generation. *Healthy People 2010* (USDHHS, 2000) addresses maternal health in two objectives: reducing maternal deaths and reducing maternal illness and complications due to pregnancy. In addition, another objective addresses increasing the proportion of pregnant women who attend prepared childbirth classes. (See Chapters 12 and 22 for more information on these objectives.)

This chapter provides information about nursing management during labor and birth. First, the essentials for in-depth assessment of maternal and fetal status during labor and birth are discussed. This is followed by a thorough description of the major methods of promoting comfort and providing pain management. The chapter concludes by putting all the information together with a discussion of the nursing care specific to each stage of labor, including the necessary data to be obtained with the admission assessment, methods to evaluate labor progress during the first stage of labor, and key nursing measures that focus on maternal and fetal assessments and pain relief for all stages of labor.

Maternal Assessment During Labor and Birth

During labor and birth, various techniques are used to assess maternal status. These techniques provide an ongoing source of data to determine the woman's response and her progress in labor. Assess maternal vital signs, including temperature, blood pressure, pulse, respiration, and pain, which are primary components of the physical examination and ongoing assessment. Also review the prenatal record to identify risk factors that may contribute to a decrease in uteroplacental circulation during labor. If there is no vaginal bleeding on admission, a vaginal examination is performed to assess cervical dilation, after which it is monitored periodically as necessary to identify progress. Evaluate maternal pain and the effectiveness of pain-management strategies at regular intervals during labor and birth.

Vaginal Examination

Although not all nurses perform vaginal examinations on laboring women in all practice settings, most nurses working in community hospitals do so because physicians are not routinely present in labor and birth suites. Since most newborns in the United States are born in community hospitals, nurses are performing vaginal examinations (American Hospital Association, 2007). Vaginal examinations are also performed by midwives and physicians.

▶ *Take* NOTE!

A vaginal examination is an assessment skill that takes time and experience to develop; only by doing it frequently in clinical practice can the practitioner's skill level improve.

The purpose of performing a vaginal examination is to assess the amount of cervical dilation, the percentage of cervical effacement, and the fetal membrane status and to gather information on presentation, position, station, degree of fetal head flexion, and presence of fetal skull swelling or molding (Fig. 14.1). Prepare the woman by informing her about the procedure, what information will be obtained from it, how she can assist with the procedure, how it will be performed, and who will be performing it.

The woman is typically on her back during the vaginal examination. The vaginal examination is performed gently, with concern for the woman's comfort. If it is the initial vaginal examination to check for membrane status, water is used as a lubricant. If the membranes have already ruptured, an antiseptic solution is used to prevent an ascending infection. After donning sterile gloves, the examiner inserts his or her index and middle fingers into the vaginal introitus. Next, the cervix is palpated to assess dilation, effacement, and position (e.g., posterior or an-

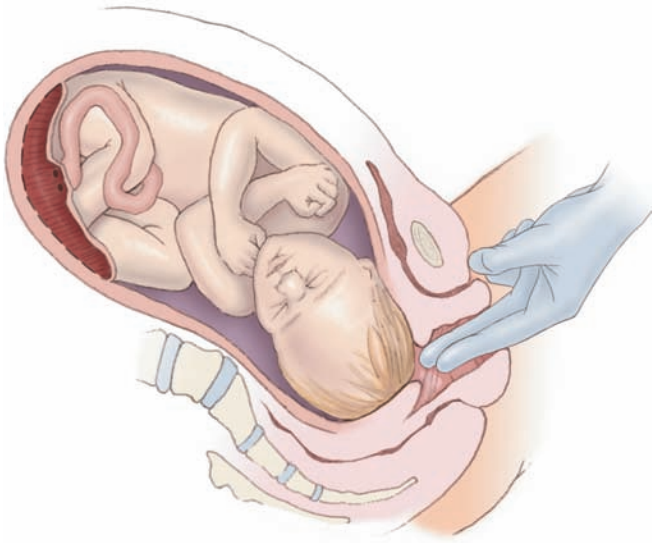


FIGURE 14.1 Vaginal examination to determine cervical dilation and effacement.

terior). If the cervix is open to any degree, the presenting fetal part, fetal position, station, and presence of molding can be assessed. In addition, the membranes can be evaluated and described as intact, bulging, or ruptured.

At the conclusion of the vaginal examination, the findings are discussed with the woman and her partner to bring them up to date about labor progress. In addition, the findings are documented either electronically or in writing and reported to the primary health care professional in charge of the case.

Cervical Dilation and Effacement

The amount of cervical dilation and the degree of cervical effacement are key areas assessed during the vaginal examination as the cervix is palpated with the gloved index finger. Although this finding is somewhat subjective, experienced examiners typically come up with similar findings. The width of the cervical opening determines dilation, and the length of the cervix assesses effacement. The information yielded by this examination serves as a basis for determining which stage of labor the woman is in and what her ongoing care should be.

Fetal Descent and Presenting Part

In addition to cervical dilation and effacement findings, the vaginal examination can also determine fetal descent (station) and presenting part. During the vaginal examination, the gloved index finger is used to palpate the fetal skull (if vertex presentation) through the opened cervix or the buttocks in the case of a breech presentation. Station is assessed in relation to the maternal ischial spines and the presenting fetal part. These spines are not sharp protrusions but rather blunted prominences at the midpelvis. The ischial spines serve as landmarks and have been designated as zero station. If the presenting part is palpated higher than the maternal ischial spines, a negative number is assigned; if the presenting fetal part is felt below the maternal ischial spines, a plus number is assigned, denoting how many centimeters below zero station.

Progressive fetal descent (−5 to +4) is the expected norm during labor—moving downward from the negative stations to zero station to the positive stations in a timely manner. If progressive fetal descent does not occur, a disproportion between the maternal pelvis and the fetus might exist and needs to be investigated.

Rupture of Membranes

The integrity of the membranes can be determined during the vaginal examination. Typically, if intact, the membranes will be felt as a soft bulge that is more prominent during a contraction. If the membranes have ruptured, the woman may have reported a sudden gush of fluid. Membrane rupture also may occur as a slow trickle of fluid. When membranes rupture, the priority focus should be on assessing fetal heart rate (FHR) first to identify a deceleration, which might indicate cord compression secondary to cord prolapse. If the membranes are ruptured when the woman comes to the hospital, it is important to ascertain when it occurred. Prolonged ruptured membranes increase the risk of infection as a result of ascending vaginal organisms for both mother and fetus. Signs of intrauterine infection to be alert for include maternal fever, fetal and maternal tachycardia, foul odor of vaginal discharge, and an increase in white blood cell count.

To confirm that membranes have ruptured, a sample of fluid is taken from the vagina and tested with Nitrazine paper to determine the fluid's pH. Vaginal fluid is acidic, whereas amniotic fluid is alkaline and turns Nitrazine paper blue. Sometimes, however, false-positive results may occur, especially in women experiencing a large amount of bloody show, because blood is alkaline. The membranes are most likely intact if the Nitrazine test tape remains yellow to olive green, with pH between 5 and 6. The membranes are probably ruptured if the Nitrazine test tape turns a blue-green to deep blue, with pH ranging from 6.5 to 7.5 (Frieden & Chan, 2007).

If the Nitrazine test is inconclusive, an additional test, called the fern test, can be used to confirm rupture of membranes. With this test, a sample of fluid is obtained, applied to a microscope slide, and allowed to dry. Using a microscope, the slide is examined for a characteristic fern pattern that indicates the presence of amniotic fluid.

Assessing Uterine Contractions

The primary power of labor is uterine contractions, which are involuntary. Uterine contractions increase intrauterine pressure, causing tension on the cervix. This tension leads to cervical dilation and thinning, which in turn eventually forces the fetus through the birth canal. Normal uterine contractions have a contraction (systole) and a relaxation (diastole) phase. The contraction resembles a wave, moving downward to the cervix and upward to the fundus of the uterus. Each contraction starts with a building up (increment), gradually reaching an acme (peak intensity), and then a letting down (decrement). Each contraction is followed by an interval of rest, which ends when the next contraction begins. At the acme (peak) of the contraction, the entire uterus is contracting, with the greatest intensity in the fundal area. The relaxation phase follows and occurs simultaneously throughout the uterus.

Uterine contractions during labor are monitored by palpation and by electronic monitoring. Assessment of the contractions includes frequency, duration, intensity, and uterine resting tone (see Chapter 13 for a more detailed discussion).

Uterine contractions with an intensity of 30 mm Hg or greater initiate cervical dilation. During active labor, the intensity usually reaches 50 to 80 mm Hg. Resting tone is normally between 5 and 10 mm Hg in early labor and between 12 and 18 mm Hg in active labor (Gilbert, 2007).

To palpate the fundus for contraction intensity, place the pads of your fingers on the fundus and describe how

FIGURE 14.2 Nurse palpating the woman's fundus during a contraction.

it feels: like the tip of the nose (mild), like the chin (moderate), or like the forehead (strong). Palpation of intensity is a subjective judgment of the indentability of the uterine wall; a descriptive term is assigned (mild, moderate, or strong) (Fig. 14.2).

▶ ***Take*** *NOTE!*

Frequent clinical experience is needed to gain accuracy in assessing the intensity of uterine contractions.

The second method used to assess the intensity of uterine contractions is electronic monitoring, either external or internal. Both methods provide an accurate measurement of the actual intensity of uterine contractions. Although the external fetal monitor is sometimes used to estimate the intensity of uterine contractions, it is not as accurate an assessment tool.

For woman at risk for preterm birth, home uterine activity monitoring can be used to screen for prelabor uterine contractility so that escalating contractility can be identified, allowing earlier intervention to prevent preterm birth. The home uterine activity monitor consists of a pressure sensor attached to a belt that is held against the abdomen and a recording/storage device that is carried on a belt or hung from the shoulder. Uterine activity is typically recorded by the woman for one hour twice daily, while she is performing routine activities. The stored data are transmitted via telephone to a perinatal nurse, and a receiving device prints out the data. The woman is contacted if there are any problems.

Although in theory identifying early contractions to initiate interventions to arrest the labor sounds reasonable, research shows that uterine activity monitoring in asymptomatic high-risk women is inadequate for predicting preterm birth (Herbst & Nilsson, 2006). This practice continues even though numerous randomized trials have found no relationship between monitoring and actual reduction of preterm labor. In more recent research findings, cervical length is predictive of preterm birth in all populations studied. A cervical length less than 25 mm warrants intervention to improve the health outcomes of pregnant women and their infants (Grimes-Dennis & Berghella, 2007).

Performing Leopold's Maneuvers

Leopold's maneuvers are a method for determining the presentation, position, and lie of the fetus through the use of four specific steps. This method involves inspection and palpation of the maternal abdomen as a screening assessment for malpresentation. A longitudinal lie is expected, and the presentation can be cephalic, breech, or shoulder. Each maneuver answers a question:

- What fetal part (head or buttocks) is located in the fundus (top of the uterus)?
- On which maternal side is the fetal back located? (Fetal heart tones are best auscultated through the back of the fetus.)
- What is the presenting part?
- Is the fetal head flexed and engaged in the pelvis?

Leopold's maneuvers are described in Nursing Procedure 14.1.

Fetal Assessment During Labor and Birth

A fetal assessment identifies well-being or signs that indicate compromise. The character of the amniotic fluid is assessed, but the fetal assessment focuses primarily on determining the FHR pattern. Fetal scalp sampling, fetal pulse oximetry, and fetal stimulation are additional assessments performed as necessary in the case of questionable FHR patterns.

Analysis of Amniotic Fluid

Amniotic fluid should be clear when the membranes rupture, either spontaneously or artificially through an amniotomy (a disposable plastic hook [Amnihook] is used to perforate the amniotic sac). Cloudy or foul-smelling amniotic fluid indicates infection. Green fluid may indicate that the fetus has passed meconium secondary to transient hypoxia; however, it is considered a normal occurrence if the fetus is in a breech presentation. If it is determined that meconium-stained amniotic fluid is due to fetal hypoxia, the maternity and pediatric teams work together to prevent meconium aspiration syndrome. This would necessitate suctioning after the head is born before the infant takes a breath and perhaps direct tracheal suctioning

Nursing Procedure 14.1

PERFORMING LEOPOLD'S MANEUVERS

Purpose: To Determine Fetal Presentation, Position, and Lie

1. Place the woman in the supine position and stand beside her.
2. Perform the first maneuver to determine presentation.
   a. Facing the woman's head, place both hands on the abdomen to determine fetal position in the uterine fundus.
   b. Feel for the buttocks, which will feel soft and irregular (indicates vertex presentation); feel for the head, which will feel hard, smooth, and round (indicates a breech presentation).

3. Complete the second maneuver to determine position.
   a. While still facing the woman, move hands down the lateral sides of the abdomen to palpate on which side the back is located (feels hard and smooth).
   b. Continue to palpate to determine on which side the limbs are located (irregular nodules with kicking and movement).

4. Perform the third maneuver to confirm presentation.
   a. Move hands down the sides of the abdomen to grasp the lower uterine segment and palpate the area just above the symphysis pubis.
   b. Place thumb and fingers of one hand apart and grasp the presenting part by bringing fingers together.
   c. Feel for the presenting part. If the presenting part is the head, it will be round, firm, and ballottable; if it is the buttocks, it will feel soft and irregular.

(continued)

Nursing Procedure 14.1 (continued)

5. Perform the fourth maneuver to determine attitude.
   a. Turn to face the client's feet and use the tips of the first three fingers of each hand to palpate the abdomen.
   b. Move fingers toward each other while applying downward pressure in the direction of the symphysis pubis. If you palpate a hard area on the side opposite the fetal back, the fetus is in flexion, because you have palpated the chin. If the hard area is on the same side as the back, the fetus is in extension, because the area palpated is the occiput.

Also, note how your hands move. If the hands move together easily, the fetal head is not descended into the woman's pelvic inlet. If the hands do not move together and stop because of resistance, the fetal head is engaged into the woman's pelvic inlet (Dillon, 2007).

after birth if the Apgar score is low. In some cases an amnioinfusion (introduction of warmed, sterile normal saline or Ringer's lactate solution into the uterus) is used to dilute moderate to heavy meconium released in utero to assist in preventing meconium aspiration syndrome.

Analysis of the FHR

Analysis of the FHR is one of the primary evaluation tools used to determine fetal oxygen status indirectly. FHR assessment can be done intermittently using a fetoscope (a modified stethoscope attached to a headpiece) or a Doppler (ultrasound) device, or continuously with an electronic fetal monitor applied externally or internally.

Intermittent FHR Monitoring

Intermittent FHR monitoring involves auscultation via a fetoscope or a hand-held Doppler device that uses ultrasound waves that bounce off the fetal heart, producing echoes or clicks that reflect the rate of the fetal heart (Fig. 14.3). Traditionally, a fetoscope was used to assess fetal heart rate, but the Doppler device has been found to have a greater sensitivity than the fetoscope (Edmonds, 2007); thus, at present it is more commonly used.

▶ *Take* NOTE!

Doppler devices are relatively low in cost and are not used only in hospitals. They are used in home births and birthing centers, and pregnant women can also purchase them to help reduce anxiety between clinical examinations if they had a previous problem during pregnancy (Walsh, 2007).

Intermittent FHR monitoring allows the woman to be mobile in the first stage of labor. She is free to move around and change position at will since she is not attached to a stationary electronic fetal monitor. However, intermittent monitoring does not provide a continuous FHR recording and does not document how the fetus responds to the stress of labor (unless listening is done during the contraction). The best way to assess fetal well-being would be to start listening to the FHR at the end of the contraction (not after one) so that late decelerations could be detected. However, the pressure of the device during a contraction is uncomfortable and can distract the woman from using her paced-breathing patterns.

Intermittent FHR auscultation can be used to detect FHR baseline and rhythm and changes from baseline. However, it cannot detect variability and types of decelerations, as electronic fetal monitoring can (Murray, 2007).

FIGURE 14.3 Auscultating fetal heart rate.

During intermittent auscultation to establish a baseline, the FHR is assessed for a full minute after a contraction. From then on, unless there is a problem, listening for 30 seconds and multiplying the value by two is sufficient. If the woman experiences a change in condition during labor, auscultation assessments should be more frequent. Changes in condition include ruptured membranes or the onset of bleeding. In addition, more frequent assessments occur after periods of ambulation, a vaginal examination, administration of pain medications, or other clinically important events (Hale, 2007).

The FHR is heard most clearly at the fetal back. In a cephalic presentation, the FHR is best heard in the lower quadrant of the maternal abdomen. In a breech presentation, it is heard at or above the level of the maternal umbilicus (Fig. 14.4). As labor progresses, the FHR location will change accordingly as the fetus descends into the maternal pelvis for the birthing process. To ensure that

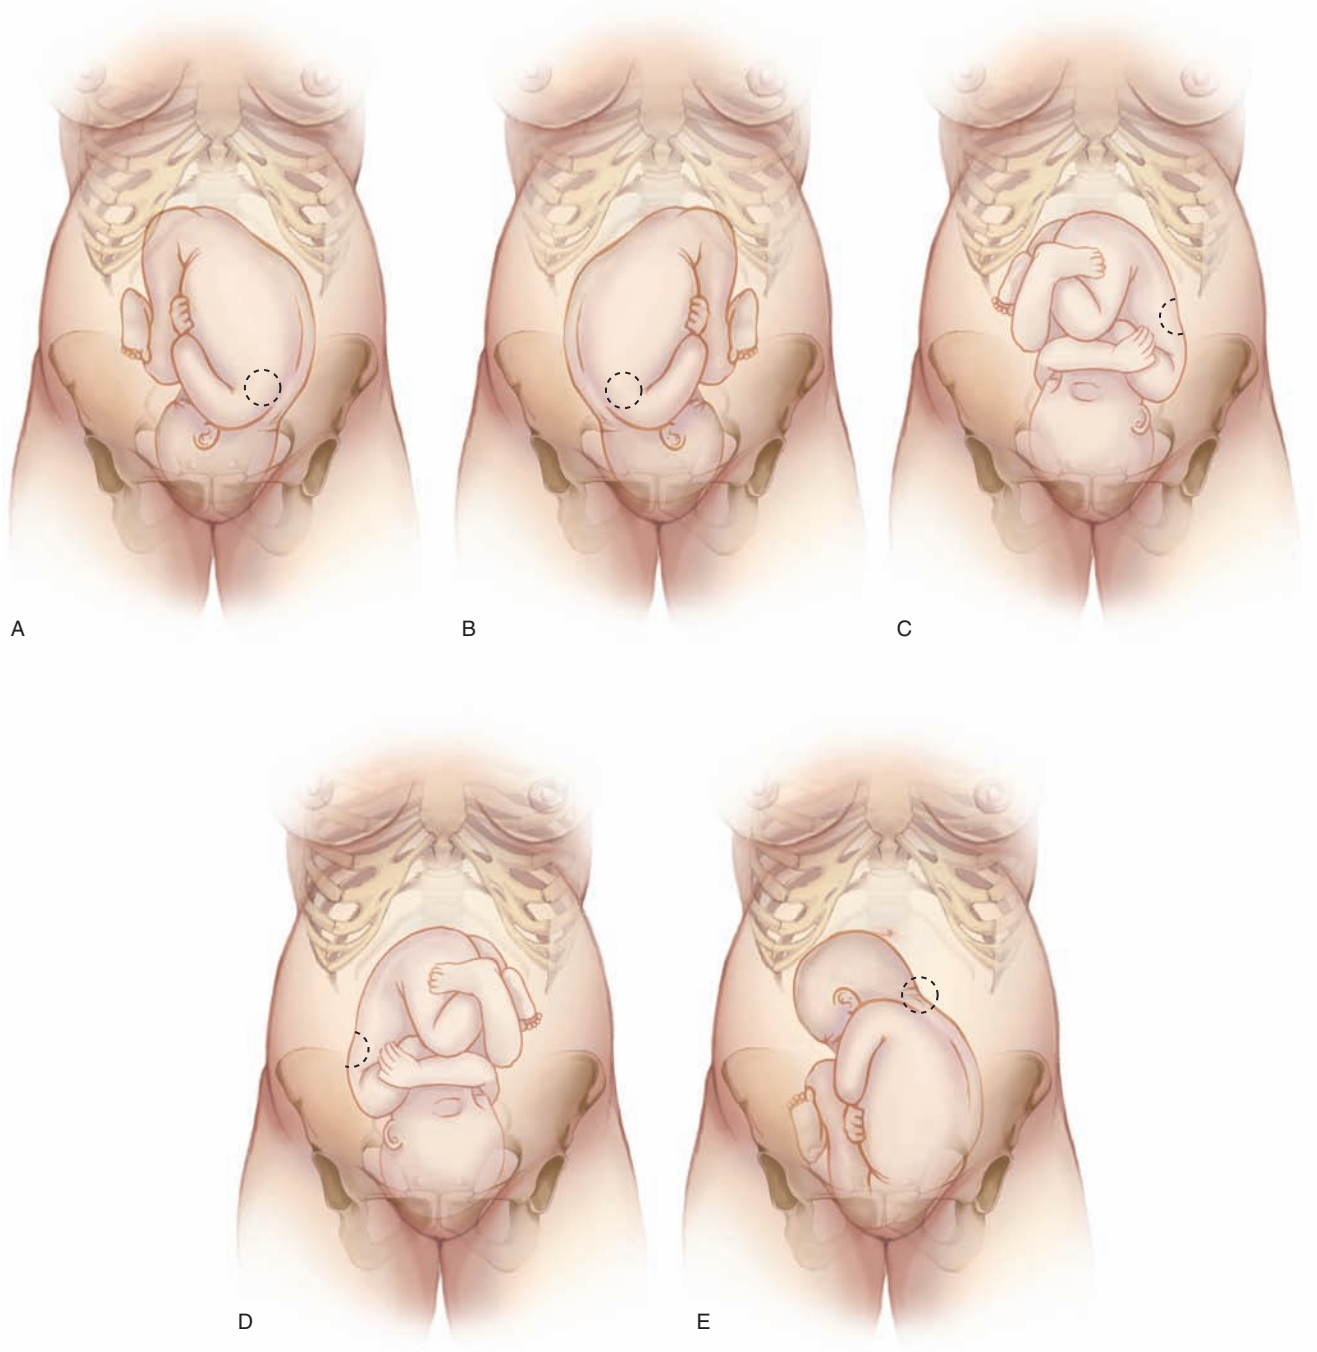

FIGURE 14.4 Locations for auscultating fetal heart rate based on fetal position. (**A**) Left occiput anterior (LOA). (**B**) Right occiput anterior (ROA). (**C**) Left occiput posterior (LOP). (**D**) Right occiput posterior (ROP). (**E**) Left sacral anterior (LSA).

the maternal heart rate is not confused with the FHR, palpate the client's radial pulse simultaneously while the FHR is being auscultated through the abdomen.

The procedure for using a fetoscope or Doppler device to assess FHR is similar (see Nursing Procedure 12.1 in Chapter 12). The main difference is that a small amount of water-soluble gel is applied to the woman's abdomen or ultrasound device before auscultation with the Doppler device to promote sound wave transmission. This gel is not needed when a fetoscope is used. Usually the FHR is best heard in the woman's lower abdominal quadrants; if it is not found quickly, it may help to locate the fetal back by performing Leopold's maneuvers.

Although the intermittent method of FHR assessment allows the client to move about during labor, the information obtained fails to provide a complete picture of the well-being of the fetus moment to moment. This leads to the question of what the fetal status is during the times that are not assessed. For women who are considered at low risk for complications, this period of non-assessment is not a problem. However, for the undiagnosed high-risk woman, it might prove ominous.

National professional organizations have provided general guidelines for the frequency of assessments based on existing evidence. The American College of Obstetricians and Gynecologists (ACOG), the Institute for Clinical Systems Improvement (ICSI), and the Association of Women's Health, Obstetric, and Neonatal Nurses (AWHONN) have published guidelines designed to assist clinicians in caring for laboring clients. Their recommendations are supported by large controlled studies. They recommend the following guidelines for assessing FHR:

- Initial 10- to 20-minute continuous FHR assessment on entry into labor/birth area
- Completion of a prenatal and labor risk assessment on all clients
- Intermittent auscultation every 30 minutes during active labor for a low-risk woman and every 15 minutes for a high-risk woman
- During the second stage of labor, every 15 minutes for the low-risk woman and every 5 minutes for the high-risk woman and during the pushing stage (ACOG, 2005; AWHONN, 2006; ICSI, 2007).

In several randomized controlled studies comparing intermittent auscultation with electronic monitoring in both low- and high-risk clients, no difference in intrapartum fetal death was found. However, in each study a nurse–client ratio of 1:1 was consistently maintained during labor (ICSI, 2007). This suggests that adequate staffing is essential with intermittent FHR monitoring to ensure optimal outcomes for the mother and fetus. There is insufficient evidence to indicate specific situations where continuous electronic fetal monitoring might result in better outcomes when compared to intermittent assessment. However, in pregnancies involving an increased risk of perinatal death, cerebral palsy, or neonatal encephalopathy and when oxytocin is used for induction or augmentation, it is recommended that continuous electronic fetal monitoring be used rather than intermittent fetal auscultation (Society of Obstetricians and Gynecologists of Canada, 2006).

Continuous Electronic Fetal Monitoring

Electronic fetal monitoring uses a machine to produce a continuous tracing of the FHR. When the monitoring device is in place, a sound is produced with each heartbeat. In addition, a graphic record of the FHR pattern is produced.

Current methods of continuous electronic fetal monitoring were introduced in the United States during the 1960s, specifically for use in clients considered to be at high risk. However, the use of these methods gradually increased and they eventually came to be used for women other than just those at high risk. This increased use has become controversial because it is suspected of being associated with the steadily increasing rates of cesarean births. Many studies suggest that when compared with standardized intermittent auscultation, the use of intrapartum electronic fetal monitoring seems to increase the number of preterm and surgical births but has no significant effect on reducing the incidence of intrapartum death or long-term neurologic injury (Lockwood, 2007).

With electronic fetal monitoring, there is a continuous record of the FHR: no gaps exist, as they do with intermittent auscultation. The concept of hearing and evaluating every beat of the fetus's heart to allow for early intervention seems logical. On the downside, however, using continuous monitoring can limit maternal movement and encourages the woman to lie in the supine position, which reduces placental perfusion. Despite the criticisms, electronic fetal monitoring remains an accurate method for determining fetal health status by providing a moment-to-moment printout of FHR status.

Various groups within the medical community have criticized the use of continuous fetal monitoring for all pregnant clients, whether high risk or low risk. Concerns about the efficiency and safety of routine electronic fetal monitoring in labor have led expert panels in the United States to recommend that such monitoring be limited to high-risk pregnancies. However, its use in low-risk pregnancies continues globally (Gagnon, Meier, & Waghorn, 2007). This remains an important research issue.

Continuous electronic fetal monitoring can be performed externally (indirectly), with the equipment attached to the maternal abdominal wall, or internally (directly), with the equipment attached to the fetus. Both methods provide a continuous printout of the FHR, but they differ in their specificity. The efficacy of electronic fetal monitoring depends on the accurate interpretation of the tracings, not necessarily which method (external vs. internal) is used.

Continuous External Monitoring

In external or indirect monitoring, two ultrasound transducers, each of which is attached to a belt, are applied around the woman's abdomen. They are similar to the hand-held Doppler device. One transducer, called a tocotransducer, detects changes in uterine pressure and converts the pressure registered into an electronic signal that is recorded on graph paper (Murray, 2007). The tocotransducer is placed over the uterine fundus in the area of greatest contractility to monitor uterine contractions. The other ultrasound transducer records the baseline FHR, long-term variability, accelerations, and decelerations. It is positioned on the maternal abdomen in the midline between the umbilicus and the symphysis pubis. The diaphragm of the ultrasound transducer is moved to either side of the abdomen to obtain a stronger sound and is then attached to the second elastic belt. This transducer converts the fetal heart movements into beeping sounds and records them on graph paper (Fig. 14.5).

Good continuous data are provided on the FHR. External monitoring can be used while the membranes are still intact and the cervix is not yet dilated. It is noninvasive and can detect relative changes in abdominal pressure between uterine resting tone and contractions. External monitoring also measures the approximate duration and frequency of contractions, providing a permanent record of FHR (Murray, 2007).

However, external monitoring can restrict the mother's movements. It also cannot detect short-term variability. Signal disruptions can occur due to maternal obesity, fetal malpresentation, and fetal movement, as well as by artifact. **Artifact** describes irregular variations or absence of FHR on the fetal monitor record that result from mechanical limitations of the monitor or electrical interference. For instance, the monitor may pick up transmissions from CB radios used by truck drivers on nearby roads and translate them into a signal. Additionally, gaps in the monitor strip can occur periodically without explanation.

FIGURE 14.5 Continuous external electronic fetal monitoring device applied to the woman in labor.

Continuous Internal Monitoring

Continuous internal monitoring is usually indicated for women or fetuses considered to be at high risk. Possible conditions might include multiple gestation, decreased fetal movement, abnormal FHR on auscultation, intrauterine growth restriction (IUGR), maternal fever, preeclampsia, dysfunctional labor, preterm birth, or medical conditions such as diabetes or hypertension. It involves the placement of a spiral electrode into the fetal presenting part, usually the head, to assess FHR and a pressure transducer placed internally within the uterus to record uterine contractions (Fig. 14.6). The fetal spiral electrode is considered the most accurate method of detecting fetal heart characteristics and patterns because it involves receiving a signal directly from the fetus (Murray, 2007). Trained labor and birth nurses can place the spiral electrode on the fetal head when the membranes rupture in some health care facilities, but they do not place the intrauterine pressure catheter in the uterus. Internal monitoring does not have to include both an intrauterine pressure catheter and a scalp electrode. A fetal scalp electrode can be used to monitor the fetal heartbeat without monitoring the maternal intrauterine pressure.

Both the FHR and the duration and interval of uterine contractions are recorded on the graph paper. This method permits evaluation of baseline heart rate and changes in rate and pattern.

Four specific criteria must be met for this type of monitoring to be used:

- Ruptured membranes
- Cervical dilation of at least 2 cm

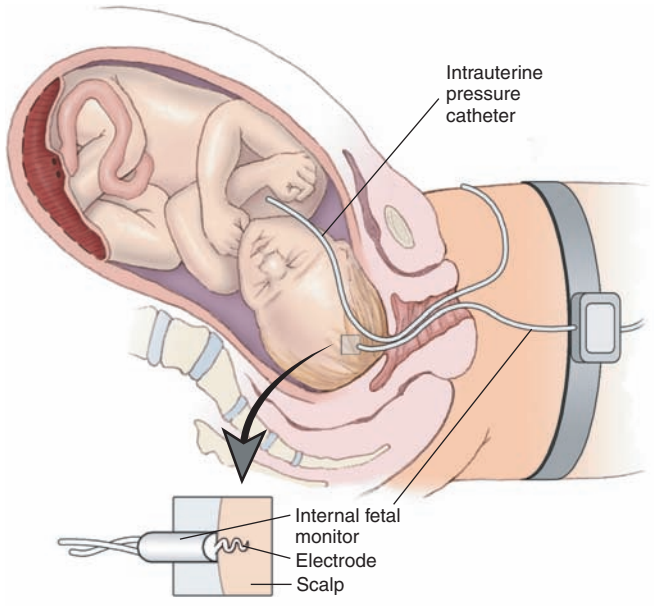

FIGURE 14.6 Continuous internal electronic fetal monitoring.

- Presenting fetal part low enough to allow placement of the scalp electrode
- Skilled practitioner available to insert spiral electrode (ICSI, 2007)

Compared to external monitoring, continuous internal monitoring can accurately detect both short-term (moment-to-moment) changes and long-term variability (fluctuations within the baseline) and FHR dysrhythmias. In addition, maternal position changes and movement do not interfere with the quality of the tracing.

Determining FHR Patterns

Assessment parameters of the FHR are classified as baseline rate, baseline variability (long-term and short-term), and periodic changes in the rate (accelerations and decelerations). The nurse must be able to interpret the various FHR parameters to determine if the pattern is reassuring (indicating fetal well-being) or nonreassuring (indicating fetal problems) to care for the woman effectively during labor and birth. Table 14.1 summarizes these patterns.

Baseline FHR

Baseline fetal heart rate refers to the average FHR that occurs during a 10-minute segment that excludes periodic or episodic rate changes, such as tachycardia or bradycardia. It is assessed when the woman has no contractions and the fetus is not experiencing episodic FHR changes. The normal baseline FHR ranges between 110 and 160 beats per minute (bpm) (National Institute of Child Health and Human Development [NICHD], 2006). The normal baseline FHR can be obtained by auscultation, ultrasound, or Doppler, or by a continuous internal direct fetal electrode.

Fetal bradycardia occurs when the FHR is below 110 bpm and lasts 10 minutes or longer (NICHD, 2006).

TABLE 14.1 INTERPRETING FHR PATTERNS

Reassuring FHR signs	• Normal baseline (110–160 bpm) • Moderate bradycardia (100–110 bpm); good variability • Good beat-to-beat variability and fetal accelerations
Nonreassuring signs	• Fetal tachycardia (>160 bpm) • Moderate bradycardia (100–110 bpm); lost variability • Absent beat-to-beat variability • Marked bradycardia (90–100 bpm) • Moderate variable decelerations
Ominous signs	• Fetal tachycardia with loss of variability • Prolonged marked bradycardia (<90 bpm) • Severe variable decelerations (<70 bpm) • Persistent late decelerations

Sources: Hale, 2007; Lockwood, 2007; Murray, 2007, NICHD, 2006.

It can be the initial response of a healthy fetus to asphyxia. Causes of fetal bradycardia might include fetal hypoxia, prolonged maternal hypoglycemia, fetal acidosis, administration of drugs to the mother, hypothermia, maternal hypotension, prolonged umbilical cord compression, and fetal congenital heart block (Arenson & Drake, 2007). Bradycardia may be benign if it is an isolated event, but it is considered an ominous sign when accompanied by a decrease in long-term variability and late decelerations.

Fetal tachycardia is a baseline FHR greater than 160 bpm that lasts for 10 minutes or longer (NICHD, 2006). It can represent an early compensatory response to asphyxia. Other causes of fetal tachycardia include fetal hypoxia, maternal fever, maternal dehydration, amnionitis, drugs (e.g., cocaine, amphetamines, nicotine), maternal hyperthyroidism, maternal anxiety, fetal anemia, prematurity, fetal heart failure, and fetal arrhythmias. Fetal tachycardia is considered an ominous sign if it is accompanied by a decrease in variability and late decelerations (Hale, 2007).

Baseline Variability

Baseline variability is defined as normal physiologic variations in the time intervals that elapse between each fetal heartbeat observed along the baseline in the absence of contractions, decelerations, and accelerations (Menihan & Kopel, 2008). It represents the interplay between the parasympathetic and sympathetic nervous systems. The constant interplay (push-and-pull effect) on the FHR from the parasympathetic and sympathetic systems produces a moment-to-moment change in the FHR. Because variability is in essence the combined result of autonomic nervous system branch function, its presence implies that the both branches are working and receiving adequate oxygen (Hale, 2007). Thus, variability is one of the most important characteristics of the FHR.

Variability is described in three ways: minimal or absent, moderate, and marked. Minimal or absent variability typically is caused by uteroplacental insufficiency, cord compression, maternal hypotension, uterine hyperstimulation, abruptio placentae, or a fetal dysrhythmia. Interventions to improve uteroplacental blood flow and perfusion through the umbilical cord include lateral positioning of the mother, increasing the IV fluid rate to improve maternal circulation, administering oxygen at 8 to 10 L/min by mask, considering internal fetal monitoring, documenting findings and reporting to the health care provider. Preparation for a surgical birth may be necessary if no changes occur after attempting the interventions.

Moderate viability indicates that the autonomic and central nervous systems of the fetus are well developed and well oxygenated. It is considered a good sign of fetal well-being and correlates with the absence of significant metabolic acidosis (Fig. 14.7).

Marked variability occurs when there are more than 25 beats of fluctuation in the FHR baseline. Causes of this include cord prolapse or compression, maternal hypotension, uterine hyperstimulation, and

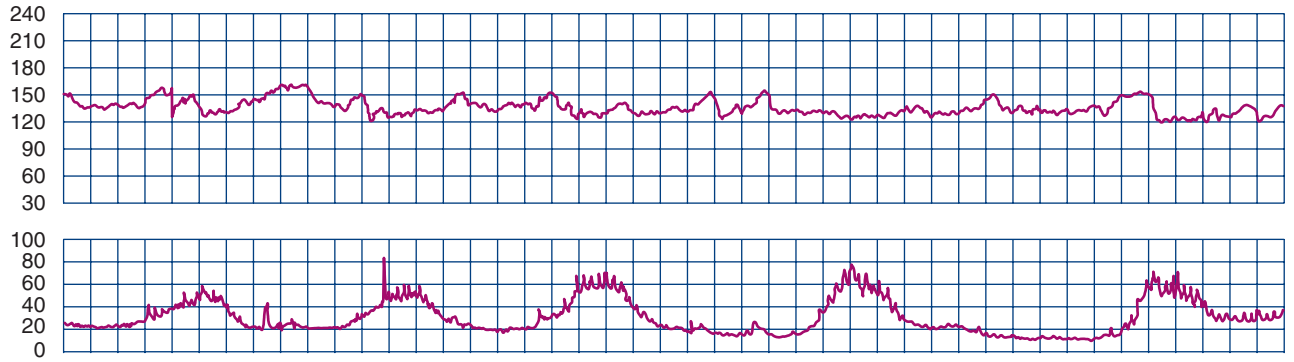

FIGURE 14.7 Long-term variability (average or moderate).

abruptio placentae. Interventions include determining the cause if possible, lateral positioning, increasing IV fluid rate, administering oxygen at 8 to 10 L/min by mask, discontinuing oxytocin infusion, observing for changes in tracing, considering internal fetal monitoring, communicating an abnormal pattern to the health care provider, and preparing for a surgical birth if no change in pattern is noted (Menihan & Kopel, 2008).

FHR variability is an important clinical indicator that is predictive of fetal acid–base balance and cerebral tissue perfusion (Bakker et al., 2007). As the central nervous system is desensitized by hypoxia and acidosis, FHR decreases until a smooth baseline pattern appears. Loss of variability may be associated with a poor outcome. Some causes of decreased variability include fetal hypoxia/acidosis, drugs that depress the central nervous system, congenital abnormalities, fetal sleep, prematurity, and fetal tachycardia (Walsh, 2007).

▶ ***Take*** NOTE!

External electronic fetal monitoring cannot assess short-term variability. Therefore, if external monitoring shows a baseline that is smoothing out, use of an internal spiral electrode should be considered to gain a more accurate picture of the fetal health status.

Periodic Baseline Changes

Periodic baseline changes are temporary, recurrent changes made in response to a stimulus such as a contraction. The FHR can demonstrate patterns of acceleration or deceleration in response to most stimuli. Fetal **accelerations** are transitory increases in the FHR above the baseline associated with sympathetic nervous stimulation. They are visually apparent, with elevations of FHR of more than 15 bpm above the baseline, and their duration is less than 2 minutes (NICHD, 2006). They are generally considered reassuring and require no interventions. Accelerations denote fetal movement and fetal well-being and are the basis for nonstress testing.

A **deceleration** is a transient fall in FHR caused by stimulation of the parasympathetic nervous system. Decelerations are described by their shape and association to a uterine contraction. They are classified as early, late, variable, and prolonged (Fig. 14.8).

Early decelerations are characterized by a gradual decrease in the FHR in which the nadir (lowest point) occurs at the peak of the contraction. They rarely decrease more than 30 to 40 bpm below the baseline. Typically, the onset, nadir, and recovery of the deceleration occur at the same time as the onset, peak and recovery of the contraction. They are most often seen during the active stage of any normal labor, during pushing, crowning, or vacuum extraction. They are thought to be a result of fetal head compression that results in a reflex vagal response with a resultant slowing of the FHR during uterine contractions. Early decelerations are not indicative of fetal distress and do not require intervention.

Late decelerations are transitory decreases in FHR that occur after a contraction begins. The FHR does not return to baseline levels until well after the contraction has ended. Delayed timing of the deceleration occurs, with the nadir of the uterine contraction. Late decelerations are associated with uteroplacental insufficiency, which occurs when blood flow within the intervillous space is decreased to the extent that fetal hypoxia exists (Bakker et al., 2007). Conditions that may decrease uteroplacental perfusion with resultant decelerations include maternal hypotension, gestational hypertension, placental aging secondary to diabetes and postmaturity, hyperstimulation via oxytocin infusion, maternal smoking, anemia, and cardiac disease. They imply some degree of fetal hypoxia. Repetitive late decelerations and late decelerations with decreasing baseline variability are nonreassuring signs. Box 14.1 highlights interventions for decelerations.

Variable decelerations present as visually apparent abrupt decreases in FHR below baseline and have an unpredictable shape on the FHR baseline, possibly demonstrating no consistent relationship to uterine contractions. The shape of variable decelerations may be U, V, or W, or they may not resemble other patterns (Hale, 2007). Variable decelerations usually occur abruptly with quick deceleration. They are the most common deceleration pattern

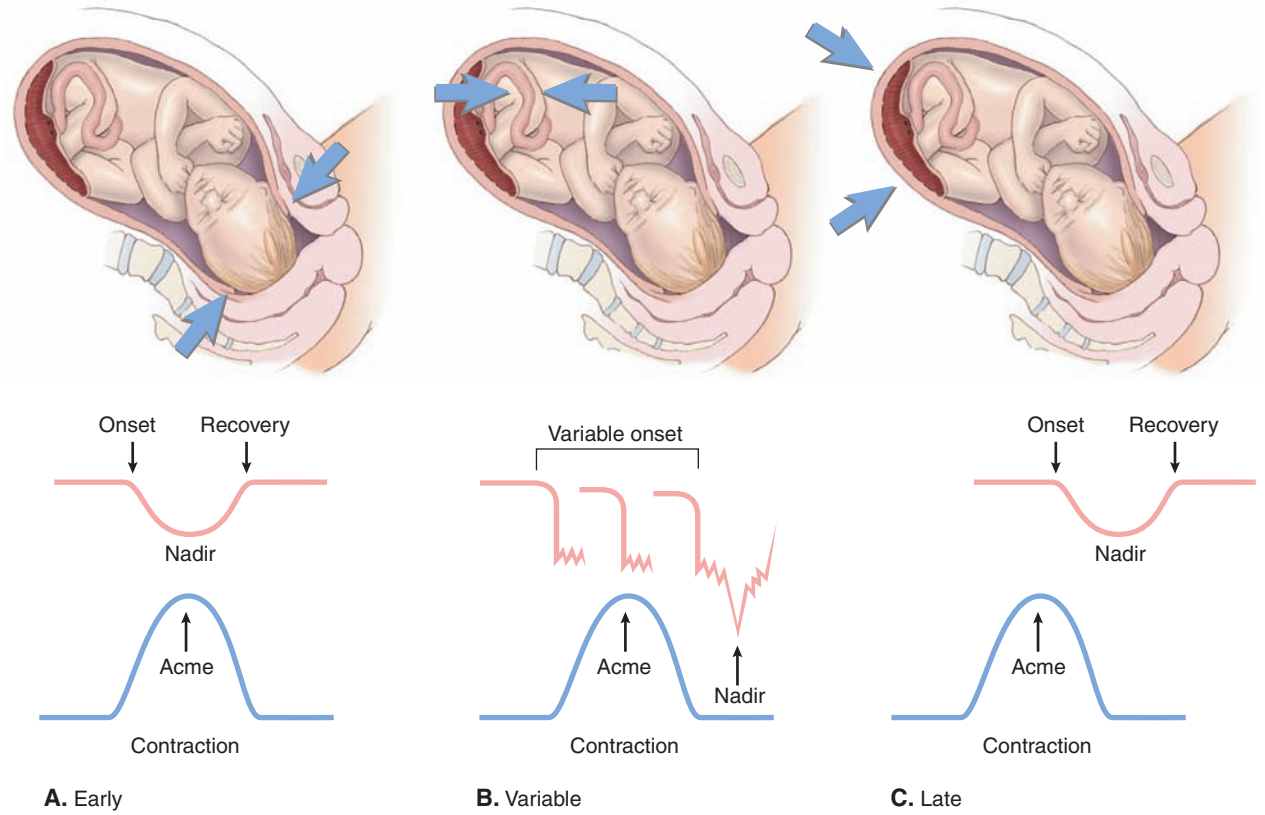

FIGURE 14.8 Decelerations. (**A**) Early. (**B**) Variable. (**C**) Late.

found in the laboring woman and are usually transient and correctable (Murray, 2007). Variable decelerations are associated with cord compression. However, they become a nonreassuring sign when the FHR decreases to less than 60 bpm, persists at that level for at least 60 seconds, and is repetitive (ICSI, 2007). The pattern of variable deceleration consistently related to the contractions with a slow return to FHR baseline is also nonreassuring.

Prolonged decelerations are abrupt FHR declines of at least 15 bpm that last longer than 2 minutes but less than 10 minutes (NICHD, 2006). The rate usually drops to less than 90 bpm. Many factors are associated with this pattern, including prolonged cord compression, abruptio placentae, cord prolapse, supine maternal position, vaginal examination, fetal blood sampling, maternal seizures, regional anesthesia, or uterine rupture (Murray, 2007). Prolonged decelerations can be remedied by identifying the underlying cause and correcting it.

Combinations of FHR patterns obtained by electronic fetal monitoring during labor are not infrequent. Nonreassuring patterns are more significant if they are mixed and persist for long periods. Other nonreassuring patterns include prolonged late decelerations, absent or minimal variability, bradycardia or tachycardia, and prolonged variable decelerations lower than 60 bpm. The likelihood of fetal compromise is increased if various nonreassuring patterns coexist, particularly those associated with decreased baseline variability or abnormal contraction patterns (ICSI, 2007).

Other Fetal Assessment Methods

In situations suggesting the possibility of fetal compromise, such as inconclusive or nonreassuring FHR patterns, further ancillary testing such as fetal scalp sampling, fetal pulse oximetry, and fetal stimulation may be used to validate the FHR findings and assist in planning interventions.

Fetal Scalp Sampling

Fetal scalp sampling was developed as a means of measuring fetal distress in conjunction with electronic fetal monitoring to make critical decisions about the management of labor and to prevent unnecessary operative interventions resulting from the use of electronic fetal monitoring alone. Nonreassuring FHR patterns may not necessarily indicate fetal hypoxia or acidosis. Therefore, assessing fetal acid–base status through fetal scalp sampling may help to prevent unnecessary surgical intervention.

A sample of fetal scalp blood is obtained to measure the pH. Sampling requires that the woman have ruptured membranes, cervical dilation of at least 3 to 5 cm, and a vertex presentation at –1 station (Moses, 2007). Normal fetal blood pH is 7.25 to 7.35. When the fetal scalp pH is below 7.15, this is a nonreassuring finding indicating acidosis (Moses, 2007).

BOX 14.1 Interventions for Nonreassuring Decelerations

If a patient develops a nonreassuring deceleration pattern such as late or variable decelerations:
- Notify the health care provider about the pattern and obtain further orders, making sure to document all interventions and their effects on the FHR pattern.
- Reduce or discontinue oxytocin as dictated by the facility's protocol, if it is being administered.
- Provide reassurance that interventions are being done to effect a pattern change.

Additional interventions specific for a late deceleration FHR pattern would include:
- Turning the client on her left side to increase placental perfusion
- Administering oxygen by mask to increase fetal oxygenation
- Increasing the IV fluid rate to improve intravascular volume
- Assessing client for any underlying contributing causes
- Providing reassurance that interventions are to effect pattern change

Specific interventions for a variable deceleration FHR pattern would include:
- Changing the client's position to relieve compression on the cord
- Providing reassurance that interventions are to effect pattern change
- Giving oxygen and IV fluids as ordered

▶ ***Take*** *NOTE!*

During the past decade, the use of fetal scalp sampling has decreased, being replaced by less invasive techniques that yield similar information.

Fetal Oxygen Saturation Monitoring (Fetal Pulse Oximetry)

Fetal pulse oximetry measures fetal oxygen saturation directly and in real time. It is used with electronic fetal monitoring as an adjunct method of assessment when the FHR pattern is nonreassuring or inconclusive. Normal oxygen saturation of a healthy fetus is 30% to 70% (Miller, 2007). If the fetal oxygen saturation is reassuring (a trend of more than 30% between contractions), unnecessary cesarean births, invasive procedures such as fetal blood sampling, and operative vaginal births can be minimized (Peek, Condous, & Nanan, 2007). Any reduction in unnecessary interventions during labor and birth has the potential to improve maternal and fetal outcomes and reduce costs.

Adequate maintenance of fetal oxygenation is necessary for fetal well-being. Fetal oxygen saturation monitoring is used for a singleton term fetus in a vertex presentation, at a –2 station or below, and with a nonreassuring FHR pattern. In addition, the fetal membranes must be ruptured and the cervix dilated at least 2 cm (Gilbert, 2007). A soft sensor is introduced through the dilated cervix and placed on the cheek, forehead, or temple of the fetus. It is held in place by the uterine wall. The sensor then is attached to a special adaptor on the fetal monitor that provides a real-time recording that is displayed on the uterine activity panel of the tracing. It is a noninvasive, safe, and accurate method for assessing fetal oxygenation.

The fetal pulse oximetry traces along the contraction portion of the monitoring strip, so it is easy to see how the saturation changes with the contraction. This adjunct test can help support decisions to allow labor to continue or to intervene surgically. Observing the trend of oxygen saturation on the tracing and documenting the values on the labor flow sheet or other medical record forms is crucial. The physician or midwife must be notified if the fetal oxygen saturation becomes nonreassuring (less than 30% between contractions) in conjunction with a nonreassuring FHR pattern. Ongoing communication is needed between the nurse and the primary care provider to enhance the maternal–fetus status.

Fetal Stimulation

An indirect method used to evaluate fetal oxygenation and acid–base balance to identify fetal hypoxia is fetal scalp stimulation and vibroacoustic stimulation. If the fetus does not have adequate oxygen reserves, carbon dioxide builds up, leading to acidemia and hypoxemia. These metabolic states are reflected in nonreassuring FHR patterns as well as fetal inactivity. Fetal stimulation is performed to promote fetal movement with the hope that FHR accelerations will accompany the movement.

Fetal movement can be stimulated with a vibroacoustic stimulator (artificial larynx) applied to the woman's lower abdomen and turned on for a few seconds to produce sound and vibration or by tactile stimulation via pelvic examination and stimulation of the fetal scalp with the gloved fingers. A well-oxygenated fetus will respond when stimulated (tactile or by noise) by moving in conjunction with an acceleration of 15 bpm above the baseline heart rate that lasts at least 15 seconds. This FHR acceleration reflects a pH of more than 7 and a fetus with an intact central nervous system. Fetal scalp stimulation is not done if the fetus is preterm, or if the woman has an intrauterine infection, a diagnosis of placenta previa (which could lead to hemorrhage), or a fever (which increases the risk of an ascending infection) (Gilbert, 2007).

Promoting Comfort and Providing Pain Management During Labor

Pain during labor is a universal experience, although the intensity of the pain may vary. Although labor and childbirth are viewed as natural processes, both can produce significant pain and discomfort. The physical causes of pain during labor include cervical stretching, hypoxia of the uterine muscle due to a decrease in perfusion during contractions, pressure on the urethra, bladder, and rectum, and distention of the muscles of the pelvic floor (Leonard, 2007). A woman's pain perception can be influenced by her previous experiences with pain, fatigue, pain anticipation, positive or negative support system, labor and birth environment, cultural expectations, and level of emotional stress and anxiety (Albers, 2007).

The techniques used to manage the pain of labor vary according to geography and culture. For example, some Appalachian women believe that placing a hatchet or knife under the bed of a laboring woman may help "cut the pain of childbirth," and a woman from this background may wish to do so in the hospital setting (Bowers, 2007). Asian, Latino, and Orthodox Jewish women may request that their own mothers, not their husbands, attend their births; husbands do not actively participate in the birthing process. Cherokee, Hmong, and Japanese women will often remain quiet during labor and birth and not complain of pain because outwardly expressing pain is not appropriate in their cultures. Never interpret their quietness as freedom from pain (Bowers, 2007).

Culturally diverse childbearing families present to the labor and birth suites with the same needs and desires of all families. Give them the same respect and sense of welcome shown to all families. Make sure they have a high-quality birth experience: uphold their religious, ethnic, and cultural values and integrate them into care.

Today, women have many safe nonpharmacologic and pharmacologic choices for the management of pain during labor and birth, which may be used separately or in combination with one another.

Nurses are in an ideal position to provide childbearing women with balanced, clear, concise information about effective nonpharmacologic and pharmacologic measures to relieve pain. Pain management standards issued by JCAHO mandate that pain be assessed in all clients admitted to a health care facility. Thus, it is important for nurses to be knowledgeable about the most recent scientific research on labor pain-relief modalities, to make sure that accurate and unbiased information about effective pain-relief measures is available to laboring women, to be sure that the woman determines what is an acceptable labor pain level for her, and to allow the woman the choice of pain-relief method.

Nonpharmacologic Measures

Nonpharmacologic measures may include continuous labor support, hydrotherapy, ambulation and position changes, acupuncture and acupressure, attention focusing and imagery, therapeutic touch and massage, breathing techniques, and effleurage. Most of these methods are based on the "gate control" theory of pain, which proposes that local physical stimulation can interfere with pain stimuli by closing a hypothetical gate in the spinal cord, thus blocking pain signals from reaching the brain (Arenson & Drake, 2007). It has long been a standard of care for labor nurses to first provide or encourage a variety of nonpharmacologic measures before moving to the pharmacologic interventions.

Nonpharmacologic measures are usually simple, safe, and inexpensive to use. Many of these measures are taught in childbirth classes, and women should be encouraged to try a variety of methods prior to the real labor. Many of the measures need to be practiced for best results and coordinated with the partner/coach. The nurse provides support and encouragement for the woman and her partner using nonpharmacologic methods. Although women can't consciously direct the labor contractions, they can control how they respond to them, thereby enhancing their feelings of control.

Continuous Labor Support

Continuous labor support involves offering a sustained presence to the laboring woman by providing emotional support, comfort measures, advocacy, information and advice, and support for the partner (Gagnon, Meier, & Waghorn, 2007). A woman's family, a midwife, a nurse, a doula, or anyone else close to the woman can provide this continuous presence. A support person can assist the woman to ambulate, reposition herself, and use breathing techniques. A support person can also aid with the use of acupressure, massage, music therapy, or therapeutic touch. During the natural course of childbirth, a laboring woman's functional ability is limited secondary to pain, and she often has trouble making decisions. The support person can help make them based on his or her knowledge of the woman's birth plan and personal wishes.

Research has validated the value of continuous labor support versus intermittent support in terms of lower operative deliveries, cesarean births, and requests for pain medication (Armstrong & Feldman, 2007).

▶ *Take* NOTE!

The human presence is of immeasurable value to make the laboring woman feel secure.

Hydrotherapy

Hydrotherapy is a nonpharmacologic measure in which the woman immerses herself in warm water for relaxation

and relief of discomfort. When the woman enters the warm water, the warmth and buoyancy help to release muscle tension and can impart a sense of well-being (Koenig, 2007). Warm water provides soothing stimulation of nerves in the skin, promoting vasodilatation, reversal of sympathetic nervous response, and a reduction in catecholamines (Blackburn, 2007). Contractions are usually less painful in warm water because the warmth and buoyancy of the water have a relaxing effect.

There are a wide range of hydrotherapy options available, from ordinary bathtubs to whirlpool baths and showers, combined with low lighting and music. Many hospitals provide showers and whirlpool baths for laboring women for pain relief. However, hydrotherapy is more commonly practiced in birthing centers managed by midwives. The recommendation for initiating hydrotherapy is that the woman be in active labor (more than 5 cm dilated) to prevent the slowing of labor contractions secondary to muscular relaxation. The woman's membranes can be intact or ruptured. Women are encouraged to stay in the bath or shower as long as they feel they are comfortable. The water temperature should not exceed body temperature, and the bath time typically is limited to 1 to 2 hours (Koenig, 2007).

Hydrotherapy is an effective pain-management option for many women. Women who are experiencing a healthy pregnancy can be offered this option, but the potential benefits or risks to the woman are still not known (Fink, Irwin, & Mitchell, 2007).

Ambulation and Position Changes

Ambulation and position changes during labor are another extremely useful comfort measure. Historically, women adopted a variety of positions during labor, rarely using the recumbent position until recently. The medical profession has favored recumbent positions during labor, but without evidence to demonstrate their appropriateness (Sleutel, Schultz, & Wyble, 2007).

Changing position frequently (every 30 minutes or so)—sitting, walking, kneeling, standing, lying down, getting on hands and knees, and using a birthing ball—helps relieve pain (Fig. 14.9). Position changes also may help to speed labor by adding the benefits of gravity and changing the shape of the pelvis. Research has found that the position that the woman assumes and the frequency of position changes have a profound effect on uterine activity and efficiency. Allowing the woman to obtain a position of comfort frequently facilitates a favorable fetal rotation by altering the alignment of the presenting part with the pelvis. As the mother continues to change position based on comfort, the optimal presentation is afforded (Gilbert, 2007). Supine and sitting positions should be avoided, since they may interfere with labor progress and can cause compression of the vena cava and decrease blood return to the heart.

Swaying from side to side, rocking, or other rhythmic movements may also be comforting. If labor is progressing slowly, ambulating may speed it up again. Upright positions such as walking, kneeling forward, or doing the lunge on the birthing ball give most women a greater sense of control and active movement than just lying down. Table 14.2 highlights some of the more common positions that can be used during labor and birth.

Acupuncture and Acupressure

Acupuncture and acupressure can be used to relieve pain during labor. Although controlled research studies of these methods are limited, there is adequate evidence that both are useful in relieving pain associated with labor and birth. However, both methods require a trained, certified clinician, and such a person is not available in many birth facilities (Hantoushzadeh, Alhusseini, & Lebaschi, 2007).

Acupuncture involves stimulating key trigger points with needles. This form of Chinese medicine has been practiced for approximately 3,000 years. Classical Chinese teaching holds that throughout the body there are meridians or channels of energy (*qi*) that when in balance regulate body functions. Pain reflects an imbalance or obstruction of the flow of energy. The purpose of acupuncture is to restore *qi,* thus diminishing pain (Koenig, 2007). Stimulating the trigger points causes the release of endorphins, reducing the perception of pain.

Acupressure involves the application of a firm finger or massage at the same trigger points to reduce the pain sensation. The amount of pressure is important. The intensity of the pressure is determined by the needs of the woman. Holding and squeezing the hand of a woman in labor may trigger the point most commonly used for both techniques. Some acupressure points are found along the spine, neck, shoulder, toes, and soles of the feet (Armstrong & Feldman, 2007). A Cochrane Collaboration review found that acupuncture may indeed reduce labor pain, but the number of women studied has been small (Smith et al., 2006).

Attention Focusing and Imagery

Attention focusing and imagery uses many of the senses and the mind to focus on stimuli. The woman can focus on tactile stimuli such as touch, massage, or stroking. She may focus on auditory stimuli such as music, humming, or verbal encouragement. Visual stimuli might be any object in the room, or the woman can imagine the beach, a mountaintop, a happy memory, or even the contractions of the uterine muscle pulling the cervix open and the fetus pressing downward to open the cervix. Some women focus on a particular mental activity such as a song, a chant, counting backwards, or a Bible verse. Breathing, relaxation, positive thinking, and positive visualization work well for mothers in labor. The use of these techniques keeps the sensory input perceived during the contraction from reaching the pain center in the cortex of the brain (Armstrong & Feldman, 2007).

FIGURE 14.9 Various positions for use during labor. (**A**) Ambulation. (**B**) Leaning forward. (**C**) Sitting in a chair. (**D**) Using a birthing ball.

Therapeutic Touch and Massage

Therapeutic touch and massage use the sense of touch to promote relaxation and pain relief. Massage works as a form of pain relief by increasing the production of endorphins in the body. Endorphins reduce the transmission of signals between nerve cells and thus lower the perception of pain (Blackburn, 2007). In addition, touching and massage distract the woman from discomfort.

Therapeutic touch is based on the premises that the body contains energy fields that lead to either good or ill health and that the hands can be used to redirect the energy fields that lead to pain (Arenson & Drake, 2007). To be done correctly, this technique must be learned and practiced. Some women prefer a light touch, while others find a firmer touch more soothing. Massage of the neck, shoulders, back, thighs, feet, and hands can be very comforting. The use of firm counterpressure in the lower back or sacrum is especially helpful for back pain during contractions (Fig. 14.10). Contraindications for massage include skin rashes, varicose veins, bruises, or infections (Leonard, 2007).

Effleurage is a light, stroking, superficial touch of the abdomen, in rhythm with breathing during contractions. It is used as a relaxation and distraction technique from discomfort. The external fetal monitor belts may interfere with the ability to accomplish this.

TABLE 14.2 COMMON POSITIONS FOR USE DURING LABOR AND BIRTH

Standing	• Takes advantage of gravity during and between contractions • Makes contractions feel less painful and be more productive • Helps fetus line up with angle of maternal pelvis • Helps to increase urge to push in second stage of labor
Walking	• Has the same advantages as standing • Causes changes in the pelvic joints, helping the fetus move through the birth canal
Standing and leaning forward on partner, bed, birthing ball	• Has the same advantages as standing • Is a good position for a backrub • May feel more restful than standing • Can be used with electronic fetal monitor
Slow dancing (standing with woman's arms around partner's neck, head resting on his chest or shoulder, with his hands rubbing woman's lower back; sway to music and breathe in rhythm if it helps)	• Has the same advantages as walking • Back pressure helps relieve back pain • Rhythm and music help woman relax and provide comfort
The lunge (standing facing a straight chair with one foot on the seat with knee and foot to the side; bending raised knee and hip, and lunging sideways repeatedly during a contraction, holding each lunge for 5 seconds; partner holds chair and helps with balance)	• Widens one side of the pelvis (the side toward lunge) • Encourages rotation of baby • Can also be done in a kneeling position
Sitting upright	• Helps promote rest • Has more gravity advantage than lying down • Can be used with electronic fetal monitor
Semi-sitting (setting the head of the bed at a 45-degree angle with pillows used for support)	• Has the same advantages as sitting upright • Is an easy position if on a bed
Sitting on toilet or commode	• Has the same advantages as sitting upright • May help relax the perineum for effective bearing down
Rocking in a chair	• Has the same advantages as sitting upright • May help speed labor (rocking movement)
Sitting, leaning forward with support	• Has the same advantages as sitting upright • Is a good position for a backrub
On all fours, on hands and knees	• Helps relieve backache • Assists rotation of baby in posterior position • Allows for pelvic rocking and body movement • Relieves pressure on hemorrhoids • Allows for vaginal examinations • Is sometimes preferred as a pushing position by women with back labor
Kneeling, leaning forward with support on a chair seat, the raised head of the bed, or on a birthing ball	• Has the same advantages as all-fours position • Puts less strain on wrists and hands
Side-lying	• Is a very good position for resting and convenient for many kinds of medical interventions • Helps lower elevated blood pressure • May promote progress of labor when alternated with walking • Is useful to slow a very rapid second stage • Takes pressure off hemorrhoids • Facilitates relaxation between contractions

(continued)

TABLE 14.2 COMMON POSITIONS FOR USE DURING LABOR AND BIRTH (continued)

Squatting	• May relieve backache • Takes advantage of gravity • Requires less bearing-down effort • Widens pelvic outlet • May help fetus turn and move down in a difficult birth • Helps if the woman feels no urge to push • Allows freedom to shift weight for comfort • Offers an advantage when pushing, since upper trunk presses on the top of the uterus
Supported squat (leaning back against partner, who supports woman under the arms and takes the entire woman's weight; standing up between contractions)	• Requires great strength in partner • Lengthens trunk, allowing more room for fetus to maneuver into position • Lets gravity help
Dangle (partner sitting high on bed or counter with feet supported on chairs or footrests and thighs spread; woman leaning back between partner's legs, placing flexed arms over partner's thighs; partner gripping sides with his thighs; woman lowering herself and allowing partner to support her full weight; standing up between contractions)	• Has the same advantages of a supported squat • Requires less physical strength from the partner

EVIDENCE-BASED PRACTICE 14.1
The Effects of Complementary and Alternative Therapies for Pain Management in Labor on Maternal and Perinatal Morbidity

● Study
The pain of labor can be intense, with tension, anxiety, and fear making it worse. Many women would like to labor without using drugs and turn to alternatives to manage pain. These alternative methods include acupuncture, mind-body techniques, massage, reflexology, herbal medicines or homoeopathy, hypnosis, and music. This review examined currently available evidence supporting the use of alternative and complementary therapies for pain management in labor. Fourteen trials were included in the review, with data reporting on 1,537 women using different modalities of pain management; 1,448 women were included in the meta-analysis.

▲ Findings
Acupuncture and hypnosis may help relieve labor pain. There is insufficient evidence about the benefits of music, massage, relaxation, white noise, acupressure, and aromatherapy, and no evidence about the effectiveness of massage or other complementary therapies. In summary, acupuncture and hypnosis may be beneficial for the management of pain during labor; however, the number of women studied has been small. Few other complementary therapies have been subjected to proper scientific study.

■ Nursing Implications
Although this study didn't offer conclusive evidence that alternative therapies for pain management work better than pharmacologic or invasive methods, they should not be discounted. Many women wish to avoid artificial means to control the discomfort of labor. The nurse should be supportive and open-minded about a woman's efforts to meet her pain management goals.

Smith, C. A., Collins, C. T., Cyna, A. M., & Crowther, C. A. (2006). Complementary and alternative therapies for pain management in labor. *Cochrane Database of Systematic Reviews* 2006, Issue 4. Art. No.: CD003521. DOI: 10.1002/14651858.CD003521.pub2.

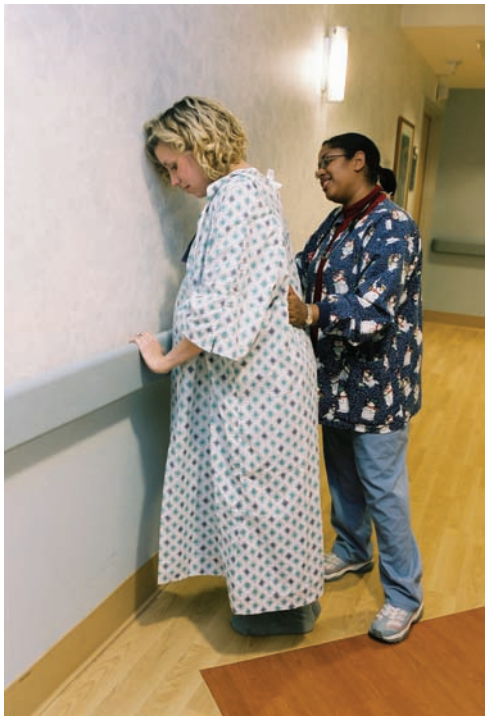

FIGURE 14.10 Nurse massaging the client's back during a contraction while she ambulates during labor.

Breathing Techniques

Breathing techniques are effective in producing relaxation and pain relief through the use of distraction. If the woman is concentrating on slow-paced rhythmic breathing, she isn't likely to fully focus on contraction pain. Breathing techniques are often taught in childbirth education classes (see Chapter 12 for additional information).

Breathing techniques use controlled breathing to reduce the pain experienced through a stimulus–response conditioning. The woman selects a focal point within her environment to stare at during the first sign of a contraction. This focus creates a visual stimulus that goes directly to her brain. The woman takes a deep cleansing breath, which is followed by rhythmic breathing. Verbal commands from her partner supply an ongoing auditory stimulus to her brain. Effleurage can be combined with the breathing to provide a tactile stimulus, all blocking pain sensations to her brain.

Benefits of practicing patterned breathing include:

- Breathing becomes an automatic response to pain.
- Breathing increases relaxation and can be used for deal with life's everyday stresses.
- The steady rhythm of breathing is calming during labor.
- Breathing provides a sense of well-being and a measure of control.
- Breathing brings purpose to each contraction, making them more productive.
- Breathing provides more oxygen for the mother and fetus (American Pregnancy Association, 2007).

Many couples learn patterned-paced breathing during their childbirth education classes. Three levels may be taught, each beginning and ending with a cleansing breath. In the first pattern, also known as slow-paced breathing, the woman inhales slowly through her nose and exhales through pursed lips. The breathing rate is typically 6 to 9 bpm. In the second pattern, also called shallow or modified-paced breathing, the woman inhales and exhales through her mouth at a rate of 4 breaths every 5 seconds. The rate can be accelerated to 2 breaths per second to assist her to relax. The third pattern, pattern paced breathing, is similar to modified-paced breathing except that the breathing is punctuated every few breaths by a forceful exhalation through pursed lips. All breaths are kept equal and rhythmic and can increase as contractions increase in intensity (Lyon, 2007).

Many childbirth educators do not recommend specific breathing techniques or try to teach parents to breathe the "right" way during labor and birth. Couples are encouraged to find breathing styles that enhance their relaxation and use them. There are numerous benefits to controlled and rhythmic breathing in childbirth (outlined above), and many women choose these techniques to manage their discomfort during labor.

Pharmacologic Measures

With varying degrees of success, generations of women have sought ways to relieve the pain of childbirth. Pharmacologic pain relief during labor includes systemic analgesia and regional or local anesthesia. Women have seen dramatic changes in pharmacologic pain management options over the years. Methods have evolved from biting down on a stick to a more complex pharmacologic approach such as epidural/intrathecal analgesia. Systemic analgesia and regional analgesia/anesthesia have become less common, while newer neuraxial analgesia/anesthesia techniques involving minimal motor blockade have become more popular. **Neuraxial analgesia/anesthesia** is the administration of analgesic (opioids) or anesthetic (medication capable of producing a loss of sensation in an area of the body) agents, either continuously or intermittently, into the epidural or intrathecal space to relieve pain. Low-dose and ultra-low-dose epidural analgesia, spinal analgesia, and combined spinal-epidural analgesia have replaced the traditional epidural for labor (Kuczkowski, 2007). This shift in pain management allows a woman to be an active participant in labor.

▶ ***Take*** NOTE!

Regardless of which approach is used during labor, the woman has the right to choose the methods of pain control that will best suit her and meet her needs.

▶ *Consider THIS!*

When I was expecting my first child, I was determined to put my best foot forward and do everything right. I was an experienced OB nurse, and in my mind doing everything right was expected behavior. I was already 2 weeks past my calculated due date and I was becoming increasingly worried. That particular day I went to work with a backache but felt no contractions.

I managed to finish my shift but felt completely wiped out. As I walked to my car outside the hospital, my water broke and I felt the warm fluid run down my legs. I went back inside to be admitted for this much-awaited event.

Although I had helped thousands of women go through their childbirth experience, I was now the one in the bed and not standing alongside it. My husband and I had practiced our breathing techniques to cope with the discomfort of labor, but this "discomfort" in my mind was more than I could tolerate. So despite my best intentions of doing everything right, within an hour I begged for a painkiller to ease the pain. While the medication took the edge off my pain, I still felt every contraction and truly now appreciate the meaning of the word "labor." Although I wanted to use natural childbirth without any medication, I know that I was a full participant in my son's birthing experience, and that is what "doing everything right" was for me!

Thoughts: Doing what is right varies for each individual, and as nurses we need to support whatever that is. Having a positive outcome from the childbirth experience is the goal; the means it takes to achieve it is less important. How can nurses support women in making their personal choices to achieve a healthy outcome? Are any women "failures" if they ask for pain medication to tolerate labor? How can nurses help women overcome this stigma of being a "wimp"?

Systemic Analgesia

Systemic analgesia involves the use of one or more drugs administered orally, intramuscularly, or intravenously; they become distributed throughout the body via the circulatory system. Depending on which administration method is used, the therapeutic effect of pain relief can occur within minutes and last for several hours. The most important complication associated with the use of this class of drugs is respiratory depression. Therefore, women given these drugs require careful monitoring. Opioids given close to the time of birth can cause central nervous system depression in the newborn, necessitating the administration of naloxone (Narcan) to reverse the depressant effects of the opioids.

Several drug categories may be used for systemic analgesia:

- Opioids, such as butorphanol (Stadol), nalbuphine (Nubain), meperidine (Demerol), or fentanyl (Sublimaze)
- Ataractics, such as hydroxyzine (Vistaril) or promethazine (Phenergan)
- Benzodiazepines, such as diazepam (Valium) or midazolam (Versed)
- Barbiturates, such as secobarbital (Seconal) or pentobarbital (Nembutal)

Drug Guide 14.1 highlights some of the major drugs used for systemic analgesia.

Systemic analgesics are typically administered parenterally, usually through an existing intravenous (IV) line. Nearly all medications given during labor cross the placenta and have a depressant effect on the fetus; therefore, it is important for the woman to receive the least amount of systemic medication that relieves her discomfort so that it does not cause any harm to the fetus (Cheng & Caughey, 2007). Historically opioids have been administered by nurses, but in the past decade there has been increasing use of client-controlled intravenous analgesia (patient-controlled analgesia [PCA]). With this system, the woman is given a button connected to a computerized pump on the IV line. When the woman desires analgesia, she presses the button and the pump delivers a preset amount of medication. This system provides the woman with a sense of control over her own pain management and active participation in the childbirth process.

Opioids

Opioids are morphine-like medications that are most effective for the relief of moderate to severe pain. Opioids typically are administered IV. Of all of the synthetic opioids (butorphanol [Stadol], nalbuphine [Nubain], fentanyl [Sublimaze], and meperidine [Demerol]), meperidine is the most commonly used opioid for the management of pain during labor. Opioids are associated with newborn respiratory depression, decreased alertness, inhibited sucking, and a delay in effective feeding (Bagwell, 2007).

Opioids decrease the transmission of pain impulses by binding to receptor site pathways that transmit the pain signals to the brain. The effect is increased tolerance to pain and respiratory depression related to a decrease in sensitivity to carbon dioxide (Skidmore-Roth, 2007).

All opioids are considered good analgesics. However, respiratory depression can occur in the mother and fetus depending on the dose given. They may also cause a decrease in FHR variability identified on the fetal monitor strip. This FHR pattern change is usually transient. Other systemic side effects include nausea, vomiting, pruritus, delayed gastric emptying, drowsiness, hypoventilation, and newborn depression. To reduce the incidence of new-

DRUG GUIDE 14.1 COMMON AGENTS USED FOR SYSTEMIC ANALGESIA

Type	Drug	Comments
Opioids	Morphine 2–5 mg IV	May be given IV, intrathecally, or epidurally Rapidly crosses the placenta Can cause maternal and neonatal CNS depression Decreases uterine contractions
	Meperidine (Demerol) 25–50 mg IV	May be given IV or epidurally with maximal fetal uptake 2–3 hours after administration Can cause CNS depression Decreases fetal variability
	Butorphanol (Stadol) 1 mg IV q3–4h	Is given IV Is rapidly transferred across the placenta Causes neonatal respiratory depression
	Nalbuphine (Nubain) 10 mg IV	Is given IV Causes less maternal nausea and vomiting Causes decreased FHR variability, fetal bradycardia and respiratory depression
	Fentanyl (Sublimaze) 25–50 mcg IV	Is given IV or epidurally Can cause maternal hypotension, maternal and fetal respiratory depression Rapidly crosses placenta
Ataractics	Hydroxyzine (Vistaril) 50 mg IM	Does not relieve pain but reduces anxiety and potentiates opioid analgesic effects Is used to decrease nausea and vomiting
	Promethazine (Phenergan) 25 mg IV	Is used for antiemetic effect when combined with opioids Causes sedation and reduces apprehension May contribute to maternal hypotension and neonatal depression
Benzodiazepines	Diazepam (Valium) 2–5 mg IV	Is given to enhance pain relief of opioid and cause sedation May be used to stop eclamptic seizures Decreases nausea and vomiting Can cause newborn depression; therefore, lowest possible dose should be used
	Midazolam (Versed) 1–5 mg IV	Is not used for analgesic but amnesia effect Is used as adjunct for anesthesia Is excreted in breast milk
Barbiturates	Secobarbital (Seconal) 100 mg PO/IM Pentobarbital (Nembutal) 100 mg PO/IM	Causes sedation Is used in very early labor to alter a dysfunctional pattern Is not used for pain relief in active labor Crosses placenta and is secreted in breast milk

Sources: Cheng & Caughey, 2007; Edmonds, 2007; Evron & Ezri, 2007; Skidmore-Roth, 2007; Wood, 2007.

born depression, birth should occur within 1 hour or after 4 hours of administration to prevent the fetus from receiving the peak concentration (Cheng & Caughey, 2007).

Opioid antagonists such as naloxone (Narcan) are given to reverse the effects of the central nervous system depression, including respiratory depression, caused by opioids. Opioid antagonists also are used to reverse the side effects of neuraxial opioids, such as pruritus, urinary retention, nausea, and vomiting, without significantly decreasing analgesia (Skidmore-Roth, 2007). Consult a current drug guide for more specifics on these drug categories.

Ataractics

The ataractic group of medications is used in combination with an opioid to decrease nausea and vomiting and lessen anxiety. These adjunct drugs potentiate the effectiveness of the opioid so that a lesser dose can be given. They may also be used to increase sedation. Promethazine (Phenergan) can be given IV, but hydroxyzine (Vistaril) must be given by mouth or by intramuscular injection into a large muscle mass. Neither drug affects the progress of labor, but either may cause a decrease in FHR variability and possible newborn depression (Albers, 2007).

Benzodiazepines

Benzodiazepines are used for minor tranquilizing and sedative effects. Diazepam (Valium) also is given IV to stop seizures due to pregnancy-induced hypertension. However, it is not used during labor itself. It can be administered to calm a woman who is out of control, thereby enabling her to relax enough so that she can participate effectively during her labor process rather than fighting against it. Lorazepam (Ativan) can also be used for its tranquilizing effect, but increased sedation is experienced with this medication (Skidmore-Roth, 2007). Midazolam (Versed), also given IV, produces good amnesia but no analgesia. It is most commonly used as an adjunct for anesthesia. Diazepam and midazolam cause central nervous system depression for both the woman and the newborn.

Barbiturates

The barbiturate drug group is used only in early labor or in a prolonged latent phase that produces enough discomfort that the woman cannot sleep. Barbiturates are given orally or intramuscularly to produce a light sleep to alter a dysfunctional labor pattern or to calm a very anxious woman in early labor. The goal in giving a barbiturate is to promote therapeutic rest for a few hours to enhance the woman's ability to cope with active labor. These drugs cross the placenta and cause central nervous system depression in the newborn (Skidmore-Roth, 2007).

Regional Analgesia/Anesthesia

Regional analgesia/anesthesia provides pain relief without loss of consciousness. It involves the use of local anesthetic agents, with or without added opioids, to bring about pain relief or numbness through the drug's effects on the spinal cord and nerve roots. Obstetric regional analgesia generally refers to a partial or complete loss of pain sensation below the T8 to T10 level of the spinal cord (Edmonds, 2007).

The routes for regional pain relief include epidural block, combined spinal–epidural block, local infiltration, pudendal block, and intrathecal (spinal) analgesia/anesthesia. Local and pudendal routes are used during birth for episiotomies; epidural and intrathecal routes are used for pain relief during active labor and birth. The major advantage of regional pain-management techniques is that the woman can participate in the birthing process and still have good pain control.

Epidural Block

Approximately 60% of laboring women in the United States receive an epidural block for pain relief during labor. In urban areas, many hospitals approach 90% use of epidurals (Kuczkowski, 2007).

An epidural block involves the injection of a drug into the epidural space, which is located outside the dura mater between the dura and the spinal canal. The epidural space is typically entered through the third and fourth lumbar vertebrae with a needle, and a catheter is threaded into the epidural space. The needle is removed and the catheter is left in place to allow for continuous infusion or intermittent injections of medicine (Fig. 14.11). An epidural block provides analgesia and anesthesia and can be used for both vaginal and cesarean births. It has evolved from a regional block producing total loss of sensation to analgesia with minimal blockade. The effectiveness of epidural analgesia depends on the technique and medications used. It is usually started after labor is well established, typically when cervical dilation is greater than 5 cm.

Theoretically, epidural local anesthetics could block all labor pain if used in large volumes and high concentrations. However, pain relief is balanced against other goals such as walking during the first stage of labor, pushing effectively in the second stage, and minimizing maternal and fetal side effects.

An epidural is contraindicated for women with a previous history of spinal surgery or spinal abnormalities, coagulation defects, infections, and hypovolemia. It also is contraindicated for the woman who is receiving anticoagulation therapy.

Complications include nausea and vomiting, hypotension, fever, pruritus, intravascular injection, and respiratory depression. Effects on the fetus during labor include fetal distress secondary to maternal hypotension (Bagwell, 2007). Ensuring that the woman avoids a supine position after an epidural catheter has been placed will help to minimize hypotension.

Changes in epidural drugs and techniques have been made to optimize pain control while minimizing side effects. Today most women receive a continuous lumbar epidural infusion of a local anesthetic, typically a drug whose name ends in "caine," and an opioid. To decrease motor blockade, bupivacaine (Sensorcaine) and ropivacaine (Naropin) have replaced lidocaine (Xylocaine), and drug concentrations have been lowered (Kuczkowski, 2007).

The addition of opioids, such as fentanyl or morphine, to the local anesthetic helps decrease the amount of motor block obtained. Continuous infusion pumps are used to administer the epidural analgesia, allowing the woman to be in control and administer a bolus dose on demand (Smiley & Stephenson, 2007).

Combined Spinal–Epidural Analgesia

Another epidural technique is combined spinal–epidural (CSE) analgesia. This technique involves inserting the epidural needle into the epidural space and subsequently inserting a small-gauge spinal needle through the epidural needle into the subarachnoid space. An opioid, without a local anesthetic, is injected into this space. The spinal needle is then removed and an epidural catheter is inserted for later use.

CSE is advantageous because of its rapid onset of pain relief (within 3 to 5 minutes) that can last up to 3 hours. It also allows the woman's motor function to remain active.

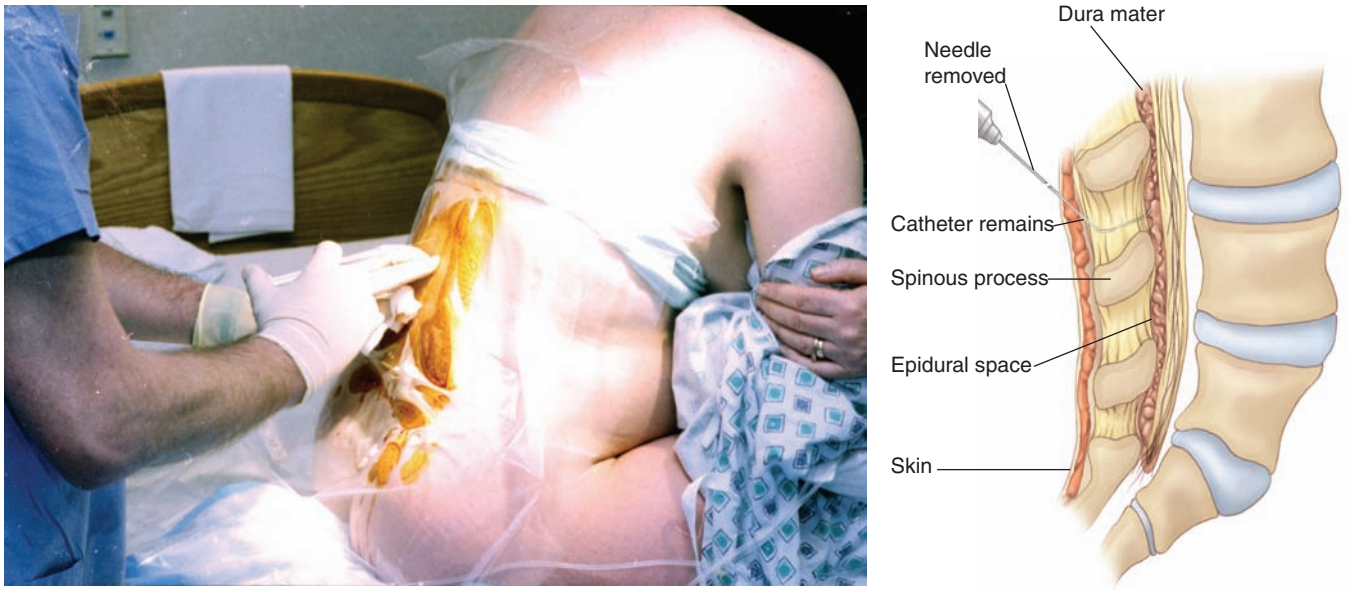

FIGURE 14.11 Epidural catheter insertion. (**A**) A needle is inserted into the epidural space. (**B**) A catheter is threaded into the epidural space; the needle is then removed. The catheter allows medication to be administered intermittently or continuously to relieve pain during labor and childbirth.

Her ability to bear down during the second stage of labor is preserved because the pushing reflex is not lost, and her motor power remains intact. The CSE technique provides greater flexibility and reliability for labor than either spinal or epidural analgesia alone (Kuczkowski, 2007). When compared with traditional epidural or spinal analgesia, which often keeps the woman lying in bed, CSE allows her to ambulate ("walking epidural") (Kuczkowski, 2007). Ambulating during labor provides several benefits: it may help control pain better, shorten the first stage of labor, increase the intensity of the contractions, and decrease the possibility of an operative vaginal or cesarean birth.

Although women can walk with CSE, they often choose not to because of sedation and fatigue. Often health care providers don't encourage or assist women to ambulate for fear of injury (Ros et al., 2007). Currently, anesthesiologists are performing walking epidurals using continuous infusion techniques as well as CSE and patient-controlled epidural analgesia (Smiley & Stephenson, 2007).

Complications include maternal hypotension, intravascular injection, accidental intrathecal blockade, postdural puncture headache, inadequate or failed block, and pruritus. Hypotension and associated FHR changes are managed with maternal positioning (semi-Fowler's position), intravenous hydration, and supplemental oxygen (Kuczkowski, 2007).

Patient-Controlled Epidural Analgesia

Patient-controlled epidural analgesia (PCEA) involves the use of an indwelling epidural catheter with an infusion of medication and a programmed pump that allows the woman to control the dosing. This method allows the woman to have a sense of control over her pain and reach her own individually acceptable analgesia level. When compared with the traditional epidural analgesia, PCEA provides equivalent analgesia with lower anesthetic use, lower rates of supplementation, and higher client satisfaction (Smiley & Stephenson, 2007).

With PCEA, the woman uses a hand-held device connected to an analgesic agent that is attached to an epidural catheter. When she pushes the button, a bolus dose of agent is administered via the catheter to reduce her pain. This method allows her to manage her pain at will without having to ask a staff member to provide pain relief.

Local Infiltration

Local infiltration involves the injection of a local anesthetic, such as lidocaine, into the superficial perineal nerves to numb the perineal area. This technique is done by the physician or midwife just before performing an episiotomy (surgical incision into the perineum to facilitate birth) or before suturing a laceration. Local infiltration does not alter the pain of uterine contractions, but it does numb the immediate area of the episiotomy or laceration. Local infiltration does not cause side effects for the woman or her newborn.

Pudendal Nerve Block

A pudendal nerve block refers to the injection of a local anesthetic agent (e.g., bupivacaine, ropivacaine) into the

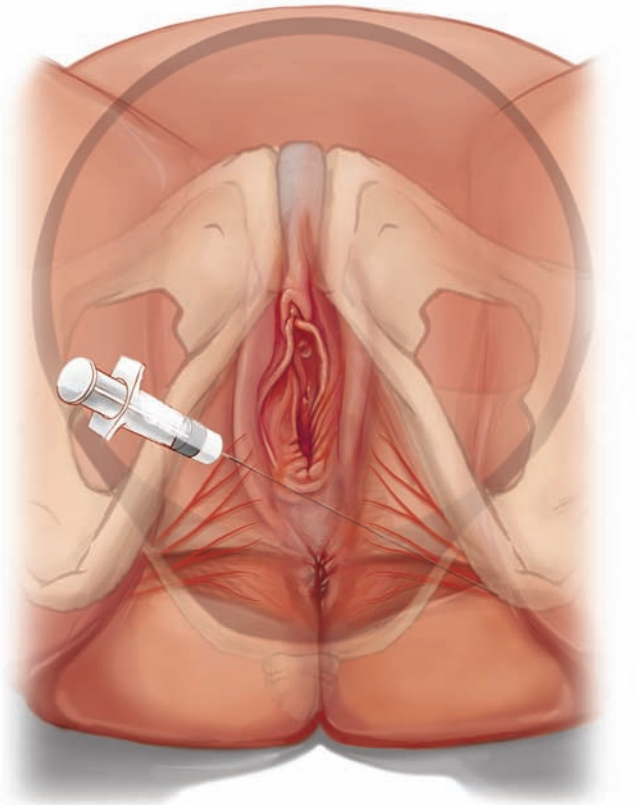

FIGURE 14.12 Pudendal nerve block.

pudendal nerves near each ischial spine. It provides pain relief in the lower vagina, vulva, and perineum (Fig. 14.12).

A pudendal block is used for the second stage of labor, an episiotomy, or an operative vaginal birth with outlet forceps or vacuum extractor. It must be administered about 15 minutes before it would be needed to ensure its full effect. A transvaginal approach is generally used to inject an anesthetic agent at or near the pudendal nerve branch. Neither maternal nor fetal complications are common.

Spinal (Intrathecal) Analgesia/Anesthesia

The spinal (intrathecal) pain-management technique involves injection of an anesthetic "caine" agent, with or without opioids, into the subarachnoid space to provide pain relief during labor or cesarean birth. The contraindications are similar to those for the epidural block. Adverse reactions for the woman include hypotension and spinal headache.

The subarachnoid injection of opioids alone, a technique termed intrathecal narcotics, has been gaining popularity since it was introduced in the 1980s. A narcotic is injected into the subarachnoid space, providing rapid pain relief while still maintaining motor function and sensation (Edmonds, 2007). An intrathecal narcotic is given during the active phase (more than 5 cm dilation) of labor. Compared with epidural blocks, intrathecal narcotics are easy to administer, provide rapid-onset pain relief, are less likely to cause newborn respiratory depression, and do not cause motor blockade (Edmonds, 2007). Although pain relief is rapid with this technique, it is limited by the narcotic's duration of action, which may be only a few hours and not last through the labor. Additional pain measures may be needed to sustain pain management.

General Anesthesia

General anesthesia is typically reserved for emergency cesarean births when there is not enough time to provide spinal or epidural anesthesia or if the woman has a contraindication to the use of regional anesthesia. It can be started quickly and causes a rapid loss of consciousness. General anesthesia can be administered by IV injection, inhalation of anesthetic agents, or both. Commonly, thiopental, a short-acting barbiturate, is given IV to produce unconsciousness. This is followed by administration of a muscle relaxant. After the woman is intubated, nitrous oxide and oxygen are administered. A volatile halogenated agent may also be administered to produce amnesia (Cheng & Caughey, 2007).

All anesthetic agents cross the placenta and affect the fetus. The primary complication with general anesthesia is fetal depression, along with uterine relaxation and potential maternal vomiting and aspiration.

Although the anesthesiologist or nurse anesthetist administers the various general anesthesia agents, the nurse needs to be knowledgeable about the pharmacologic aspects of the drugs used and must be aware of airway management. Ensure that the woman is NPO and has a patent IV. In addition, administer a non-particulate (clear) oral antacid (e.g., Bicitra or sodium citrate) or a proton pump inhibitor (Protonix) as ordered to reduce gastric acidity. Assist with placement of a wedge under the woman's right hip to displace the gravid uterus and prevent vena cava compression in the supine position. Once the newborn has been removed from the uterus, assist the perinatal team in providing supportive care.

Nursing Care During Labor and Birth

WATCH & LEARN

Childbirth, a physiologic process that is fundamental to all human existence, is one of the most significant cultural, psychological, spiritual, and behavioral events in a woman's life. Although the act of giving birth is a universal phenomenon, it is a unique experience for each woman. Continuous evaluation and appropriate intervention for women during labor are key to promoting a positive outcome for the family.

The nurse's role in childbirth is to ensure a safe environment for the mother and her newborn. Nurses begin evaluating the mother and fetus during the admission procedures at the health care agency and continue to do

so throughout labor. It is critical to provide anticipatory guidance and explain each procedure (fetal monitoring, intravenous therapy, medications given, and expected reactions) and what will happen next. This will prepare the woman for the upcoming physical and emotional challenges, thereby helping to reduce her anxiety. Acknowledging her support systems (family or partner) helps allay their fears and concerns, thereby assisting them in carrying out their supportive role. Knowing how and when to evaluate a woman during the various stages of labor is essential for all labor and birth nurses to ensure a positive maternal experience and a healthy newborn.

A major focus of care for the woman during labor and birth is assisting her with maintaining control over her pain, emotions, and actions while being an active participant. Nurses can help and support women to be actively involved in their childbirth experience by allowing time for discussion, offering companionship, listening to worries and concerns, paying attention to the woman's emotional needs, and offering information to help her understand what is happening in each stage of labor.

Nursing Care During the First Stage of Labor

Depending on how far advanced the woman's labor is when she arrives at the facility, the nurse will determine assessment parameters of maternal–fetal status and plan care accordingly. The nurse will provide high-touch, low-tech supportive nursing care during the first stage of labor when admitting the woman and orienting her to the labor and birth suite. Nursing care during this stage will include taking an admission history (reviewing the prenatal record); checking the results of routine laboratory tests and any special tests such as chorionic villi sampling, amniocentesis, genetic studies, and biophysical profile done during pregnancy; asking the woman about her childbirth preparation (birth plan, classes taken, coping skills); and completing a physical assessment of the woman to establish a baseline of values for future comparison.

Key nursing interventions include:

- Identifying the estimated date of birth from the client and the prenatal chart
- Validating the client's prenatal history to determine fetal risk status
- Determining fundal height to validate dates and fetal growth
- Performing Leopold's maneuvers to determine fetal position, lie, and presentation
- Checking FHR
- Performing a vaginal examination (as appropriate) to evaluate effacement and dilation progress
- Instructing the client and her partner about monitoring techniques and equipment
- Assessing fetal response and FHR to contractions and recovery time
- Interpreting fetal monitoring strips
- Checking FHR baseline for accelerations, variability, and decelerations
- Repositioning the client to obtain an optimal FHR pattern
- Recognizing FHR problems and initiating corrective measures
- Checking amniotic fluid for meconium staining, odor, and amount
- Comforting client throughout testing period and labor
- Supporting client's decisions regarding intervention or avoidance of intervention
- Assessing client's support system and coping status frequently

In addition to these interventions to promote optimal outcomes for the mother and fetus, the nurse must document care accurately and in a timely fashion. Accurate and timely documentation helps to decrease professional liability exposure and minimize the risk of preventable injuries to women and infants during labor and birth (Walsh, 2007). Guidelines for recording care include documenting:

- All care rendered, to prove that standards were met
- Conversations with all providers, including notification times
- Nursing interventions before and after notifying provider
- Use of the chain of command and response at each level
- All flow sheets and forms, to validate care given
- All education given to client and response to it
- Facts, not personal opinions
- Initial nursing assessment, all encounters, and discharge plan
- All telephone conversations (Hamilton & Wright, 2007)

This standard of documentation is needed to prevent or defend against litigation, which is prevalent in the childbirth arena.

Assessing the Woman upon Admission

The nurse usually first comes in contact with the woman either by phone or in person. It is important to ascertain whether the woman is in true or false labor and whether she should be admitted or sent home. Upon admission to the labor and birth suite, the highest priorities include assessing FHR, assessing cervical dilation/effacement, and determining whether membranes have ruptured or are intact. These assessment data will guide the critical thinking in planning care for the patient.

If the initial contact is by phone, establish a therapeutic relationship with the woman. Speaking in a calm, caring tone facilitates this. When completing a phone assessment, include questions about the following:

- Estimated date of birth, to determine if term or preterm
- Fetal movement (frequency in the past few days)

- Other premonitory signs of labor experienced
- Parity, gravida, and previous childbirth experiences
- Time from start of labor to birth in previous labors
- Characteristics of contractions, including frequency, duration, and intensity
- Appearance of any vaginal bloody show
- Membrane status (ruptured or intact)
- Presence of supportive adult in household or if she is alone

When speaking with the woman over the telephone, review the signs and symptoms that denote true versus false labor, and suggest various positions she can assume to provide comfort and increase placental perfusion. Also suggest walking, massage, and taking a warm shower to promote relaxation. Outline what foods and fluids are appropriate for oral intake in early labor. Throughout the phone call, listen to the woman's concerns and answer any questions clearly.

Reducing the risk of liability exposure and avoiding preventable injuries to mothers and fetuses during labor and birth can be accomplished by adhering to two basic tenets of clinical practice: (1) use applicable evidence and/or published standards and guidelines as the foundation of care, and (2) whenever a clinical choice is presented, chose client safety (Collins, 2006). With these two tenets in mind, advise the woman on the phone to contact her health care provider for further instructions or to come to the facility to be evaluated, since ruling out true labor and possible maternal–fetal complications cannot be done accurately over the phone.

Additional nursing responsibilities associated with a phone assessment include:

- Consulting the woman's prenatal record for parity status, estimated date of birth, and untoward events
- Calling the health care provider to inform him or her of the woman's status
- Preparing for admission to the perinatal unit to ensure adequate staff assignment
- Notifying the admissions office of a pending admission

If the nurse's first encounter with the woman is in person, an assessment is completed to determine whether she should be admitted to the perinatal unit or sent home until her labor advances. Entering a facility is often an intimidating and stressful event for women since it is an unfamiliar environment. Giving birth for the first time is a pivotal event in the lives of most women. Therefore, demonstrate respect when addressing the client; listen carefully and express interest and concern. Nurses must value and respect women and promote their self-worth and sense of control by allowing them to participate in making decisions (Hackley, Kriebs, & Rousseau, 2007).

An admission assessment includes maternal health history, physical assessment, fetal assessment, laboratory studies, and assessment of psychological status. Usually the facility has a form that can be used throughout labor and birth to document assessment findings (Fig. 14.13).

Maternal Health History

A maternal health history should include typical biographical data such as the woman's name and age and the name of the delivering health care provider. Other information that is collected includes the prenatal record data, including the estimated date of birth, a history of the current pregnancy, and the results of any laboratory and diagnostic tests, such as blood type, Rh status, and group B streptococcal status; past pregnancy and obstetric history; past health history and family history; prenatal education; list of medications; risk factors such as diabetes, hypertension, and use of tobacco, alcohol, or illicit drugs; reason for admission, such as labor, cesarean birth, or observation for a complication; history of potential domestic violence; history of previous preterm births; allergies; time of last food ingestion; method chosen for infant feeding; name of birth attendant and pediatrician; and pain management plan.

Ascertaining this information is important so that an individualized plan of care can be developed for the woman. If, for example, the woman's due date is still 2 months away, it is important to establish this information so interventions can be initiated to arrest the labor immediately or notify the intensive perinatal team to be available. In addition, if the woman is a diabetic, it is critical to monitor her glucose levels during labor, to prepare for a surgical birth if dystocia of labor occurs, and to alert the newborn nursery of potential hypoglycemia in the newborn after birth. By collecting important information about each woman they care for, nurses can help improve the outcomes for all concerned.

Be sure to observe the woman's emotions, support system, verbal interaction, body language and posture, perceptual acuity, and energy level. Also note her cultural background and language spoken. This psychosocial information provides cues about the woman's emotional state, culture, and communication systems. For example, if the woman arrives at the labor and birth suite extremely anxious, alone, and unable to communicate in English, how can the nurse meet her needs and plan her care appropriately? It is only by assessing each woman physically and psychosocially that the nurse can make astute decisions regarding proper care. In this case, an interpreter would be needed to assist in the communication process between the staff and the woman to initiate proper care.

It is important to acknowledge and try to understand the cultural differences in women with cultural backgrounds different from that of the nurse. Attitudes toward childbirth are heavily influenced by the culture in which the woman has been raised. As a result, within every society, specific attitudes and values shape the woman's childbearing behaviors. Be aware of what these are. When carrying out a cultural assessment during the admission

PAIN ASSESSMENT

1. Do you have any ongoing pain problems? ☐ No ☐ Yes
2. Do you have any pain now? ☐ No ☐ Yes
3. If any of the above questions are answered yes, the patient has a positive pain screening.
4. *Patient to be given pain management education material. Complete pain / symptom assessment on flowsheet.*
5. *Please proceed to complete pain assessment.*

BOX 14.2 Questions for Providing Culturally Competent Care During Labor and Birth

- Where were you born? How long have you lived in the Untied States?
- What languages do you speak and read?
- Who are your major support people?
- What are your religious practices?
- How do you view childbearing?
- Are there any special precautions or restrictions that are important?
- Is birth considered a private or a social experience?
- How would you like to manage your labor discomfort?
- Who will provide your labor support?

Sources: Bowers (2007); D'Avanzo (2008); Giger & Davidhizar (2007).

process, ask questions (Box 14.2) to help plan culturally competent care during labor and birth.

Physical Examination

The physical examination typically includes a generalized assessment of the woman's body systems, including hydration status, vital signs, auscultation of heart and lung sounds, and measurement of height and weight. The physical examination also includes the following assessments:

- Fundal height measurement
- Uterine activity, including contraction frequency, duration, and intensity
- Status of membranes (intact or ruptured)
- Cervical dilatation and degree of effacement
- Fetal status, including heart rate, position, and station
- Pain level

These assessment parameters form a baseline against which the nurse can compare all future values throughout labor. The findings should be similar to those of the woman's prepregnancy and pregnancy findings, with the exception of her pulse rate, which might be elevated secondary to her anxious state with beginning labor.

Laboratory Studies

On admission, laboratory studies typically are done to establish a baseline. Although the exact tests may vary among facilities, they usually include a urinalysis via clean-catch urine specimen and complete blood count (CBC). Blood typing and Rh factor analysis may be necessary if the results of these are unknown or unavailable. In addition, if the following test results are not included in the maternal prenatal history, it may be necessary to perform them at this time. They include syphilis screening, hepatitis B (HbsAg) screening, group B streptococcus, HIV testing (if woman gives consent), and possible drug screening if the history is positive.

Group B streptococcus (GBS) is a gram-positive organism that is present in 10% to 30% of all healthy women (Kenner & Lott, 2007). These women are asymptomatic carriers but can cause GBS disease of the newborn through vertical transmission. The mortality rate of infected newborns varies according to time of onset (early or late). Risk factors for GBS include maternal intrapartum fever, prolonged ruptured membranes, previous birth of an infected newborn, and GBS bacteriuria in the present pregnancy.

In 2002 ACOG and the American Academy of Pediatrics (AAP) issued guidelines that advised universal screening of pregnant women at 35 to 37 weeks' gestation for GBS and intrapartum antibiotic therapy for GBS carriers (Reingold et al., 2007). Maternal infections associated with GBS include acute chorioamnionitis, endometritis, and urinary tract infection. Neonatal clinical manifestations include pneumonia and sepsis. Identified GBS carriers receive IV antibiotic prophylaxis (penicillin G or ampicillin) at the onset of labor or ruptured membranes.

If her HIV status is not documented, the woman being admitted to the labor and birth suite should have rapid HIV testing done. To reduce perinatal transmission, HIV-positive women are given zidovudine (2 mg/kg IV over an hour, and then a maintenance infusion of 1 mg/kg per hour until birth) or a single 200-mg oral dose of nevirapine at the onset of labor; the newborn is given 2 mg/kg orally between 48 and 72 hours of life (Kenner & Lott, 2007). To further reduce the risk of perinatal transmission, ACOG and the U.S. Public Health Service recommend that HIV-infected women with plasma viral loads of more than 1,000 copies per milliliter be counseled regarding the benefits of elective cesarean birth (Jamieson et al., 2007). Additional interventions to reduce the transmission risk would include avoiding use of scalp electrode for fetal monitoring or doing a scalp blood sampling for fetal pH, delaying amniotomy, and avoiding invasive procedures such as forceps or vacuum-assisted devices. The nurse stresses the importance of all interventions and the goal to reduce transmission of HIV to the newborn.

Continuing Assessment During the First Stage of Labor

After the admission assessment is complete, assessment continues for changes that would indicate that labor is progressing as expected. Assess the woman's knowledge, experience, and expectations of labor. Typically, blood pressure, pulse, and respirations are assessed every hour during the latent phase of labor unless the clinical situation dictates that vital signs be taken more frequently. During the active and transition phases, they are assessed every 30 minutes. The temperature is taken every 4 hours throughout the first stage of labor unless the clinical situation dictates more frequent measurement (maternal fever).

Vaginal examinations are performed periodically to track labor progress. This assessment information is shared with the woman to reinforce that she is making progress toward the goal of birth. Uterine contractions are monitored for frequency, duration, and intensity every 30 to 60 minutes during the latent phase, every 15 to 30 minutes during the active phase, and every 15 minutes during transition. Note the changes in the character of the contractions as labor progresses, and inform the woman of her progress. Continually determine the woman's level of pain and her ability to cope and use relaxation techniques effectively.

When the fetal membranes rupture, spontaneously or artificially, assess the FHR and check the amniotic fluid for color, odor, and amount. Assess the FHR intermittently or continuously via electronic monitoring. During the latent phase of labor, assess the FHR every 30 to 60 minutes; in the active phase, assess FHR at least every 15 to 30 minutes. Also, be sure to assess the FHR before ambulation, prior to any procedure, and prior to administering analgesia or anesthesia to the mother. Table 14.3 summarizes assessments for the first stage of labor.

Remember Sheila from the chapter-opening scenario? What is the nurse's role with Sheila in active labor? What additional comfort measures can the labor nurse offer Sheila?

Nursing Interventions

Nursing interventions during the admission process should include:

- Asking about the client's expectations of the birthing process
- Providing information about labor, birth, pain-management options, and relaxation techniques
- Presenting information about fetal monitoring equipment and the procedures needed
- Monitoring FHR and identifying patterns that need further intervention
- Monitoring the mother's vital signs to obtain a baseline for later comparison
- Reassuring the client that her labor progress will be monitored closely and nursing care will focus on ensuring fetal and maternal well-being throughout

As the woman progresses through the first stage of labor, nursing interventions include:

- Encouraging the woman's partner to participate
- Keeping the woman and her partner up to date on the progress of the labor
- Orienting the woman and her partner to the labor and birth unit and explaining all of the birthing procedures
- Providing clear fluids (e.g., ice chips) as needed or requested
- Maintaining the woman's parenteral fluid intake at the prescribed rate if she has an IV

TABLE 14.3 SUMMARY OF ASSESSMENTS DURING THE FIRST STAGE OF LABOR

Assessments*	Latent Phase (0–3 cm)	Active Phase (4–7 cm)	Transition (8–10 cm)
Vital signs (BP, pulse, respirations)	Every 30–60 min	Every 30 min	Every 15–30 min
Temperature	Every 4 hours	Every 4 hours	Every 4 hours
Contractions (frequency, duration, intensity)	Every 30–60 min by palpation or continuously if EFM	Every 15–30 min by palpation or continuously if EFM	Every 15 min by palpation or continuously if EFM
Fetal heart rate	Every hour by Doppler or continuously by EFM	Every 30 min by Doppler or continuously by EFM	Every 15–30 min by Doppler or continuously by EFM
Vaginal examination	Initially on admission to determine phase and as needed based on maternal cues to document labor progression	As needed to monitor labor progression	As needed to monitor labor progression
Behavior/psychosocial	With every client encounter: talkative, excited, anxious	With every client encounter: self-absorbed in labor; intense and quiet now	With every client encounter: discouraged, irritable, feels out of control, declining coping ability

*The frequency of assessments is dictated by the health status of the woman and fetus and can be altered if either one of their conditions changes.

EFM, electronic fetal monitoring.

- Initiating or encouraging comfort measures, such as backrubs, cool cloths to the forehead, frequent position changes, ambulation, showers, slow dancing, leaning over a birth ball, side-lying, or counterpressure on lower back (Teaching Guidelines 14.1)
- Encouraging the partner's involvement with breathing techniques
- Assisting the woman and her partner to focus on breathing techniques
- Informing the woman that the discomfort will be intermittent and of limited duration; urging her to rest between contractions to preserve her strength; and encouraging her to use distracting activities to lessen the focus on contractions
- Changing bed linens and gown as needed
- Keeping the perineal area clean and dry

TEACHING GUIDELINES 14.1

Positioning During the First Stage of Labor

- Walking with support from your partner (adds the force of gravity to contractions to promote fetal descent)
- Slow-dancing position with your partner holding you (adds the force of gravity to contractions and promotes support from and active participation of your partner)
- Side-lying with pillows between the knees for comfort (offers a restful position and improves oxygen flow to the uterus)
- Semi-sitting in bed or on a couch leaning against the partner (reduces back pain because fetus falls forward, away from the sacrum)
- Sitting in a chair with one foot on the floor and one on the chair (changes pelvic shape)
- Leaning forward by straddling a chair, a table, or a bed or kneeling over a birth ball (reduces back pain, adds the force of gravity to promote descent; possible pain relief if partner can apply sacral pressure)
- Sitting in a rocking chair or on a birth ball and shifting weight back and forth (provides comfort because rocking motion is soothing; uses the force of gravity to help fetal descent)
- Lunge by rocking weight back and forth with foot up on chair during contraction (uses force of gravity by being upright; enhances rotation of fetus through rocking)
- Open knee–chest position (helps to relieve back discomfort) (Armstrong & Feldman, 2007)

- Supporting the woman's decisions about pain management
- Monitoring maternal vital signs frequently and reporting any abnormal values
- Ensuring that the woman takes deep cleansing breaths before and after each contraction to enhance gas exchange and oxygen to the fetus
- Educating the woman and her partner about the need for rest and helping them plan strategies to conserve strength
- Monitoring FHR for baseline, accelerations, variability, and decelerations
- Checking on bladder status and encouraging voiding at least every 2 hours to make room for birth
- Repositioning the woman as needed to obtain optimal heart rate pattern
- Communicating requests from the woman to appropriate personnel
- Respecting the woman's sense of privacy by covering her when appropriate
- Offering human presence by being present with the woman, not leaving her alone for long periods
- Being patient with the natural labor pattern to allow time for change
- Reporting any deviations from normal to the health care professional so that interventions can be initiated early to be effective (Sauls, 2007)

See Nursing Care Plan 14.1.

Remember Sheila, who was admitted in active labor? She has progressed to the transition phase (8 cm dilated) and is becoming increasingly more uncomfortable. She is using a patterned-paced breathing pattern now but thrashing around in the hospital bed.

Nursing Management During the Second Stage of Labor

Nursing care during the second stage of labor focuses on supporting the woman and her partner in making active decisions about her care and labor management, implementing strategies to prolong the early passive phase of fetal descent, supporting involuntary bearing-down efforts, providing instruction and assistance, and using maternal positions that can enhance descent and reduce pain (Sleutel, Schultz, & Wyble, 2007). Research suggests that strong pushing during the second stage may be accompanied by a significant decline in fetal pH and may cause maternal muscle and nerve damage if done too early (Sauls, 2007). Shortening the phase of active pushing and lengthening the early phase of passive descent can be achieved by encouraging the woman not to push until she has a strong desire to do so and until the descent and rotation of the fetal head are well advanced. Effective

Nursing Care Plan 14.1

OVERVIEW OF THE WOMAN IN THE ACTIVE PHASE OF THE FIRST STAGE OF LABOR

Candice, a 23-year-old gravida 1, para 0 (G1,P0) is admitted to the labor and birth suite at 39 weeks' gestation having contractions of moderate intensity every 5 to 6 minutes. A vaginal examination reveals her cervix is 80% effaced and 5 cm dilated. The presenting part (vertex) is at 0 station and her membranes ruptured spontaneously 4 hours ago at home. She is admitted and an IV is started for hydration and vascular access. An external fetal monitor is applied. FHR is 140 bpm and regular. Her partner is present at her bedside. Candice is now in the active phase of the first stage of labor, and her assessment findings are as follows: cervix dilated 7 cm, 80% effaced; moderate to strong contractions occurring regularly, every 3 to 5 minutes, lasting 45 to 60 seconds; at 0 station on pelvic examination; FHR auscultated loudest below umbilicus at 140 bpm; vaginal show—pink or bloody vaginal mucus; currently apprehensive, inwardly focused, with increased dependency; voicing concern about ability to cope with pain; limited ability to follow directions.

NURSING DIAGNOSIS: Anxiety related to labor and birth process and fear of the unknown related to client's first experience

Outcome Identification and Evaluation

Client will remain calm and in control as evidenced by ability to make decisions and use positive coping strategies.

Interventions: Promoting Positive Coping Strategies

- Provide instruction regarding the labor process to allay anxiety.
- Reorient the woman to the physical environment and equipment as necessary to keep her informed of events.
- Encourage verbalization of feelings and concerns to reduce anxiety.
- Listen attentively to woman and partner to demonstrate interest and concern.
- Inform woman and partner of standard procedures/processes to ensure adequate understanding of events and procedures.
- Frequently update woman of progress and labor status to provide positive reinforcement for actions.
- Reinforce relaxation techniques and provide instruction if needed to aid in coping.
- Encourage participation of the partner in the coaching role; role-model to facilitate partner participation in labor process to provide support and encouragement to the client.
- Provide a presence and remain with woman as much as possible to provide comfort and support.

NURSING DIAGNOSIS: Pain related to effects of contractions and cervical dilatation and events of labor

Outcome Identification and Evaluation

Client will maintain a tolerable level of pain and discomfort as evidenced by statements of pain relief, pain rating of 2 or less on pain rating scale, and absence of adverse effects in client and fetus from analgesia or anesthesia.

Interventions: Providing Pain Relief

- Monitor vital signs, observe for signs of pain, and have client rate pain on a scale of 0 to 10 to provide baseline for comparison.
- Encourage client to void every 1 to 2 hours to decrease pressure from a full bladder.
- Assist woman to change positions frequently to increase comfort and promote labor progress.
- Encourage use of distraction to reduce focus on contraction pain.
- Suggest pelvic rocking, massage, or back counterpressure to reduce pain.
- Assist with use of relaxation and breathing techniques to promote relaxation.
- Use touch appropriately (backrub) when desired by the woman to promote comfort.
- Integrate use of nonpharmacologic measures for pain relief, such as warm water, birthing ball, or other techniques to facilitate pain relief.
- Administer pharmacologic agents as ordered when requested to control pain.
- Provide reassurance and encouragement between contractions to foster self-esteem and continued participation in labor process.

(continued)

Nursing Care Plan 14.1 (continued)

NURSING DIAGNOSIS: Risk of infection related to vaginal examinations following rupture of membranes

Outcome Identification and Evaluation

Client will remain free of infection as evidenced by absence of signs and symptoms of infection, vital signs and FHR within acceptable parameters, lab test results within normal limits, and clear amniotic fluid without odor.

Interventions: Preventing Infection

- Monitor vital signs (every 1 to 2 hours after ROM) and FHR frequently as per protocol to allow for early detection of problems; report fetal tachycardia (early sign of maternal infection) to ensure prompt treatment.
- Provide frequent perineal care and pad changes to maintain good perineal hygiene.
- Change linens and woman's gown as needed to maintain cleanliness.
- Ensure that vaginal examinations are performed only when needed to prevent introducing pathogens into the vaginal vault.
- Monitor lab test results such as white blood cell count to assess for elevations indicating infection.
- Use aseptic technique for all invasive procedures to prevent infection transmission.
- Carry out good handwashing techniques before and after procedures and use standard precautions as appropriate to minimize risk of infection transmission.
- Document amniotic fluid characteristics—color, odor—to establish baseline for comparison.

pushing can be achieved by assisting the woman to assume a more upright or squatting position (Hanson, 2006).

Perineal lacerations or tears can occur during the second stage when the fetal head emerges through the vaginal introitus. The extent of the laceration is defined by depth: a first-degree laceration extends through the skin; a second-degree laceration extends through the muscles of the perineal body; a third-degree laceration continues through the anal sphincter muscle; and a fourth-degree laceration also involves the anterior rectal wall. Special attention needs to be paid to third- and fourth-degree lacerations to prevent fecal incontinence (Lowder et al., 2007). The primary care provider should repair any lacerations during the third stage of labor.

An **episiotomy** is an incision made in the perineum to enlarge the vaginal outlet and theoretically to shorten the second stage of labor. Alternative measures such as warm compresses and continual massage with oil have been successful in stretching the perineal area to prevent cutting it. Certified nurse midwives (CNMs) can cut and repair episiotomies, but they frequently use alternative measures if possible.

▶ *Take* NOTE!

Further research needs to be done to validate the efficacy of natural measures versus the episiotomy.

The midline episiotomy is the most commonly used one in the United States because it can be easily repaired and causes the least amount of pain (Albers & Borders, 2007). Figure 14.14 shows episiotomy locations.

Assessment

Assessment is continuous during the second stage of labor. Hospital policies dictate the specific type and timing of assessments, as well as the way in which they are documented. Assessment involves identifying the signs typical of the second stage of labor, including:

- Increase in apprehension or irritability
- Spontaneous rupture of membranes
- Sudden appearance of sweat on upper lip
- Increase in blood-tinged show
- Low grunting sounds from the woman
- Complaints of rectal and perineal pressure
- Beginning of involuntary bearing-down efforts

Other ongoing assessments include the contraction frequency, duration, and intensity; maternal vital signs every 5 to 15 minutes; fetal response to labor as indicated by FHR monitor strips; amniotic fluid for color, odor, and amount when membranes are ruptured; and the woman and her partner's coping status (Table 14.4).

Assessment also focuses on determining the progress of labor. Associated signs include bulging of the perineum, labial separation, advancing and retreating of the newborn's head during and between bearing-down efforts,

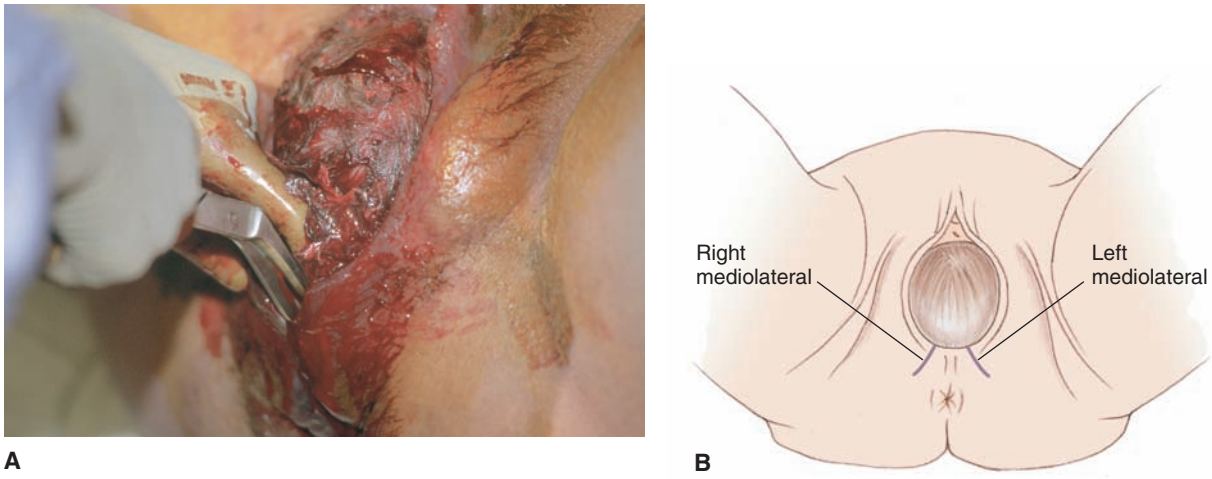

FIGURE 14.14 Location of an episiotomy. (**A**) Midline episiotomy. (**B**) Right and left mediolateral episiotomies.

and **crowning** (fetal head is visible at vaginal opening; Fig. 14.15).

A vaginal examination is completed to determine if it is appropriate for the woman to push. Pushing is appropriate if the cervix has fully dilated to 10 cm and the woman feels the urge to do so.

Nursing Interventions

Nursing interventions during this stage focus on motivating the woman, encouraging her to put all her efforts to pushing this newborn to the outside world, and giving her feedback on her progress. If the woman is pushing and not making progress, suggest that she keep her eyes open

TABLE 14.4 SUMMARY OF ASSESSMENTS DURING THE SECOND, THIRD, AND FOURTH STAGES OF LABOR

Assessments*	Second Stage of Labor (Birth of Neonate)	Third Stage of Labor (Placenta Expulsion)	Fourth Stage of Labor (Recovery)
Vital signs (BP, pulse, respirations)	Every 5–15 min	Every 15 min	Every 15 min
Fetal heart rate	Every 5–15 min by Doppler or continuously by EFM	Apgar scoring at 1 and 5 min	Newborn—complete head-to-toe assessment; vital signs every 15 min until stable
Contractions/uterus	Palpate every one	Observe for placental separation	Palpating for firmness and position every 15 min for first hour
Bearing down/pushing	Assist with every effort	None	None
Vaginal discharge	Observe for signs of descent—bulging of perineum, crowning	Assess bleeding after expulsion	Assess every 15 min with fundus firmness
Behavior/psychosocial	Observe every 15 min: cooperative, focus is on work of pushing newborn out	Observe every 15 min: often feelings of relief after hearing newborn crying; calmer	Observe every 15 min: usually excited, talkative, awake; needs to hold newborn, be close, and inspect body

*The frequency of assessments is dictated by the health status of the woman and fetus and can be altered if either one of their conditions changes.

EFM, electronic fetal monitoring.

Figure 14.15 Crowning.

during the contractions and look toward where the infant is coming out. Changing positions every 20 to 30 minutes will also help in making progress. Positioning a mirror so the woman can visualize the birthing process and how successful her pushing efforts are can help motivate her.

During the second stage of labor, an ideal position would be one that opens the pelvic outlet as wide as possible, provides a smooth pathway for the fetus to descend through the birth canal, takes advantage of gravity to assist the fetus to descend, and gives the mother a sense of being safe and in control of the labor process (Hanson, 2006). Some suggestions for positions in the second stage include:

- Lithotomy with feet up in stirrups: most convenient position for caregivers
- Semi-sitting with pillows underneath knees, arms, and back
- Lateral/side-lying with curved back and upper leg supported by partner
- Sitting on birthing stool: opens pelvis, enhances the pull of gravity, and helps with pushing
- Squatting/supported squatting: gives the woman a sense of control
- Kneeling with hands on bed and knees comfortably apart

Other important nursing interventions during the second stage include:

- Providing continuous comfort measures such as mouth care, position changes, changing bed linen and underpads, and providing a quiet, focused environment
- Instructing the woman on the following bearing-down positions and techniques:
  - Pushing only when she feels an urge to do so
  - Using abdominal muscles when bearing down
  - Using short pushes of 6 to 7 seconds
  - Focusing attention on the perineal area to visualize the newborn
  - Relaxing and conserving energy between contractions
  - Pushing several times with each contraction
  - Pushing with an open glottis and slight exhalation (Roberts, Gonzalez, & Sampselle, 2007)
- Continuing to monitor contraction and FHR patterns to identify problems
- Providing brief, explicit directions throughout this stage
- Continuing to provide psychosocial support by reassuring and coaching
- Facilitating the upright position to encourage the fetus to descend
- Continuing to assess blood pressure, pulse, respirations, uterine contractions, bearing-down efforts, FHR, coping status of the client and her partner
- Providing pain management if needed
- Providing a continuous nursing presence
- Offering praise for the client's efforts
- Preparing for and assisting with delivery by:
  - Notifying the health care provider of the estimated time frame for birth
  - Preparing the delivery bed and positioning client
  - Preparing the perineal area according to the facility's protocol
  - Offering a mirror and adjusting it so the woman can watch the birth
  - Explaining all procedures and equipment to the client and her partner
  - Setting up delivery instruments needed while maintaining sterility
  - Receiving newborn and transporting him or her to a warming environment, or covering the newborn with a warmed blanket on the woman's abdomen
  - Providing initial care and assessment of the newborn (see the Birth section that follows)

Sheila is completely dilated now and experiencing the urge to push. How can the nurse help Sheila with her pushing efforts? What additional interventions can the labor nurse offer Sheila now?

Birth

The second stage of labor ends with the birth of the newborn. The maternal position for birth varies from the standard lithotomy position to side-lying to squatting to standing or kneeling, depending on the birthing location, the woman's preference, and standard protocols. Once the woman is positioned for birth, cleanse the vulva and perineal areas. The primary health care provider then takes charge after donning protective eyewear, masks, gowns, and gloves and performing hand hygiene.

Once the fetal head has emerged, the primary care provider explores the fetal neck to see if the umbilical cord is wrapped around it. If it is, the cord is slipped over the head to facilitate delivery. As soon as the head emerges, the health care provider suctions the newborn's mouth first (because the newborn is an obligate nose breather) and then the nares with a bulb syringe to prevent aspiration of mucus, amniotic fluid, or meconium (Fig. 14.16). The umbilical cord is double-clamped and cut between the clamps. With the first cries of the newborn, the second stage of labor ends.

In addition to encouraging Sheila to rest between pushing and offering praise for her efforts, what is the nurse's role during the birthing process?

Immediate Care of the Newborn

Once the infant is born, place him or her under the radiant warmer, dry him or her, assess him or her, wrap him or her in warmed blankets, and place him or her on the woman's abdomen for warmth and closeness. In some health care facilities, the newborn is placed on the woman's abdomen immediately after birth and covered with a warmed blanket. In either scenario, the stability of the newborn dictates the location of aftercare. The nurse can also assist the mother with breastfeeding her newborn for the first time.

FIGURE 14.16 Suctioning the newborn immediately after birth.

Assessment of the newborn begins at the moment of birth and continues until the newborn is discharged. Drying the newborn and providing warmth to prevent heat loss by evaporation is essential to help support thermoregulation and provide stimulation. Placing the newborn under a radiant heat source and putting on a stockinet cap will further reduce heat loss after drying.

Assess the newborn by assigning an Apgar score at 1 and 5 minutes. The Apgar score assesses five parameters—heart rate (absent, slow, or fast), respiratory effort (absent, weak cry, or good strong yell), muscle tone (limp, or lively and active), response to irritation stimulus, and color—that evaluate a newborn's cardiorespiratory adaptation after birth. The parameters are arranged from the most important (heart rate) to the least important (color). The newborn is assigned a score of 0 to 2 in each of the five parameters. The purpose of the Apgar assessment is to evaluate the physiologic status of the newborn; see Chapter 18 for additional information on Apgar scoring.

Secure two identification bands on the newborn's wrist and ankle that match the band on the mother's wrist to ensure the newborn's identity. This identification process is completed in the birthing suite before anyone leaves the room. Some health care agencies also take an early photo of the newborn for identification in the event of abduction (Healthcare Risk Management, 2007).

Other types of newborn security systems can also be used to prevent abduction. Some systems have sensors that are attached to the newborn's identification bracelet or cord clamp. An alarm is set off if the bracelet or clamp activates receivers near exits. Others have an alarm that is activated when the sensor is removed from the newborn (Fig. 14.17). Even with the use of electronic sensors, the parents, nursing staff, and security personnel are responsible for prevention strategies and ensuring the safety and protection of all newborns (Healthcare Risk Management, 2007).

Sheila gave birth to a healthy 7-pound, 7-ounce baby girl. She is eager to hold and nurse her newborn. What is the initial care of the newborn? How can the nurse meet the needs of both the newborn and Sheila, who is exhausted but eager to bond with her newborn?

Nursing Management During the Third Stage of Labor

During the third stage of labor, strong uterine contractions continue at regular intervals under the continuing influence of oxytocin. The uterine muscle fibers shorten, or retract, with each contraction, leading to a gradual decrease in the

FIGURE 14.17 An example of a security sensor applied to a newborn's arm.

size of the uterus, which helps shear the placenta away from its attachment site. The third stage is complete when the placenta is delivered. Nursing care during the third stage of labor primarily focuses on immediate newborn care and assessment and being available to assist with the delivery of the placenta and inspecting it for intactness.

Three hormones play important roles in the third stage. During this stage the woman experiences peak levels of oxytocin and endorphins, while the high adrenaline levels that occurred during the second stage of labor to aid with pushing begin falling. The hormone oxytocin causes uterine contractions and helps the woman to enact instinctive mothering behaviors such as holding the newborn close to her body and cuddling the baby.

Skin-to-skin contact immediately after birth and the newborn's first attempt at breastfeeding further augment maternal oxytocin levels, strengthening the uterine contractions that will help the placenta to separate and the uterus to contract to prevent hemorrhage. Endorphins, the body's natural opiates, produce an altered state of consciousness and aid in blocking out pain. In addition, the drop in adrenaline level from the second stage, which had kept the mother and baby alert at first contact, causes most women to shiver and feel cold shortly after giving birth.

▶ *Take* NOTE!

A crucial role for nurses during this time is to protect the natural hormonal process by ensuring unhurried and uninterrupted contact between mother and newborn after birth, providing warmed blankets to prevent shivering, and allowing skin-to-skin contact and breastfeeding.

Assessment

Assessment during the third stage of labor includes:

- Monitoring placental separation by looking for the following signs:
  - Firmly contracting uterus
  - Change in uterine shape from discoid to globular ovoid
  - Sudden gush of dark blood from vaginal opening
  - Lengthening of umbilical cord protruding from vagina
- Examining placenta and fetal membranes for intactness the second time (the health care provider assesses the placenta for intactness the first time) (Fig. 14.18)
- Assessing for any perineal trauma, such as the following, before allowing the birth attendant to leave:
  - Firm fundus with bright-red blood trickling: laceration
  - Boggy fundus with red blood flowing: uterine atony
  - Boggy fundus with dark blood and clots: retained placenta

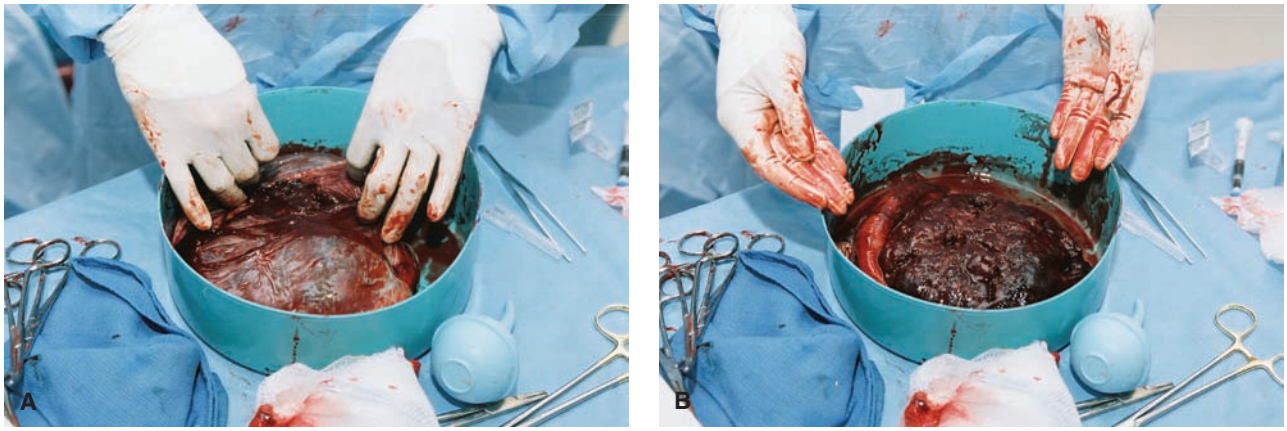

FIGURE 14.18 Placenta. (**A**) Fetal side. (**B**) Maternal side.

- Inspecting the perineum for condition of episiotomy, if performed
- Assessing for perineal lacerations and ensuring repair by birth attendant

Nursing Interventions

Interventions during the third stage of labor include:

- Describing the process of placental separation to the couple
- Instructing the woman to push when signs of separation are apparent
- Administering an oxytocic if ordered and indicated after placental expulsion
- Providing support and information about episiotomy and/or laceration
- Cleaning and assisting client into a comfortable position after birth, making sure to lift both legs out of stirrups (if used) simultaneously to prevent strain
- Repositioning the birthing bed to serve as a recovery bed if applicable
- Assisting with transfer to the recovery area if applicable
- Providing warmth by replacing warmed blankets over the woman
- Applying an ice pack to the perineal area to provide comfort to episiotomy if indicated
- Explaining what assessments will be carried out over the next hour and offering positive reinforcement for actions
- Ascertaining any needs
- Monitoring maternal physical status by assessing:
  - Vaginal bleeding: amount, consistency, and color
  - Vital signs: blood pressure, pulse, and respirations taken every 15 minutes
  - Uterine fundus, which should be firm, in the midline, and at the level of the umbilicus
- Recording all birthing statistics and securing primary caregiver's signature
- Documenting birthing event in the birth book (official record of the facility that outlines every birth event), detailing any deviations

Nursing Management During the Fourth Stage of Labor

The fourth stage of labor begins after the placenta is expelled and lasts up to 4 hours after birth, during which time recovery takes place. This recovery period may take place in the same room where the woman gave birth, in a separate recovery area, or in her postpartum room. During this stage, the woman's body is beginning to undergo the many physiologic and psychological changes that occur after birth. The focus of nursing management during the fourth stage of labor involves frequent close observation for hemorrhage, provision of comfort measures, and promotion of family attachment.

Assessment

Assessments during the fourth stage center on the woman's vital signs, status of the uterine fundus and perineal area, comfort level, lochia amount, and bladder status. During the first hour after birth, vital signs are taken every 15 minutes, then every 30 minutes for the next hour if needed. The woman's blood pressure should remain stable and within normal range after giving birth. A decrease may indicate uterine hemorrhage; an elevation might suggest preeclampsia.

The pulse usually is typically slower (60 to 70 bpm) than during labor. This may be associated with a decrease in blood volume following placental separation. An elevated pulse rate may be an early sign of blood loss. The blood pressure usually returns to its prepregnancy level and therefore is not a reliable early indicator of shock. Fever is indicative of dehydration (less than 100.4°F or 38°C) or infection (above 101°F), which may involve the genitourinary tract. Respiratory rate is usually between 16 and 24 breaths per minute and regular. Respirations should be unlabored unless there is an underlying preexisting respiratory condition.

Assess fundal height, position, and firmness every 15 minutes during the first hour following birth. The fundus needs to remain firm to prevent excessive postpartum bleeding. The fundus should be firm (feels like the size and consistency of a grapefruit), located in the midline and below the umbilicus. If it is not firm (boggy), gently massage it until it is firm (see Nursing Procedure 22.1 for more information). Once firmness is obtained, stop massaging.

▶ *Take* NOTE!

If the fundus is displaced to the right of the midline, suspect a full bladder as the cause.

The vagina and perineal areas are quite stretched and edematous following a vaginal birth. Assess the perineum, including the episiotomy if present, for possible hematoma formation. Suspect a hematoma if the woman reports excruciating pain or cannot void or if a mass is noted in the perineal area. Also assess for hemorrhoids, which can cause discomfort.

Assess the woman's comfort level frequently to determine the need for analgesia. Ask the woman to rate her pain on a scale of 1 to 10; it should be less than 3. If it is higher, further evaluation is needed to make sure there aren't any deviations contributing to her discomfort.

Assess vaginal discharge (lochia) every 15 minutes for the first hour and every 30 minutes for the next hour. Palpate the fundus at the same time to ascertain its firmness and help to estimate the amount of vaginal discharge. In addition, palpate the bladder for fullness, since many

women receiving an epidural block experience limited sensation in the bladder region. Voiding should produce large amounts of urine (diuresis) each time. Palpation of the woman's bladder after each voiding helps to ensure complete emptying. A full bladder will displace the uterus to either side of the midline and potentiate uterine hemorrhage secondary to bogginess.

Nursing Interventions

Nursing interventions during the fourth stage might include:

- Providing support and information to the woman regarding episiotomy repair and related pain-relief and self-care measures
- Applying an ice pack to the perineum to promote comfort and reduce swelling
- Assisting with hygiene and perineal care; teaching the woman how to use the perineal bottle after each pad change and voiding; helping the woman into a new gown
- Monitoring for return of sensation and ability to void (if regional anesthesia was used)
- Encouraging the woman to void by ambulating to bathroom, listening to running water, or pouring warm water over the perineal area with the peribottle
- Monitoring vital signs and fundal and lochia status every 15 minutes and documenting them
- Promoting comfort by offering analgesia for afterpains and warm blankets to reduce chilling
- Offering fluids and nourishment if desired
- Encouraging parent–infant attachment by providing privacy for the family
- Being knowledgeable about and sensitive to typical cultural practices after birth
- Assisting the mother to nurse, if she chooses, during the recovery period to promote uterine firmness (the release of oxytocin from the posterior pituitary gland stimulates uterine contractions)
- Teaching the woman how to assess her fundus for firmness periodically and to massage it if it is boggy
- Describing the lochia flow and normal parameters to observe for postpartum
- Teaching safety techniques to prevent newborn abduction
- Demonstrating the use of the portable sitz bath as a comfort measure for her perineum if she had a laceration or an episiotomy repair
- Explain comfort/hygiene measures and when to use them
- Assisting with ambulation when getting out of bed for the first time
- Providing information about the routine on the mother–baby unit or nursery for her stay
- Observing for signs of early parent–infant attachment: fingertip touch to palm touch to enfolding of the infant (Leonard, 2007)

Key Concepts

- A nurse provides physical and emotional support during the labor and birth process to assist a woman to achieve her goals.
- When a woman is admitted to the labor and birth area, the admitting nurse must assess and evaluate the risk status of the pregnancy and initiate appropriate interventions to provide optimal care for the client.
- Completing an admission assessment includes taking a maternal health history; performing physical assessment on the woman and fetus, including her emotional and psychosocial status; and obtaining the necessary laboratory studies.
- The nurse's role in fetal assessment for labor and birth includes determining fetal well-being and interpreting signs and symptoms of possible compromise. Determining the fetal heart rate (FHR) pattern and assessing amniotic fluid characteristics are key.
- FHR can be assessed intermittently or continuously. Although the intermittent method allows the client to move about during labor, the information obtained intermittently does not provide a complete picture of fetal well-being from moment to moment.
- Assessment parameters of the FHR are classified as baseline rate, baseline variability (long-term and short-term), and periodic changes in the rate (accelerations and decelerations).
- The nurse monitoring the laboring client needs to be knowledgeable about which parameters are reassuring, nonreassuring, and ominous so that appropriate interventions can be instituted.
- For a nonreassuring FHR pattern, the nurse should notify the health care provider about the pattern and obtain further orders, making sure to document all interventions and their effects on the FHR pattern.
- In addition to interpreting assessment findings and initiating appropriate inventions for the laboring client, accurate and timely documentation must be carried out continuously.
- Today's women have many safe nonpharmacologic and pharmacologic choices for the management of pain during childbirth. They may be used individually or in combination to complement one another.
- Nursing management for the woman during labor and birth includes comfort measures, emotional support, information and instruction, advocacy, and support for the partner.
- Nursing care during the first stage of labor includes taking an admission history (reviewing the prenatal record), checking the results of routine laboratory work and special tests done during pregnancy, asking the woman about her childbirth preparation (birth plan, classes taken, coping skills), and completing a physical assessment of the woman to establish a baseline of values for future comparison.

- Nursing care during the second stage of labor focuses on supporting the woman and her partner in making decisions about her care and labor management, implementing strategies to prolong the early passive phase of fetal descent, supporting involuntary bearing-down efforts, providing instruction and assistance, and encouraging the use of maternal positions that can enhance descent and reduce the pain.
- Nursing care during the third stage of labor primarily focuses on immediate newborn care and assessment and being available to assist with the delivery of the placenta and inspecting it for intactness.
- The focus of nursing management during the fourth stage of labor involves frequently observing the mother for hemorrhage, providing comfort measures, and promoting family attachment.

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

1. When a client in labor is fully dilated, which instruction would be most effective to assist her in encouraging effective pushing?
   a. Hold your breath and push through entire contraction.
   b. Use chest-breathing with the contraction.
   c. Pant and blow during each contraction.
   d. Push for 6 to 7 seconds several times during each contraction.
2. During the fourth stage of labor, the nurse palpates the uterus on the right side and sees a saturated perineal pad. What is the nurse's first action?
   a. Massage the uterus vigorously.
   b. Have the client void and reassess her.
   c. Notify the primary care provider.
   d. Document as a normal finding.
3. When managing a client's pain during labor, nurses should:
   a. Make sure the agents given don't prolong labor.
   b. Know that all pain-relief measures are similar.
   c. Support the client's decisions and requests.
   d. Not recommend nonpharmacologic methods.
4. When caring for a client during the active phase of labor without continuous electronic fetal monitoring, the nurse would intermittently assess FHR every:
   a. 15 minutes
   b. 5 minutes
   c. 30 minutes
   d. 60 minutes
5. The nurse notes the presence of transient fetal accelerations on the fetal monitoring strip. Which intervention would be most appropriate?
   a. Reposition the client on the left side.
   b. Begin 100% oxygen via face mask.
   c. Document this reassuring pattern.
   d. Call the health care provider immediately.

CRITICAL THINKING EXERCISES

1. Carrie, a 20-year-old primigravida at term, comes to the birthing center in active labor (dilation 5 cm and 80% effaced, –1 station) with ruptured membranes. She states she wants an "all-natural" birth without medication. Her partner is with her and appears anxious but supportive. On the admission assessment, Carrie's prenatal history is unremarkable; vital signs are within normal limits; FHR via Doppler ranges between 140 and 144 bpm and is regular.
   a. Based on your assessment data and the woman's request not to have medication, what nonpharmacologic interventions could you offer her?
   b. What positions might be suggested to facilitate fetal descent?
2. Several hours later, Carrie complains of nausea and turns to her partner and angrily tells him to not touch her and to go away.
   a. What assessment needs to be done to determine what is happening?
   b. What explanation can you offer Carrie's partner regarding her change in behavior?

STUDY ACTIVITIES

1. Share experiences within a post-clinical conference group regarding the pain management interventions of the patients to which you were assigned. Compare and evaluate the effectiveness of different methods used, maternal behavior observed, and neonatal outcome in terms of Apgar scores.
2. On the fetal heart monitor, the nurse notices an elevation of the fetal baseline with the onset of contractions. This elevation would describe _____.
3. Compare and contrast a local birthing center to a community hospital's birthing suite in terms of the pain-management techniques and fetal monitoring used.
4. Select a childbirth website for expectant parents and critique the information provided in terms of its educational level and amount of advertising.

CHAPTER 15

POSTPARTUM ADAPTATIONS

KEY TERMS

engorgement
engrossment
involution
lactation
letting-go phase
lochia
puerperium
taking-hold phase
taking-in phase
uterine atony

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms used in this chapter.
2. Explain the systemic physiologic changes occurring in the woman after childbirth.
3. Identify the phases of maternal role adjustment as described by Reva Rubin.
4. Analyze the psychological adaptations occurring in the mother's partner after childbirth.

Betsy had been home only 3 days when she called the OB unit where she had given birth and asked to speak to the lactation consultant. She reported pain in both breasts. Her nipples were tender due to frequent breastfeeding and she described her breasts as heavy, hard, and swollen.

Wow

A new mother's expectations are seen through rose-colored glasses, and at times her fantasy is better than the reality.

The postpartum period is a critical transitional time for a woman, her newborn, and her family on physiologic and psychological levels. The **puerperium** period begins after the delivery of the placenta and lasts approximately 6 weeks. During this period the woman's body begins to return to its prepregnant state, and these changes generally resolve by the sixth week after giving birth. However, the postpartum period can also be defined to include the changes in all aspects of the mother's life that occur during the first year after a child is born. Some believe that the postpartum adjustment period lasts well into the first year, making the fourth phase of labor the longest. Keeping this in mind, the true postpartum period may last between 9 and 12 months as the mother works to lose the weight she gained while pregnant, adjusts psychologically to the changes in her life, and takes on the new role of mother.

This chapter describes the major physiologic and psychological changes that occur in a woman after childbirth. Various systemic adaptations take place throughout the woman's body. In addition, the mother and the family adjust to the new addition psychologically. The birth of a child changes the family structure and the roles of the family members. The adaptations are dynamic and continue to evolve as physical changes occur and new roles emerge.

Maternal Physiologic Adaptations

During pregnancy, the woman's entire body changed to accommodate the needs of the growing fetus. After birth, the woman's body once again undergoes significant changes in all body systems to return her body to its prepregnant state.

Reproductive System Adaptations

The reproductive system goes through tremendous adaptations to return to the prepregnancy state. All organs and tissues of the reproductive system are involved. The female reproductive system is unique in its capacity to remodel throughout the woman's reproductive life. The events after birth, with the shedding of the placenta and subsequent uterine involution, involve substantial tissue destruction and subsequent repair and remodeling. For example, the woman's menstrual cycle, interrupted during pregnancy, will begin to return several weeks after childbirth. The uterus, which has undergone tremendous expansion during pregnancy to accommodate progressive fetal growth, will return to its prepregnant size over several weeks. The mother's breasts have grown to prepare for lactation and do not return to their prepregnant size as the uterus does.

Uterus

The uterus returns to its normal size through a gradual process of **involution**, which involves retrogressive changes that return it to its nonpregnant size and condition. Involution involves three retrogressive processes:

1. Contraction of muscle fibers to reduce those previously stretched during pregnancy
2. Catabolism, which reduces enlarged, individual myometrial cells
3. Regeneration of uterine epithelium from the lower layer of the decidua after the upper layers have been sloughed off and shed during lochial discharge (Blackburn, 2007)

The uterus, which weighs approximately 1,000 g (2.2 lb) soon after birth, undergoes physiologic involution as it returns to its nonpregnant state. Approximately 1 week after birth, the uterus shrinks in size by 50% and weighs about 500 g (1 lb); at the end of 6 weeks, it weighs approximately 60 g (2 oz), about the weight before the pregnancy (Arenson & Drake, 2007; Blackburn, 2007; Fig. 15.1). During the first few days after birth, the uterus typically descends from the level of the umbilicus at a rate of 1 cm (1 fingerbreadth) per day. By 3 days, the fundus lies 2 to 3 fingerbreadths below the umbilicus (or slightly higher in multiparous women). By the end of 10 days, the fundus usually cannot be palpated because it has descended into the true pelvis.

If these retrogressive changes do not occur as a result of retained placental fragments or infection, subinvolution results. Subinvolution is generally responsive to early diagnosis and treatment. Factors that facilitate uterine involution include complete expulsion of amniotic membranes and placenta at birth, a complication-free labor and birth process, breastfeeding, and early ambulation.

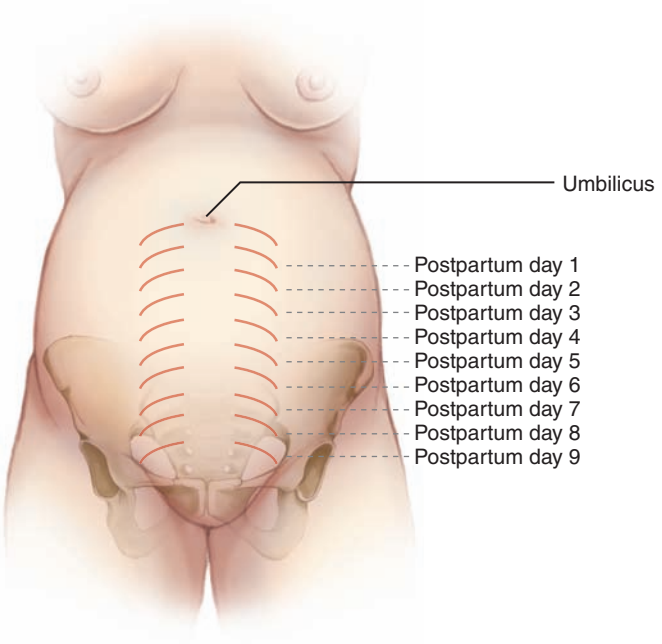

FIGURE 15.1 Uterine involution.

Factors that inhibit involution include a prolonged labor and difficult birth, incomplete expulsion of amniotic membranes and placenta, uterine infection, overdistention of uterine muscles (such as by multiple gestation, hydramnios, or a large singleton fetus), a full bladder (which displaces the uterus and interferes with contractions), anesthesia (which relaxes uterine muscles), and close childbirth spacing (frequent and repeated distention decreases tone and causes muscular relaxation).

Lochia

Lochia is the vaginal discharge that occurs after birth. It results from involution, during which the superficial layer of the decidua basalis becomes necrotic and is sloughed off. Immediately after childbirth, lochia is bright red and consists mainly of blood, fibrinous products, decidual cells, and red and white blood cells. The lochia from the uterus is alkaline but becomes acidic as it passes through the vagina. It is roughly equal to the amount occurring during a heavy menstrual period. The average amount of lochial discharge is 240 to 270 mL (8 to 9 oz) (Nash, 2007).

Women who have had cesarean births tend to have less flow because the uterine debris is removed manually along with delivery of the placenta. Lochia is present in most women for at least 3 weeks after childbirth, but it persists in some women for as long as 6 weeks.

Lochia passes through three stages: lochia rubra, lochia serosa, and lochia alba:

- Lochia rubra is a deep-red mixture of mucus, tissue debris, and blood that occurs for the first 3 to 4 days after birth. As uterine bleeding subsides, it becomes paler and more serous.
- Lochia serosa is the second stage. It is pinkish brown and is expelled 3 to 10 days postpartum. Lochia serosa primarily contains leukocytes, decidual tissue, red blood cells, and serous fluid.
- Lochia alba is the final stage. The discharge is creamy white or light brown and consists of leukocytes, decidual tissue, and reduced fluid content. It occurs from days 10 to 14 but can last 3 to 6 weeks postpartum in some women and still be considered normal.

Lochia at any stage should have a fleshy smell; an offensive odor usually indicates an infection, such as endometritis.

▶ *Take* NOTE!

A danger sign is the reappearance of bright-red blood after lochia rubra has stopped. Reevaluation by the health care professional is essential if this occurs.

Afterpains

Part of the involution process involves uterine contractions. Subsequently, many women are frequently bothered by painful uterine contractions termed afterpains. All women experience afterpains, but they are more acute in multiparous women secondary to repeated stretching of the uterine muscles. This repeated stretching reduces muscle tone, allowing for alternate uterine contraction and relaxation. The uterus of a primiparous woman tends to remain contracted after giving birth unless she is breastfeeding; had a prolonged, difficult labor and birth; or had an overdistended uterus secondary to multiple gestation, hydramnios, or retained blood clots or placental fragments.

▶ *Take* NOTE!

Afterpains are usually stronger during breastfeeding because oxytocin released by the sucking reflex strengthens the contractions. Mild analgesics can reduce this discomfort.

Cervix

The cervix typically returns to its prepregnant state by week 6 of the postpartum period. The cervix gradually closes but never regains its prepregnant appearance. Immediately after childbirth, the cervix is shapeless and edematous and is easily distensible for several days. The cervical os gradually closes and returns to normal by 2 weeks, whereas the external os widens and never appears the same after childbirth. The external cervical os is no longer shaped like a circle, but instead appears as a jagged slit-like opening, often described as a "fish mouth" (Fig. 15.2).

Vagina

Shortly after birth, the vaginal mucosa is edematous and thin, with few rugae. As ovarian function returns and estrogen production resumes, the mucosa thickens and rugae return in approximately 3 weeks. The vagina gapes at the

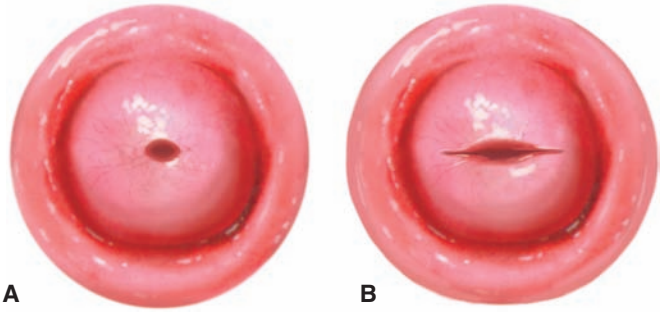

FIGURE 15.2 Appearance of the cervical os. (**A**) Before the first pregnancy. (**B**) After pregnancy.

opening and is generally lax. The vagina returns to its approximate prepregnant size by 6 to 8 weeks postpartum but will always remain a bit larger than it had been before pregnancy.

Normal mucus production and thickening of the vaginal mucosa usually return with ovulation (Edmonds, 2007). Ovulation can return as early as a month after childbirth in women who are not breastfeeding, with a mean time frame of 3 months. The mean time to ovulation in breastfeeding women is approximately 6 months, but this can vary greatly depending on breast-feeding patterns (Walsh, 2007). Localized dryness and coital discomfort (dyspareunia) usually plague most women until menstruation returns. Water-soluble lubricants can reduce discomfort during intercourse. Box 15.1 lists some commonly available water-soluble lubricants.

Perineum

The perineum is often edematous and bruised for the first day or two after birth. If the birth involved an episiotomy or laceration, complete healing may take as long as 4 to 6 months in the absence of complications at the site, such as hematoma or infection (Blackburn, 2007). Perineal lacerations may extend into the anus and cause considerable discomfort for the mother when she is attempting to defecate or ambulate. The presence of swollen hemorrhoids may also heighten discomfort. Local comfort measures such as ice packs, pouring warm water over the area via a peribottle, witch hazel pads, anesthetic sprays, and sitz baths can relieve pain. See Evidence-Based Practice 15.1.

Supportive tissues of the pelvic floor are stretched during the childbirth process, and restoring their tone may take up to 6 months. Pelvic relaxation can occur in any woman experiencing a vaginal birth. Nurses should encourage all women to practice Kegel exercises to improve pelvic floor tone, strengthen the perineal muscles, and promote healing.

BOX 15.1 Water-Soluble Lubricants

- Astroglide
- Aqua Lube Personal
- Devine No. 9
- Emerita
- Eros
- ID Glide sensual lubricant
- JO water-based lubricant
- K-Y personal lubricant
- Life Styles personal lubricant
- Liquid Silk
- Nature's Dew
- Pre-Seed Intimate
- Replens
- Slippery Stuff

▶ *Take* NOTE!

Failure to maintain and restore perineal muscular tone leads to urinary incontinence later in life for many women.

Cardiovascular System Adaptations

The cardiovascular system undergoes dramatic changes after birth. During pregnancy, the heart is displaced slightly upward and to the left. This reverses as the uterus undergoes involution. Cardiac output remains high for the first few days postpartum and then gradually declines to nonpregnant values within 3 months of birth.

Blood volume, which increased substantially during pregnancy, drops rapidly after birth and returns to normal within 4 weeks postpartum (Arenson & Drake, 2007). The decrease in both cardiac output and blood volume reflects the birth-related blood loss (an average of 500 mL with a vaginal birth and 1,000 mL with a cesarean birth). Blood plasma volume is further reduced through diuresis, which occurs during the early postpartum period (Cheng & Caughey, 2007). Despite the decrease in blood volume, the hematocrit level remains relatively stable and may even increase, reflecting the predominant loss of plasma. Thus, an acute decrease in hematocrit is not an expected finding and may indicate hemorrhage.

Pulse and Blood Pressure

The increase in cardiac output during pregnancy begins to diminish after birth. This decrease in cardiac output is reflected in bradycardia (50 to 70 bpm) for the first 2 weeks postpartum. This slowing of the heart rate is related to the increased blood that flows back to the heart and to the central circulation after it is no longer perfusing the placenta. This increase in central circulation brings about an increased stroke volume and allows a slower heart rate to provide ample maternal circulation. Gradually, cardiac output returns to prepregnant levels by 3 months after childbirth (Blackburn, 2007).

Tachycardia (heart rate above 100 bpm) in the postpartum woman warrants further investigation. It may indicate hypovolemia, dehydration, or hemorrhage. However, because of the increased blood volume during pregnancy, a considerable loss may be well tolerated and not cause a compensatory cardiovascular response such as tachycardia. In most instances of postpartum hemorrhage, blood pressure and cardiac output remain increased because of the compensatory increase in heart rate. Thus, a decrease

EVIDENCE-BASED PRACTICE 15.1
Rectal Analgesia for Pain From Perineal Trauma Following Childbirth

● Study
Perineal pain from a tear and/or surgical cut (episiotomy) is a common problem following vaginal birth. Strategies to reduce perineal trauma and the appropriate repair of any perineal damage sustained are important for avoiding and alleviating pain. Numerous pain-relief treatments are used in clinical practice, such as local anesthetics, oral analgesics, therapeutic ultrasound, antiseptics, and nonpharmacologic applications such as ice packs and baths. This review assesses the evidence for using rectal analgesia for pain relief following perineal trauma caused by childbirth.

▲ Findings
This review of trials found that NSAID rectal suppositories are associated with less pain up to 24 hours after birth, and less additional analgesia is required. More research is required to assess the longer-term outcomes, maternal satisfaction, and effects, if any, on breast milk, mother–baby bonding, and sexual functioning.

■ Nursing Implications
According to the study, NSAID rectal suppositories were helpful in relieving postpartum pain. Nurses can offer this intervention to their patients and explain the evidence-based practice behind it.

Hedayati, H., Parsons, J., & Crowther, C. A. (2003). Rectal analgesia for pain from perineal trauma following childbirth. *Cochrane Database of Systematic Reviews* 2003, Issue 3. Art. No.: CD003931. DOI: 10.1002/14651858.CD003931.

in blood pressure and cardiac output are not expected changes during the postpartum period. Early identification is essential to ensure prompt intervention.

Blood pressure values should be similar to those obtained during the labor process. In some women there may be a slight transient increase lasting for about a week after childbirth (Edmonds, 2007). A significant increase accompanied by headache might indicate preeclampsia and requires further investigation. A decreased blood pressure may suggest orthostatic hypotension or uterine hemorrhage.

Coagulation
Clotting factors that increased during pregnancy tend to remain elevated during the early postpartum period. Giving birth stimulates this hypercoagulability state further. As a result, these coagulation factors remain elevated for 2 to 3 weeks postpartum (Hackley, Kriebs, & Rousseau, 2007). This hypercoagulable state, combined with vessel damage during birth and immobility, places the woman at risk for thromboembolism (blood clots) in the lower extremities and the lungs.

Blood Cellular Components
Red blood cell production ceases early in the puerperium, causing mean hemoglobin and hematocrit levels to decrease slightly in the first 24 hours. Over the next 2 weeks, both levels rise slowly. The white blood count, which increases in labor, remains elevated for first 4 to 6 days after birth but then falls to 6,000 to 10,000/mm^3. This white blood cell elevation can complicate a diagnosis of infection in the immediate postpartum period.

Urinary System Adaptations
Pregnancy and birth can have profound effects on the urinary system. During pregnancy, the glomerular filtration rate and renal plasma flow increase significantly. Both usually return to normal by 6 weeks after birth.

Many women have difficulty feeling the sensation to void after giving birth if they received an anesthetic block during labor (which inhibits neural functioning of the bladder) or if they received oxytocin to induce or augment their labor (antidiuretic effect). These women will be at risk for incomplete emptying, bladder distention, difficulty voiding, and urinary retention. In addition, urination may be impeded by:

- Perineal lacerations
- Generalized swelling and bruising of the perineum and tissues surrounding the urinary meatus
- Hematomas
- Decreased bladder tone as a result of regional anesthesia
- Diminished sensation of bladder pressure as a result of swelling, poor bladder tone, and numbing effects of regional anesthesia used during labor (Nash, 2007)

Difficulty voiding can lead to urinary retention, bladder distention, and ultimately urinary tract infection (UTI). Urinary retention and bladder distention can cause displacement of the uterus from the midline to the right and can inhibit the uterus from contracting properly, which increases the risk of postpartum hemorrhage. Urinary retention is a major cause of **uterine atony**, which allows excessive bleeding. Frequent voiding of small amounts (less than 150 mL) suggests urinary retention with overflow,

and catheterization may be necessary to empty the bladder to restore tone.

Postpartum diuresis occurs as a result of several mechanisms: the large amounts of intravenous fluids given during labor, a decreasing antidiuretic effect of oxytocin as its level declines, the buildup and retention of extra fluids during pregnancy, and a decreasing production of aldosterone—the hormone that decreases sodium retention and increases urine production (Blackburn, 2007). All these factors contribute to rapid filling of the bladder within 12 hours of birth. Diuresis begins within 12 hours after childbirth and continues throughout the first week postpartum. Normal function returns within a month after birth (Edmonds, 2007).

▸ *Consider* THIS!

Have you ever felt like a real idiot by not being able to complete a simple task in life? I had a beautiful baby boy after only 6 hours of labor. My epidural worked well and I actually felt very little discomfort throughout my labor. Because it was in the middle of the night when they brought me to my postpartum room, I felt a few hours of sleep would be all I needed to be back to normal. During an assessment early the next morning, the nurse found my uterus had shifted to the right from my midline, and I was instructed to empty my bladder. I didn't understand why the nurse was concerned about where my uterus was located and, besides, I didn't feel any sensation of a full bladder. But I did get up anyway and tried to comply. Despite all the nurse's tricks of running the faucet for sound effects, in addition to having warm water poured over my thighs via the peri-bottle, I was unable to urinate. How could I not accomplish one of life's simplest tasks?

Thoughts: Women who receive regional anesthesia frequently experience reduced sensation to their perineal area and do not feel a full bladder. The nursing assessment revealed a displaced uterus secondary to a full bladder. What additional "tricks" can be used to assist this woman to void? What explanation should be offered to her regarding why she is having difficulty urinating?

Gastrointestinal System Adaptations

The GI system quickly returns to normal because the gravid uterus is no longer filling the abdominal cavity and producing pressure on the abdominal organs. Progesterone levels, which caused relaxation of smooth muscle during pregnancy and diminished bowel tone, also are declining.

Regardless of the type of delivery, most women experience decreased bowel tone and sluggish bowels for several days after birth. Decreased peristalsis occurs in response to analgesics, surgery, diminished intraabdominal pressure, low-fiber diet and insufficient fluid intake, and diminished muscle tone. In addition, women with an episiotomy, perineal laceration, or hemorrhoids may fear pain or damage to the perineum with their first bowel movement and may attempt to delay it. Subsequently, constipation is a common problem during the postpartum period. A stool softener can be prescribed for this reason.

Most women are hungry and thirsty after childbirth, commonly related to NPO restrictions and the energy expended during labor. Their appetite returns to normal immediately after giving birth.

▸ *Take* NOTE!

Anticipate the woman's need to replenish her body with food and fluids, and provide both soon after she gives birth.

Musculoskeletal System Adaptations

The effects of pregnancy on the muscles and joints vary widely. During pregnancy, the hormones relaxin, estrogen, and progesterone relax the joints. After birth, levels of these hormones decline, resulting in a return of all joints to their prepregnant state, with the exception of the woman's feet. Parous women will note a permanent increase in their shoe size (Hackley, Kriebs, & Rousseau, 2007).

Woman commonly experience fatigue and activity intolerance and have a distorted body image for weeks after birth secondary to declining relaxin and progesterone levels, which cause hip and joint pain that interferes with ambulation and exercise. Good body mechanics and correct position are important during this time to prevent low back pain and injury to the joints. Within 6 to 8 weeks after delivery, joints are completely stabilized and return to normal.

During pregnancy, stretching of the abdominal wall muscles occurs to accommodate the enlarging uterus. This stretching leads to a loss in muscle tone and possibly separation of the longitudinal muscles (rectus abdominis muscles) of the abdomen. Separation of the rectus abdominis muscles, called diastasis recti, is more common in women who have poor abdominal muscle tone before pregnancy. After birth, muscle tone is diminished and the abdominal muscles are soft and flabby. Specific exercises are necessary to help the woman regain muscle tone. Fortunately, diastasis responds well to exercise, and abdominal muscle tone can be improved (see Chapter 16 for more information about exercises to improve muscle tone).

▸ *Take* NOTE!

If rectus muscle tone is not regained through exercise, support may not be adequate during future pregnancies.

Integumentary System Adaptations

Another system that experiences lasting effects of pregnancy is the integumentary system. As estrogen and progesterone levels decrease, the darkened pigmentation on the abdomen (linea nigra), face (melasma), and nipples gradually fades. Some women experience hair loss during pregnancy and the postpartum periods. Approximately 90% of hairs are growing at any one time, with the other 10% entering a resting phase. Because of the high estrogen levels present during pregnancy, an increased number of hairs go into the resting phase, which is part of the normal hair loss cycle. The most common period for hair loss is within 3 months after birth, when estrogen returns to normal levels and more hairs are allowed to fall out. This hair loss is temporary, and regrowth generally returns to normal levels in 6 to 12 months (Lyon, 2007).

Striae gravidarum (stretch marks) that developed during pregnancy on the breasts, abdomen, and hips gradually fade to silvery lines. However, these lines do not disappear completely. Although many products on the market claim to make stretch marks disappear, their effectiveness is highly questionable.

The profuse diaphoresis (sweating) that is common during the early postpartum period is one of the most noticeable adaptations in the integumentary system. Many women will wake up drenched with perspiration during the puerperium. This postpartal diaphoresis is a mechanism to reduce the amount of fluids retained during pregnancy and restore prepregnant body fluid levels. It can be profuse at times. It is common, especially at night during the first week after birth. Reassure the client that this is normal and encourage her to change her gown to prevent chilling.

Respiratory System Adaptations

Respirations usually remain within the normal adult range of 16 to 24 breaths per minute. As the abdominal organs resume their nonpregnant position, the diaphragm returns to its usual position. Anatomic changes in the thoracic cavity and rib cage caused by increasing uterine growth resolve quickly. As a result, discomforts such as shortness of breath and rib aches are relieved. Tidal volume, minute volume, vital capacity, and functional residual capacity return to prepregnant values, typically within 1 to 3 weeks of birth (Blackburn, 2007).

Endocrine System Adaptations

The endocrine system undergoes several changes rapidly after birth. Levels of circulating estrogen and progesterone drop quickly with delivery of the placenta. Decreased estrogen levels are associated with breast engorgement and with the diuresis of excess extracellular fluid accumulated during pregnancy (Edmonds, 2007). Estrogen is at its lowest level a week after birth. For the woman who is not breastfeeding, estrogen levels begin to increase by 2 weeks after birth. For the breastfeeding woman, estrogen levels remain low until breastfeeding frequency decreases.

Other placental hormones (hCG, hPL, progesterone) decline rapidly after birth. hCG levels are nonexistent at the end of the first postpartum week and hPL is undetectable within 1 day after birth (Blackburn, 2007). Progesterone levels are undetectable by 3 days after childbirth, and production is reestablished with the first menses. Prolactin levels decline within 2 weeks for the woman who is not breastfeeding and remain elevated for the lactating woman (Blackburn, 2007).

Think back to Betsy, the woman experiencing painful changes in her breasts. What is Betsy describing to the lactation consultant? Why has the condition of her breasts changed compared to when she was in the hospital?

Lactation

Lactation is the secretion of milk by the breasts. It is thought to be brought about by the interaction of progesterone, estrogen, prolactin, and oxytocin. Breast milk typically appears 3 days after childbirth.

During pregnancy, the breasts increase in size and functional ability in preparation for breastfeeding. Within the first month of gestation, the ducts of the mammary glands grow branches, forming more lobules and alveoli. These structural changes make the breasts larger, more tender, and heavy. Each breast gains nearly 1 lb in weight by term, the glandular cells fill with secretions, blood vessels increase in number, and there are increased amounts of connective tissue and fat cells (Blackburn, 2007).

Prolactin from the anterior pituitary gland, secreted in increasing levels throughout pregnancy, triggers the synthesis and secretion of milk after the woman gives birth. During pregnancy, prolactin, estrogen, and progesterone cause synthesis and secretion of colostrum, which contains protein and carbohydrate but no milk fat. It is only after birth takes place, when the high levels of estrogen and progesterone are abruptly withdrawn, that prolactin is able to stimulate the glandular cells to secrete milk instead of colostrum. This takes place within 2 to 3 days after giving birth. Oxytocin acts so that milk can be ejected from the alveoli to the nipple. Therefore, sucking by the newborn will release milk. Prolactin levels increase in response to nipple stimulation during feedings. Prolactin and oxytocin result in milk production if stimulated by sucking (Walsh, 2007) (Fig. 15.3). If the stimulus (sucking) is not present, as with a woman who is not breastfeeding, breast engorgement and milk production will subside within 2 to 3 days postpartum.

Typically, during the first 2 days after birth, the breasts are soft and nontender. The woman also may report a tingling sensation in both breasts. After this time, breast changes depend on whether the mother is breastfeeding or taking measures to prevent lactation.

Figure 15.3 Physiology of lactation.

Engorgement is the process of swelling of the breast tissue as a result of an increase in blood and lymph supply as a precursor to lactation (Bainbridge, 2007). Breasts increase in vascularity and swell in response to prolactin 2 to 4 days after birth. If engorged, the breasts will be hard and tender to touch. They are temporarily full, tender, and very uncomfortable until the milk supply is ready. Frequent emptying of the breasts helps to minimize discomfort and resolve engorgement. Standing in a warm shower or applying warm compresses immediately before feedings will help to soften the breasts and nipples in order to allow the newborn to latch on easier. These measures will also enhance the letdown reflex. Between feedings, applying cold compresses to the breasts helps to reduce swelling. To maintain milk supply, the breasts need to be stimulated by a nursing infant, a breast pump, or manual expression of the milk (Fig. 15.4).

Remember Betsy, with the breast discomfort? The lactation consultant explained that she was experiencing normal breast engorgement and offered several suggestions to help her. What relief measures might they be? What reassurance can be given to Betsy at this time?

Figure 15.4 Mother using breast pumps to stimulate milk production.

If the woman is not breastfeeding, relief measures include wearing a tight, supportive bra 24 hours daily, applying ice to her breasts for approximately 15 to 20 minutes every other hour, and not stimulating the breasts by squeezing or manually expressing milk from the nipples. In addition, avoiding exposing the breasts to warmth (e.g., a hot shower) will help relieve breast engorgement. In women who are not breastfeeding, engorgement typically subsides within 2 to 3 days with these measures.

Ovulation and Return of Menstruation

Changing hormone levels constantly interact with one another to produce bodily changes. Four major hormones are influential during the postpartum period: estrogen, progesterone, prolactin, and oxytocin. Estrogen is the major female hormone during pregnancy, but levels drop profoundly at birth and reach their lowest level a week into the postpartum period. Progesterone quiets the uterus to prevent a preterm birth during pregnancy, and its increasing levels during pregnancy prevent lactation from starting before birth takes place. As with estrogen, progesterone levels decrease dramatically after birth and are undetectable 72 hours after birth. Progesterone levels are reestablished with the first menstrual cycle (Blackburn, 2007).

During the postpartum period, oxytocin stimulates the uterus to contract during the breastfeeding session and for as long as 20 minutes after each feeding. Oxytocin also acts on the breast by eliciting the milk letdown reflex during breastfeeding. Prolactin is also associated with the breastfeeding process by stimulating milk production. In women who breastfeed, prolactin levels remain elevated

into the sixth week after birth (Nash, 2007). The levels of the hormone increase and decrease in proportion to nipple stimulation. Prolactin levels decrease in nonlactating women, reaching prepregnant levels by the third postpartum week (Edmonds, 2007). High levels of prolactin have been found to delay ovulation by inhibiting ovarian response to FSH (Edmonds, 2007).

The timing of first menses and ovulation after birth differs between women who are and are not breastfeeding. For nonlactating women, menstruation usually resumes 7 to 9 weeks after giving birth, with the first cycle being anovulatory (Walsh, 2007). The return of menses in the lactating woman depends on breastfeeding frequency and duration. It can return anytime from 2 to 18 months after childbirth, depending on whether the woman is exclusively breastfeeding or supplementing with formula. The first postpartum menstrual period may be heavier than prepregnant ones and is frequently anovulatory (Hackley, Kriebs, & Rousseau, 2007).

▶ *Take* NOTE!

Ovulation may occur before menstruation; therefore, breastfeeding is not a reliable method of contraception. Other methods of family planning must be used to control fertility (Alexander et al., 2007).

Betsy tries several of the measures the lactation consultant suggested to relieve her breast discomfort but is still having heaviness and pain. She feels discouraged and tells the nurse she is thinking of reducing her breastfeeding and using formula to feed her newborn. Is that a good choice? Why or why not? What interventions will help Betsy get through this difficult time?

Psychological Adaptations

Mothers' and fathers' experiences of pregnancy are necessarily different, and this difference continues after childbirth as they both adjust to their new parenting roles. Parenting involves caring for infants physically and emotionally to foster the growth and development of responsible, caring adults. During the early months of parenthood, mothers experience more life changes and get more satisfaction from their new roles than fathers. However, fathers interact with their newborns much like mothers (Thorpe, 2007). Early parent–infant contact after birth improves attachment behaviors. Other members of the newborn's family, such as siblings and grandparents, also experience changes related to the birth of the newborn. Chapter 16 describes these changes.

Maternal Psychological Adaptations

Postpartum depression affects the transition to the maternal role for many mothers. Between 50% and 80% of new mothers suffer from the short-lived postpartum mood disorder termed "baby blues." In addition, each year in the United States, up to 28% of new mothers or more than 400,000 new mothers suffer debilitating postpartum depression, a prevalence that continues unabated (AWHONN, 2007). Postpartum depression can lead to alienation from loved ones, daily dysfunction secondary to overwhelming sorrow and disorientation, and, at its most extreme, personal terror resulting in dangerous thoughts and violent actions. For additional information, see Chapter 22.

The woman experiences a variety of responses as she adjusts to a new family member, postpartum discomforts, changes in her body image, and the reality of change in her life. In the early 1960s, Reva Rubin identified three phases that a mother goes through to adjust to her new maternal role. Rubin's maternal role framework can be used to monitor the client's progress as she "tries on" her new role as a mother. Absence of these processes or inability to progress through the phases satisfactorily may impede the appropriate development of the maternal role (Rubin, 1984). Although Rubin's maternal role development theories are of value, some of her observations regarding the length of each phase may not be completely relevant for the contemporary woman of the 21st century. Today, many women know their infant's gender, have "seen" their fetus in utero through four-dimensional ultrasound, and have a working knowledge of childbirth and child care. They are less passive than in years past and progress through the phases of attaining the maternal role at a much faster pace than Rubin would have imagined. Still, Rubin's framework is timeless for assessing and monitoring expected role behaviors when planning care and appropriate interventions.

Taking-In Phase

The **taking-in phase** is the time immediately after birth when the client needs sleep, depends on others to meet her needs, and relives the events surrounding the birth process. This phase is characterized by dependent behavior. During the first 24 to 48 hours after giving birth, mothers often assume a very passive role in meeting their own basic needs for food, fluids, and rest, allowing the nurse to make decisions for them concerning activities and care. They spend time recounting their labor experience to anyone who will listen. Such actions help the mother integrate the birth experience into reality—that is, the pregnancy is over and the newborn is now a unique individual, separate from herself. When interacting with the newborn, new mothers

spend time claiming the newborn and touching him or her, commonly identifying specific features in the newborn, such as "he has my nose" or "his fingers are long like his father's" (Fig. 15.5).

▶ *Take* NOTE!

The taking-in phase typically lasts 1 to 2 days and may be the only phase observed by nurses in the hospital setting because of the shortened postpartum stays that are the norm today.

Taking-Hold Phase

The **taking-hold phase**, the second phase of maternal adaptation, is characterized by dependent and independent maternal behavior. This phase typically starts on the second to third day postpartum and may last several weeks.

As the client regains control over her bodily functions during the next few days, she will be taking hold and becoming preoccupied with the present. She will be particularly concerned about her health, the infant's condition, and her ability to care for him or her. She demonstrates increased autonomy and mastery of her own body's functioning, and a desire to take charge with support and help from others. She will show independence by caring for herself and learning to care for her newborn, but she still requires assurance that she is doing well as a mother. She expresses a strong interest in caring for the infant by herself.

Letting-Go Phase

In the **letting-go phase**, the third phase of maternal adaptation, the woman reestablishes relationships with other people. She adapts to parenthood through her new role as a mother. She assumes the responsibility and care for the newborn with a bit more confidence now (Arenson & Drake, 2007). The focus of this phase is to move forward by assuming the parental role and to separate herself from the symbiotic relationship that she and her newborn had during pregnancy. She establishes a lifestyle that includes the infant. The mother relinquishes the fantasy infant and accepts the real one.

Partner Psychological Adaptations

For partners, whether they are husbands, significant others, boyfriends, same-sex life partners, or just friends, becoming a parent or just sharing the childbirth experience can be a perplexing time as well as a time of great change. This transition is influenced by many factors, including participation in childbirth, relationships with significant others, competence in child care, the family role organization, the individual's cultural background, and the method of infant feeding.

▶ *Take* NOTE!

Most research findings stress the importance of early contact between the father or significant other and the newborn, as well as participation in infant care activities, to foster the relationship (Thorpe, 2007).

Infants have a powerful effect on their fathers and others, who become intensely involved with them (Fig. 15.6). The father's or significant other's developing bond with the newborn—a time of intense absorption, preoccupation, and interest—is called engrossment.

Figure 15.5 Mother bonding with newborn during the taking-in phase.

Figure 15.6 Engrossment of the father and his newborn.

Engrossment

Engrossment is characterized by seven behaviors:

1. Visual awareness of the newborn—the father or partner perceives the newborn as attractive, pretty, or beautiful
2. Tactile awareness of the newborn—the father or partner has a desire to touch or hold the newborn and considers this activity to be pleasurable
3. Perception of the newborn as perfect—the father or partner does not "see" any imperfections
4. Strong attraction to the newborn—the father or partner focuses all attention on the newborn when he is in the room
5. Awareness of distinct features of the newborn—the father or partner can distinguish his newborn from others in the nursery
6. Extreme elation—the father or partner feels a "high" after the birth of his child
7. Increased sense of self-esteem—the father or partner feels proud, "bigger," more mature, and older after the birth of his child (Sears & Sears, 2006)

Frequently, fathers or partners are portrayed as well-meaning but bumbling when caring for newborns. However, they have their own unique way of relating to their newborns and can become as nurturing as mothers. A father or partner's nurturing responses may be less automatic and slower to unfold than a mother's, but they are capable of a strong bonding attachment to their newborns (Sears & Sears, 2006). Encouraging fathers or partners to express their feelings by seeing, touching, and holding their son or daughter and by cuddling, talking to, and feeding him or her will help to cement this new relationship. Reinforcement of this engrossing behavior helps fathers or partners to make a positive attachment during this critical period.

Three-Stage Role Development Process

Similar to mothers, fathers or partners also go through a predictable three-stage process during the first 3 weeks as they too "try on" their roles as parents. The three stages are expectations, reality, and transition to mastery (Sears & Sears, 2006).

Stage 1: Expectations

New fathers or partners pass through stage 1 (expectations) with preconceptions about what home life will be like with a newborn. Many men may be unaware of the dramatic changes that can occur when this newborn comes home to live with them. For some, it is an eye-opening experience.

Stage 2: Reality

Stage 2 (reality) occurs when fathers or partners realize that their expectations in stage 1 are not realistic. Their feelings change from elation to sadness, ambivalence, jealousy, and frustration. Many wish to be more involved in the newborn's care and yet do not feel prepared to do so. Some find parenting fun but at the same time do not feel fully prepared to take on that role.

Stage 3: Transition to Mastery

In stage 3 (transition to mastery), the father or partner makes a conscious decision to take control and be at the center of his newborn's life regardless of his preparedness. This adjustment period is similar to that of the mother's letting-go phase, when she incorporates the newest member into the family.

Key Concepts

- The puerperium period refers to the first 6 weeks after delivery. During this period, the mother experiences many physiologic and psychological adaptations to return her to the prepregnant state.
- Involution involves three processes: contraction of muscle fibers to reduce stretched ones, catabolism (which reduces enlarged, individual cells), and regeneration of uterine epithelium from the lower layer of the decidua after the upper layers have been sloughed off and shed in lochia.
- Lochia passes through three stages: lochia rubra, lochia serosa, and lochia alba during the postpartal period.
- Maternal blood plasma volume decreases rapidly after birth and returns to normal within 4 weeks postpartum.
- Reva Rubin (1984) identified three phases the mother goes through to adjust to her new maternal role. The phases of maternal postpartum adjustment are taking in, taking hold, and letting go.
- The transition to fatherhood is influenced by many factors, including participation in childbirth, relationships with significant others, competence in child care, the family role organization, the father's cultural background, and the method of infant feeding.
- Like mothers, men go through a predictable three-stage process during the first 3 weeks as they too "try on" their roles as fathers or partners. The three stages include expectations, reality, and transition to mastery.

CHAPTER WORKSHEET

MULTIPLE CHOICE QUESTIONS

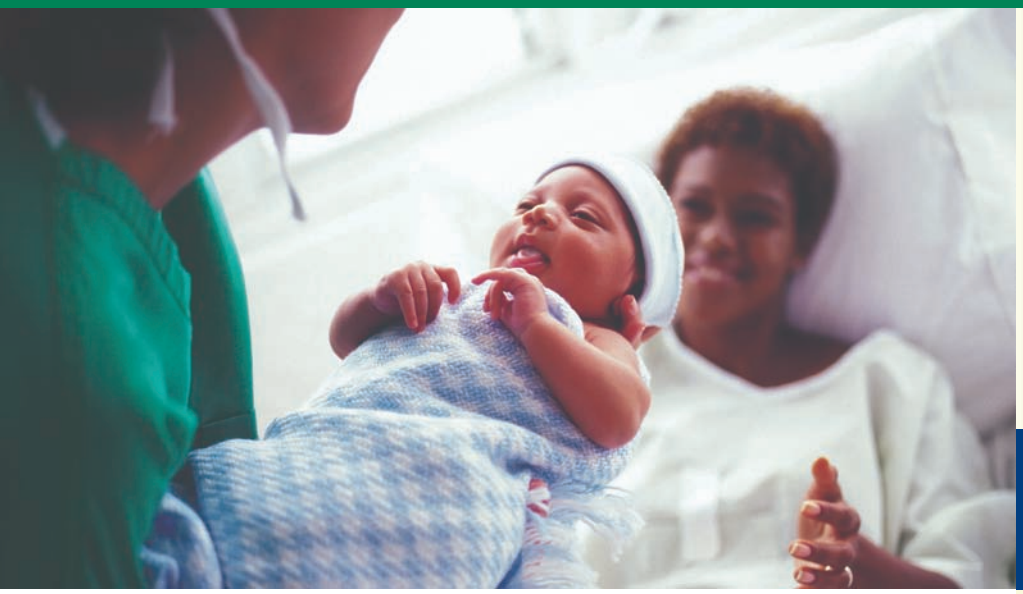
1. Postpartal breast engorgement occurs 48 to 72 hours after giving birth. What physiologic change influences breast engorgement?
   a. An increase in blood and lymph supply to the breasts
   b. A decrease in estrogen and progesterone levels
   c. Colostrum production increases dramatically
   d. Fluid retention in the breasts due to the intravenous fluids given during labor
2. In the taking-in maternal role phase described by Rubin (1984), the nurse would expect the woman's behavior to be characterized as which of the following?
   a. Gaining self-confidence
   b. Adjusting to her new relationships
   c. Being passive and dependent
   d. Resuming control over her life
3. The nurse is explaining to a postpartal woman that the afterpains she is experiencing can be the result of which of the following?
   a. Manipulation of the uterus during labor
   b. A large infant weighing more than 8 lb
   c. Pregnancies that were too closely spaced
   d. Contractions of the uterus after birth
4. The nurse would expect a postpartal woman to demonstrate lochia in which sequence?
   a. Rubra, alba, serosa
   b. Rubra, serosa, alba
   c. Serosa, alba, rubra
   d. Alba, rubra, serosa
5. The nurse is assessing Ms. Smith, who gave birth to her first child 5 days ago. What findings by the nurse would be expected?
   a. Cream-colored lochia; uterus above the umbilicus
   b. Bright-red lochia with clots; uterus 2 fingerbreadths below umbilicus
   c. Light pink or brown lochia; uterus 4 to 5 fingerbreadths below umbilicus
   d. Yellow, mucousy lochia; uterus at the level of the umbilicus
6. Prioritize the postpartum mother's needs 4 hours after giving birth by placing a number 1, 2, 3, or 4 in the blank before each need.
   _____Learn how to hold and cuddle the infant
   _____Watch a baby bath demonstration given by the nurse
   _____Sleep and rest without being disturbed for a few hours
   _____Interaction time with the infant to facilitate bonding

CRITICAL THINKING EXERCISES

1. A new nurse assigned to the postpartum mother–baby unit makes a comment to the oncoming shift that Ms. Griffin, a 25-year-old primipara, seems lazy and shows no initiative in taking care of herself or her baby. The nurse reported that Ms. Griffin talks excessively about her labor and birth experience and seems preoccupied with herself and her needs, not her newborn's care. She wonders if something is wrong with this mother because she seems so self-centered and has to be directed to do everything.
   a. Is there something "wrong" with Ms. Griffin's behavior? Why or why not?
   b. What maternal role phase is being described by the new nurse?
   c. What role can the nurse play to support the mother through this phase?
2. Mrs. Lenhart, a primipara, gave birth to a healthy baby boy yesterday. Her husband John seemed elated at the birth, calling his friends and family on his cell phone minutes after the birth. He passed out cigars and praised his wife for her efforts. Today, when the nurse walked into their room, Mr. Lenhart seemed very anxious around his new son and called for the nurse whenever the baby cried or needed a diaper change. He seemed standoffish when asked to hold his son, and he spent time talking to other fathers in the waiting room, leaving his wife alone in the room.
   a. Would you consider Mr. Lenhart's paternal behavior to be normal at this time?
   b. What might Mr. Lenhart be feeling at this time?
   c. How can the nurse help this new father adjust to his new role?

Study Activities

1. Find an Internet resource that discusses general postpartum care for new mothers who might have questions after discharge. Evaluate the website's information as to how credible, accurate, and current it is.
2. Prepare a teaching plan for new mothers, outlining the various physiologic changes that will take place after discharge.
3. The term that describes the return of the uterus to its prepregnant state is _____.
4. A deviated fundus to the right side of the abdomen would indicate a _____.



CHAPTER 16

Nursing Management During the Postpartum Period

KEY TERMS

attachment
bonding
en face position
Kegel exercises
mastitis
peribottle
postpartum blues
sitz bath

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms.
2. List the parameters that need to be assessed during the postpartum period.
3. Compare the bonding and attachment process.
4. Identify behaviors that enhance or inhibit the attachment process.
5. Outline nursing management for the woman and her family during the postpartum period.
6. Discuss the role of the nurse in promoting successful breast-feeding.
7. List areas of health education needed for discharge planning, home care, and follow-up.

Raina is a 24-year-old Muslim primipara who has just been admitted to the postpartum unit. Her husband sits at the bedside but doesn't seem to give her any physical or emotional support after her lengthy labor and difficult birth.

Wow

Parenting is an intimate, interactive, continuous, lifelong process.

The postpartum period is a time of major adjustments and adaptations not just for the mother, but for all members of the family. It is during this time that parenting starts and a relationship with the newborn begins. A positive, loving relationship between parents and their newborn promotes the emotional well-being of all. This relationship endures and has profound effects on the child's growth and development.

▶ *Take* NOTE!

Parenting is a skill that is often learned by trial and error, with varying degrees of success. Successful parenting, a continuous and complex interactive process, requires the parents to learn new skills and to integrate the new member into the family.

HEALTHY PEOPLE 2010

Objective	Significance
Increase the proportion of mothers who breast-feed their babies. Increase the number of mothers who breast-feed during early postpartum from a baseline of 64% to 75%. Increase the number of mothers who breast-feed at 6 months from a baseline of 29% to 50%. Increase the number of mothers who breast-feed at 1 year from a baseline of 16% to 25%.	• Will provide infants with the most complete form of nutrition, improving their health, growth and development, and immunity • Will improve maternal health via breast-feeding's beneficial effects • Will increase the rate of breast-feeding, particularly among low-income and certain racial and ethnic populations who are less likely to begin breast-feeding in the hospital or to sustain it through the infant's first year

Once the infant is born, each system in the mother's body takes several weeks to return to its nonpregnant state. The physiologic changes in women during the postpartum period are dramatic. Nurses should be aware of these changes and should be able to make observations and assessments to validate normal occurrences and detect any deviations.

In addition to physical assessment and care of the woman in the postpartum period, strong social support is vital to help her integrate the baby into the family. In today's mobile society, extended families may live far away and may be unable to help care for the new family. As a result, many new parents turn to health care professionals for information as well as physical and emotional support during this adjustment period. Nurses can be an invaluable resource by serving as mentors, teaching about self-care measures and baby care basics, and providing emotional support. Nurses can "mother" the new mother by offering physical care, emotional support, and information and practical help. The nurse's support and care through this critical time can increase the new parents' confidence, giving them a sense of accomplishment in their parenting skills.

One important intervention during the postpartum period is promotion of breast-feeding. *Healthy People 2010* includes breast-feeding as a goal for maternal, infant, and child health.

As in all nursing care, nurses should provide culturally competent care during the postpartum period. The nurse should engage in ongoing cultural self-assessment and overcome any stereotypes that perpetuate prejudice or discrimination against any cultural group (Bowers, 2007). Providing culturally competent nursing care during the postpartum period requires time, open-mindedness, and patience. To promote positive outcomes, the nurse should be sensitive to the woman's and family's culture, religion, and ethnic influences (see "Providing Optimal Cultural Care" in the Nursing Interventions section).

Remember the couple introduced at the beginning of the chapter? When the postpartum nurse comes to examine Raina, her husband quickly leaves the room and returns a short time later after the examination is complete. How do you interpret his behavior toward his wife? What might you communicate to this couple?

This chapter describes the nursing management of the woman and her family during the postpartum period. It outlines physical assessment parameters for new mothers and newborns. It also focuses on bonding and attachment behaviors; nurses need to be aware of these behaviors so they can perform appropriate interventions. Steps to address physiologic needs such as comfort, self-care, nutrition, and contraception are described. Ways to help the woman and her family adapt to the birth of the newborn are also discussed (Fig. 16.1).

Nursing management during the postpartum period focuses on assessing the woman's ability to adapt to the physiologic and psychological changes occurring at this time (see Chap. 15 for a detailed discussion of these adaptations). Family members are also assessed to determine how well they are making the transition to this new stage. Based on assessment findings, the nurse plans and implements care to address the family's needs. Because of today's shortened lengths of stay, the nurse may be able to focus only on priority needs and may need to arrange for follow-up in the home to ensure that all the family's needs are met.

FIGURE 16.1 Parents and grandmother interacting with the newborn.

Assessment

Comprehensive nursing assessment begins within an hour after the woman gives birth and continues through discharge.

▶ ***Take NOTE!***

Nurses need a firm grasp of normal findings so that they can recognize abnormal findings and intervene appropriately.

This assessment includes vital signs and physical and psychosocial assessments. Although the exact protocol may vary among facilities, postpartum assessment typically is performed as follows:

- During the first hour: every 15 minutes
- During the second hour: every 30 minutes
- During the first 24 hours: every 4 hours
- After 24 hours: every 8 hours (Simpkin & James, 2006)

During each assessment, keep in mind risk factors that may lead to complications, such as infection or hemorrhage, during the recovery period (Box 16.1). Early identification is critical to ensure prompt intervention.

As with any assessment, always review the woman's medical record for information about her pregnancy, labor, and birth. Note any preexisting conditions, any complications that occurred during pregnancy, labor, birth, and immediately afterward, and any treatments provided.

Postpartum assessment of the mother typically includes vital signs, pain level, and a systematic head-to-toe review of body systems. The acronym BUBBLE-EE—breasts, uterus, bladder, bowels, lochia, episiotomy/perineum, extremities, and emotional status—can be used as a guide for this head-to-toe review (Blackburn, 2007).

BOX 16.1 Factors Increasing the Woman's Risk for Postpartum Complications

Risk Factors for Postpartum Infection

- Operative procedure (forceps, cesarean birth, vacuum extraction)
- History of diabetes, including gestational-onset diabetes
- Prolonged labor (more than 24 hours)
- Use of indwelling urinary catheter
- Anemia (hemoglobin less than 10.5 mg/dL)
- Multiple vaginal examinations during labor
- Prolonged rupture of membranes (more than 24 hours)
- Manual extraction of placenta
- Compromised immune system (HIV positive)

Risk Factors for Postpartum Hemorrhage

- Precipitous labor (less than 3 hours)
- Uterine atony
- Placenta previa or abruptio placentae
- Labor induction or augmentation
- Operative procedures (vacuum extraction, forceps, cesarean birth)
- Retained placental fragments
- Prolonged third stage of labor (more than 30 minutes)
- Multiparity, more than three births closely spaced
- Uterine overdistention (large infant, twins, hydramnios)

While assessing the woman and her family during the postpartum period, be alert for danger signs (Box 16.2). Notify the primary health care provider immediately if any are noted.

Postpartum assessment also includes assessing the parents and other family members, such as siblings and grandparents, for attachment and bonding with the newborn.

BOX 16.2 Postpartum Danger Signs

- Fever more than 38°C (100.4°F)
- Foul-smelling lochia or an unexpected change in color or amount
- Visual changes, such as blurred vision or spots, or headaches
- Calf pain with dorsiflexion of the foot
- Swelling, redness, or discharge at the episiotomy site
- Dysuria, burning, or incomplete emptying of the bladder
- Shortness of breath or difficulty breathing
- Depression or extreme mood swings

Vital Signs

Obtain vital signs and compare them with the previous values, noting and reporting any deviations. Vital sign changes can be an early indicator of complications.

Temperature

Use a consistent measurement technique (oral, axillary, or tympanic) to get the most accurate readings. Typically, the new mother's temperature during the first 24 hours postpartum is within the normal range. Some women experience a slight fever, up to 38°C (100.4°F), during the first 24 hours. This elevation may be the result of dehydration because of fluid loss during labor. Temperature should be normal after 24 hours with replacement of fluids lost during labor and birth (Arenson & Drake, 2007). A temperature above 38°C (100.4°F) at any time or an abnormal temperature after the first 24 hours may indicate infection and must be reported. Abnormal temperature readings warrant continued monitoring until an infection can be ruled out through cultures or blood studies.

Pulse

Because of the changes in blood volume and cardiac output after delivery, relative bradycardia may be noted. The woman's pulse rate may range from 50 to 70 bpm. Pulse usually stabilizes to prepregnancy levels within 10 days (Blackburn, 2007).

Tachycardia in the postpartum woman can suggest anxiety, excitement, fatigue, pain, excessive blood loss, infection, or underlying cardiac problems. Further investigation is warranted to rule out complications.

Respirations

Respiratory rates in the postpartum woman should be within the normal range of 16 to 20 breaths per minute. Any change in respiratory rate out of the normal range might indicate pulmonary edema, atelectasis, or pulmonary embolism and must be reported. Lungs should be clear on auscultation.

Blood Pressure

Assess the woman's blood pressure and compare it with her usual range. Report any deviation from this range. Elevations in blood pressure from baseline might suggest pregnancy-induced hypertension; decreases may suggest dehydration or excessive blood loss.

Blood pressure also may vary based on the woman's position, so assess blood pressure with the woman in the same position every time. Be alert for orthostatic hypotension, which can occur when the woman moves rapidly from a lying or sitting position to a standing one.

Pain

Pain, the fifth vital sign, is assessed along with the other four parameters. Question the woman about the type of pain and its location and severity. Have the woman rate the pain using a numeric scale from 0 to 10 points.

Many postpartum orders will have the nurse premedicate the woman routinely for afterbirth pains rather than wait for her to experience them first. The goal of pain management is to have the woman's pain scale rating maintained between 0 to 2 points at all times, especially after breast-feeding. This can be accomplished by assessing the woman's pain level frequently and preventing pain by administering analgesics. If the woman has severe pain in the perineal region despite use of physical comfort measures, check for a hematoma by inspecting and palpating the area. If one is found, notify the health care provider immediately.

Breasts

Inspect the breasts for size, contour, asymmetry, engorgement, or erythema. Check the nipples for cracks, redness, fissures, or bleeding, and note whether they are erect, flat, or inverted. Flat or inverted nipples can make breast-feeding challenging for both mother and infant. Cracked, blistered, fissured, bruised, or bleeding nipples in the breast-feeding woman are generally indications that the baby is improperly positioned on the breast. Palpate the breasts lightly to ascertain if they are soft, filling, or engorged, and document your findings. For women who are not breast-feeding, use a gentle, light touch to avoid breast stimulation, which would exacerbate engorgement. As milk is starting to come in, the breasts become firmer; this is charted as "filling." Engorged breasts are hard, tender, and taut. Ask the woman if she is having any nipple discomfort. Palpate the breasts for any nodules, masses, or areas of warmth, which may indicate a plugged duct that may progress to **mastitis** if not treated promptly. Any discharge from the nipple should be described and documented if it is not colostrum (creamy yellow) or foremilk (bluish white).

Uterus

Assess the fundus (top portion of the uterus) to determine the degree of uterine involution. If possible, have the woman empty her bladder before assessing the fundus. If the patient has had a cesarean birth and has a PCA pump, instruct her to self-medicate prior to fundal assessment to decrease her discomfort. Using a two-handed approach with the woman in the supine position and the bed in a flat position or as low as possible, palpate the abdomen gently, feeling for the top of the uterus while the other hand is placed on the lower segment of the uterus to stabilize it (Fig. 16.2).

The fundus should be midline and should feel firm. A boggy or relaxed uterus is a sign of uterine atony. This can be the result of bladder distention, which displaces the uterus upward and to the right, or retained placental fragments. Either situation predisposes the woman to hemorrhage.

FIGURE 16.2 Palpating the fundus.

Once the fundus is located, place your index finger on the fundus and count the number of fingerbreadths between the fundus and the umbilicus (1 fingerbreadth is approximately equal to 1 cm). One to 2 hours after birth, the fundus typically is between the umbilicus and the symphysis pubis. Approximately 6 to 12 hours after birth, the fundus usually is at the level of the umbilicus.

Normally, the fundus progresses downward at a rate of one fingerbreadth (or 1 cm) per day after childbirth (Cunningham et al., 2005). On the first postpartum day, the top of the fundus is located 1 cm below the umbilicus and is recorded as U-1. Similarly, on the second postpartum day, the fundus would be 2 cm below the umbilicus and should be recorded as U-2, and so on. If the fundus is not firm, gently massage the uterus using a circular motion until it becomes firm.

Bladder

Considerable diuresis—as much as 3,000 mL—may follow for several days after childbirth, decreasing by the third day (Blackburn, 2007). However, many postpartum women do not sense the need to void even if their bladder is full. Women who received regional anesthesia during labor are at risk for bladder distention and for difficulty voiding until sensation returns within several hours after birth.

Assess for voiding problems by asking the woman the following questions:

- Have you (passed your water, urinated, gone to the bathroom) yet?
- Have you noticed any burning or discomfort with urination?
- Do you have any difficulty passing your urine?
- Do you feel that your bladder is empty when you finish urinating?
- Do you have any signs of infection such as urgency, frequency, or pain?
- Are you able to control the flow of urine by squeezing your muscles?
- Have you noticed any leakage of urine when you cough, laugh, or sneeze?

Assess the bladder for distention and adequate emptying after efforts to void. Palpate the area over the symphysis pubis. If empty, the bladder is not palpable. Palpation of a rounded mass suggests bladder distention. Also percuss the area: a full bladder is dull to percussion. If the bladder is full, lochia drainage will be more than normal because the uterus cannot contract to suppress the bleeding.

▶ *Take* NOTE!

Note the location and condition of the fundus; a full bladder tends to displace the uterus up and to the right.

After the woman voids, palpate and percuss the area again to determine adequate emptying of the bladder. If the bladder remains distended, the woman may be retaining urine in her bladder, and measures to initiate voiding should be instituted. Be alert for signs of infection, including infrequent or insufficient voiding (less than 200 mL), discomfort, burning, urgency, or foul-smelling urine (Simpkin & James, 2006). Document urine output.

Bowels

Spontaneous bowel movements may not occur for 2 to 3 days after giving birth because of a decrease in muscle tone in the intestines during labor. Normal patterns of bowel elimination usually return within 8 to 14 days after birth (Blackburn, 2007).

Inspect the woman's abdomen for distention, auscultate for bowel sounds in all four quadrants, and palpate for tenderness. The abdomen typically is soft, nontender, and nondistended. Bowel sounds are present in all four quadrants. Ask the woman if she has had a bowel movement or has passed gas since giving birth, because constipation is a common problem during the postpartum period and most women do not offer this information unless asked about it. Normal assessment findings are active bowel sounds, passing gas, and a nondistended abdomen.

Lochia

Assess lochia in terms of amount, color, odor, and change with activity and time. To assess how much a woman is

bleeding, ask her how many perineal pads she has used in the past 1 to 2 hours and how much drainage was on each pad. For example, did she saturate the pad completely, or was only half of the pad covered with drainage? Ask about the color of the drainage, odor, and the presence of any clots. Lochia has a definite musky scent, with an odor similar to that of menstrual flow without any large clots. Foul-smelling lochia suggests an infection, and large clots suggest poor uterine involution, necessitating additional intervention.

To determine the amount of lochia, observe the amount of lochia saturation on the perineal pad and relate it to time (Fig. 16.3). Lochia flow will increase when the woman gets out of bed (lochia pools in the vagina and the uterus while she is lying down) and when she breastfeeds (oxytocin release causes uterine contractions). A woman who saturates a perineal pad within 30 to 60 minutes is bleeding much more than one who saturates a pad in 2 hours. Typically, the amount of lochia is described as follows:

- Scant: a 1- to 2-inch lochia stain on the perineal pad or approximately a 10-mL loss
- Light or small: an approximately 4-inch stain or a 10- to 25-mL loss
- Moderate: a 4- to 6-inch stain with an estimated loss of 25 to 50 mL
- Large or heavy: a pad is saturated within 1 hour after changing it (Nash, 2007)

The total volume of lochia is approximately 240 to 270 mL (8 to 9 oz), and the amount decreases daily (Blackburn, 2007). Check under the woman to make sure there isn't additional blood hidden and not absorbed on her perineal pad.

Report any abnormal findings, such as heavy, bright-red lochia with large tissue fragments or a foul odor. If excessive bleeding occurs, the first step would be to massage the boggy fundus until it is firm to reduce the flow of blood. Document all findings.

Women who had a cesarean birth will have less lochia discharge than those who had a vaginal birth, but stages and color changes remain the same. Although the woman's abdomen will be tender after surgery, the nurse must palpate the fundus and assess the lochia to make sure they are within the normal range and that there is no excessive bleeding.

Anticipatory guidance to give the woman at discharge should include information about lochia and the expected changes. Urge the woman to notify her health care provider if lochia rubra returns after the serosa and alba transitions have taken place. This is abnormal and may indicate subinvolution or that the woman is too active and needs to rest more. Lochia is an excellent medium for bacterial growth. Explain to the woman that frequent changing of perineal pads, continued use of her peribottle for rinsing her perineal area, and handwashing before and after pad changes are important infection control measures.

Episiotomy and Perineum

To assess the episiotomy and perineal area, position the woman on her side with her top leg flexed upward at the knee and drawn up toward her waist. If necessary, use a penlight to provide adequate lighting during the assessment. Wearing gloves and standing at the woman's side with her back to you, gently lift the upper buttock to expose the perineum and anus (Fig. 16.4). Inspect the episiotomy for irritation, ecchymosis, tenderness, or hematomas. Assess for hemorrhoids and their condition.

During the early postpartum period, the perineal tissue surrounding the episiotomy is typically edematous and slightly bruised. The normal episiotomy site should not have redness, discharge, or edema. The majority of healing takes place within the first 2 weeks, but it may take 4 to 6 months for the episiotomy to heal completely (Blackburn, 2007).

Figure 16.3 Assessing lochia.

Figure 16.4 Inspecting the perineum.

Lacerations to the perineal area sustained during the birthing process that were identified and repaired also need to be assessed to determine their healing status. Lacerations are classified based on their severity and tissue involvement:

- First-degree laceration—involves only skin and superficial structures above muscle
- Second-degree laceration—extends through perineal muscles
- Third-degree laceration—extends through the anal sphincter muscle
- Fourth-degree laceration—continues through anterior rectal wall

Assess the episiotomy and any lacerations at least every 8 hours to detect hematomas or signs of infection. Large areas of swollen, bluish skin with complaints of severe pain in the perineal area indicate pelvic or vulvar hematomas. Redness, swelling, increasing discomfort, or purulent drainage may indicate infection. Both findings need to be reported immediately.

A white line the length of the episiotomy is a sign of infection, as is swelling or discharge. Severe, intractable pain, perineal discoloration, and ecchymosis indicate a perineal hematoma, a potentially dangerous condition. Report any unusual findings. Ice can be applied to relieve discomfort and reduce edema; sitz baths also can promote comfort and perineal healing (see "Promoting Comfort" in the Nursing Interventions section).

Extremities

During pregnancy, the state of hypercoagulability protects the mother against excessive blood loss during childbirth and placental separation. However, this hypercoagulable state can increase the risk of thromboembolic disorders during pregnancy and postpartum. Three factors predispose women to thromboembolic disorders during pregnancy: stasis (compression of the large veins because of the gravid uterus), altered coagulation (state of pregnancy), and localized vascular damage (may occur during birthing process). All of these increase the risk of clot formation.

▶ *Take* NOTE!

Pulmonary embolism occurs in 1 in 2,000 pregnancies and is a major cause of maternal mortality (Moses, 2007).

Pulmonary emboli typically result from dislodged deep vein thrombi in the lower extremities. Risk factors associated with thromboembolic conditions include:

- Anemia
- Diabetes mellitus
- Cigarette smoking
- Obesity
- Preeclampsia secondary to exaggeration of hypercoagulable state
- Hypertension
- Varicose veins
- Pregnancy
- Oral contraceptive use
- Cesarean birth
- Previous thromboembolic disease
- Multiparity
- Inactivity
- Advanced maternal age (Hackley, Kriebs, & Rousseau, 2007)

Because of the subtle presentation of thromboembolic disorders, the physical examination may not be enough to detect them. The woman may report lower extremity tightness or aching when ambulating that is relieved with rest and elevation of the leg. Edema in the affected leg (typically the left), along with warmth and tenderness, may also be noted. A duplex ultrasound (two-dimensional ultrasound and Doppler ultrasound that compresses the vein to assess for changes in venous flow) in conjunction with the physical findings frequently is needed for a conclusive diagnosis (Kuntz, Cheesman, & Powers, 2006).

Women with an increased risk for this condition during the postpartum period should wear antiembolism stockings or use sequential compression devices to reduce their risk of thrombophlebitis. Encouraging the client to ambulate after childbirth reduces the incidence of thrombophlebitis.

Emotional Status

Assess the woman's emotional status by observing how she interacts with her family, her level of independence, energy levels, eye contact with her infant (within a cultural context), posture and comfort level while holding the newborn, and sleep and rest patterns. Be alert for mood swings, irritability, or crying episodes.

Remember Raina and her "quiet" husband, the Muslim couple? The postpartum nurse informs Raina that her doctor, Nancy Schultz, has been called away for emergency surgery and won't be available the rest of the day. The nurse explains that Dr. Robert Nappo will be making rounds for her. Raina and her husband become upset. Why? Is culturally competent care being provided to this couple?

Bonding and Attachment

Nurses can be instrumental in promoting attachment by assessing attachment behaviors (positive and negative) and intervening appropriately if needed. Nurses must be able to

identify any family discord that might interfere with the attachment process. Remember, however, that mothers from different cultures may behave differently from what is expected in your own culture. For example, Native American mothers tend to handle their newborns less often and use cradle boards to carry them. Native American mothers and many Asian-American mothers delay breast-feeding until their milk comes in, because colostrum is considered harmful for the newborn (Bowers, 2007). Don't assume that different behavior is wrong.

Meeting the newborn for the first time after birth can be an exhilarating experience for parents. Although the mother has spent many hours dreaming of her unborn and how he or she will look, it is not until after birth that they meet face to face. They both need to get to know one another and to develop feelings for one another.

Bonding is the close emotional attraction to a newborn by the parents that develops during the first 30 to 60 minutes after birth. It is unidirectional, from parent to infant. It is thought that optimal bonding of the parents to a newborn requires a period of close contact within the first few minutes to a few hours after birth (Mercer, 2006). The mother initiates bonding when she caresses her infant and exhibits certain behaviors typical of a mother tending her child. The infant's responses to this, such as body and eye movements, are a necessary part of the process. During this initial period, the infant is in a quiet, alert state, looking directly at the holder.

▶ ***Take*** NOTE!

The length of time necessary for bonding depends on the health of the infant and mother, as well as the circumstances surrounding the labor and birth (Fowles & Horowitz, 2006).

Attachment is the development of strong affection between an infant and a significant other (mother, father, sibling, and caretaker) (Grossman, Grossman, & Waters, 2006). This tie between two people is psychological rather than biological, and it does not occur overnight. The process of attachment follows a progressive or developmental course that changes over time. Attachment is an individualized and multifactorial process that differs based on the health of the infant, the mother, environmental circumstances, and the quality of care the infant receives (Wilson et al., 2007). It occurs through mutually satisfying experiences. Maternal attachment begins during pregnancy as the result of fetal movement and maternal fantasies about the infant and continues through the birth and postpartum periods. Attachment behaviors include seeking, staying close to, and exchanging gratifying experiences with the infant (Grossman, Grossman, & Waters, 2006). In a high-risk pregnancy, the attachment process may be complicated by premature birth (lack of time to develop a relationship with the unborn baby) and by parental stress due to the fetal and/or maternal vulnerability.

Bonding is a vital component of the attachment process and is necessary in establishing parent–infant attachment and a healthy, loving relationship. During this early period of acquaintance, mothers touch their infants in a very characteristic manner. Mothers visually and physically "explore" their infants, initially using their fingertips on the infant's face and extremities and progressing to massaging and stroking the infant with their fingers. This is followed by palm contact on the trunk. Eventually, mothers draw their infant toward them and hold the infant. Mothers also interact with their infants through eye-to-eye contact in the ***en face*** **position** (Mercer, 2006) (Fig. 16.5).

Generally, research on attachment has found that the process is similar for fathers as for mothers, but the pace may be different. Like mothers, fathers manifest attachment behaviors during pregnancy; indeed, Grossman et al. (2006) found that the best predictor of early postnatal attachment for fathers is fetal attachment. Becoming a father requires a man to build on the experiences he has had throughout childhood and adolescence. Fathers develop an emotional tie with their infants in a variety of ways. They seek and maintain closeness with the infant and can recognize characteristics of the infant. They feel a sense of responsibility for the infant's growth and development (Wilson et al., 2007).

Attachment is a process; it does not occur instantaneously, even though many parents believe in a romanticized version of attachment, which happens right after birth. A delay in the attachment process can occur if a mother's physical and emotional states are adversely affected by exhaustion, pain, the absence of a support system, anesthesia, or an unwanted outcome (Feldman, 2007).

FIGURE 16.5 *En face* position.

▶ *Take* NOTE!

Many midwives teach fathers to massage their partners, which has been proven to have a positive effect on the pregnancy, labor, bonding and attachment, and perhaps on family dynamics (Whitehouse, 2006).

The developmental task for the infant is learning to differentiate between trust and mistrust. If the mother or caretaker is consistently responsive to the infant's care, meeting the baby's physical and psychological needs, the infant will likely learn to trust the caretaker, view the world as a safe place, and grow up to be secure, self-reliant, trusting, cooperative, and helpful. However, if the infant's needs are not met, the child is more likely to face developmental delays, neglect, and child abuse (Logsdon, Wisner, & Pinto-Foltz, 2006).

"Becoming" a parent may take 4 to 6 months. The transition to parenthood, according to Mercer (2006), involves four stages:

1. Commitment, attachment, and preparation for an infant during pregnancy
2. Acquaintance with and increasing attachment to the infant, learning how to care for the infant, and physical restoration during the first weeks after birth
3. Moving toward a new normal routine in the first 4 months after birth
4. Achievement of a parenthood role around 4 months

The stages overlap, and the timing of each is affected by variables such as the environment, family dynamics, and the partners (Mercer, 2006).

Factors Affecting Attachment

Attachment behaviors are influenced by three major factors:

1. Parents' background (includes the care that the parents received when growing up, cultural practices, relationship within the family, experience with previous pregnancies and planning and course of events during pregnancy, postpartum depression)
2. Infant (includes the infant's temperament and health at birth)
3. Care practices (the behaviors of physicians, midwives, nurses, and hospital personnel, care and support during labor, first day of life in separation of mother and infant, and rules of the hospital or birthing center) (Grossman, Grossman, & Waters 2006)

Attachment occurs more readily with the infant whose temperament, health, appearance, and gender fit the parent's expectations. If the infant does not meet these expectations, attachment can be delayed (Wilson et al., 2007).

Factors associated with the health care facility or birthing unit can also hinder attachment. These include:

- Separation of infant and parents immediately after birth and for long periods during the day
- Policies that discourage unwrapping and exploring the infant
- Intensive care environment, restrictive visiting policies
- Staff indifference or lack of support for parent's caretaking attempts and abilities

Critical Attributes of Attachment

The terms "bonding" and "attachment" are often used interchangeably, even though they involve different time frames and interactions. Attachment stages include proximity, reciprocity, and commitment.

Proximity refers to the physical and psychological experience of the parents being close to their infant. This attribute has three dimensions:

1. Contact—The sensory experiences of touching, holding, and gazing at the infant are part of proximity-seeking behavior.
2. Emotional state—The emotional state emerges from the affective experience of the new parents toward their infant and their parental role.
3. Individualization—Parents are aware of the need to differentiate the infant's needs from themselves and to recognize and respond to them appropriately, making the attachment process also, in some way, one of detachment.

Reciprocity is the process by which the infant's abilities and behaviors elicit parental response. Reciprocity is described by two dimensions: complementary behavior and sensitivity. Complementary behavior involves taking turns and stopping when the other is not interested or becomes tired. An infant can coo and stare at the parent to elicit a similar parental response to complement his or her behavior. Parents who are sensitive and responsive to their infant's cues will promote their development and growth. Parents who become skilled at recognizing the ways their infant communicates will respond appropriately by smiling, vocalizing, touching, and kissing.

Commitment refers to the enduring nature of the relationship. The components of this are twofold: centrality and parent role exploration. In centrality, parents place the infant at the center of their lives. They acknowledge and accept their responsibility to promote the infant's safety, growth, and development. Parent role exploration is the parents' ability to find their own way and integrate the parental identity into themselves (Grossman, Grossman, & Waters, 2006).

TABLE 16.1 Positive and Negative Attachment Behaviors

	Positive Behaviors	Negative Behaviors
Infant	Smiles; is alert; demonstrates strong grasp reflex to hold parent's finger; sucks well, feeds easily; enjoys being held close; makes eye-to-eye contact; follows parent's face; appears facially appealing; is consolable when crying	Feeds poorly, regurgitates often; cries for long periods, colicky and inconsolable; shows flat affect, rarely smiles even when prompted; resists holding and closeness; sleeps with eyes closed most of time; stiffens body when held; is unresponsive to parents; doesn't pay attention to parents' faces
Parent	Makes direct eye contact; assumes *en face* position when holding infant; claims infant as family member, pointing out common features; expresses pride in infant; assigns meaning to infant's actions; smiles and gazes at infant; touches infant, progressing from fingertips to holding; names infant; requests to be close to infant as much as allowed; speaks positively about infant	Expresses disappointment or displeasure in infant; fails to "explore" infant visually or physically; fails to claim infant as part of family; avoids caring for infant; finds excuses not to hold infant close; has negative self-concept; appears uninterested in having infant in room; frequently asks to have infant taken back to nursery to be cared for; assigns negative attributes to infant and calls infant inappropriate, negative names (e.g., frog, monkey, tadpole)

Sources: Grossman, Grossman, & Waters, 2007; Nash, 2007; Oppenheim & Goldsmith, 2007.

Positive and Negative Attachment Behaviors

Positive bonding behaviors include maintaining close physical contact, making eye-to-eye contact, speaking in soft, high-pitched tones, and touching and exploring the infant. Table 16.1 highlights typical positive and negative behaviors of attachment.

Nursing Interventions

In terms of postpartum hospital stays today, "less is more." If the woman had a vaginal delivery, she may be discharged within 48 hours. If she had a cesarean birth, she may remain hospitalized from 72 to 96 hours. This shortened stay leaves little time for nurses to prepare the woman and her family for the many changes that will occur when she returns home. Nurses need to use this limited time to address the following topics: pain and discomfort, immunizations, nutrition, activity and exercise, lactation, discharge teaching, sexuality and contraception, and follow-up (see Nursing Care Plan 16.1).

▶ ***Take*** *NOTE!*

Always adhere to standard precautions when providing direct care to reduce the risk of disease transmission.

Providing Optimal Cultural Care

As the face of America is becoming more diverse, nurses must be prepared to care for childbearing families from various cultures. In many cultures, women and their families are cared for and nurtured by their community for weeks and even months after the birth of a new family member. Box 16.3 highlights some of the major cultural variants during the postpartum period.

Nurses need to remember that childbearing practices and beliefs vary in different cultures. To provide appropriate nursing care, the nurse should determine the patient's preferences before intervening. Cultural practices may include dietary restrictions, certain clothes, taboos, activities for maintaining mental health, and the use of silence, prayer, or meditation. Restoring health may involve taking folk medicines or conferring with a tribal healer (Srivastava, 2007).

Raina and her husband are upset at the thought of having a male doctor care for her because Muslim women are very modest and prefer having a same-sex care provider. What should the nurse do in this situation?

Promoting Comfort

The postpartum woman may have discomfort and pain from a variety of sources, such as an episiotomy, perineal lacerations, an edematous perineum, inflamed hemorrhoids, engorged breasts, afterbirth pains secondary to uterine contractions in breast-feeding and multiparous mothers, and sore nipples if breast-feeding. Nonpharmacologic and pharmacologic measures can be used to decrease pain and discomfort.

Applications of Cold and Heat

Commonly, an ice pack is the first measure used after a vaginal birth to relieve perineal discomfort from edema, an

Nursing Care Plan 16.1

OVERVIEW OF THE POSTPARTUM WOMAN

Belinda, a 26-year-old G2P2, is a patient on the mother–baby unit after giving birth to a term 8-lb, 12-oz baby boy yesterday. The night nurse reports that she has an episiotomy, complains of a pain rating of 7 points on a scale of 1 to 10, is having difficulty breast-feeding, and had heavy lochia most of the night. The nurse also reports that the patient seems focused on her own needs and not on her infant. Assessment this morning reveals the following:

B: Breasts are soft with colostrum leaking; nipples cracked
U: Uterus is one fingerbreadth below the umbilicus; deviated to right
B: Bladder is palpable; patient states she hasn't been up to void yet
B: Bowels have not moved; bowel sounds present; passing flatus
L: Lochia is moderate; peripad soaked from night accumulation
E: Episiotomy site intact; swollen, bruised; hemorrhoids present
—
E: Extremities; no edema over tibia, no warmth or tenderness in calf
E: Emotional status is "distressed" as a result of discomfort and fatigue

NURSING DIAGNOSIS: Impaired tissue integrity related to episiotomy

Outcome Identification and Evaluation

The woman remains free of infection, without any signs and symptoms of infection, and exhibits evidence of progressive healing as demonstrated by clean, dry, intact episiotomy site.

Interventions: Promoting Tissue Integrity

- Monitor episiotomy site for redness, edema, and signs of infection.
- Assess vital signs at least every 4 hours *to identify changes suggesting infection.*
- Apply ice pack to episiotomy site *to reduce swelling.*
- Instruct patient on use of sitz bath *to promote healing, hygiene, and comfort.*
- Encourage frequent perineal care and peripad changes *to prevent infection.*
- Recommend ambulation *to improve circulation and promote healing.*
- Instruct patient on positioning *to relieve pressure on perineal area.*
- Demonstrate use of anesthetic sprays *to numb perineal area.*

NURSING DIAGNOSIS: Pain related to episiotomy, sore nipples, and hemorrhoids

Outcome Identification and Evaluation

The woman experiences a decrease in pain, reporting that her pain has diminished to a tolerable level, rating it as 2 points or less.

Interventions: Providing Pain Relief

- Thoroughly inspect perineum *to rule out hematoma as cause of pain.*
- Administer analgesic medication as ordered as needed *to promote comfort.*
- Carry out comfort measures to episiotomy as outlined earlier *to reduce pain.*
- Explain discomforts and reassure the client that they are time-limited to assist in coping with pain.
- Apply Tucks pads to swollen hemorrhoids *to induce shrinkage and reduce pain.*
- Suggest frequent use of sitz bath *to reduce hemorrhoid pain.*
- Administer stool softener and laxative *to prevent straining with first bowel movement.*
- Observe positioning and latching-on technique while breast-feeding. Offer suggestions based on observations to correct positioning/latching on *to minimize trauma to the breast.*
- Suggest air-drying of nipples after breast-feeding and use of plain water *to prevent nipple cracking.*
- Teach relaxation techniques when breast-feeding *to reduce anxiety and discomfort.*

(continued)

Nursing Care Plan 16.1 (continued)

NURSING DIAGNOSIS: Risk for ineffective coping related to mood alteration and pain

Outcome Identification and Evaluation

The woman copes with mood alterations, as evidenced by positive statements about newborn and participation in newborn care.

Interventions: Promoting Effective Coping

- Provide a supportive, nurturing environment and encourage the mother to vent her feelings and frustrations to relieve anxiety.
- Provide opportunities for the mother to rest and sleep *to combat fatigue.*
- Encourage the mother to eat a well-balanced diet *to increase her energy level.*
- Provide reassurance and explanations that mood alterations are common after birth secondary to waning hormones after pregnancy *to increase the mother's knowledge.*
- Allow the mother relief from newborn care *to afford opportunity for self-care.*
- Discuss with partner expected behavior from mother and how additional support and help are needed during this stressful time *to promote partner's participation in care.*
- Make appropriate community referrals for mother–infant support *to ensure continuity of care.*
- Encourage frequent skin-to-skin contact and closeness between mother and infant *to facilitate bonding and attachment behaviors.*
- Encourage client to participate in infant care and provide instructions as needed *to foster a sense of independence and self-esteem.*
- Offer praise and reinforcement of positive mother–infant interactions *to enhance self-confidence in care.*

episiotomy, or laceration. It is applied during the fourth stage of labor and can be used for the first 24 hours to reduce perineal edema and to prevent hematoma formation, thus reducing pain and promoting healing. Ice packs are wrapped in a disposable covering or clean washcloth and are applied to the perineal area. Usually the ice pack is applied for 20 minutes and removed for 10 minutes. Many commercially prepared ice packs are available, but a latex glove filled with crushed ice and covered can also be used if the mother is not allergic to latex. Ensure that the ice pack is changed frequently to promote good hygiene and to allow for periodic assessments.

The **peribottle** is a plastic squeeze bottle filled with warm tap water that is sprayed over the perineal area after each voiding and before applying a new perineal pad. Usually the peribottle is introduced to the woman when she is assisted to the bathroom to freshen up and void for the first time—in most instances, once vital signs are stable after the first hour. Provide the woman with instructions on how and when to use the peribottle. Reinforce this practice each time she changes her pad, voids, or defecates, making sure that she understands to direct the flow of water from front to back. The woman can take the peribottle home and use it over the next several weeks until her lochia discharge stops. The peribottle can be used by women who had either vaginal or cesarean births to provide comfort and hygiene to the perineal area.

After the first 24 hours, a **sitz bath** with warm water may be prescribed and substituted for the ice pack to reduce local swelling and promote comfort for an episiotomy, perineal trauma, or inflamed hemorrhoids. The change from cold to warm therapy enhances vascular circulation and healing (Steen, Briggs, & King, 2006). Before using a sitz bath, the woman should cleanse the perineum with a peribottle or take a shower using mild soap.

Most health care agencies use plastic disposable sitz baths that women can take home. The plastic sitz bath consists of a basin that fits on the commode; a bag filled with warm water is hung on a hook and connected via a tube onto the front of the basin (Fig. 16.6). Teaching Guidelines 16.1 highlights the steps in using a sitz bath.

Advise the woman to use the sitz bath several times daily to provide hygiene and comfort to the perineal area. Encourage her to continue this measure after discharge.

Some facilities have hygienic sitz baths called Suri-Gators in the bathroom that spray an antiseptic, water, or both onto the perineum. The woman sits on the toilet with legs apart so that the nozzle spray reaches her perineal area.

Keep in mind that tremendous hemodynamic changes are taking place within the mother during this early postpartum period, and her safety must be a priority. Fatigue, blood loss, the effects of medications, and lack of food may cause her to feel weak when she stands up. Assisting the woman to the bathroom to instruct her on how to use the peribottle and sitz bath is necessary to ensure her safety. Many women become lightheaded or dizzy when they get out of bed and need direct physical assistance. Staying in the woman's room, ensuring that the emer-

BOX 16.3 Cultural Influences During the Postpartum Period

African-American
- Mother may share care of the infant with extended family members.
- Experiences of older women within the family influence infant care.
- Mothers may protect their newborns from strangers for several weeks.
- Mothers may not bathe their newborns for the first week. Oils are applied to skin and hair to prevent dryness and cradle cap.
- Silver dollars may be taped over the infant's umbilicus in an attempt to flatten the slightly protruding umbilical stump.
- Sleeping with parents is a common practice (Bowers, 2007).

Amish
- Women consider childbearing their primary role in society.
- They generally oppose birth control.
- Pregnancy and childbirth are considered a private matter; they may conceal it from public knowledge.
- Women typically do not respond favorably when hurried to complete a self-care task. Nurses need to take cues from women indicating their readiness to complete morning self-care activities (Bowers, 2007).

Appalachian
- Infant colic is treated by passing the newborn through a leather horse's collar or administering weak catnip tea.
- An asafetida bag (a gum resin with a strong odor) is tied around the infant's neck to ward off disease.
- Women may avoid eye contact with nurses and health care providers.
- Women typically avoid asking questions even though they do not understand directions.
- The grandmother may rear the infant for the mother (Armstrong & Feldman, 2007).

Filipino-American
- Grandparents often assist in the care of their grandchildren.
- Breast-feeding is encouraged, and some mothers breast-feed their children for up to 2 years.
- Women have difficulty discussing birth control and sexual matters.
- Strong religious beliefs prevail and bedside prayer is common.
- Families are very close-knit and numerous visitors can be expected to the hospital after childbirth (Srivastava, 2007).

Japanese-American
- Cleanliness and protection from cold are essential components of newborn care. Nurses should give the daily bath to the infant.
- Newborns routinely are not taken outside the home because it is believed that they should not be exposed to outside or cold air. Infants should be kept in a quiet, clean, warm place for the first month of life.
- Breast-feeding is the primary method of feeding.
- Many women stay in their parents' home for 1 to 2 months after birth.
- Bathing the infant can be the center of family activity at home (Bowers, 2007).

Mexican-American
- The newborn's grandmother lives with the mother for several weeks after birth to help with housekeeping and child care.
- Most women will breast-feed more than 1 year. The infant is carried in a *rebozo* (shawl) that allows easy access for breast-feeding.
- Women may avoid eye contact and may not feel comfortable being touched by a stranger. Nurses need to respect this feeling.
- Some women may bring religious icons to the hospital and may want to display them in their room (Srivastava, 2007).

Muslim
- Modesty is a primary concern; nurses need to protect the client's modesty.
- Muslims are not permitted to eat pork; check all food items before serving.
- Muslims prefer a same-sex health care provider; male–female touching is prohibited except in an emergency situation.
- A Muslim woman stays in the house for 40 days after birth, being cared for by the female members of her family.
- Most women will breast-feed, but religious events call for periods of fasting, which may increase the risk of dehydration or malnutrition.
- Women are exempt from obligatory five-times-daily prayers as long as lochia is present.
- Extended family is likely to be present throughout much of the woman's hospital stay. They will need an empty room to perform their prayers without having to leave the hospital (Cassar, 2006).

Native American
- Women are secretive about pregnancies and do not reveal them early.
- Touching is not a typical female behavior and eye contact is brief.
- They resent being hurried and need time for sitting and talking.
- Most mothers breast-feed and practice birth control (Srivastava, 2007).

FIGURE 16.6 Sitz bath set-up.

TEACHING GUIDELINES 16.1

Using a Sitz Bath

1. Close clamp on tubing before filling bag with water to prevent leakage.
2. Fill sitz bath basin and plastic bag with warm water (comfortable to touch).
3. Place the filled basin on the toilet with the seat raised and the overflow opening facing toward the back of the toilet.
4. Hang the filled plastic bag on a hook close to the toilet or an IV pole.
5. Attach the tubing to the opening on the basin.
6. Sit on the basin positioned on the toilet seat and release the clamp to allow warm water to irrigate the perineum.
7. Remain sitting on the basin for approximately 15 to 20 minutes.
8. Stand up and pat the perineum area dry. Apply a clean peripad.
9. Tip the basin to remove any remaining water and flush the toilet.
10. Wash the basin with warm water and soap and dry it in the sink.
11. Store basin and tubing in a clean, dry area until the next use.
12. Wash hands with soap and water.

gency call light is readily available, and being available if needed during this early period will ensure safety and prevent accidents and falls.

Topical Preparations

Several treatments may be applied topically for temporary relief of pain and discomfort. One such treatment is a local anesthetic spray such as Dermoplast or Americaine. These agents numb the perineal area and are used after cleansing the area with water via the peribottle and/or a sitz bath.

For hemorrhoid discomfort, cool witch hazel pads, such as Tucks Pads, can be used. The pads are placed at the rectal area, between the hemorrhoids and the perineal pad. These pads cool the area, help relieve swelling, and minimize itching.

Analgesics

Analgesics such as acetaminophen (Tylenol) and oral nonsteroidal anti-inflammatory drugs (NSAIDs) such as ibuprofen (Motrin) are prescribed to relieve mild postpartum discomfort. For moderate to severe pain, a narcotic analgesic such as codeine or oxycodone in conjunction with aspirin or acetaminophen may be prescribed. Instruct the woman about adverse effects of any medication prescribed. Common adverse effects of oral analgesics include dizziness, lightheadedness, nausea and vomiting, constipation, and sedation (Skidmore-Roth, 2007).

Also inform the woman that the drugs are secreted in breast milk. Nearly all medications that the mother takes are passed into her breast milk; however, the mild analgesics (e.g., acetaminophen or ibuprofen) are considered relatively safe for breast-feeding mothers (Tomasulo, 2007). Administering a mild analgesic approximately an hour before breast-feeding will usually relieve afterpains and/or perineal discomfort.

Assisting With Elimination

The bladder is edematous, hypotonic, and congested immediately postpartum. Consequently, bladder distention, incomplete emptying, and inability to void are common. A full bladder interferes with uterine contraction and may lead to hemorrhage, because it will displace the uterus out of the midline. Encourage the woman to void. Often, assisting her to assume the normal voiding position on the commode facilitates this. If the woman has difficulty voiding, pouring warm water over the perineal area, hearing the sound of running tap water, blowing bubbles through a straw, taking a warm shower, drinking fluids, or placing her hand in a basin of warm water may stimulate voiding. If these actions do not stimulate urination within 4 to 6 hours after giving birth, catheterization may be needed. Palpate the bladder for distention and ask the woman if she is voiding in small amounts (less than 100 mL) frequently (retention with overflow). If catheterization is necessary, use sterile technique to reduce the risk of infection.

EVIDENCE-BASED PRACTICE 16.1
Topically Applied Anesthetics for Treating Perineal Pain After Childbirth

● Study
The perineum (the area between the vagina and rectum) may be traumatized during childbirth following a tear or a surgical cut (episiotomy). Perineal trauma after childbirth affects millions of women around the world each year. The degree of perineal pain and discomfort associated with perineal trauma is often underestimated. Pain often interferes with basic daily activities such as walking, sitting, and passing urine and also detracts from the experience of motherhood. Local anesthetics are easy to use and inexpensive, but their effectiveness needs to be assessed. A study was performed to assess the effects of topically applied anesthetics to relieve perineal pain after childbirth while the mother was still in the hospital and after discharge. This review of trials found eight studies using a variety of anesthetics.

▲ Findings
Data were insufficient to show that the topical anesthetics helped relieve perineal pain, and long-term effects were not assessed. More research is required to assess the effectiveness of topical anesthetics on pain, longer-term outcomes, women's relationships, and quality of life, as well as the effectiveness of different topical anesthetics.

■ Nursing Implications
Although this study could not validate topical anesthetics' effectiveness in relieving perineal pain, they do provide relief to many postpartum women. The nurse should assess each woman individually and offer other comfort alternatives such as warm sitz baths, ice packs, and ambulation. Further research will be needed to offer proof that topical anesthetics are an effective pain relief measure.

Hedayati, H., Parsons, J., & Crowther, C. A. (2006). Topically applied anesthetics for treating perineal pain after childbirth. *Cochrane Database of Systematic Reviews* 2006, Issue 2. Art. No.: CD004223. DOI: 10.1002/14651858.CD004223.pub2.

Decreased bowel motility during labor, high iron content in prenatal vitamins, postpartum fluid loss, and the adverse effects of pain medications and/or anesthesia may predispose the postpartum woman to constipation. In addition, the woman may fear that bowel movements will cause pain or injury, especially if she had an episiotomy or a laceration that was repaired with sutures.

Usually a stool softener, such as docusate (Colace), with or without a laxative might be helpful if the client has difficulty with bowel elimination. Other measures, such as ambulating and increasing fluid and fiber intake, may also help. Nutritional instruction might include increasing fruits and vegetables in the diet; drinking plenty of fluids (8 to 12 cups) to keep the stool soft; drinking small amounts of prune juice and/or hot liquids to stimulate peristalsis; eating high-fiber foods such as bran cereals, whole grains, dried fruits, fresh fruits, and raw vegetables; and walking daily.

Promoting Activity, Rest, and Exercise

The postpartum period is an ideal time for nurses to promote the importance of physical fitness, help women incorporate exercise into their lifestyle, and encourage them to overcome barriers to exercise. The lifestyle changes that occur postpartum may affect a woman's health for decades. Early ambulation is encouraged to reduce the risk of thromboembolism and to improve strengthening.

Many changes occur postpartum, and caring for a newborn alters the woman's eating and sleeping habits, work schedules, and time allocation. Postpartum fatigue is common during the early days after childbirth, and it may continue for weeks or months (Runquist, 2007). It affects the mother's relationships with significant others and her ability to fulfill household and child care responsibilities. Be sure that the mother recognizes her need for rest and sleep and is realistic about her expectations. Some suggestions include the following:

- Nap when the infant is sleeping, because getting uninterrupted sleep at night is difficult.
- Reduce participation in outside activities and limit the number of visitors.
- Determine the infant's sleep–wake cycles and attempt to increase wakeful periods during the day so the baby sleeps for longer periods at night.
- Eat a balanced diet to promote healing and to increase energy levels.
- Share household tasks to conserve your energy.
- Ask the father or other family members to provide infant care during the night periodically so that you can get an uninterrupted night of sleep.
- Review your family's daily routine and see if you can "cluster" activities to conserve energy and promote rest.

The demands of parenthood may reduce or prevent exercise in even the most committed person. A targeted exercise program and proper body mechanics can help new mothers deal with the physical challenges of motherhood. Emphasize the benefits of a regular exercise program, which include:

- Helps the woman to lose pregnancy weight
- Increases energy level so the woman can cope with her new responsibilities

- Speeds the return to prepregnant size and shape
- Provides an outlet for stress (Druxman & Petersen, 2006)

More than one third of American women are overweight (CDC, Office of Women's Health, 2007). Although the average gestational weight gain is small (approximately 25 to 35 lb), excess weight gain and failure to lose weight after pregnancy are important predictors of long-term obesity. Breast-feeding and exercise may help to control weight in the long term (AAP, 2005).

▶ *Take* NOTE!

Women who have not returned to their prepregnant weight by 6 months are likely to retain the extra weight (Hackley, Kriebs, & Rousseau, 2007). Encourage women to lose their pregnancy weight by 6 months postpartum, and refer those who don't to community weight-loss programs.

The postpartum woman may face some obstacles to exercising, including physical changes (ligament laxity), competing demands (newborn care), lack of information about weight retention (inactivity equates to weight gain), and stress incontinence (leaking of urine during activity).

A healthy woman with an uncomplicated vaginal birth can resume exercise in the immediate postpartum period. Advise the woman to start slowly and increase the level of exercise over a period of several weeks as tolerated. Jogging strollers may be an option for some women, allowing them to exercise with their newborns. Also, exercise videos and home exercise equipment allow mothers to work out while the newborn naps.

Exercising after giving birth promotes feelings of well-being and restores muscle tone lost during pregnancy. Routine exercise should be resumed gradually, beginning with Kegel exercises on the first postpartum day and, by the second week, progressing to abdominal, buttock, and thigh-toning exercises (Druxman & Petersen, 2006). Walking is an excellent form of early exercise as long as the woman avoids jarring and bouncing movements, because joints do not stabilize until 6 to 8 weeks postpartum. Exercising too much too soon can cause the woman to bleed more and her lochia may return to bright red.

Recommended exercises for the first few weeks postpartum include abdominal breathing, head lifts, modified sit-ups, double knee roll, and pelvic tilt (Teaching Guidelines 16.2). The number of exercises and their duration is gradually increased as the woman gains strength.

Remember that cultures have different attitudes toward exercise. Some cultures (e.g., Haitian, Arab-

TEACHING GUIDELINES 16.2

Exercising

Abdominal Breathing

1. While lying on a flat surface (floor or bed), take a deep breath through your nose and expand your abdominal muscles (they will rise up from your midsection).
2. Slowly exhale and tighten your abdominal muscles for 3 to 5 seconds.
3. Repeat this several times.

Head Lift

1. Lie on a flat surface with knees flexed and feet flat on the surface.
2. Lift your head off the flat surface, tuck it onto your chest, and hold for 3 to 5 seconds.
3. Relax your head and return to the starting position.
4. Repeat this several times.

Modified Sit-Ups

1. Lie on a flat surface and raise your head and shoulders 6 to 8 inches so that your outstretched hands reach your knees.
2. Keep your waist on the flat surface.
3. Slowly return to the starting position.
4. Repeat, increasing in frequency as your comfort level allows.

Double Knee Roll

1. Lie on a flat surface with your knees bent.
2. While keeping your shoulders flat, slowly roll your knees to your right side to touch the flat surface (floor or bed).
3. Roll your knees back over your body to the left side until they touch the opposite side of the flat surface.
4. Return to the starting position on your back and rest.
5. Repeat this exercise several times.

Pelvic Tilt

1. Lie on your back on a flat surface with your knees bent and your arms at your side.
2. Slowly contract your abdominal muscles while lifting your pelvis up toward the ceiling.
3. Hold for 3 to 5 seconds and slowly return to your starting position.
4. Repeat several times..

American, and Mexican) expect new mothers to observe a specific period of bed rest or activity restriction; thus, it would be inappropriate to recommend active exercise during the early postpartum period (Bowers, 2007).

Preventing Stress Incontinence

Fifty percent of all parous women develop some degree of pelvic prolapse in their lifetime that is associated with stress incontinence (Thomason & DeLancey, 2007). The more vaginal deliveries a woman has had, the more likely she is to have stress incontinence. Stress incontinence can occur with any activity that causes an increase in intra-abdominal pressure. Postpartum women might consider low-impact activities such as walking, biking, swimming, or low-impact aerobics so they can resume physical activity while strengthening the pelvic floor.

Suggestions to prevent stress incontinence are:

- Start a regular program of Kegel exercises after childbirth.
- Lose weight if necessary; obesity is associated with stress incontinence.
- Avoid smoking; limit intake of alcohol and caffeinated beverages, which irritate the bladder.

Kegel exercises help to strengthen the pelvic floor muscles if done properly and regularly (Lemarck, 2007). Kegel exercises were originally developed by Dr. Arnold Kegel as a method of controlling incontinence in women after childbirth. The principle behind these exercises is that strengthening the muscles of the pelvic floor improves urethral sphincter function.

While providing postpartum care, instruct women on primary prevention of stress incontinence by discussing the value and purpose of Kegel exercises. Approach the subject sensitively, avoiding the term "incontinent." The terms "leakage," "loss of urine," or "bladder control issues" are more acceptable to most women.

▶ ***Take*** *NOTE!*

When properly performed, Kegel exercises have been effective in preventing or improving urinary continence (Lemack, 2007).

Women can perform Kegel exercises, doing ten 5-second contractions, whenever they change diapers, talk on the phone, or watch TV. Teach the woman to perform Kegel exercises properly; help her to identify the correct muscles by trying to stop and start the flow of urine when sitting on the toilet (Teaching Guidelines 16.3). Kegel exercises can be done without anyone knowing.

Assisting With Self-Care Measures

Demonstrate and discuss with the woman ways to prevent infection during the postpartum period. Because she may experience lochia drainage for as long as a month after childbirth, describe practices to promote well-being and healing. These measures include:

- Frequently change perineal pads, applying and removing them from front to back to prevent spreading contamination from the rectal area to the genital area.
- Avoid using tampons after giving birth to decrease the risk of infection.
- Shower once or twice daily using a mild soap. Avoid using soap on nipples.
- Use a sitz bath after every bowel movement to cleanse the rectal area and relieve enlarged hemorrhoids.
- Use the peribottle filled with warm water after urinating and before applying a new perineal pad.
- Avoid tub baths for 4 to 6 weeks, until joints and balance are restored, to prevent falls.
- Wash your hands before changing perineal pads, after disposing of soiled pads, and after voiding (Brown, 2006).

To reduce the risk of infection at the episiotomy site, reinforce proper perineal care with the client, showing her how to rinse her perineum with the peribottle after she voids or defecates. Stress the importance of always patting gently from front to back and washing her hands thoroughly before and after perineal care. For hemorrhoids, have the client apply witch hazel-soaked pads

TEACHING GUIDELINES 16.3

Performing Kegel Exercises

1. Identify the correct pelvic floor muscles by contracting them to stop the flow of urine while sitting on the toilet.
2. Repeat this contraction several times to become familiar with it.
3. Start the exercises by emptying the bladder.
4. Tighten the pelvic floor muscles and hold for 10 seconds.
5. Relax the muscle completely for 10 seconds.
6. Perform 10 exercises at least three times daily. Progressively increase the number that you perform.
7. Perform the exercises in different positions, such as standing, lying, and sitting.
8. Keep breathing during the exercises.
9. Don't contract your abdominal, thigh, leg, or buttocks muscles during these exercises.
10. Relax while doing Kegel exercises and concentrate on isolating the right muscles.
11. Attempt to tighten your pelvic muscles before sneezing, jumping, or laughing.
12. Remember that you can perform Kegel exercises anywhere without anyone noticing.

(Tucks Pads), ice packs to relieve swelling, or hemorrhoidal cream or ointment if ordered.

Ensuring Safety

One of the safety concerns during the postpartum period is orthostatic hypotension. When the woman moves from a lying or sitting position to a standing one rapidly, her blood pressure can suddenly drop, causing her pulse rate to increase. She may become dizzy and faint. Be aware of this problem and initiate the following safeguards:

- Check blood pressure first before ambulating the client.
- Elevate the head of the bed for a few minutes before ambulating the client.
- Have the client sit on the side of the bed for a few moments before getting up.
- Help the client to stand up, and stay with her.
- Ambulate alongside the client and provide support if needed.
- Frequently ask the client how her head feels.
- Stay close by to assist if she feels lightheaded.

Additional topics to address concern infant safety. Instruct the woman to place the newborn back in the crib on his or her back if she is feeling sleepy. If the woman falls asleep while holding the infant, she might drop him or her. Also, instruct mothers to keep the door to their room closed when their infant is in their room with them. They should check the identification of anyone who enters their room or who wants to take the infant out of the room. This will prevent infant abduction.

Counseling About Sexuality and Contraception

Sexuality is an important part of every woman's life. Women want to get back to "normal" as soon as possible after giving birth, but the couple's sexual relationship cannot be isolated from the psychological and psychosocial adjustments that both partners are going through.

Postpartum women may hesitate to resume sexual relations for a number of reasons. Many postpartum women have fatigue, weakness, vaginal bleeding, perineal discomfort, hemorrhoids, sore breasts, decreased vaginal lubrication resulting from low estrogen levels, and dyspareunia. Fatigue, the physical demands made by the infant, and the stress of new roles and responsibilities may stress the emotional reserves of couples. New parents may not get much privacy or rest, both of which are necessary for sexual pleasure (Pastore, Owens, & Raymond, 2007).

Men may feel they now have a secondary role within the family, and they may not understand their partner's daily routine. These issues, combined with the woman's increased investment in the mothering role, can strain the couple's sexual relationship.

Although couples are reluctant to ask, they often want to know when they can safely resume sexual intercourse after childbirth. Typically, sexual intercourse can be resumed once bright-red bleeding has stopped and the perineum is healed from an episiotomy or lacerations. This is usually by the third to the sixth week postpartum. However, there is not a set, prescribed time to resume sexual intercourse after childbirth. Each couple must set their own time frame when they feel it is appropriate to resume sexual intercourse.

When counseling the couple about sexuality, determine what knowledge and concerns the couple have about their sexual relationship. Inform the couple that fluctuations in sexual interest are normal. Also inform the couple about what to expect when resuming sexual intercourse and how to prevent discomfort. Precoital vaginal lubrication may be impaired during the postpartum period, especially in women who are breast-feeding. Use of water-based gel lubricants (KY jelly, Astroglide) can help. Pelvic floor exercises, in addition to preventing stress incontinence, can also enhance sensation.

Contraceptive options should be included in the discussions with the couple so that they can make an informed decision before resuming sexual activity. Many couples are overwhelmed with the amount of new information given to them during their brief hospitalization, so many are not ready for a lengthy discussion about contraceptives. Presenting a brief overview of the options, along with literature, may be appropriate. It may be suitable to ask them to think about contraceptive needs and preferences and advise them to use a barrier method (condom with spermicidal gel or foam) until they choose another form of contraceptive. This advice is especially important if the follow-up appointment will not occur for 4 to 6 weeks after childbirth, as many couples will resume sexual activity before this time. Some postpartum women ovulate before their menstrual period returns and thus need contraceptive protection to prevent another pregnancy.

Open and effective communication is necessary for effective contraceptive counseling so that information is clearly understood. Provide clear, consistent information appropriate to the woman and her partner's language, culture, and educational level. This will help them select the best contraceptive method (Engin-Ustun et al., 2007).

Promoting Nutrition

The postpartum period can be a stressful one for myriad reasons, such as fatigue, the physical stress of pregnancy and birth, and the nonstop work required to take care of the newborn and to meet the needs of other family members. As a result, the new mother may ignore her own nutrition needs. Whether she is breast-feeding or bottle-feeding, encourage the new mother to take good care of herself and eat a healthy diet so that the nutrients lost during pregnancy can be replaced and she can return to a healthy weight. In general, nutrition recommendations for the postpartum woman include the following:

- Eat a wide variety of foods with high nutrient density.
- Eat meals that require little or no preparation.

- Avoid high-fat fast foods.
- Drink plenty of fluids daily—at least 2,500 mL (approximately 84 oz).
- Avoid fad weight-reduction diets and harmful substances such as alcohol, tobacco, and drugs.
- Avoid excessive intake of fat, salt, sugar, and caffeine.
- Eat the recommended daily servings from each food group (Box 16.4).

The breast-feeding mother's nutritional needs are higher than they were during pregnancy. The mother's diet and nutritional status influence the quantity and quality of breast milk. To meet the needs for milk production, the woman's nutritional needs increase as follows:

- Calories: +500 cal/day for the first and second 6 months of lactation
- Protein: +20 g/day, adding an extra 2 cups of skim milk
- Calcium: +400 mg daily—consumption of four or more servings of milk
- Fluid: +2 to 3 quarts of fluids daily (milk, juice or water); no sodas

Certain foods (usually gaseous or strong-flavored ones) eaten by the mother may affect the flavor of the breast milk or cause gastrointestinal problems for the infant. Not all infants are affected by the same foods. If the particular food item seems to cause a problem, urge the mother to eliminate that food for a few days to see if the problem disappears.

BOX 16.4 Nutritional Recommendations for Nutrition During the Postpartum Period

Recommendations for the Lactating Woman From the Food Guide Pyramid
- Fruits: 4 servings
- Vegetables: 4 servings
- Milk: 4 to 5 servings
- Bread, cereal, pasta: 12 or more servings
- Meat, poultry, fish, eggs: 7 servings
- Fats, oils, and sweets: 5 servings (Dudek, 2006)

General Dietary Guidelines for Americans from the Food Guide Pyramid (for the Non-lactating Woman)
- Fruits: 2 to 4 servings
- Vegetables: 3 to 5 servings
- Milk: 2 to 3 servings
- Breads, grains, and cereals: 6 to 11 servings
- Meat, poultry, fish, eggs: 2 to 3 servings
- Fats, oils, and sweets: use sparingly (USDA & USDHHS, 2005)

▶ *Take NOTE!*

During the woman's brief stay in the health care facility, she may demonstrate a healthy appetite and eat well. Nutritional problems usually start at home when the mother needs to make her own food selections and prepare her own meals. This is a crucial area to address during follow-up.

Supporting the Woman's Choice of Feeding Method

While there is considerable evidence that breast-feeding has numerous health benefits, many mothers choose to feed their infants formula for the first year of life. Nurses must be able to deliver sound, evidence-based information to help the new mother choose the best way to feed her infant and must support her in her decision (Lawson, 2007).

Many factors affect a woman's choice of feeding method, such as culture, employment demands, support from significant others and family, and knowledge base. Although breast-feeding is encouraged, be sure that couples have the information they need to make an informed decision. Whether a couple chooses to breast-feed or bottle-feed the newborn, support and respect their choice.

Certain women should not breast-feed. Drugs such as antithyroid drugs, antineoplastic drugs, alcohol, or street drugs (amphetamines, cocaine, PCP, marijuana) enter the breast milk and would harm the infant, so women taking these substances should not breast-feed. To prevent HIV transmission to the newborn, women who are HIV positive should not breast-feed. Other contraindications to breast-feeding include a newborn with an inborn error of metabolism such as galactosemia or PKU, a current pregnancy, or a serious mental health disorder that would prevent the mother from remembering to feed the infant consistently.

Providing Assistance With Breast-Feeding and Bottle-Feeding

First-time mothers often have many questions about feeding, and even women who have had experience with feeding may have questions. Regardless of whether the postpartum woman is breast-feeding or bottle-feeding her newborn, she can benefit from instruction.

Providing Assistance with Breast-Feeding

WATCH & LEARN

The American Academy of Pediatrics (AAP, 2005) recommends breast-feeding for all full-term newborns. Exclusive breast-feeding is sufficient to support optimal growth and development for approximately the first 6 months of life. Breast-feeding should be continued for at least the first year of life and beyond for as long as mutually desired by

mother and child. Educating a mother about breast-feeding will increase the likelihood of a successful breast-feeding experience.

At birth, all newborns should be quickly dried, assessed, and, if stable, placed immediately in uninterrupted skin-to-skin contact (kangaroo care) with their mother. This is good practice whether the mother is going to breast-feed or bottle-feed her infant. Kangaroo care provides the newborn with optimal physiologic stability, warmth, and opportunities for the first feed (Kenner & Lott, 2007).

The benefits of breast-feeding are clear (see Chap. 18). To promote breast-feeding, the Baby-Friendly Hospital Initiative, an international program of the World Health Organization and the United Nations Children's Fund, was started in 1991. As part of this program, the hospital or birth center should take the following 10 steps to provide "an optimal environment for the promotion, protection, and support of breast-feeding":

1. Have a written breast-feeding policy that is communicated to all staff.
2. Educate all staff to implement this written policy.
3. Inform all women about the benefits and management of breast-feeding.
4. Show all mothers how to initiate breast-feeding within 30 minutes of birth.
5. Give no food or drink other than breast milk to all newborns.
6. Demonstrate to all mothers how to initiate and maintain breast-feeding.
7. Encourage breast-feeding on demand.
8. Allow no pacifiers to be given to breast-feeding infants.
9. Establish breast-feeding support groups and refer mothers to them.
10. Practice rooming-in 24 hours daily (UNICEF, 2007).

The nurse is responsible for encouraging breast-feeding when appropriate. For the woman who chooses to breast-feed her infant, the nurse or lactation consultant will need to spend time instructing her how to do so successfully. Many women have the impression that breast-feeding is simple. Although it is a natural process, women may experience some difficulty in breast-feeding their newborns. Nurses can assist mothers in smoothing out this transition. Assist and provide one-to-one instruction to breast-feeding mothers, especially first-time breast-feeding mothers, to ensure correct technique. Suggestions are highlighted in Teaching Guidelines 16.4.

▶ ***Take*** NOTE!

Some newborns "latch on and catch on" right away, and others take more time and patience. Inform new mothers about this to reduce their frustration and uncertainty about their ability to breast-feed.

Tell mothers that they need to believe in themselves and their ability to accomplish this task. They should not panic if breast-feeding does not go smoothly at first; it takes time and practice. Additional suggestions to help mothers relax and feel more comfortable breast-feeding, especially when they return home, include the following:

- Select a quiet corner or room where you won't be disturbed.
- Use a rocking chair to soothe both you and your infant.
- Take long, slow deep breaths to relax before nursing.
- Drink while breast-feeding to replenish body fluids.
- Listen to soothing music while breast-feeding.
- Cuddle and caress the infant while feeding.
- Set out extra cloth diapers within reach to use as burping cloths.
- Allow sufficient time to enjoy each other in an unhurried atmosphere.
- Involve other family members in all aspects of the infant's care from the start.

Providing Assistance With Bottle-Feeding

If the mother or couple has chosen to bottle-feed their newborn, the nurse should respect and support their decision. Discuss with the parents what type of formula they will use. Commercial formulas are classified as cow's milk-based (Enfamil, Similac), soy protein-based (Isomil, Prosobee, Nursoy), or specialized or therapeutic formulas for infants with protein allergies (Nutramigen, Pregestimil, Alimentum). Commercial formulas can also be purchased in various forms: powdered (must be mixed with water), condensed liquid (must be diluted with equal amounts of water), ready to use (poured directly into bottles), and prepackaged (ready to use in disposable bottles).

Newborns need about 108 cal/kg or approximately 650 cal/day (Dudek, 2006). Therefore, explain to parents that a newborn will need to 2 to 4 ounces to feel satisfied at each feeding. Until about age 4 months, most bottle-fed infants need six feedings a day. After this time, the number of feedings declines to accommodate other foods in the diet, such as fruits, cereals, and vegetables (Escott-Stump, 2007). For more information on newborn nutrition and bottle feeding, see Chapter 18.

When teaching the mother about bottle-feeding, provide the following guidelines:

- Make feeding a relaxing time, a time to provide both food and comfort to your newborn.
- Use the feeding period to promote bonding by smiling, singing, making eye contact, and talking to the infant.
- Always hold the newborn when feeding. Never prop the bottle.
- Use a comfortable position when feeding the newborn. Place the newborn in your dominant arm, which is supported by a pillow. Or have the newborn in a semi-upright position supported in the crook of your arm (this position reduces choking and the flow of milk into the middle ear).

TEACHING GUIDELINES 16.4

Breast-Feeding Suggestions

- Explain that breast-feeding is a learned skill for both parties.
- Offer a thorough explanation about the procedure.
- Instruct the mother to wash her hands before starting.
- Inform her that her afterpains will increase during breast-feeding.
- Make sure the mother is comfortable (pain-free) and not hungry.
- Tell the mother to start the feeding with an awake and alert infant showing hunger signs.
- Assist the mother to position herself correctly for comfort.
- Urge the mother to relax to encourage the let-down reflex.
- Guide the mother's hand to form a "C" to access the nipple.
- Have the mother lightly tickle the infant's upper lip with her nipple to stimulate the infant to open the mouth wide.
- Help her to latch on by bringing the infant rapidly to the breast with a wide-open mouth.
- Show her how to check that the newborn's mouth position is correct, and tell her to listen for a sucking noise.
- Demonstrate correct removal from the breast, using her finger to break the suction.
- Instruct the mother on how to burp the infant between breasts.
- Show her different positions, such as cradle and football holds and side-lying positions (see Chap. 18).
- Reinforce and praise the mother for her efforts.
- Allow ample time to answer questions and address concerns.
- Refer the mother to support groups and community resources.

- Tilt the bottle so that the nipple and the neck of the bottle are always filled with formula. This prevents the infant from taking in too much air.
- Stimulate the sucking reflex by touching the nipple to the infant's lips.
- Refrigerate any powdered formula that has been combined with tap water.
- Discard any formula not taken; do not keep it for future feedings.
- Burp the infant frequently, and place the baby on his or her back or side for sleeping.
- Use only iron-fortified infant formula for first year (Lawson, 2007).

Teaching About Breast Care

Regardless of whether or not the mother is breast-feeding her newborn, urge her to wear a very supportive, snug bra 24 hours a day to support enlarged breasts and promote comfort. A woman who is breast-feeding should wear a supportive bra throughout the lactation period. A woman who is not nursing should wear it until engorgement ceases, and then should wear a less restrictive one. The bra should fit snugly while still allowing the mother to breathe without restriction. All new mothers should use plain water to clean their breasts, especially the nipple area; soap is drying and should be avoided.

Assessing the Breasts

Instruct the mother how to examine her breasts daily. Daily assessment includes the milk supply (breasts will feel full as they are filling), the condition of the nipples (red, bruised, fissured, or bleeding), and the success of breast-feeding. The fullness of the breasts may progress to engorgement in the breast-feeding mother if feedings are delayed or breast-feeding is ineffective. Palpating both breasts will help identify whether the breasts are soft, filling, or engorged. A similar assessment of the breasts should be completed on the nonlactating mother to identify any problems, such as engorgement or mastitis.

Alleviating Breast Engorgement

Breast engorgement usually occurs during the first week postpartum. It is a common response of the breasts to the sudden change in hormones and the presence of an increased amount of milk. Reassure the woman that this condition is temporary and usually resolves within 72 hours.

Alleviating Breast Engorgement in the Breastfeeding Woman

If the mother is breast-feeding, encourage frequent feedings, at least every 2 to 3 hours, using manual expression just before feeding to soften the breast so the newborn can latch on more effectively. Advise the mother to allow the newborn to feed on the first breast until it softens before switching to the other side. See Chapter 18 for more information on alleviating breast engorgement and other common breast-feeding concerns.

Alleviating Breast Engorgement and Suppressing Lactation in the Bottle-Feeding Woman

If the woman is bottle-feeding, explain that breast engorgement is a self-limiting phenomenon that disappears as increasing estrogen levels suppress milk formation (i.e., lactation suppression). Encourage the woman to use ice packs, to wear a snug, supportive bra 24 hours a day, and to take mild analgesics such as acetaminophen. Encourage her to avoid any stimulation to the breasts that might foster milk production, such as warm showers or pumping or massaging the breasts. Medication is no longer given to hasten lactation suppression. Teaching Guidelines 16.5 provides tips on lactation suppression.

TEACHING GUIDELINES 16.5

Suppressing Lactation

1. Wear a supportive, snugly fitting bra 24 hours daily, but not one that binds the breasts too tightly or interferes with your breathing.
2. Suppression may take 5 to 7 days to accomplish.
3. Take mild analgesics to reduce breast discomfort.
4. Let shower water flow over your back rather than your breasts.
5. Avoid any breast stimulation in the form of sucking or massage.
6. Drink to quench your thirst. Restricting your fluid intake will not dry up your milk.
7. Reduce your salt intake to decrease fluid retention.
8. Use ice packs or cool compresses (e.g., cool cabbage leaves) inside the bra to decrease local pain and swelling; change them every 30 minutes (Arenson & Drake, 2007).

Promoting Family Adjustment and Well-Being

The postpartum period involves extraordinary physiologic, psychological, and sociocultural changes in the life of a woman and her family. Adapting to the role of a parent is not an easy process. The postpartum period is a "getting-to-know-you" time when parents begin to integrate the newborn into their lives as they reconcile the fantasy child with the real one. This can be a very challenging period for families. Nurses play a major role in assisting families to adapt to the changes, promoting a smooth transition into parenthood. Appropriate and timely interventions can help parents adjust to the role changes and promote attachment to the newborn.

For couples who already have children, the addition of a new member may bring role conflict and challenges. The nurse should provide anticipatory guidance about siblings' responses to the new baby, increased emotional tension, child development, and meeting the multiple needs of the expanding family. Although the multiparous woman has had experience with newborns, do not assume that her knowledge is current and accurate, especially if some time has elapsed since her previous child was born. Reinforcing information is important for all families.

Promoting Parental Roles

Parents' roles develop and grow when they interact with their newborn (see Chap. 15 for information on maternal and paternal adaptation). The pleasure they derive from this interaction stimulates and reinforces this behavior. With repeated, continued contact with the newborn, parents learn to recognize cues and understand the newborn's behavior. This positive interaction contributes to family harmony.

Nurses need to know the stages parents go through as they make their new parenting roles fit into their life experience. Assess the parents for attachment behaviors (normal and deviant), adjustment to the new parental role, family member adjustment, social support system, and educational needs. To promote parental role adaptation and parent–newborn attachment, include the following nursing interventions:

- Provide as much opportunity as possible for parents to interact with their newborn. Encourage exploration, holding, and providing care.
- Model behaviors by holding the newborn close and speaking positively.
- Always refer to the newborn by name in front of the parents.
- Speak directly to the newborn in a calm voice.
- Encourage both parents to pick up and hold the newborn.
- Point out the newborn's response to parental stimulation.
- Point out the positive physical features of the newborn.
- Involve both parents in the newborn's care and praise them for their efforts.
- Evaluate the family's strengths and weaknesses and readiness for parenting.
- Assess for risk factors such as lack of social support and the presence of stressors.
- Observe the effect of culture on the family interaction to determine whether it is appropriate.
- Monitor parental attachment behaviors to determine whether alterations require referral. Positive behaviors include holding the newborn closely or in an *en face* position, talking to or admiring the newborn, or demonstrating closeness. Negative behaviors include avoiding contact with the newborn, calling it names, or showing a lack of interest in caring for the newborn (see Table 16.1).
- Monitor the parents' coping behaviors to determine alterations that need intervention. Positive coping behaviors include positive conversations between the partners, both parents wanting to be involved with newborn care, and lack of arguments between the parents. Negative behaviors include not visiting, limited conversations or periods of silence, and heated arguments or conflict.
- Identify the support systems available to the new family and encourage them to ask for help. Ask direct questions about home or community support. Make referrals to community resources to meet the family's needs.
- Arrange for community home visits in high-risk families to provide positive reinforcement of parenting skills and nurturing behaviors with the newborn.
- Provide anticipatory guidance about the following before discharge to reduce the new parents' frustration:
  - Newborn sleep–wake cycles (they may be reversed)
  - Variations in newborn appearance
  - Infant developmental milestones (growth spurts)
  - How to interpret crying cues (hunger, wet, discomfort)
  - Techniques to quiet a crying infant (car ride)
  - Sensory enrichment/stimulation (colorful mobile)
  - Signs and symptoms of illness and how to assess for fever
  - Important phone numbers, follow-up care, and needed immunizations

FIGURE 16.7 Father participating in newborn care.

  - Physical and emotional changes associated with the postpartum period
  - Need to integrate siblings into care of the newborn; stress that sibling rivalry is normal and offer ways to reduce it
  - Ways to make time together for the couple
  - Appropriate community referral resources

In addition, nurses can help fathers to feel more competent in assuming their parental role by teaching and providing information (Fig. 16.7). Education can dispel any unrealistic expectations they may have, helping them to cope more successfully with the demands of fatherhood and thereby fostering a nurturing family relationship.

Explaining Sibling Roles

It can be overwhelming to a young child to have another family member introduced into his or her small, stable world. Although most parents try to prepare siblings for the arrival of their new little brother or sister, many young children experience stress. They may view the new infant as competition, or fear that they will be replaced in the parents' affection. All siblings need extra attention from their parents and reassurance that they are loved and important.

▸ *Consider* THIS!

Katie and Molly have been excited about having a new baby sister since they were told about their mother's pregnancy. The 6-year-old twins are eagerly looking out the front window, waiting for their parents to bring their new sister, Jessica, home. The girls are big enough to help their mother care for their new sibling, and for the past few months they have been fixing up the new nursery and selecting baby clothes. They practiced diapering their dolls—their mother was specific about not using any powder or lotion on Jessica's bottom—and

(continued)

▶ **Consider** THIS! *(continued)*

holding them correctly to feed them bottles. Finally, their mother arrives home from the hospital with Jessica in her arms!

The girls notice that their mother is very protective of Jessica and watches them carefully when they care for her. They fight over the opportunity to hold her or feed her. What is special to both of them is the time they spend alone with their parents. Although a new family member has been added, the twins still feel special and loved by their parents.

Thoughts: Bringing a new baby into an established family can cause conflict and jealousy. What preparation did the older siblings have before Jessica arrived? Why is it important for parents to spend time with each sibling separately?

Many parents need reassurance that sibling rivalry is normal. Suggest the following to help parents minimize sibling rivalry:

- Expect and tolerate some regression (thumb sucking, bedwetting).
- Explain childbirth in an appropriate way for the child's age.
- Encourage discussion about the new infant during relaxed family times.
- Encourage the sibling(s) to participate in decisions, such as the baby's name and toys to buy.
- Take the sibling on the tour of the maternity suite.
- Buy a T-shirt that says "I'm the [big brother or big sister]."
- Spend "special time" with the child.
- Read with the child. Some suggested title include *Things to Do with A New Baby* (Ormerod, 1984); *Betsy's Baby Brother* (Wolde, 1975); *The Berenstain Bears' New Baby* (Berenstain, 1974); and *Mommy's Lap* (Horowitz & Sorensen, 1993).
- Plan time for each child throughout the day.
- Role-play safe handling of a newborn, using a doll. Give the preschooler or school-age child a doll to care for.
- Encourage older children to verbalize emotions about the newborn.
- Purchase a gift that the child can give to the newborn.
- Purchase a gift that can be given to the child by the newborn.
- Arrange for the child to come to the hospital to see the newborn (Fig. 16.8).
- Move the sibling from his or her crib to a youth bed months in advance of the birth of the newborn.
- Encourage grandparents to pay attention to the older child when visiting (Rector, 2007).

FIGURE 16.8 Sibling visitation.

Discussing Grandparents' Role

Grandparents can be a source of support and comfort to the postpartum family if effective communication skills are used and roles are defined. The grandparents' role and involvement will depend on how close they live to the family, their willingness to become involved, and cultural expectations of their role. Just as parents and siblings go through developmental changes, so too do grandparents. These changes can have a positive or negative effect on the relationship.

Newborn care, feeding, and childrearing practices have changed since the grandparents raised the parents. New parents may lack parenting skills but nonetheless want their parents' support without criticism. A grandparent's "take-charge approach" may not be welcome by new parents who are testing their own parenting roles, and family conflict may ensue. However, many grandparents respect their adult children's wishes for autonomy and remain "resource people" for them when requested.

▶ **Take** NOTE!

Grandparents' involvement can enrich the lives of the entire family if accepted in the right context and dose by the family.

Nurses can assist in the grandparents' role transition by assessing their communication skills, role expectations, and support skills during the prenatal period. Find out whether the grandparents are included in the couple's social support network and whether their support is wanted

or helpful. If they are, and it is, then encourage the grandparents to learn about the parenting, feeding, and childrearing skills their children have learned in childbirth classes. This information is commonly found in "grandparenting" classes, which introduce new parenting concepts and bring the grandparents up to date on childbirth practices today.

Teaching About Postpartum Blues

The postpartum period is typically a happy yet stressful time, because the birth of an infant is accompanied by enormous physical, social, and emotional changes. The postpartum woman may report feelings of emotional lability, such as crying one minute and laughing the next. **Postpartum blues** are transient emotional disturbances beginning in the first week after childbirth and are characterized by anxiety, irritability, insomnia, crying, loss of appetite, and sadness (Fooladi, 2006). These symptoms typically begin 3 to 4 days after childbirth and resolve by day 10 (Bennett, 2007). These mood swings may be confusing to new mothers but usually are self-limiting.

Postpartum blues are thought to affect up to 75% of all new mothers; this condition is the mildest form of emotional disturbance associated with childbearing (March of Dimes, 2007). The mother maintains contact with reality consistently and symptoms tend to resolve spontaneously without therapy within 1 to 2 weeks.

▶ ***Take*** *NOTE!*

Postpartum blues have been regarded as brief, benign, and without clinical significance, but several studies have proposed a link between blues and subsequent depression in the 6 months following childbirth (Vaughn, 2006).

Postpartum blues requires no formal treatment other than support and reassurance because it does not usually interfere with the woman's ability to function and care for her infant. Further evaluation is necessary, however, if symptoms persist more than 2 weeks (Ey, 2007). Nurses can ease a mother's distress by encouraging her to vent her feelings and by demonstrating patience and understanding with her and her family. Suggest that getting outside help with housework and infant care might help her to feel less overwhelmed until the blues ease. Provide telephone numbers she can call when she feels down during the day. Making women aware of this disorder while they are pregnant will increase their knowledge about this mood disturbance, which may lessen their embarrassment and increase their willingness to ask for and accept help if it does occur.

The postpartum woman also is at risk for postpartum depression and postpartum psychosis; these conditions are discussed in Chapter 22.

Preparing for Discharge

The AAP and the American College of Obstetricians and Gynecologists (ACOG) state that the length of stay in the health care facility should be individualized for each mother and baby. A shortened hospital stay may be indicated if the following criteria are met:

- Mother is afebrile and vital signs are within normal range.
- Lochia is appropriate amount and color for stage of recovery.
- Hemoglobin and hematocrit values are within normal range.
- Uterine fundus is firm; urinary output is adequate.
- ABO blood groups and RhD status are known and, if indicated, anti-D immunoglobulin has been administered.
- Surgical wounds are healing and no signs of infection are present.
- Mother is able to ambulate without difficulty.
- Food and fluids are taken without difficulty.
- Self-care and infant care are understood and demonstrated.
- Family or other support system is available to care for both.
- Mother is aware of possible complications (AAP & ACOG, 2007).

Providing Immunizations

Prior to discharge, check the immunity status for rubella for all mothers and give a subcutaneous injection of rubella vaccine if they are not serologically immune (titer less than 1:10). Be sure that the client signs a consent form to receive the vaccine. Nursing mothers can be vaccinated because the live, attenuated rubella virus is not communicable. Inform all mothers receiving immunization about adverse effects (rash, joint symptoms, and a low-grade fever 5 to 21 days later) and the need to avoid pregnancy for at least 3 months after being vaccinated because of the risk of teratogenic effects (CDC, 2007).

If the client is Rh negative, check the Rh status of the newborn. Verify that the woman is Rh negative and has not been sensitized, that the Coombs' test is negative, and that the newborn is Rh positive. Mothers who are Rh negative and have given birth to an infant who is Rh positive should receive an injection of Rh immunoglobulin within 72 hours after birth to prevent a sensitization reaction in the Rh-negative woman who received Rh-positive blood cells during the birthing process. The usual protocol for the Rh-negative woman is to receive two doses of Rh immunoglobulin (RhoGAM), one at 28 weeks' gestation and the second dose within 72 hours after childbirth. A signed consent form is needed after a thorough explanation is provided about the procedure, including its purpose, possible adverse effects, and effect on future pregnancies.

Ensuring Follow-Up Care

New mothers and their families need to be attended to over an extended period of time by nurses knowledgeable about mother care, infant feeding (breast-feeding and bottle-feeding), infant care, and nutrition. Although continuous nursing care stops on discharge from the hospital or birthing center, extended episodic nursing care needs to be provided at home. Some of the challenges faced by the current families after discharge are described in Box 16.5.

Many new mothers are reluctant to "cut the cord" after their brief stay in the health care facility and need expanded community services. Women who are discharged too early from the hospital run the risk of uterine subinvolution, discomfort at an episiotomy or cesarean site, infection, fatigue, and maladjustment to their new role. Postpartum nursing care should include a range of family-focused care, including telephone calls, outpatient clinics, and home visits. Typically, public health nurses, community and home health nurses, and the health care provider's office staff will provide postpartum care after hospital discharge.

Providing Telephone Follow-Up

Telephone follow-up typically occurs during the first week after discharge to check on how things are going at home. Calls can be made by perinatal nurses within the agency as part of follow-up care or by the local health department nurses. A disadvantage to a phone call assessment is that the nurse cannot see the client and thus must rely on the mother or the family's observations. The experienced nurse needs to be able to recognize distress and give appropriate advice and referral information if needed.

BOX 16.5 Challenges Facing Families After Discharge

- Lack of role models for breast-feeding and infant care
- Lack of support from the new mother's own mother if she did not breast-feed
- Increased mobility of society, which means that extended family may live far away and cannot help care for the newborn and support the new family
- Feelings of isolation and limited community ties for women who work full time
- Shortened hospital stays: parents may be overwhelmed by all the information they are given in the brief hospital stay
- Prenatal classes usually focus on the birth itself rather than on skills needed to care for themselves and the newborn during the postpartum period
- Limited access to education and support systems for families from diverse cultures

Source: Nash, 2007.

Providing Outpatient Follow-Up

For mothers with established health care providers such as private pediatricians and obstetricians, visits to the office are arranged soon after discharge. For the woman with an uncomplicated vaginal birth, an office visit is usually scheduled for 4 to 6 weeks after childbirth. A woman who had a cesarean birth frequently is seen within 2 weeks after hospital discharge. Hospital discharge orders will specify when these visits should be made. Newborn examinations and further diagnostic laboratory studies are scheduled within the first week.

▶ *Take* NOTE!

Infants discharged before they are 48 hours old should be seen by a pediatrician or health care provider by the time they are 96 hours old; those discharged after they are 48 hours old should be seen by the time they are 120 hours old (Langan, 2006).

Outpatient clinics are available in many communities. If family members run into a problem, the local clinic is available to provide assessment and treatment. Clinic visits can replace or supplement home visits. Although these clinics are open during daytime hours only and the staff members are unfamiliar with the family, they can be a valuable resource for the new family with a problem or concern.

Providing Home Visit Follow-Up

Home visits are usually made within the first week after discharge to assess the mother and newborn. During the home visit, the nurse assesses for and manages common physical and psychosocial problems. In addition, the home nurse can help the new parents adjust to the change in their lives. The postpartum home visit usually includes the following:

- Maternal assessment: general well-being, vital signs, breast health and care, abdominal and musculoskeletal status, voiding status, fundus and lochia status, psychological and coping status, family relationships, proper feeding technique, environmental safety check, newborn care knowledge and health teaching needed (Fig. 16.9 shows sample assessment forms)
- Infant assessment: physical examination, general appearance, vital signs, home safety check, child development status, any education needed to improve parents' skills

The home care nurse must be prepared to support and educate the woman and her family in the following areas:

- Breast-feeding or bottle-feeding technique and procedures

B

FIGURE 16.9 (continued) (**B**) Newborn assessment. (Used with permission: Copyright Briggs Corporation. Professional Nurse Associates.)

- Appropriate parenting behavior and problem solving
- Maternal/newborn physical, psychosocial, and culture–environmental needs
- Emotional needs of the new family
- Warning signs of problems and how to prevent or eliminate them
- Sexuality issues, including contraceptive use
- Immunization needs for both mother and infant
- Family dynamics for smooth transition
- Links to health care providers and community resources

Key Concepts

- The transitional adjustment period between birth and parenthood includes education about baby care basics, the role of the new family, emotional support, breast-feeding or bottle-feeding support, and maternal mentoring.
- Sensitivity to how childbearing practices and beliefs vary for multicultural families and how best to provide appropriate nursing care to meet their needs are important during the postpartum period.
- A thorough postpartum assessment is key to preventing complications as is frequent handwashing by the nurse, especially between handling mothers and infants.
- The postpartum assessment using the acronym BUBBLE-EE (breasts, uterus, bowel, bladder, lochia, episiotomy/perineum, extremities, and emotions) is a helpful guide in performing a systematic head-to-toe postpartum assessment.
- Lochia is assessed according to its amount, color, and change with activity and time. It proceeds from lochia rubra to serosa to alba.
- Because of shortened agency stays, nurses must use this brief time with the client to address areas of comfort, elimination, activity, rest and exercise, self-care, sexuality and contraception, nutrition, family adaptation, discharge, and follow-up.
- The AAP advocates breast-feeding for all full-term newborns, maintaining that, ideally, breast milk should be the sole nutrient for the first 6 months and continued with foods until 12 months of life or longer.
- Successful parenting is a continuous and complex interactive process that requires the acquisition of new skills and the integration of the new member into the existing family unit.
- Bonding is a vital component of the attachment process and is necessary in establishing parent–infant attachment and a healthy, loving relationship; attachment behaviors include seeking and maintaining close proximity to, and exchanging gratifying experiences with, the infant.
- Nurses can be instrumental in facilitating attachment by first understanding attachment behaviors (positive and negative) of newborns and parents, and intervening appropriately to promote and enhance attachment.
- New mothers and their families need to be attended to over an extended period of time by nurses knowledgeable about mother care, newborn feeding (breast-feeding and bottle-feeding), newborn care, and nutrition.

Chapter Worksheet

Multiple Choice Questions

1. When assessing a postpartum woman, which of the following would lead the nurse to suspect postpartum blues?
   a. Panic attacks and suicidal thoughts
   b. Anger toward self and infant
   c. Periodic crying and insomnia
   d. Obsessive thoughts and hallucinations
2. Which of these activities would best help the postpartum nurse to provide culturally sensitive care for the childbearing family?
   a. Taking a transcultural course
   b. Caring for only families of his or her cultural origin
   c. Teaching Western beliefs to culturally diverse families
   d. Educating himself or herself about diverse cultural practices
3. Which of the following suggestions would be most appropriate to include in the teaching plan for a postpartum woman who needs to lose weight?
   a. Increase fluid intake and acid-producing foods in her diet.
   b. Avoid empty-calorie foods and increase exercise.
   c. Start a high-protein diet and restrict fluids.
   d. Eat no snacks or carbohydrates.
4. After teaching a group of breast-feeding women about nutritional needs, the nurse determines that the teaching was successful when the women state that they need to increase their intake of which nutrients?
   a. Carbohydrates and fiber
   b. Fats and vitamins
   c. Calories and protein
   d. Iron-rich foods and minerals
5. Which of the following would lead the nurse to suspect that a postpartum woman was developing a complication?
   a. Fatigue and irritability
   b. Perineal discomfort and pink discharge
   c. Pulse rate of 60 bpm
   d. Swollen, tender, hot area on breast
6. Which of the following would the nurse assess as indicating positive bonding between the parents and their newborn?
   a. Holding the infant close to the body
   b. Having visitors hold the infant
   c. Buying expensive infant clothes
   d. Requesting that the nurses care for the infant
7. Which activity would the nurse include in the teaching plan for parents with a newborn and an older child to reduce sibling rivalry when the newborn is brought home?
   a. Punishing the older child for bedwetting behavior
   b. Sending the sibling to the grandparents' house
   c. Planning a special time daily for the older sibling
   d. Allowing the sibling to share a room with the infant
8. The major purpose of the first postpartum homecare visit is to:
   a. Identify complications that require interventions
   b. Obtain a blood specimen for PKU testing
   c. Complete the official birth certificate
   d. Support the new parents in their parenting roles

Critical Thinking Exercises

1. As a nurse working on a postpartum unit, you enter the room of Ms. Jones, a 22-year-old primipara, and find her chatting on the phone while her newborn is crying loudly in the bassinette, which has been pushed into the bathroom. You pick up and comfort the newborn. While holding the baby, you ask the client if she was aware her newborn was crying. She replies, "That's about all that monkey does since she was born!" You hand the newborn to her and she places the newborn on the bed away from her and continues her phone conversation.
   a. What is your nursing assessment of this encounter?
   b. What nursing interventions would be appropriate?
   c. What specific discharge interventions may be needed?

2. Jennifer Adamson, a 34-year-old single primipara, left the hospital after a 36-hour stay with her newborn son. She lives alone in a one-bedroom walk-up apartment. As the postpartum home health nurse visiting her 2 days later, you find the following:
   - Tearful client pacing the floor holding her crying son
   - Home cluttered and in disarray
   - Fundus firm and displaced to right of midline
   - Moderate lochia rubra; episiotomy site clean, dry, and intact
   - Vital signs within normal range; pain rating less than 3 points on scale of 1 to 10
   - Breasts engorged slightly; supportive bra on
   - Newborn assessment within normal limits
   - Distended bladder upon palpation; reporting urinary frequency

   a. Which of these assessment findings warrants further investigation?

   b. What interventions are appropriate at this time, and why?

   c. What health teaching is needed before you leave this home?

3. The nurse walks into the room of Lisa Drew, a 24-year-old primigravida. She asks the nurse to hand her the bottle sitting on the bedside table, stating, "I'm going to finish it off because my baby only ate half of it 3 hours ago when I fed him."

   a. What response by the nurse would be appropriate at this time?

   b. What action should the nurse take?

   c. What health teaching is needed for Lisa prior to discharge?

Study Activities

1. Identify three questions that a nurse would ask a postpartum woman to assess for postpartum blues.
2. Find a website that offers advice to new parents about breast-feeding. Critique the site, the author's credentials, and the accuracy of the content.
3. Outline instructions you would give to a new mother on how to use her peribottle.
4. Breast tissue swelling secondary to vascular congestion after childbirth and preceding lactation describes _____.
5. Listen to the postpartum story of one of your assigned patients and share it with your peers in class or as part of online discussion.

CHAPTER 17

NEWBORN ADAPTATION

KEY TERMS

cold stress
jaundice
meconium
neonatal period
neurobehavioral response
neutral thermal environment (NTE)
periodic breathing
reflex
thermoregulation

LEARNING OBJECTIVES

Upon completion of the chapter, the learner will be able to:

1. Define the key terms used in this chapter.
2. Identify the major changes in body systems that occur as the newborn adapts to extrauterine life.
3. List the primary challenges faced by the newborn during the adaptation to extrauterine life.
4. Explain the three behavioral patterns of newborn behavioral adaptation.
5. Discuss the five typical behavioral responses of the newborn.

The Healthy Start home care nurse reviewed the patient's file in her car before she got out: 18-year-old primipara, 1 week postpartum with a term newborn girl weighing 7 pounds. The new mother, Maria, greeted the nurse at the door and let her inside the house. After performing a postpartum assessment on Maria and an assessment of her newborn daughter, the nurse asked Maria if she had any questions or concerns. Maria's eyes welled up with tears: she is worried that her daughter can't see.

Wow

Newborns can't always be judged by their outer wrapping; rather, we should focus on the awesome gift inside.

When a child is born, the exhaustion and stress of labor are over for the parents, but now the newborn must begin the work of physiologically and behaviorally adapting to the new environment. The first 24 hours of life can be the most precarious (Blackburn, 2007).

The **neonatal period** is defined as the first 28 days of life. After birth, the newborn is exposed to a whole new world of sounds, colors, smells, and sensations. The newborn, previously confined to the warm, dark, wet intrauterine environment, is now thrust into an environment that is much brighter and cooler. As the newborn adapts to life after birth, numerous physiologic changes occur (Table 17.1).

Awareness of the adaptations that are occurring forms the foundation for providing support to the newborn during this crucial time. Physiologic and behavioral changes occur quickly during this transition period. Being aware of any deviations from the norm is crucial to ensure early identification and prompt intervention.

This chapter describes the physiologic changes of the newborn's major body systems. It also discusses the behavioral adaptations, including behavioral patterns and the newborn's behavioral responses, that occur during this transition period.

Physiologic Adaptations

The mechanics of birth require a change in the newborn for survival outside the uterus. Immediately, respiratory gas exchange, along with circulatory modifications, must occur to sustain extrauterine life. During this time, as newborns strive to attain homeostasis, they also experience complex changes in major organ systems. Although the transition usually takes place within the first 6 to 10 hours of life, many adaptations take weeks to attain full maturity.

Cardiovascular System Adaptations

During fetal life, the heart relies on certain unique structures that assist it in providing adequate perfusion of vital body parts. The umbilical vein carries oxygenated blood from the placenta to the fetus. The ductus venosus allows the majority of the umbilical vein blood to bypass the liver and merge with blood moving through the vena cava, bringing it to the heart sooner. The foramen ovale allows more than half the blood entering the right atrium to cross immediately to the left atrium, thereby passing the pulmonary circulation. The ductus arteriosus connects the pulmonary artery to the aorta, which allows bypassing of the pulmonary circuit. Only a small portion of blood passes through the pulmonary circuit for the main purpose of perfusion of the structure, rather than for oxygenation. The fetus depends on the placenta to provide oxygen and nutrients and to remove waste products.

At birth, the circulatory system must switch from fetal to newborn circulation and from placental to pulmonary gas exchange. The physical forces of the contractions of labor and birth, mild asphyxia, increased intracranial pressure as a result of cord compression and uterine contractions, as well as cold stress immediately experienced after birth lead to an increased release in catecholamines that is critical for the changes involved in the transition to

TABLE 17.1 ANATOMIC AND PHYSIOLOGIC COMPARISON OF THE FETUS AND NEWBORN

Comparison	Fetus	Newborn
Respiratory system	Fluid-filled, high-pressure system causes blood to be shunted from the lungs through the ductus arteriosus to the rest of the body.	Air-filled, low-pressure system encourages blood flow through the lungs for gas exchange; increased oxygen content of blood in the lungs contributes to the closing of the ductus arteriosus (becomes a ligament).
Site of gas exchange	Placenta	Lungs
Circulation through the heart	Pressures in the right atrium are greater than in the left, encouraging blood flow through the foreman ovale.	Pressures in the left atrium are greater than in the right, causing the foreman ovale to close.
Hepatic portal circulation	Ductus venosus bypasses; maternal liver performs filtering functions	Ductus venosus closes (becomes a ligament); hepatic portal circulation begins.
Thermoregulation	Body temperature is maintained by maternal body temperature and the warmth of the intrauterine environment.	Body temperature is maintained through a flexed posture and brown fat.

extrauterine life. The increased levels of epinephrine and norepinephrine stimulate increased cardiac output and contractility, surfactant release, and promotion of pulmonary fluid clearance (Kenner & Lott, 2007).

Fetal Structures

Changes in circulation occur immediately at birth as the fetus separates from the placenta (Fig. 17.1). When the umbilical cord is clamped, the first breath is taken and the lungs begin to function. As a result, systemic vascular resistance increases and blood return to the heart via the inferior vena cava decreases. Concurrently with these changes, there is a rapid decrease in pulmonary vascular resistance and an increase in pulmonary blood flow (Blackburn, 2007). The foramen ovale functionally closes with a decrease in pulmonary vascular resistance, which leads to a decrease in right-sided heart pressures. An increase in systemic pressure, after clamping of the cord, leads to an increase in left-sided heart pressures. Ductus arteriosus, ductus venosus, and umbilical vessels that were vital during fetal life are no longer needed. Over a period of months these fetal vessels form nonfunctional ligaments.

Before birth, the foramen ovale allowed most of the oxygenated blood entering the right atrium from the inferior vena cava to pass into the left atrium of the heart. With the newborn's first breath, air pushes into the lungs, triggering an increase in pulmonary blood flow and pulmonary venous return to the left side of the heart. As a result, the pressure in the left atrium becomes higher than in the right atrium. The increased left atrial pressure causes the foramen ovale to close, thus allowing the output from the right ventricle to flow entirely to the lungs. With closure of this fetal shunt, oxygenated blood is now separated from nonoxygenated blood. The subsequent increase in tissue oxygenation further promotes the increase in systemic blood pressure and continuing blood flow to the lungs. The foramen ovale normally closes functionally at birth when left atrial pressure increases and right atrial pressure decreases. Permanent anatomic closure, though, really occurs throughout the next several weeks.

During fetal life, the ductus arteriosus, located between the aorta and the pulmonary artery, protected the lungs against circulatory overload by shunting blood (right to left) into the descending aorta, bypassing the pulmonary circulation. Its patency during fetal life is promoted by continual production of prostaglandin E2 (PGE2) by the ductus arteriosus (T. W. Hansen, 2007). The ductus arteriosus becomes functionally closed within the first few hours after birth. Oxygen is the most important factor in controlling its closure. Closure depends on the high oxygen content of the aortic blood resulting from aeration of the lungs at birth. At birth, pulmonary vascular resistance decreases, allowing pulmonary blood flow to increase and oxygen exchange to occur in the lungs. It occurs secondary to an increase in PO_2 coincident with the first breath and umbilical cord occlusion when it is clamped.

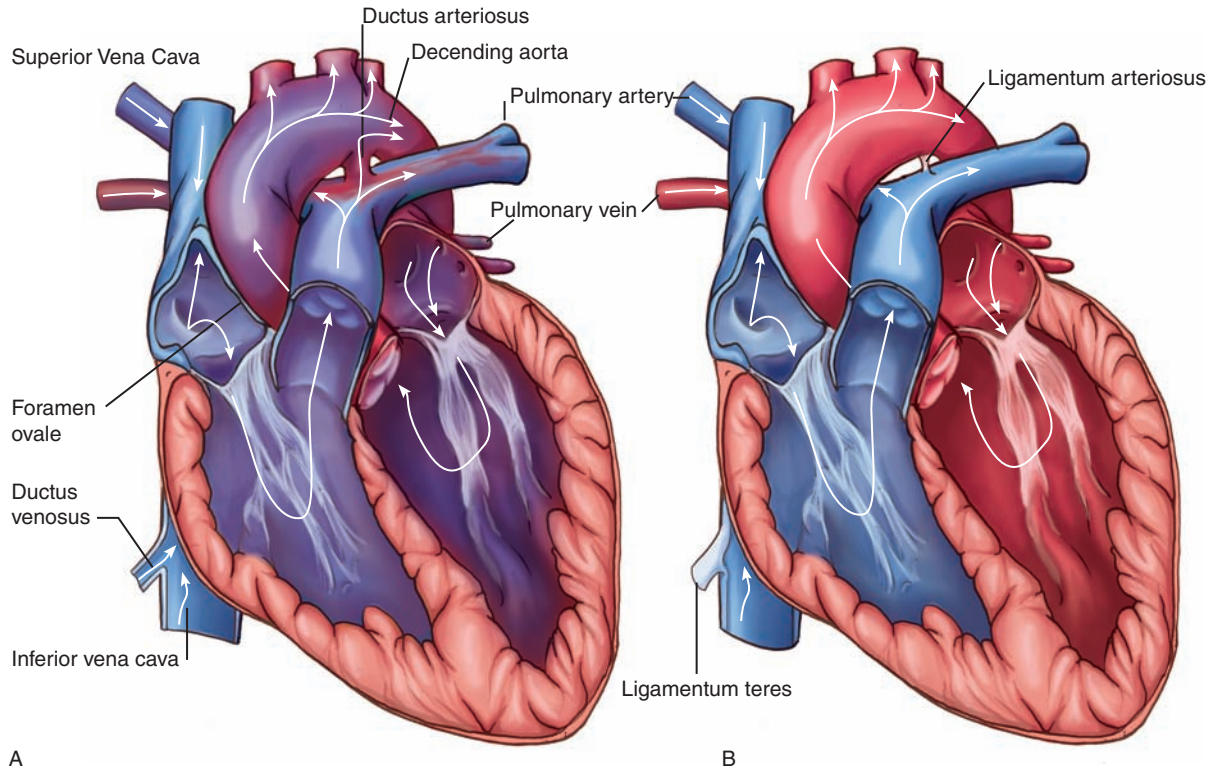

FIGURE 17.1 Cardiovascular adaptations of the newborn. Note the changes in oxygenation between (**A**) prenatal circulation and (**B**) postnatal (pulmonary) circulation.

The ductus venosus shunted blood from the left umbilical vein to the inferior vena cava during intrauterine life. It closes within a few days after birth, because this shunting is no longer needed as a result of activation of the liver. The activated liver now takes over the functions of the placenta (which was expelled at birth). The ductus venosus becomes a ligament in extrauterine life.

The two umbilical arteries and one umbilical vein begin to constrict at birth, because with placental expulsion, blood flow ceases. In addition, peripheral circulation increases. Thus, the vessels are no longer needed and they too become ligaments.

Heart Rate

During the first few minutes after birth, the newborn's heart rate is approximately 120 to 180 bpm. Thereafter, it begins to decrease to an average of 120 to 130 bpm (Arenson & Drake, 2007). The newborn is highly dependent on heart rate for maintenance of cardiac output and blood pressure. Although the blood pressure is not taken routinely in the healthy term newborn, it is usually highest after birth and reaches a plateau within a week after birth.

▶ *Take* NOTE!

Transient functional cardiac murmurs may be heard during the neonatal period as a result of the changing dynamics of the cardiovascular system at birth (Wheeler & McCaffrey, 2007).
